In a star the plasma is bound together by gravitational forces, and the enormous energy that it emits originates in thermonuclear fusion reactions within the interior. Heat is transferred from the interior to the exterior by radiation; in the outer layers, convection or circulation of the plasma is important. In the vicinity of a hot star the interstellar medium consists almost entirely of completely ionized hydrogen, ionized by the star's ultraviolet radiation. Such regions are referred to as H II regions. The greater proportion by far of interstellar medium, however, exists in the form of neutral hydrogen clouds, referred to as H I regions. Because the heavy atoms in such clouds are ionized by ultraviolet radiation (or photoionized), they also are considered to be plasmas, although degree of ionization is probably only one part in 10,000. Other components of the interstellar medium are grains of dust and cosmic rays, the latter consisting of very high-energy atomic nuclei completely stripped of electrons. The almost isotropic velocity distribution of the cosmic rays is believed to stem from interactions with waves of the background thermal plasma.

Throughout this universe of plasma there are magnetic fields. In interstellar space magnetic fields are about 5×10^{-6} gauss (a unit of magnetic field strength), in interplanetary space 5×10^{-5} gauss, whereas in intergalactic space they could be as low as 10^{-9} gauss. These values are exceedingly small compared with the Earth's surface field of about one-half gauss. Although small in an absolute sense, these fields are nevertheless gigantic, considering the scales involved. For example, to simulate interstellar phenomena in the laboratory, fields of about 10^{15} gauss would be necessary. Thus, these fields play a major role in nearly all astrophysical phenomena. On the Sun the average surface field is something like one to two gauss, but magnetic disturbances arise, such as sunspots, in which fields of between 10 gauss and 1,000 gauss occur. Many other stars are also known to have magnetic fields, whereas such fields as 10^{-3} gauss are associated with various extragalactic nebulae, synchrotron radiation being observed.

Magnetic fields in space

Solar–terrestrial. The visible region of the Sun is the photosphere (see Table), with its radiation about the same as the continuum radiation from a blackbody.

Various Natural Plasmas, Their Electron Densities and Temperatures

plasma	n_e (per cu m)	T_e (°K)
Sun		
Centre	10^{31}	1.5×10^7
Photosphere	10^{20}	4,200
Chromosphere	10^{17}–10^{20}	5×10^5
Corona	10^{13}	1.5×10^6
Solar wind (near Earth)	5×10^6	4×10^5
Interstellar space		
H II regions	10^6	10^4
H I regions	10^2	100–125
Intergalactic space	1	3 (?)
Earth		
Outer magnetosphere	10^7–10^6	10^4
Plasmasphere	10^{10}–10^9	10^4
Ionosphere	10^{11}–10^{12}	250–3,000
Metals	10^{28}	10^4

Lying above the photosphere, the chromosphere is characterized by the emission of line radiation from atoms and ions. Outside the chromosphere, the corona expands into the everblowing solar wind (see below), which on passing through the planetary system eventually encounters the interstellar magnetic field.

The Sun's corona is believed to be heated by magnetohydrodynamic or acoustic waves generated in the photosphere. The solar wind, a collisionless plasma made up primarily of electrons and protons, represents an outflow of matter moving at supersonic speed. The wind takes with it frozen-in extensions of the Sun's magnetic field. In the region of the Earth, the wind has an average speed of 400 kilometres (128.5 miles) per second; and on encountering the Earth's magnetic field, a shock front develops, the pressures acting to compress the field on the side toward the Sun and elongate it on the night side (in the Earth's lee away from the Sun). The Earth's magnetic field is, therefore, confined to a cavity called the magnetosphere, into which the direct entry of the solar wind is prohibited. This cavity extends for about ten Earth radii on the Sun's side and about 1,000 Earth radii on the night side.

The magnetosphere contains plasma. At about four Earth radii from the centre of the Earth, electron density markedly increases. Within this region, plasma particles are confined in closed orbits by the Earth's magnetic field, whereas those outside the region may drift to the edge of the magnetosphere. The inner region is called the plasmasphere. To within about 2,500 kilometres of the Earth's surface, the plasma throughout the magnetosphere consists of completely ionized hydrogen. In a somewhat ill-defined region below 2,500 kilometres and above 350 kilometres, oxygen and helium ions predominate. The degree of ionization decreases but the electron density increases with decreasing height. The degree of ionization at 350 kilometres is about 5×10^{-3} per cubic

metre, whereas the electron density reaches a maximum of about 10^{12} cubic metres. Below this level, the electron density slowly decreases, falling away rapidly beneath 100 kilometres.

The region between about 100 and 350 kilometres is normally referred to as the ionosphere, although this term has also been used to describe the entire magnetospheric plasma. In the ionosphere the dominant ions are those of atomic and molecular oxygen and nitric oxide. These are produced by photo-ionization of the upper atmosphere by solar ultraviolet radiation.

High-energy particles also exist in the magnetosphere. At about 1.5 and 3.5 Earth radii from the centre of the Earth, two regions contain high-energy protons. These regions are the Van Allen belts; the protons in them are trapped in mirror systems formed by the Earth's magnetic dipole field. In general, the inner regions of the plasmasphere are stable, but in the outer regions disturbances can lead to the rejection and ejection of particles. These precipitate into the upper atmosphere in the region of the poles, causing auroral displays (see IONOSPHERE).

Terrestrial. Plasma can exist also in the lowest regions of the Earth's atmosphere. A lightning stroke is actually an oxygen–nitrogen plasma heated to approximately 20,000° K, with an ionization of about 20 percent, similar to that of a laboratory arc. Although the bolt or stroke is only a few centimetres thick and lasts only a fraction of a second, tremendous energies are dissipated.

Lightning flashes and ball lightning

A lightning flash between ground and a cloud, on the average, consists of four such strokes. An associated phenomenon is ball lightning. There are authenticated reports of glowing, floating, stable balls of light several tens of centimetres in diameter occurring at times of intense electrical activity in the atmosphere. On contact with an object these balls release large amounts of energy. Although lightning balls are probably plasmas, so far no adequate explanation of them has been given.

Considering the origins of plasma physics and the fact that the universe is little more than a vast sea of plasma, it is ironic that the only naturally occurring plasmas at the surface of the earth besides lightning are those to be found in ordinary matter. The free electrons responsible for electrical conduction in a metal constitute a plasma. Ions are fixed in position at lattice points (crystal sites), and so plasma behaviour in metals is limited to such phenomena as plasma oscillations and electron cyclotron waves (called helicon waves) in which the electron component behaves separately from the ion component. In semiconductors (a special class of conductors), on the other hand, the current carriers are electrons and positive holes, the latter behaving in the material as free positive charges of finite mass. By proper preparation, the number of electrons and holes can be made approximately equal so that the full range of plasma behaviour can be observed.

The importance of magnetic fields in astrophysical phenomena has already been emphasized. It is believed that these fields are produced by self-generating dynamos, although the exact details are still not fully understood. On Earth, differential rotation in its liquid core causes the external magnetic dipole field (manifest as the North and South Poles). Fields inside the core are twisted into circular loops; cyclonic turbulence in the liquid, generated by heat conduction and Coriolis forces (apparent forces accompanying all rotating systems, including the heavenly bodies) then regenerate the original dipole field from these loops.

Similar processes are believed to occur both in the Sun and the Galaxy. In the Sun the circular internal magnetic field is observed by lines of force apparently breaking the solar surface to form exposed loops; entry and departure points are what are observed as sunspots. Although the exterior magnetic field of the Earth is that of a dipole, this is further modified by currents in both the ionosphere and magnetosphere. Lunar and solar tides in the ionosphere lead to motions across the Earth's field that produce currents, like a dynamo, which modify the initial field. Again, changes in the intensity of the solar wind induce or produce other currents in the magnetosphere; such currents constitute the essence of a magnetic storm (see EARTH, MAGNETIC FIELD OF).

Plastics and Resins

Plastics, in the modern meaning of the word, are synthetic materials that are capable of being formed into usable products by heating, milling, molding, and similar processes. The term is derived from the Greek *plastikos*, "to form." By some interpretations of the word, rubber and other natural products are said to be plastic, but the modern definition, especially in relation to industry, excludes natural rubber and also such other natural products as wood, leather, and metals. Resins are both natural and synthetic. Natural resins range from pitch and asafetida to frankincense, myrrh, and amber. Synthetic resins are the bases of an enormous range of products the growth of which shows no signs of abating.

The distinction between plastics and resins is at best arbitrary, since many of today's synthetic materials can properly be called both resins and plastics. Historically, it appears that the term resin was applied to those products primarily used as substitutes for the natural product in coating compositions, whereas the term plastic was applied to designate those compositions that involved a molding operation in their fabrication.

By custom, the fibre industry is considered to be outside the plastics industry, although the same raw materials—polyamides (nylon), cellulose, and cellulose acetate—are used by the two industries. For a detailed discussion of these substances and their use in the manufacture of fibres, see FIBRES, MAN-MADE.

Composition of plastics

The characteristic ability of most plastics to soften but not melt when heated, so that their shape can be changed under mechanical stress without losing cohesion, producing a rigid new form upon cooling, is a property resulting from their molecular structure. Plastics are composed of giant molecules, known as polymers, with immensely long chains of repeating units derived from short molecules; in the case of addition polymers the short molecules are known as monomers. The chains are built up by formation of chemical bonds. The assembly of polymeric chains is held together by a number of different types of forces: (a) London, Van der Waals, or dispersion forces, which are relatively weak; (b) for more polar materials, hydrogen bonding or dipole-dipole interactions can be involved and result, in general, in somewhat higher softening points; (c) the long polymer molecules are inevitably entangled with each other and considerable forces are required to disentangle them. When heated, these chains move apart sufficiently to permit them to slide over one another but retain their cohesiveness because of the forces still operating. By contrast, the components in crystals of small molecules move apart sufficiently to melt to mobile liquids.

This ability to slide into new positions, which are retained on cooling, is the basis of plastics fabricating processes, such as molding or extrusion of sheets or other forms from heated granules, vacuum forming of sheets into desired forms, blowing of extruded tubes into bottles, and other processes. At higher temperatures maximum mobility is attained, allowing injection molding (in which the plastic is injected into a hollow casting and

cooled) into an infinite variety of forms. These processes require only moderately high temperatures, usually in the range of 150–250° C (300–480° F), and are very versatile, enabling easy fabrication of a variety of forms. Plastics also have the advantages of toughness, lightness, and of lack of colour, giving rise to an enormous range of coloured products by the addition of dyes and pigments; some plastics are transparent.

Intermeshing of the long-chain molecules of the polymers of which plastics are composed is responsible for their mechanical toughness and ductility, in contrast to the brittleness of low molecular weight organic substances, whether glasslike or crystalline. The hardness and ductility of polymers may be modified by the choice of the constituents that make up the chains. The intensity of the molecular attraction between neighbouring chains and flexibility within the chains (*i.e.*, freedom or restriction of rotation about main chain bonds) are important factors.

All these polymers are known as thermoplastics. Some long-chain materials known as thermosets can also be fabricated; on heating or with chemical treatment during fabrication, the chains of thermosets link with one another to produce a network structure that prevents softening on reheating. Phenol–formaldehyde is a typical thermoset.

This article is divided into the following sections:

I. History of the plastics industry
II. Types of plastic materials: their formation and usage
  Polymerization: the basic reaction
  Thermosetting resins
  Thermoplastic resins
  Other types of resins
III. Plastics manufacture and fabrication
  Natural raw materials
  Chemicals and additives
  Basic techniques for processing plastics
  Fabrication and finishing
IV. Industrial plastics
  Structural foams
  Sheets and films
  Laminates, reinforced plastics, and composites
  Miscellaneous industrial plastics

I. History of the plastics industry

The first plastic was Parkesine, later called Xylonite, exhibited by the English chemist and inventor Alexander Parkes in 1862. Essentially this substance was nitrocellulose softened by vegetable oils and a little camphor. It was John W. Hyatt in the United States who recognized in 1869 the vital plasticizing effect of camphor and named the product Celluloid. Though primarily regarded as a substitute for ivory and tortoiseshell, Celluloid, despite its inflammability, found substantial early uses as carriage and automobile windshields and motion picture film.

Celluloid

The first completely synthetic plastic was commercially produced from phenol and formaldehyde in 1910 by Leo Hendrik Baekeland, a Belgian-born American chemist. A dark thermosetting resin, later called Bakelite, this substance was used in the electrical industry. The first colourless resin, from urea–formaldehyde, though patented in 1918, was not marketed until 1928. Though available in any colour, it was moisture adsorbent (that is, moisture clung to its surface); this problem was overcome in 1939 by using melamine instead of urea.

Meanwhile, cellulose acetates received intensive study. At first, only the triacetate, soluble in toxic solvents, was produced and applied as a waterproof varnish to the fabric on airplane wings; at the end of World War I, the triacetate was manufactured in powdered form for later melting and molding.

During the same period, transparent acetate film was developed and used for packaging. With development of methylene chloride manufacture, triacetate film came into use as a photographic base in 1935.

Three principal factors contributed to the immense progress in plastics that took place after 1920. Of these, the work of the German chemist Hermann Staudinger is outstanding. In May 1922 he published a paper that demonstrated that rubber was composed of a chain of isoprene units, and the word macromolecule first appeared. His views aroused much opposition and this led him to an intensive study of styrene resin. By examination of the viscosities of its solutions, Staudinger showed that styrene resin was an assembly of macromolecules or giant polymers of different lengths that he called polystyrene. Staudinger's discovery of the theoretical background of polymerization coincided with two other factors: the growth of the chemical industry in general and a political impetus in Germany toward independence from many natural materials, leading to the industrial development of processes long known in the laboratory.

Vinyl chloride, discovered in 1835, is formed by the reaction of acetylene with hydrochloric acid. The polymer polyvinyl chloride (PVC) was first produced in 1912. There was a similar background to polymethyl methacrylate, starting with acrylates, which were polymerized in the laboratory in 1880 and came into production in 1927. A great deal of this work was done in Germany, including large-scale production of polystyrene.

Plastics research and manufacture was proceeding on a considerable scale in the United States as well. Outstanding was the study of polymers in the laboratory of E.I. du Pont de Nemours & Company from 1928 onward, which led to the "superpolyamide" now known as nylon.

The next great step forward was the British invention of polyethylene, which came into commercial production in 1939. Originally of unique value in radar, it is now used in enormous quantities in the form of film and in products made by injection-molding techniques. Further developments included polyurethanes in 1937, epoxy resins in 1943, polyethylene terephthalate in 1941, and polycarbonates in 1956.

Invention of polyethylene

Along with the work on polymers, there was a corresponding development of special machinery for plastics fabrication. When Celluloid was invented, the only equipment available for possible fabrication was that used in the rubber industry, such as the crude hydraulically operated "stuffing" machines for extrusion. The first patent for an extrusion machine employing an Archimedean screw was dated 1879; as thermoplastics were developed, more of these machines were used until one was designed especially for thermoplastics in 1935. Later, extrusion machines were produced for manufacture of plastic sheets and film and for blown bottles. The injection-molding machine was introduced in 1921. The first automatic machine was produced in 1937; later, an improved feed mechanism was added.

II. Types of plastic materials: their formation and usage

POLYMERIZATION: THE BASIC REACTION

Principles. The manufacture of plastics depends upon the building of chains and networks either by condensation polymerization or by addition polymerization.

A condensation polymer is formed by a synthesis that involves the stepwise reaction of reactive molecules with one another, with the elimination of small molecules such as water. The reaction gradually slows down as polymers are built up.

An addition polymer forms chains by the linking of small identical units (which may be diversified to a degree) without elimination of small molecules.

The most important concept in condensation polymers is that of "functionality" (f)—*i.e.*, the number of reactive groups in each molecule participating in the chain build-up. Each molecule must have at least two reactive groups, of which hydroxyl ($-OH$), acidic endings ($-COOH$), and amine endings ($-NH_2$) are the simplest.

Hydroxyl is characteristic of alcohol endings, combining with an acid ending to give an ester, the polymer being known as a polyester. Examples are polyethylene terephthalate (by reaction of ethylene glycol containing hydroxyl groups at each end and terephthalic acid containing two acidic groups) and polycarbonate resins. (For a detailed description of polymerization, see POLYMERS.)

Alcohols are a particular class of oxygen-containing chemical compounds with a structure analogous to ethyl alcohol (C_2H_5OH). Amines are various compounds derived from ammonia by replacement of hydrogen by one

or more hydrocarbon radicals (molecular groups that act as a unit). Esters are compounds formed by the reaction between an acid and an alcohol or phenol with the elimination of water.

Processes. Bulk addition polymerization of pure monomers is mainly confined to styrene and methyl methacrylate. The process is highly exothermic, or heat producing. The dissipation of heat (necessary to maintain chain length) is achieved in the case of styrene by intensive stirring of the viscous, partially polymerized mixture, which is then passed down a tower through zones of increasing temperature. Alternatively, polymerization may be completed in containers or molds that are small enough to avoid an excessive temperature rise as a result of the heat released during polymerization.

Methyl methacrylate is also partially polymerized before pouring into molds formed between sheets of plate glass, to produce clear acrylic sheet.

Ethylene polymerization

Ethylene is polymerized in tubular reactors about 100 feet (30 metres) long and less than one inch (25 millimetres) in diameter at pressures of 600–3,000 atmospheres (one atmosphere equals the pressure of air at sea level) to give 10–20 percent conversion to low-density polyethylene. Residual gas is recycled.

Solution polymerization. Polymerization of monomers in solution gives easy temperature control but reduces the molecular weight of polymers formed as a result of chain transfer reactions. (Such reactions involve growing polymer chains reacting with small solvent molecules to give inactive polymers and starting a new chain, rather than allowing the original chain to grow to the high molecular weight which would have been obtained in the absence of such transfer.) Solvent removal from such a solution may also be very difficult. The process can be applied particularly to vinyl acetate and acrylic esters.

Solution polymerization. Polymerization of monomers tion producing beads of plastic is extensively applied to styrene, methyl methacrylate, vinyl chloride, and vinyl acetate. The monomer, in which the initiator or catalyst must be soluble, is maintained in droplet form suspended in water by agitation in the presence of a stabilizer such as gelatin, each monomer droplet behaving as a small bulk polymerization.

Emulsion polymerization. In emulsion polymerization the monomer is dispersed in water by means of a surface-active agent (a substance that reduces the surface tension of a liquid), slightly soluble in water, its bulk aggregating into tiny particles held in suspension (micelles). The monomer enters the hydrocarbon part of the surface-active micelles and is polymerized there by a water-soluble catalyst. This process is particularly useful for the preparation of very high molecular weight polymers.

Radiation polymerization. This process operates by molecular excitation leading to ejection of an electron. It can be used for manufacture of such thermoplastics as polyethylene and polyvinyl chloride.

THERMOSETTING RESINS

These include the phenolics, furan resins, aminoplastics, alkyds, allyls, epoxy resins, polyurethanes, polyesters, and silicones.

Phenolics or phenol–aldehydes. The most important commercial phenolic resin is based on phenol and formaldehyde. The two processes in general use are the one-step process producing resol resins (the first stage in the formation of a phenolic resin) that are either liquid or brittle, soluble, fusible solids, from more than one molecule of formaldehyde per phenol molecule; and the two-step process, using an excess of phenol to produce novolacs, resins that have no reactive methylol groups and must be mixed with an aldehyde to undergo further reaction.

Resol resins thermoset on heating and are used for adhesives. Novolacs require a further source of formaldehyde in the form of hexamethylenetetramine to produce molding powders. Both resins are run out from the reaction vessel, after removal of water by distillation, and ground up, then compounded on heated rolls with fillers that vary from wood flour to mica; for strength and heat resistance fibrous asbestos is used as a filler (hexamethylenetetramine is also added at this stage in the case of the two-step resin). Final grinding produces the molding powders, which on further heat treatment will yield the typical thermoset resin.

Characteristics of phenolic moldings

Phenolic moldings are resistant to heat, chemicals, and moisture and are preferred for wet-dry applications as in washing machines. Their high heat resistance and low heat conductivity recommend them for appliance parts, and their high electrical insulation for electric fittings such as switches, plugs, and distributor caps; resistance to hydraulic fluids has led to their use in automotive parts, and all these applications have been substantially increased by the development of injection molding and extrusion methods not hitherto applied to thermosets. Complex phenols from; *e.g.*, cashew-nut shell liquid are used in manufacture of brake linings.

Furan resins. Furfural is a five-membered ring compound (*i.e.*, the basic molecule has a ring shape and contains five atoms) of four carbon atoms and one oxygen atom, carrying the aldehyde group, – CHO; it reacts like formaldehyde with phenols in the presence of an acid catalyst to give a rigid polymer with high chemical resistance, used for coatings in industry. It can be prepared in semiliquid form with a low viscosity and remarkable penetrating power when applied to porous forms such as foundry sand cores or graphite blocks, being in this respect superior to other liquid resins.

Aminoplastics. Urea resins are made by the condensation in aqueous solution of formaldehyde and urea in the presence of ammonia as an alkaline catalyst, giving a colourless syrupy solution to which cellulose filler is added to yield a molding powder upon drying, which when heated in a mold gives a water-white (transparent) molding unless previously coloured by pigment.

The filler confers considerable strength, so that thin sections such as in cups and tumblers can be molded. Very large quantities of urea–formaldehyde resin are used in closures, kitchen and bathroom hardware details, and electric appliance housings and fittings.

Melamine behaves in the same way as urea, but the product is more moisture resistant, harder, and stronger, leading to wide use for plates and food containers. Melamine moldings are glossy and harder than any other plastic and retain a dust-free surface. Solutions of the thermoplastic stages of urea–formaldehyde resins are widely used as bonding agents for plywood and wood-fibre products.

Alkyds. Alkyds are polyesters, generally of phthalic acid with two acid endings and glycerol, a triol—*i.e.*, an alcohol with three hydroxyl groups. The solid resins are molded at high speed under low pressure, cured quickly, and are used where insulating properties, strength, and dimensional stability over a wide range of voltage, frequency, temperature, and humidity are required, as in vacuum-tube bases and automotive ignition parts and with glass-fibre reinforcement for switchgear and portable tool housings.

DAP and DAIP resins

Polyesters of unsaturated alcohols. Known as DAP and DAIP, these resins are esters of phthalic and isophthalic acid, respectively. They are notable for maintaining rigidity and excellent electrical properties at temperatures up to 230° C (450° F), properties also manifested by allylic resin-impregnated glass cloth, used in aircraft and missile parts. Other advantages are good storage life and absence of gas evolution during polymerization.

The allyl resin allyl diglycol carbonate, optically clear and colourless, is used for making cast objects; fully cured castings are more heat and abrasion resistant than other cast resins.

Epoxy resins. These resins have outstanding mechanical and electrical properties, dimensional stability, resistance to heat and chemicals, and adhesion to other materials. They are used for casting, potting, encapsulation, protective coatings, and adhesives, and for reinforced moldings and laminates of the highest quality. Popular adhesives (epoxy glues) contain the resin components and the curing agent, usually an amine or an anhydride, in separate packages. The two are mixed just before use.

Polyurethanes. Formed by the reaction between diisocyanates and polyols (multihydroxy compounds), polyurethanes are among the most versatile of plastics, ranging from rigid to elastic forms. Their major use is for foams, with properties varying from good flexibility to high rigidity. Thermoplastic polyurethanes that can be extruded as sheet and film of extreme toughness can also be made.

Polyesters of unsaturated acids. Certain esters can be polymerized to an infusible resin and are used on a very large scale in glass-fibre-reinforced plastics. Unsaturated acid (usually maleic acid in the form of its anhydride) is first polymerized to a relatively short polymer chain by condensation with a dihydric alcohol such as propylene glycol, the chain length being determined by the relative quantities of the two ingredients. The resulting syrupy condensation polymer is then diluted with a monomer such as styrene and an initiator for addition polymerization added. This mixture is quite stable at room temperature over a long period. Frequently, a silicone compound is added to promote adhesion to glass fibres, and wax to protect the surface from oxygen inhibition of polymerization. Glass-fibre materials are impregnated with the syrup and polymerization is brought about by raising the temperature. Alternatively, the polymerization can be carried out at room temperature by addition of a polymerization accelerator to the syrup immediately before impregnation. After an induction period, which can be controlled, polymerization takes place, with rapid increase in temperature, to give a glass-fibre-reinforced cross-linked polymer, which is effectively a thermoset type of plastic and very resistant to heat. The properties of the resin are frequently varied by replacing part of the unsaturated maleic anhydride by anhydrides of saturated acids such as sebacic acid.

Silicones. Silicon, unlike carbon, does not form double bonds or long silicon chains. It does, however, form long chains with oxygen such as in siloxanes with hydrocarbon groups attached to the silicon; these result in a wide range of oils, greases, and rubbers. Produced through a series of reactions involving replacement of certain atoms in the chain, silicon resins, or silicones, can be used for high- and low-pressure lamination, with glass-fibre reinforcement and with mineral or short glass-fibre fillers, or for molding powders. The outstanding characteristic of these products is high dielectric strength (that is, they are good insulators at high voltages) with low dissipation over a wide temperature and humidity range. Silicones are not distorted by heat up to 400° C (752° F). They are also physiologically inert and therefore valuable for prostheses (artificial body parts).

THERMOPLASTIC RESINS

These include cellulose derivatives, addition polymers, and condensation polymers.

Cellulose derivatives. Cellulose is a naturally recurring chain of units, each of which carries three hydroxyl groups, which can be esterified by acids. Cellulose nitrate is formed by treating cellulose with a mixture of strong sulfuric and nitric acids; after a purification process, mixing with alcohol and camphor yields a plastic mass that is rolled into sheets. These are pressed into a block, sliced to the required thickness, and then dried and polished by hot pressing against polished metal sheets. The sheets made by slicing still contain alcohol and can be cut up and repressed in various ways to give patterned material or, if cut into dice, can be extruded as plain sheet. Nitrocellulose cannot be injection molded because of its inflammability. Otherwise it is tough and moisture resistant and is used for eyeglass frames and table tennis balls.

Cellulose acetates

If cellulose is pretreated with acetic acid, followed by more acid and its anhydride, acetate esters are formed, giving cellulose triacetate. Complete acetylation would produce an acetic acid content of 62.5 percent; in practice about 61 percent is usual, giving a moisture-resistant, dimensionally stable material with a crystalline structure, soluble in a limited range of solvents, preferably methylene chloride with 10 percent methanol. It cannot be worked into a plastic with plasticizers, but plasticizers can be incorporated in a 15–16 percent solution from which film is cast as a photographic base. This is the type of solution referred to as "dope" in Figure 5.

Further treatment of the triacetate in solution in the presence of sulfuric acid splits off some acetic acid giving diacetate, soluble in acetone, and compatible with a range of plasticizers that can be incorporated in a rugged type of mixer without solvent to yield molding powders especially suited to injection molding.

Tool handles are a common use of cellulose acetate. It can also be treated by the slicing process described above, but its largest use is as packaging film, made either by extrusion or by a casting process, which gives a superior product.

If butyric or propionic acids are included in the esterifying mixture, acetate butyrates and acetate propionates are formed. These require less plasticizer and are tougher and more moisture resistant. An important use is for automobile steering wheels.

Ethyl cellulose is formed from cellulose and ethyl chloride. Very tough and requiring little plasticization, it is used for athletic helmets, flashlight cases, and fire-extinguisher components. It is also compatible with a very wide range of plasticizers and waxes and, when mixed with wax, can be used for protective coatings.

Low-density and high-density polyethylene

Addition polymers. Polyethylene is made in two principal qualities: low density, polymerized at pressures from 9,000 to 45,000 pounds per square inch (630 to 3,150 kilograms per square centimetre); and high density, made with special catalysts at 250 to 500 pounds per square inch (18 to 35 kilograms per square centimetre).

Low-density polyethylene has a 20° C (68° F) lower softening point than high-density polyethylene, which is more crystalline and consequently stiffer. The rigidity characteristics and surface of high-density polyethylene are comparable with polystyrene. It resembles nylon in feel, has a bursting strength three times that of low-density polyethylene, and withstands repeated exposure to 120° C (250° F) so that it can be sterilized.

Low-density polyethylene is principally used in the form of film for bags of all sizes, with thickness ranging from 0.00025 inch (0.00635 millimetre) to 0.007 inch (0.178 millimetre), for agricultural mulch, building-site protection, lamination, all kinds of packaging, and electrical-cable insulation.

Because of its stiffness, high-density polyethylene is used for large drums, gasoline tanks, bottle crates, domestic appliances that can be injection molded to large sizes, and squeeze bottles. It can also be produced in the form of foam.

Polyethylene can be chlorinated either in solution in carbon tetrachloride or in suspension, both in the presence of a catalyst. Below 55–60 percent chlorine it is more stable than polyvinyl chloride and is compatible with many polymers, especially polyvinyl chloride, to which it gives increased impact strength.

The low pressure process can be used to copolymerize polyethylene with propylene and butylene to increase resistance to stress cracking.

Copolymerization with vinyl acetate at high pressures increases flexibility, resistance to stress cracking, and also sealability, which is especially valuable in the food industry.

Ionomers are ethylene polymers in which carboxyl groups are located along the ethylene chain. These acid groups are converted into salts of sodium, potassium, magnesium, or zinc; this stiffens and toughens the plastic without destroying its thermoplastic character. As a result, unplasticized sheet has drawing characteristics superior to those of any other resin.

Ionomers are highly transparent, particularly resistant to organic solvents, and maintain toughness at low temperatures. They are used in composite films with polyethylene and nylon because of their puncture resistance; they have strong natural adhesion to aluminum. Their main applications are in food packaging and as injection moldings in the shoe industry.

Polypropylene. Polypropylene is made by the polymerization of propylene. Stronger and more rigid than poly-

ethylene, polypropylene has a harder surface, softens 30° to 40° C (54° to 72° F) higher, and is the lightest common plastic. It is more prone to oxidation than polyethylene unless appropriate stabilizers and antioxidants are added.

Injection molding affords its greatest outlet over a very wide range of applications including beer crates, luggage, and automotive panels and trims. An outstanding use is for integral hinges, because of its fatigue resistance. (An integral hinge is part of an object as it is manufactured, in contrast to most hinges, which are fastened to the object later.)

Polypropylene is being used in increasing quantities for fibres and for film. The latter is extruded and develops its greatest strength when oriented by stretching biaxially—that is, along two axes at right angles. Film clarity is obtained by minimizing the size of crystals and by various additive agents. It is made in thicknesses down to 0.0002 inch (0.005 millimetre). Copolymers of propylene with minor amounts of ethylene are also used for making film.

Methylpentene polymer. Methylpentene polymer is the lightest plastic, has a high crystalline melting point of 240° C (464° F) retaining form up to 200° C (392° F), has a light transparency of 92 percent, and electrical properties similar to polytetrafluoroethylene (described later). Its impact strength is greater than that of polystyrene and polymethyl methacrylate. It is also resistant to alkalies, weak acids, and solvents (except chlorinated solvents) and is excellent for laboratory ware and medical equipment (because it can be sterilized) made by injection molding, and for food packaging and catering, since food can be cooked in methylpentene polymer containers in conventional ovens, providing a nonstick surface resistant to hot fat.

Vinyls. Vinyl chloride is made from ethylene and chlorine, though acetylene can also be used (see Figure 1). The polymer (called polyvinyl chloride) is mainly processed in a highly plasticized form, with varying degrees

Drawing by D. Meighan

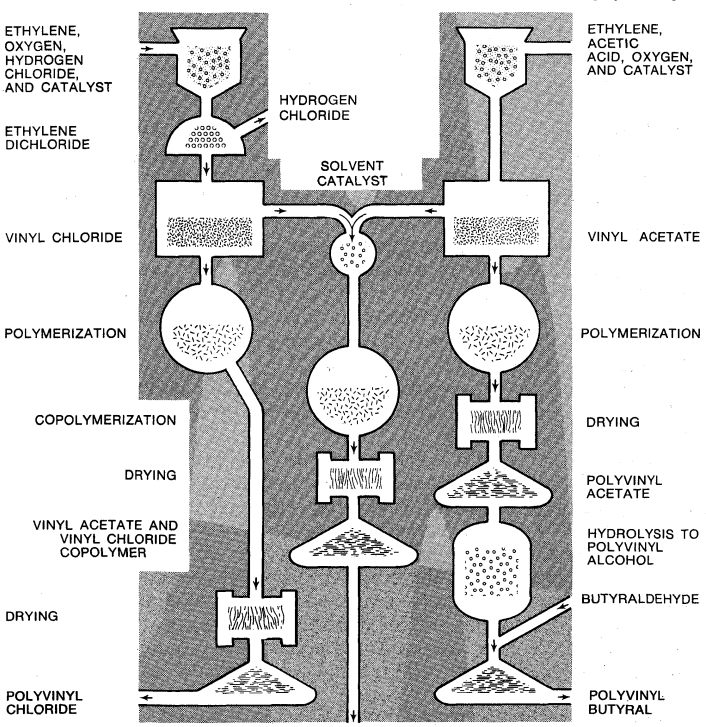

Figure 1: Principal steps in the production of vinyl resins.

of flexibility, by calendering (pressing between heavy rollers), extrusion, and molding, often from "dry blends," mixtures made below fusion temperature from polymer, plasticizer, and pigments. Plasticizers are chosen to maintain flexibility at low temperatures; the most commonly used plasticizer is dioctyl phthalate, but adipates may be used for special resistance to temperature change.

The range of applications of flexible polyvinyl chloride is enormous, covering clothing, flooring, wire insulation, home furnishings, piping, toys, and steel sheet covering. Extrusion, calendering, and molding of rigid polyvinyl chloride (*i.e.*, without plasticizer) is only possible with additions of stabilizers to prevent decomposition. Such stabilizers are mainly metallic (tin or cadmium) salts aided by epoxy resins, which also act as plasticizers, and lubricants such as stearates. Processing also may be aided by blending with such polymers as styrene acrylonitrile, polymethyl methacrylate, and chlorinated polyethylene.

Rigid polyvinyl chloride applications include bottle blowing, ducting in chemical plants, rainwater goods, piping for water and drainage mains, and light roofing. It has one of the highest combinations of stiffness and impact strength.

Plastisols and organosols

Plastisols and organosols are made by dispersing a very fine emulsion of polymerized resin in a plasticizer, usually in excess of the amount in flexible polyvinyl chloride (about 50 percent), together with stabilizers and gellants such as a calcium soap. Solvents and diluents are also used, and if they amount to more than 10 percent of the compound the product is known as an organosol.

The formulation can be difficult, as the flow characteristics can be varied greatly by choice by plasticizer and pigment (if used) and must be varied to suit the end use. Products are made by spreading, as on fabric, by dipping or by filling hot molds and pouring off excess material after gelling the outer layer at about 170° C (338° F). Plastisols can also be cast in molds; when maximum rigidity is required, diluents are used to permit lower plasticizer content. Plastisols can also be foamed.

Copolymers of vinyl chloride containing 5 to 40 percent vinyl acetate are made by the inclusion of vinyl acetate in the polymerization process; they have lower softening points and flow more easily than polyvinyl chloride at temperatures below decomposition points. They are thus suitable for making phonograph records, rigid clear sheeting, and molding powders. They are soluble in ketones, such as acetone, and certain esters, and they can be cast as film from solutions.

Copolymerization with vinylidene chloride, in quite small quantities, has the same effect on flow as vinyl-acetate and also increases the tensile strength of the plastic.

The chlorination of polyvinyl chloride, originally done in solution, is now carried out in a water–chloroform suspension. Extruded tube can be used in soil and waste systems and for central heating since its maximum service temperature is 100–105° C (212–221° F).

Vinylidene chloride can be made directly from ethylene and chlorine or by the further chlorination of vinyl chloride with subsequent removal of hydrochloric acid by alkali treatment. Copolymers of vinylidene chloride with minor proportions of vinyl chloride or acrylonitrile are used for making synthetic fibres, coating resins, and extruded thin films. The outstanding property of vinylidene chloride polymers is their low permeability for water vapour and gases. Coatings of the polymer are used on cellophane and other films to make them impervious to moisture.

Vinyl acetate is polymerized to a tough resin (polyvinyl acetate) by addition polymerization in solution to give an adhesive with a very high degree of tack (stickiness) and consequently of good adhesion; its main use, however, is as a basis of emulsion paints, in which case it is emulsion polymerized and not separated from the reaction mixture. Its use as a copolymer with ethylene and vinyl chloride has already been mentioned.

Polyvinyl alcohol is made by the saponification of polyvinyl acetate—*i.e.*, the removal of the acetic acid by alkali. In practice, a small amount of combined acetic acid is left in the molecule. The product is a water-soluble film-forming material used in dental molding and in the form of fibres for reinforcement (*e.g.*, of polyester), notably for injection-molded rail-tie retainers. If reacted with butyraldehyde, it gives polyvinyl butyral, an extremely tough but soft plastic used in sandwich-type safety glass.

Acrylics. Acrylic is a generic name applied to derivatives of acrylic acid, of which methyl methacrylate is

the most important. The process of polymerization is directed toward control of chain length, which for cast resins is from 1,800 to 3,000 monomer units; for molding powders only about 500 units are required to facilitate flow into a mold. A small amount of plasticizer such as dibutyl phthalate may be added before bulk polymerization to assist in deep molding.

Properties of transparency

The outstanding property of polymethyl methacrylate is its light transmission of 92 percent and water-whiteness (transparency), a property maintained over years of exposure to weather. It is also resistant to ultraviolet radiation from fluorescent lamps and is readily fashioned by deep drawing (*e.g.*, for airplane canopies) and by injection molding (*e.g.*, for light fittings and automotive details, including signal lights).

A most successful use is for internally illuminated signs. Any colour can be introduced, and structural uses that take advantage of its transparency and toughness are numerous and varied. Its dimensional stability recommends it for many optical uses.

Sheets can be cast in cells made from two sheets of glass plates; the cells are filled with a viscous solution of partially polymerized material. Other shapes are cast by the use of appropriate cell forms. Sheet is also made by an extrusion process, the emerging sheet being drawn through a calender with a highly polished chromium finish heated to 100° C (212° F). Acrylic dentures are made by stirring the powdered polymer into methyl methacrylate monomer containing a catalyst, and completing the polymerization in a mold formed from a dental impression.

Acrylics are also modified by copolymerization to improve impact strength, though they lose their extreme transparency and are usually pigmented, as for piano keys. An example is acrylic-modified polyvinyl chloride sheet, which is tougher than acrylonitrile–butadiene–styrene and polycarbonate and is suitable for corrosion-resistant parts, aircraft components, and materials-handling equipment.

Fluorine-carbon resins. Polytetrafluoroethylene and fluorinated ethylene–propylene are the only resins composed wholly of fluorine and carbon. The monomers are polymerized in water either to a granular solid or a dispersion. In the polymers the fluorine atoms surround the carbon chain as a sheath, giving a chemically inert and relatively dense product with immensely strong carbon–fluorine bonds. Polytetrafluoroethylene cannot be molded in the ordinary way but must be preformed at a very high pressure, followed by a sintering (heating under pressure) process and, in certain cases, by further processing to obtain an accurate form. Fluorinated ethylene–propylene can, however, be injection molded and extruded as thin film. Both plastics have exceptional heat resistance and very low friction coefficients. This leads them to be used for such mechanical applications as seal rings, nonlubricated bearings, and packings.

Resins for electrical use

For electrical applications, polytetrafluoroethylene and, to a slightly less degree, fluorinated ethylene–propylene resins are exceptional in that electrical and other properties are not adversely affected by long exposure to high temperatures. Polytetrafluoroethylene can be used in temperatures up to 260° C (500° F), and neither it nor fluorinated ethylene–propylene shows any embrittlement; they are also flexible at low temperatures and are standard insulation in aircraft and spacecraft. Their excellent electrical insulating properties lead to their use in very high frequency, ultrahigh-frequency, and other electronic applications. Polytetrafluoroethylene is also available in emulsion form to give adherent coatings to metals. Its complete inertness and low friction coefficient lead to its use in surgical prostheses, especially in joints.

Chlorotrifluoroethylene is a thermoplastic resin produced in varying formulations from combinations of fluorine-containing monomers. It has inherent flexibility, toughness, and clarity, differing in this last respect from the waxlike polytetrafluoroethylene. It is chemically resistant to all inorganic corrosive liquids and to most organic solvents, has zero moisture absorption, and a very wide range of service temperatures.

Its flexibility, combined with high insulating and thermal properties and facilitated by its extrusion properties, recommends it for wire and cable covering; its thermoplasticity, which can be augmented by plasticizer addition, or copolymerization with vinylidene fluoride, makes it an excellent material for injection molding of valve parts, closures for corrosive liquids, and for medical supplies.

Available with surfaces prepared for adhesion, polyvinyl fluoride transparent extruded film is unequalled for weatherability; it is used for external surfaces as a laminate. Polyvinylidene fluoride, a transparent injection-moldable plastic stronger than other fluoroplastics, is slightly less inert but particularly resistant to oxidizing agents found in the chemical industry.

Styrenes. Styrene is polymerized to a clear transparent water-white resin called polystyrene on a very large scale by a mass-block or continuous-mass process or by suspension polymerization in a water medium. In the mass-block method, polymerization takes place in a system of cells alternately filled with monomer and a cooling medium; continuous polymerization takes place in a tower, with cooling zones and a heated base from which the polymer is extruded. Polystyrene is an ideal injection material, hard, brilliantly transparent, and a good insulator; but it softens in boiling water, is brittle, and burns readily.

In very thin moldings for food containers, the polymer becomes oriented by flow, which toughens it; extruded film can be vacuum formed to give containers suitable for fresh food because of their high gas permeability and good water-vapour transmission. Polystyrene is readily foamed by blowing agents, flame retardants being added to the polymer.

High-impact polystyrene is made by dissolving styrene–butadiene rubber in styrene and then polymerizing the styrene. Polymerization of the mixture may be carried out by bulk or suspension processes.

Acrylonitrile–butadiene–styrene polymers are essentially similar in physical structure but with acrylonitrile added in the polymerization to harden the polymer. Minute rubber particles diminish clarity but act as stress-relief centres, making acrylonitrile–butadiene–styrene in particular an outstanding polymer, especially for large shapes (luggage, car bodies, etc.). Special grades are also made for automotive parts (softening point above 100° C, or 212° F) and for chrome plating. It is regarded as a good engineering plastic, can be foamed, injection molded, blown, and alloyed with other plastics.

Polymer for large shapes

Other addition polymers. Formaldehyde polymerizes readily to form paraformaldehyde. Under controlled conditions, a stable polymer of high molecular weight may be obtained. Polyformaldehyde is one of the strongest and stiffest thermoplastics, having a tensile strength of 10,000 pounds per square inch (700 kilograms per square centimetre). It can be injection molded and extruded. Exceptional fatigue endurance has led to its employment in automotive safety steering columns. Its impact strength and elastic recovery make it useful for snap-fit assemblies and springs, and its resistance to moisture and high abrasion and frictional resistance are advantageous in engineering uses generally. It also has good electrical properties over a wide temperature range.

Made mainly from trioxane (by condensation of formaldehyde) and ethylene oxide, acetal copolymers have properties resembling those of polyformaldehyde but in addition are notable for their stiffness at high temperatures, making them suitable for carburetor and automobile parts and for plumbing items. When glass-fibre-filled, they have exceptional resistance to creep (slow deformation over time when placed under stress).

A crystalline polymer, chlorinated polyether has a very low volume change from a melt to a solid state, permitting injection molding to very close tolerances. It has very high corrosion resistance to all reagents except oxidizing agents and is a valuable engineering plastic for valves, threaded socket connections, and precision machined gears, with stability up to at least 120° C (248° F). It can also be coated on metal parts by a number of coating techniques to give corrosion resistance.

Condensation polymers. The formation of polyamides has been briefly described earlier. By far the greatest production is of nylon-6,6, made by heating the amine and acid in an autoclave (an airtight vessel for carrying out chemical reactions under pressure) from which it is extruded on a chilled drum and cut into chips. It has a high melting point, strength, stiffness, toughness, and chemical resistance. After careful drying it can be extruded and injection molded.

Nylon-6,6 applications

Nylon plastics. These properties class it as an engineering plastic (a plastic used as a substitute for metal) and lead to a very wide range of applications such as gear wheels, oil seals, bearings, and parts for textile machinery. Extruded film is also used for boil-in-bag packaging. A large number of different molding powders is made by variation of molecular weight and copolymerization of various amide-forming constituents.

In addition, a number of different nylons are made by varying the molecular length of the diamines and the dibasic acids: nylon-6,10 using sebacic acid (ten carbon atoms); nylon-11, from an acid derived from castor oil; and nylon-12, made by a multistage process from butadiene. Terephthalic acid with methyl hexamethylenediamine gives a transparent polymer instead of the normal waxy product. The primary object of these variations is to decrease the moisture absorption.

Nylon-6 differs from these nylons in that it polymerizes directly, without elimination of water, from caprolactam. The polymer can be cast in place and is specially suited to irregular forms and thick sections because the low viscosity of the monomer prevents voids and polymerization is independent of part size, producing items ranging from 500-pound (227-kilogram) blocks to fuel tanks. The polymer can be extruded as easily sealable film and used for bake-in-bag bread and roast-in-bag meat. It is also used for packaging as a laminate with polyethylene.

Other variations are the use of amines with a ring structure, particularly the aromatic nylons, which give polymers with softening points above 300° C (572° F). A paper is made from chopped fibres from the phenylenediamine nylon that has electrical properties similar to mica.

Polyethylene terephthalate. Polyethylene terephthalate is a polyester, theoretically obtained by the reaction of glycol with dibasic terephthalic acid but actually made from glycol and dimethyl terephthalate by the process known as ester interchange. During the reaction methanol is produced instead of the water displaced during ordinary esterification. It is extruded as a transparent film in amorphous form and is immediately chilled. If it is stretched in two directions at right angles (biaxially stretched) at a temperature above 80° C (176° F), it is still mainly amorphous and can be used for shrink wrapping foodstuffs (a shrink wrapping shrinks after it is put around the object) and medical accessories by momentarily reheating it above the stretch temperature.

If, however, the film, biaxially stretched to three or four times its original dimensions, is held at a higher temperature, it crystallizes and develops very high tensile strength (25,000 pounds per square inch, or 1,760 kilograms per square centimetre) and dimensional stability.

Its main application is in food packaging, where it is used for meat packaging and for heat-and-serve packaging of convenience foods. For these applications it is frequently laminated with polyethylene. Its great strength and high dielectric strength make it ideal for insulation in electric motors, printed circuits, and cable insulation. Its dimensional stability and strength lead to its use for magnetic tape and increasingly for photographic film base. A special variety of the polymer has been developed that will mold to give the hardest plastic known.

Polycarbonates. Polycarbonates are long chain linear polyesters of carbonic acid and dihydric phenols, such as bisphenol A. This product is a faintly amber transparent plastic of good toughness, tensile strength, ductility, and dimensional stability maintained over a temperature range of 16° C to 150° C (60° F to 300° F).

It can be injection molded, blow molded, and extruded and is an ideal engineering plastic with good electrical insulating properties, finding applications in portable tool housings, safety helmets, computer parts, and vandal-proof windows and light globes. A number of special grades are made, including a special type to meet specific flammability requirements. Glass-reinforced polycarbonate can carry continuous loads up to 4,000 pounds per square inch (280 kilograms per square centimetre) at boiling-water temperature.

Uses of polycarbonates

Polyimides. Polyimides are made by a two-step reaction of dianhydride (tetrabasic acid with two molecules of water removed from each molecule of tetrabasic acid by chemical reaction) with an aromatic diamine giving first a polyamic acid that is converted by heat or catalysts to high molecular weight linear polyimides, available as film, laminating resins, adhesives, and molding compounds.

The polyamic acid is soluble; films can be cast from it and it can be used for laminates and adhesives. Polyimides are the best organic materials available for high-temperature insulators, capacitors, and bearings, and have special applications in space technology. Exposure at 275° C (527° F) for one year causes only a 1 percent elongation. Polyimides can also be produced as foamable powders for aerospace structural applications.

Other condensation polymers. If one amino group in *m*-phenylenediamine is converted to an amide group by formic acid, an intermediate is formed that on loss of water becomes benzimidazole. This reaction can be made using a wide range of reactants, producing resins (polybenzimidazoles) that can be used as high-temperature adhesives for laminates in the aerospace industry and compounded with tiny bubbles of silica (microballoons) and alumina fibres to provide insulation for re-entry vessels, fuel cells, and nuclear reactors. If the fillers are phenolic microballoons and carbon fibres, very high temperatures develop a carbonaceous char with excellent structural and ablative properties.

Aromatic polysulfones are transparent linear polymers made from the sodium salt of bisphenol A and *p, p'*-dichlorodiphenylsulfone. Light amber in colour and exceedingly resistant to oxidation, these plastics have extraordinary dimensional stability, a stress of 1,500 pounds per square inch (105 kilograms per square centimetre) for 100 hours at 150° C (300° F), producing barely visible deformation. These are first-class engineering plastics, used for underhood automotive parts, housings for power tools, and for dishwashers. Other phenols and sulfones are used for special high-heat-resistant materials.

Polyphenylene oxide is a linear polymer formed by oxidation of 2,6-xylenol by oxygen in the presence of a catalyst. It has very accurate dimensional tolerances at high temperatures and high chemical resistance. It is suitable for clock parts and surgical instruments and is in general a very good engineering plastic because of its stability, heat resistance, and low moisture take-up. Many variations in phenols are possible.

Though the starting materials for polyhydroxyethers, (phenoxy resins) are the same as for epoxy resins, phenoxy resins are of high molecular weight. An excess of epichlorohydrin is avoided to ensure thermal stability. Their properties can be varied by the use of different phenols, but the polymer from bisphenol A is commonly used. For coatings the hydroxyl group is usually esterified, and with drying oils thermosetting coatings can be made; phenoxy coatings are excellent primers because of high adhesion to metals and overall compatibility with topcoats of other plastics.

As molding powders they give tough, lightweight, clear moldings, easily printed and with good resistance to water and other liquids making them specially suitable for blown bottles. They have high abrasion and chemical resistance and can be hot gas welded. A special use is for jet-fuel tanks.

Steam at 950° C (1,740° F) converts *p*-xylene to an active intermediate that can be polymerized on a cooled surface to form poly *p*-xylylene. It is used only for very thin coatings as in miniaturized capacitors and for encapsulating such materials as lithium.

A prepolymer soluble in chlorinated solvents is made by

decomposing benzenesulfuryl dichloride in the presence of terphenyls at 300° C (570° F). Impregnation of reinforcing material with such a solution is followed by a series of heating processes with added benzenesulfuryl dichloride and catalysts, giving a cross-linked structure that is the best ablative resin, withstands temperatures up to 400° C (750° F), and remains unchanged for years at 200° C (390° F).

Coumarone–indene resins

Coumarone–indene resins, readily fusible, low-molecular-weight polymers, are not strictly plastics. They are made by polymerization of coumarone (benzofuran) and indene obtained from crude petroleum or from gas tar and coal tar resulting from the high-temperature carbonization of coal. The coumarone content is often less than 10 percent, and the polymer may contain styrene and methyl styrene, softening points varying with the composition up to 150° C (300° F). The catalysts are cationic (positively charged), and batch operation is traditional. Coatings of the resin are water and alkali resistant and are particularly useful vehicles in aluminum paint. They are also used in conjunction with chlorinated rubber and modified phenolics. They also greatly assist in the blending of fillers in rubber for floor coverings.

OTHER TYPES OF RESINS

Oil-soluble or modified resins. Alkyds used as coatings are polymers in which the spare hydroxyl, resulting from the esterification of a triol (usually glycerol) by a dibasic acid, is esterified by a long-chain (fatty) acid, which may contain double bonds. Since oils such as linseed are already glycerol esters, reaction is brought about by splitting off one or two acid chains—*i.e.*, reconstituting glycerol hydroxyl groups and re-esterifying these with more triol and a dibasic acid, usually phthalic acid, giving a complex polymer in which the acid chains polymerize among themselves and may retain double bonds which oxidize in air. As such, these are good drying oils.

Physical properties, including solubility, depend on composition, but their outstanding characteristic is compatibility with other resins.

Simple phenol– or cresol–aldehyde resins are insoluble in drying oils, but if resols are heated with an excess of an unsaturated organic acid such as rosin, they become soluble with removal of water and can be dispersed in ester gum (rosin glyceryl ester). By cooking with unsaturated oils such as tung and linseed, the rosin-modified resols disperse with some interesterification to produce air-drying varnishes.

The oil may also be incorporated by reacting phenol and formaldehyde in its presence or by reacting the phenol with the oil, with subsequent condensation with formaldehyde. Substituted phenols are sometimes used because they are more readily soluble in vegetable oils.

Plastics from other natural products. Casein plastic is made by reacting casein from milk with formaldehyde. It is produced in a variety of opaque colours, including pearl; it softens in hot water but takes a very high polish. Its use is greatly diminishing, but buttons and buckles are still made, partly because short runs, advantageous in fashion trades, are practicable.

Uses of lignin

Lignin is a mixture of complex thermoplastic phenolic polymers present in wood and straw. It can be used as a molding powder, but its chief use is for hard fibreboards, made by compressing high-lignin-content material at 10,000 pounds per square inch (700 kilograms per square centimetre) at 250° C (480° F), with or without previous treatment with phenol and formaldehyde. The lignin content is increased by disintegrating the cellulosic material and hydrolyzing part of it by treatment with steam and water at high pressure, the remaining fibre acting as reinforcement.

Synthetic resins for special applications. These applications include resin adhesives, paper, and textiles.

Apart from nitrocellulose and polyvinyl acetate resin, adhesives are thermosetting.

Resins for bonding

Phenol–formaldehyde and urea–formaldehyde resins are used chiefly for bonding wood, especially plywood. Phenol–formaldehyde joints are resistant to boiling water and by addition of resorcinol acquire greater strength, which, for metal to metal joints, achieves a maximum with the addition of polyvinyl formal. Epoxy resins also adhere well to metal and are popular for domestic as well as industrial use.

Urea–formaldehyde resins are cheap, show no glue line, and are used extensively in furniture. Polyurethane joints formed in place with diisocyanates are chiefly used to cement rubbers to metals or textiles. Polysulfones, polyimides, and polybenzimidazoles are used as high-temperature adhesives.

By the addition of small amounts of amino-resins to paper pulp, wet strength, bursting strength, rub resistance, and dry tensile strength are greatly improved. Urea–formaldehyde resin is also used to produce wallboard. Paper is rendered waterproof by coating with coumarone–indene resin and still more effectively by lamination with polythene film at very high speeds.

A number of polymers are used for external finishes, either in organic solvent solution or as emulsion, the most important being urea– and melamine–formaldehyde resins, and complicated derivatives thereof, acrylics and alkyds.

Amino resins are used for washfast, glazed, shrink-resistant chintz and for embossed effects. Acrylics stiffen without destroying flexibility and improve the abrasion resistance of both cotton and rayon, while polyethylene is applied in film form for permanent glazing. Butadiene–acrylonitrile improves the wear of cotton goods, and polyvinyl acetate is used extensively on linings that are often calendered to give a silk effect. The most interesting use of alkyds is that of a thermosetting castor-oil-modified glyptal that stiffens, is a fixing agent for pigments, and preserves mechanical finishes.

Plastics are also applied for crease resistance, especially of rayon and cotton. Urea–formaldehyde and melamine derivatives are chiefly used in solution, catalyzed by ammonium salts of strong acids; a variation is the inclusion of octadecyloxymethylpyridinium chloride, which confers water repellence, and of urea–formaldehyde resin with dichloropropanol, which produces an epoxy finish and is used in drip-dry materials.

III. Plastics manufacture and fabrication

NATURAL RAW MATERIALS

These include cellulose, coal, and petroleum products (see also COAL PROCESSING; PETROLEUM REFINING; RUBBER).

Cellulose. Originally the only source of cellulose for nitration, acetylation, and other processing was cotton linters, the short fibres left after ginning, which removes the long staple fibres. After cleaning and bleaching the linters are ready for acetylation and other processing.

Undegraded cellulose is a crystalline material with chains built up of about 3,500 repeating units of glucose anhydride, but this number falls to about 500 on acetylation, the fall being limited by process control as far as possible since molecular weight and physical properties are closely connected. Linters are now being replaced by cellulose derived from wood pulp by alkali treatment.

Coal and petroleum products. The products of the carbonization of coal are tar and light oils (or benzol), in proportions and quantities dependent upon the type of coal and the process employed. The amount of coal carbonized to make marsh gas (methane gas) is diminishing rapidly because of natural gas and the use of petroleum products, so that coke ovens are the largest source of by-products, with substantial additions from smokeless fuel plants.

Tar is distilled, and processing of the fractions yields phenol, cresols, and naphthalene, the first two used in formaldehyde resins and the latter for phthalic anhydride by oxidation.

Distillation of the light oils after alkali washing yields benzene, toluene, and xylene, and a residue of "heavy" naphtha containing coumarone and indene, which are separated by polymerization; coal tar is the only source of these polymers.

Coal by-products thus contain most of the raw materials for synthetic plastics, especially if acetylene from calcium carbide is included, but the vast quantities now required

for plastics can only be provided by recourse to the petrochemical industry.

Raw materials from oil

Ethylene and propylene are produced on an enormous scale by cracking naphtha in tubes heated by steam to 750–900° C (1,380–1,650° F) or by direct heat transfer. Ethylene is also formed by catalytic cracking at 700° C (1,290° F) of a special fraction that also gives a high content of aromatic hydrocarbons, benzene, toluene, and xylenes, as well as a residue from which napthalene is recovered.

Aromatics are also obtained by the platforming process in which feedstock is passed over platinum-coated silica–alumina, but naphthalene cannot be obtained directly from this product because most of it is present as an alkyl derivative and must be dealkylated by a special process that may also be applied to toluene to produce benzene.

Xylenes, which are also present, are separated by distillation and low-temperature crystallization, the *para*-xylene being required for oxidation to terephthalic acid; vapour-phase catalysis of the other xylenes produces more *para*-xylene.

Ethylene is now used to make vinyl chloride by way of ethylene dichloride; it combines with benzene to make styrene via ethylbenzene and yields glycol via ethylene oxide. Propylene is converted to glycerol through oxidation to acrolein; further treatment with hydrogen peroxide and chlorination of glycerol gives epichlorohydrin for epoxy resins. Ammoxidation, in which propylene reacts with air and ammonia, yields acrylonitrile. Acrolein is also an intermediate in the route to acrylic acid. The oxidation of isobutylene yields methyl methacrylates.

There are a number of ways of converting benzene to phenol—by sulfonation followed by fusion with sodium hydroxide, or chlorination and hydrolysis; and by the catalytic reaction of propylene with benzene, giving cumene, which is then oxidized with air to give cumene hydroperoxide, this product in turn being converted by strong acids to phenol and acetone. The mixture of phenol and acetone can be condensed directly to bisphenol A, widely used in epoxy resins and polycarbonates. Oxidation of benzene by air yields maleic acid, and treatment with methanol vapour gives cresols.

Methane is converted to acetylene, which reacts with acetic acid to form vinyl acetate; vinyl acetate can also be formed directly from ethylene and acetic acid in a reaction catalyzed by copper and palladium salts. Another petroleum product is cyclohexane, from which both adipic acid and hexamethylenediamine are made for polymerization to nylon-6,6.

CHEMICALS AND ADDITIVES

These include plasticizers, stabilizers, antioxidants, ultraviolet absorbers, organic peroxides, colorants, and flame retardants.

Plasticizers. Plasticizers, usually high-boiling, low-volatility esters, are incorporated with polymers by heating and mixing to increase flexibility by inserting themselves between the polymer chains and thus reducing the attractions between chains. They are essential in cellulose plastics and include triphenyl phosphate, a common ingredient to reduce flammability. The esters are usually diethyl and dimethoxy glycol phthalates but in polyvinyl chloride, which accounts for the largest proportion of plasticizer used, phthalate esters of much higher molecular weight are employed because the plasticizer proportion is higher and low volatility is imperative. It is also important that flexibility be maintained at low temperatures. The compound di-2-ethylhexyl phthalate (DOP) is much used, and for maximum low-temperature flexibility the adipate as well as the azelate are employed. These three plasticizers have the advantage of being safe in vinyl food-wrapping film. Of the phosphates, only octyl diphenyl phosphate may be used for this purpose.

Some materials are classed as extenders rather than plasticizers and cannot be used alone, nor are esters universally acceptable; nylon, for example, requires a glycol or an aromatic sulfonamide.

Another class of plasticizer, either a complete polyester made from a glycol, or an epoxy compound, usually of soya oil, is known as a "permanent" plasticizer because of its nonvolatility; the epoxy types are used with other plasticizers in vinyl compounds and also function as stabilizers.

Stabilizers and antioxidants. Polymers are subject, in varying degrees, to degradation by heat, light, and oxidation and can be protected by substances that only arrest but do not entirely prevent these processes.

Polyvinyl chloride in particular requires stabilization, especially with the development of rigid products, since the manipulation temperatures are high enough to initiate decomposition, but polyolefins and polystyrene are also improved by suitable additives. In polyvinyl chloride the main problem is emission of hydrochloric acid; this can be reduced by adding lead salts or soaps such as lead stearate. Though these are inexpensive, they cause opacity and are toxic; they are widely used for insulation compounds, however. Where a degree of transparency is required with freedom from stain, barium–cadmium salts, with or without zinc, are employed; they have the advantage that they can help to eliminate "plate out," the deposition of constituents on the metal of the processing plant.

With silicate and asbestos fillers, epoxy resins and phosphites are used, but for rigid transparent polyvinyl chloride, processed at high temperature, a different class of stabilizer, that of alkyl compounds of tin, is used.

Dibutyltin derivatives

After 1950 a series of dibutyltin derivatives, such as the dilaurate and maleate, were recognized as excellent though expensive stabilizers for high-clarity polyvinyl chloride, a property becoming more and more important with the increasing use of blown polyvinyl chloride bottles. These stabilizers are now being replaced by dioctyltin derivatives containing maleate groups or mercaptoacetates, which are far less toxic than the dibutyltin compounds.

For plastisols, barium, cadmium, and zinc compounds, together with organic additives, are preferred. Nontoxic stabilizers also include calcium–zinc compounds with phosphates and epoxies. Formulations are widely varied according to processing conditions, resin characteristics, and end uses.

Catalyst residues and metal traces from the processing plant promote degradation, which is diminished by antioxidants and ultraviolet absorbers. Organic phosphites are used to deal with metallic impurities and traces of heavy metals and also to decompose any trace of peroxide.

Antioxidants fall into five classes: phenol derivatives, amines, esters, organic phosphites, and miscellaneous—the choice depending on the polymer to be protected and the end use.

Low-density polyethylene is an important example of a polymer that must be protected by antioxidants. It is characterized by side chains, and each junction is vulnerable to oxidation, which is dealt with by phenols, alone or in conjunction with sulfur-containing esters or phosphites. Oxidation caused by light calls for ultraviolet absorbers, the most satisfactory of which is carbon black, the antioxidants in this case being phenols and naphthols containing sulfur.

Because of its structure, polypropylene is extremely susceptible to oxidation, a reaction that becomes important because the substance is handled at high temperatures. Antioxidants similar to those used for low-density polyethylene are effective, especially phenols and sulfur compounds, as distearyl thiodipropionate, used together.

Polystyrene is relatively stable to oxidation but sensitive to light degradation. High-impact polystyrene, however, because of its rubber content, requires the use of phenols. Most other polymers are less subject to oxidative degradation resulting from exposure to oxygen, but phosphite esters are often used, especially with polyurethanes, which are likely to discolour.

As already indicated, ultraviolet light combines with oxidation to promote degradation, and combinations of absorbers and antioxidants are common, the ultraviolet absorber being increasingly important as plastics are used in outdoor applications.

Classes of absorbers

The two classes of absorbers are screening agents and excited-state quenchers. Excited-state quenchers stabilize the polymer by removing energy from the molecule that has already absorbed ultraviolet light. Screening agents are the most widely used, absorbing most of the incident ultraviolet light and converting it to heat. The most effective of these are the benzophenones, especially their ethers and benzotriazoles. Ultraviolet absorbers also work by converting shortwaves into harmless longer light waves through fluorescence. Protection by fluorescent dyes is particularly applicable to films. Of the excited-state quenchers, nickel compounds are the most effective, especially organo-nickel complexes.

Organic peroxides. Organic peroxides and hydroperoxides are derivatives of hydrogen peroxide and split readily into the free radicals (groups of atoms that act as a unit in a chemical reaction) required in addition polymerization, over a temperature range determined by composition. Room temperature splitting can be brought about by activators, such as cobaltous ion or tertiary amine. Industry offers about 45 different peroxides.

Colorants. Colorants are inorganic or mineral pigments, organic pigments (either toners, insoluble organic salts, or metal complexes of dyes), or are lakes, dyes deposited on alumina.

Uniform dispersion and standardization of colour are usually accomplished by predispersion in a resin at high temperatures or, especially in the case of epoxy resins, polyesters, and urethane systems by dispersion in the plasticizer, monomer, or solvent.

Dyes must be used for transparent plastics, either dissolved in solvent or in such fine dispersions, as in the case of basic dyes, that no particles are visible.

Flame retardents. Where nonflammability is especially important, all polymers except rigid polyvinyl chloride and fluorocarbons require flame-retardant additives, even though some, such as nylons or polycarbonates, are self-extinguishing. The most important flame retardants are bromine, chlorine, antimony, and phosphorus compounds. Antimony compounds can be used only with opaque materials, however.

Additives vary with the polymer; various phosphates are used with plasticized polyvinyl chloride but with polyurethanes the phosphates must be brominated, and the same applies to polystyrene foam, where highly brominated phosphates or hydrocarbons are incorporated in the beads as supplied for molding. An alternative method is to build bromine-containing units into the polymer chains, as can be done in the case of polyesters, polyurethane foam, and epoxy resins.

Fillers and reinforcements. These fall into five main categories: mineral and synthetic inorganic powders, carbon blacks, cellulosics, metal powders, and microspheres.

Reinforcements include cotton and asbestos flocks; glass fibres, chopped or in the form of rovings, mats, or monofilaments; carbon fibres; and mineral whiskers.

A great variety of fillers especially suitable for different polymers and end uses is available—*e.g.*, wood flour, first used for phenolics, which is cheap and reduces mold shrinkage; asbestos flock (tiny fibres of asbestos), which greatly increases impact strength; various fillers that improve polyurethanes; and aluminum, magnesium, and titanium oxides, which give added stiffness to composites.

Fibre reinforcement

Cotton flock is essential in urea–formaldehyde resin moldings, and many synthetic fibres are used with different polymers; the great bulk of reinforcement, however, is glass fibre of less than 25 microns (ten millionths of an inch) in diameter and available as glass cloth; the cloth can be chopped for incorporation in moldings or used as mats or as filament for a thin surface mat or for winding.

Carbon fibres made by heating acrylonitrile fibres have enormous tensile strength, and plastics bonded with them can replace metals. Sapphire fibres and single-crystal whiskers also provide powerful reinforcement.

BASIC TECHNIQUES FOR PROCESSING PLASTICS

The chief plastics-processing techniques are extrusion, blow molding, film and sheet extrusion, calendering, thermoset molding, injection molding, rotational molding, thermoforming, laminating, casting, film casting, and foaming.

Extrusion. A major technique of the plastics industry, extrusion consists essentially of the melting and compression of plastic granules by the rotation of a screw conveyor in a long barrel to which heat or cold can be applied. The screw drives the plastic through a nozzle (see Figure 2). The technique is used on a large scale for the continuous production from thermoplastic materials of pipe, sections of various forms, sheeting and films, wire covering for insulation, plastic feed for blow-molding plants (see *Blow molding*), and preplasticizing systems for injection molding. Screws may vary considerably in design, but the most widely used is the constant pitch screw divided into feed, transition, and metering zones. The feed zone preheats the plastic granules in a deep screw channel of constant cross section and feeds them to the transition zone, which is of decreasing depth so as to compress and generally homogenize the melting plastic. This in turn discharges into the metering zone, which is of a constant depth less than that of the feed zone; it serves to complete the melting and mixing operation and to generate maximum pressure for pumping the molten plastic through the shaping nozzle. Additional homogenization may be obtained by including a mixing device; *e.g.*, a fluted cylindrical section in the screw that shears the molten plastic intensively as it passes through fine channels between the flutes and the barrel wall.

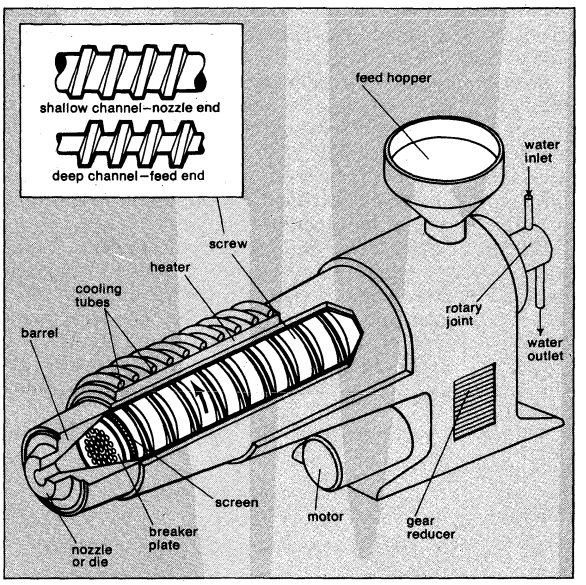

Figure 2: Extrusion-molding equipment. The screw has a shallow channel at the nozzle end and a deep channel at the feed end, as shown in inset.

The pressure of the plastic melt depends on the resistance of the nozzle but may be regulated by means of a throttle placed near the screw discharge. This may be a simple breaker plate with a screen pack, which also helps to homogenize the melt and to filter extraneous matter, or a streamlined adjustable valve that can be regulated while extrusion is in progress. Devices for automatic changing of screen packs without stopping extrusion are available.

Modern extruders may have a longer and more complex screw than the basic one described above. Such a screw is typically in two stages, each of which has a carefully selected combination of zones. Between the stages a decompression of the melt makes possible the incorporation of a vent hole in the barrel wall at this point for the removal of volatile materials and trapped air from the melt. Vacuum may be applied to this vent to increase the effect, so as to give a product of enhanced quality at high production rates.

The screws vary in design to give optimum results for different plastics. An important specification is the ratio of

length to diameter, generally about 25 to 1 although 35 to 1 or more is not uncommon for two-stage screws. Special alloys usually are used both for barrel and screw, the latter being bored for heating or cooling. Direct current motor drives are preferred for accuracy of control; the heating or cooling zones on the barrel, which may be built in, are controlled precisely, usually by electronic methods.

Normal nozzle diameters range up to eight inches (20 centimetres) but can be larger. For extruding pipe, a device called a mandrel, centred in the nozzle, determines the wall thickness.

Blow molding. Extrusion is used to push a molten tube (called a parison) into a bottle-shaped mold. Compressed air then forces the parison against the cold walls of the mold, hence blow molding. Molds are generally side fed, with wall thickness controlled by a tapered mandrel (core) or variable-orifice die. Continuous extrusion is possible by use of multiple blow molds.

Film and sheet extrusion. Thin polyethylene film is made in large quantities by extruding a tube through an annular nozzle behind which is a device through which air is introduced into the emerging tube. The air expands the tube to two or three times its original diameter. The plastic is then pressed between rollers over which the film passes as a double layer; subsequent slitting gives two flat films.

Thick-sheet extrusion

Thicker sheet is extruded through special nozzles (see Figure 3). Acrylonitrile–butadiene–styrene sheet one-

From M. Smith, *Manufacture of Plastics*; Chapman & Hall

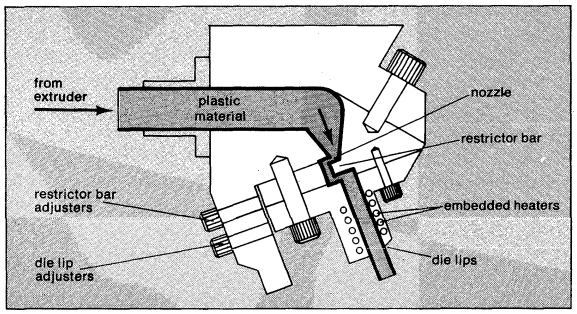

Figure 3: Apparatus for forming thick sheets by extruding plastic through a special nozzle.

quarter inch (six millimetres) thick is made in this way. Plastics that melt, such as nylon and polyethylene terephthalate, are deposited on a roll, cooled, and stretched before reeling. Controlled stretching at elevated temperatures in one or more directions can lead to improved clarity and strength (oriented films).

Calendering. Soft flexible polyvinyl chloride sheet, plain or embossed, is made in large quantities by feeding hot premix between rollers individually driven and heated to about 150–180° C (300–355° F), with an output ranging up to 10,000 pounds (4,500 kilograms) per hour. When desired, the sheet can be embossed, laminated to fabric, or laminated to another plastic sheet (to make tiles); this may be done immediately as the sheet emerges from the rollers.

Thermoset molding. Thermosetting resins are usually molded in hydraulic presses, using steel molds cored for heating or cooling. Pressures up to 3,000 pounds per square inch (210 kilograms per square centimetre) are required for cold powder or pellets, but these feeds are usually preheated by hot air or by infrared or radio frequency dielectric heating and pressures are lower. Preheating reduces curing time. Radio-frequency heating is particularly suitable for semi-automated molding.

Injection molding. Injection molding differs from compression molding in that the plastic material is rendered fluid in a separate chamber outside the mold, then is forced into the mold by external pressure. The mold is cooled and split, the two halves being locked by pressure during molding and opening automatically when the mold cavity has been filled by a shot of the liquefied plastic. The cooled article is then ejected from the mold and the process repeated.

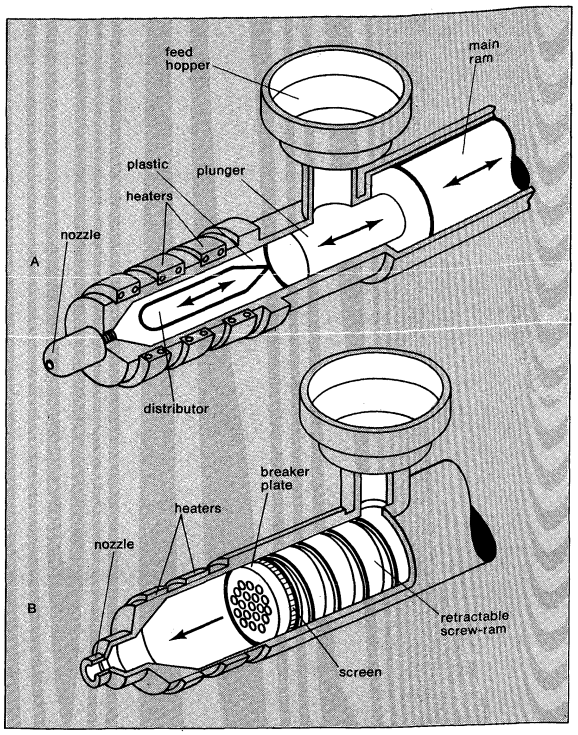

Figure 4: Thermoplastics injection machine with (A) hydraulically operated ram and (B) retractable screw-ram (see text).

In its simpliest form (see Figure 4A), the machine consists of a heated barrel with a hydraulically operated ram, an opening in the rear of the barrel being fitted with a hopper into which measured amounts of plastic pellets are fed. Falling in front of the plunger, the pellets are forced under high pressure into the heating section of the barrel, pushing out an equivalent volume of molten plastic into the mold. A torpedo-shaped distributor is fixed between the end of the ram and the nozzle feeding the mold.

The reciprocating screw feed

Of the various methods used to speed preplasticization, the most common involves a reciprocating screw feed that builds up a shot of molten plastic behind the nozzle, moving backward against the injection ram pressure until an electrical device stops rotation and the screw operates as a ram to force the plastic into the mold (Figure 4B). The two halves of the mold are clamped at a pressure that resists that exerted by the plastic entering the mold. This is usually achieved by a hydraulic ram or by a hydraulically operated toggle mechanism; the nozzle may be fitted with a device to prevent premature leakage of plastic at the nozzle and permit high pressure buildup before the shot.

Rotational molding. Plastics structures with heavy walls and complex shapes can be produced by rotational molding, in which a measured amount of plastic in powder or liquid form is placed in the cold mold, which is then rotated about both its vertical and its horizontal axis to distribute a layer of plastic evenly over the whole of the interior surface. While rotating, the mold is passed into a heated chamber where fusing or curing takes place; quick cooling solidifies the plastic, producing an accurate replica of the internal mold surface.

Heating is usually by hot air, up to 450° C (840° F); rotation speeds are infinitely variable up to about 12 revolutions per minute on the major axis and 40 revolutions per minute on the minor; the molds are inexpensive, usually made of cast aluminum. For extremely large cavities, sheet metal can be used, especially for prototypes. The ideal mold material has a high heat conductivity; beryllium copper is sometimes used. Polyethylene, polypropylene, and polyvinyl chloride are the plastics most widely used. Large commercial containers, special carrying boxes, and automotive headrests and armrests are made by rotational molding.

Thermoforming. A thermoplastic sheet, heated to its softening point, can be forced against the contours of a mold by air pressure, forming a desired shape after cooling. Many methods differing in detail are employed, but five principal techniques exist: simple vacuum forming, drape forming, and three modifications to permit deep drawing with maintenance of even thickness of walls and bottoms of the shapes. In simple vacuum forming, the plastic sheet is clamped over an airtight box, from which air is exhausted, rapidly drawing the heated plastic down on a "former" within the box, thus reproducing its shape. The sheet is heated above the box by electric heaters. In drape forming, the electric heater plate above the sheet is removed and a male former is driven up into the clamped soft sheet. Vacuum is employed to pull the sheet tight to the former.

Deep drawing

Both processes are modified to permit deep drawing. One technique involves plug-assisted drawing, in which a plug is forced down into the sheet before the application of vacuum. In drape forming, a controlled bubble is first blown upward in the sheet into which the former then enters. Another technique resembles plug-assisted forming except that the sheet is forced into the female former by compressed air.

Laminating. At first, only solutions of phenol–formaldehyde and urea–formaldehyde resins were used to impregnate paper, cotton fabric, absorbent forms of asbestos, and other fabrics. Later, melamine–formaldehyde resins were added. Material from a roll of fabric was passed through a bath and then a drying chamber; cut up sheets of the dried material were stacked in a press, then heated and cured at a pressure of over 1,000 pounds per square inch (70 kilograms per square centimetre); hence they were known as high-pressure laminates. Today, the development of polyester resins and epoxy resins that cure without giving off any by-products permits the use of low pressures, sufficient only to hold the reinforced layers in sheet form; these are known as low-pressure, or contact, laminates.

A variation of the sheeting method involves addition of the resin or its components to paper pulp, which is then sheeted according to standard paper methods. The most important of these are polyester resin laminates of glass-cloth and epoxy-resin laminates with carbon fibres. "Prepregs" and "postforming" laminates are impregnated uncured sheets that can be molded in metal molds.

Where tubes are required, the impregnated material is wrapped on suitable metal cores, revolved between heated rolls, removed, and baked to complete polymerization.

Casting. Polyesters, polyurethanes, silicones, and epoxy resins can be obtained in liquid form without solvents and can be formed by mixing in a catalyst and pouring the liquid into an inexpensive mold. Under suitable conditions, the mixture hardens into a solid shape. Electrical potting (sealing an electric component by placing it in a container and filling the container with the plastic compound) and industrial patterns are typical cast products. Specimens such as coins or butterflies can be embedded in attractive form in polymethyl methacrylate by immersing them in partially polymerized monomer and completing the polymerization very slowly.

Film casting. Film casting produces continuous rolls of thin film by spreading a polymer solution on a moving surface passing through a heated tunnel (see Figure 5). The solidified film is stripped as it returns to its casting point, and residual solvent is removed by passage through heated multiroller cabinets, in the course of which, if necessary, coatings can be applied. The moving surface may be a wheel (18 feet, or 5.5 metres, in diameter) with a polished chrome surface or a copper band, up to 200 feet (60 metres) long with a special polyvinyl alcohol surface. The process is applied almost entirely to cellulose triacetate and diacetate, the former for the production of photographic film base and the latter for packaging and diazo reproduction films.

Foamed plastics production. Foamed or expanded plastics are low-density materials made by forming gas bubbles in the plastic while in a liquid or molten state. A variety of processes and types of products are available,

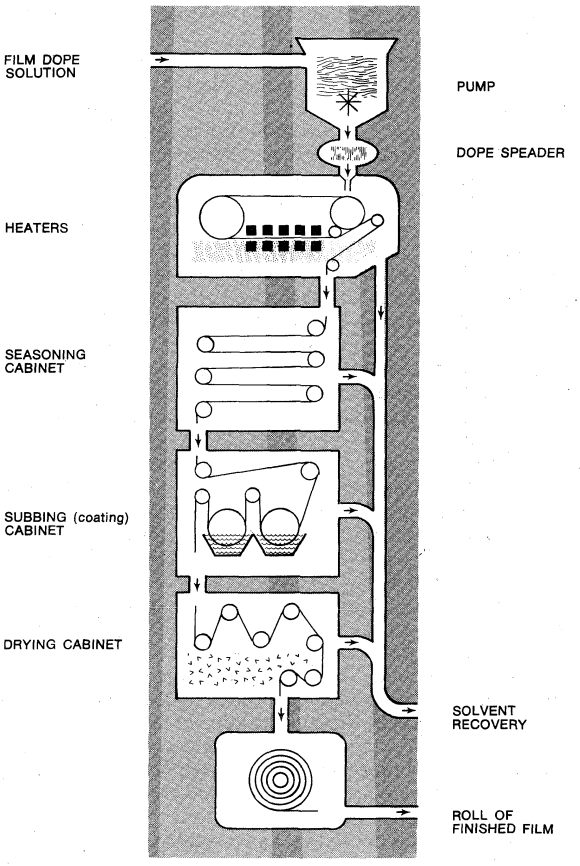

Figure 5: Basic operation of a film-casting machine.
Drawing by D. Meighan

depending upon the type of polymer and whether the structure is closed cell or open cell (*i.e.*, with the bubble cavities intercommunicating).

In some cases (*e.g.*, polyurethane foams), bubbles are produced in the low molecular weight mixture of reactants undergoing polymerization, partly arising from gases produced in the condensation process but usually supplemented by a blowing agent (*e.g.*, a volatile fluorocarbon liquid). Flexible polyurethane foams are of the open-cell type, like a sponge, and indeed are used for such purposes, as well as for heat insulation, upholstery, and other uses. Rigid or flexible thermoplastic materials (polyvinyl chloride, polyethylene, polystyrene) may be foamed in one of two general ways:

1. By dispersing a blowing agent in the material and heating it above its softening temperature. The blowing agent forms a large number of small bubbles in the material, and may be a volatile liquid such as pentane used in expanded polystyrene, or an unstable chemical such as azodicarbonamide, releasing much gas when heated.
2. By dissolving a gas such as nitrogen or carbon dioxide in the heated plastic at a high pressure. When the pressure is released, a large number of small bubbles are formed and grow in the soft plastic. This process may be carried out in autoclaves or continuously in extrusion machines, the plastic expanding as it leaves the extrusion nozzle.

Most of the foamed materials manufactured by the above two processes are produced in simple forms from which sheets or simple shapes are cut. In recent years so-called structural-foam processes have appeared, by which molded articles are produced from foamed plastics materials. Rigid plastic foams of relatively high density (*i.e.*, 0.5 grams per cubic centimetre) have a useful combination of lightness and rigidity, particularly if the molding process results in the formation of a relatively solid skin of plastic over a low-density expanded core.

FABRICATION AND FINISHING

Techniques of fabrication and finishing include mechanical machining, laser machining, roll-leaf hot stamping,

printing, welding, radiation processing, vacuum metallization, electroplating, painting and decorating, mold decoration, and inserts.

Mechanical machining. Most plastic articles do not require machining except for the removal of sprues (small projections) on injection molded parts. Parts may be machined from stock forms, however, such as tetrafluoroethylene rod or screw threads cut on pipe or laminates may be sawn and drilled. Machining properties of plastic are entirely different from those of metal. Plastic is more flexible, necessitating maximum support to prevent bending. Buildup of heat in the workpiece is rapid, causing it to soften. Furthermore, the plastic may deform slightly after machining, making it difficult to do highly accurate work. To diminish heat, tools are honed and polished. Lubrication is supplied, and the speed of cutting is adjusted for different plastics. Drills have wide polished flutes, and oversized taps are used to counter deformation after tapping.

Machining properties of plastics

Plastic sheet, especially acrylonitrile–butadiene–styrene, can be cold-formed under high pressures between metal dies. Good lubrication and polished drawings are required —these drawings control the drawing in of the sheet during forming. Attractive articles may be formed from previously decorated flat sheet. Plastics can also be forged like metals if the blank is heated nearly to the crystalline melting temperature. Forged parts can have ten times the impact strength of the blank.

Laser machining. A laser beam removes material by vaporizing it. Holes can be drilled in less than a thousandth of a second; thus perforations can be made on a moving plastic web, using a controlled pulse rate from the laser. The holes range in size from two to 50 mils (one thousand mils equal one inch or 25 millimetres) in diameter and are slightly tapered.

Aerosol nozzles in nylon and acetal are satisfactorily bored with lasers. Film can be slit with a continuous beam, without forming any dust; the beam can also be used for heat sealing.

Roll-leaf hot stamping. This process derives from the art of tooling gold leaf on leather. It is applied mainly to decoration or labelling of thermoplastic articles and consists of the application of a complex layer of which a typical composition includes a carrier film, usually polyglycol terephthalate, 12–25 microns (0.0005–0.001 inch) thick; a release coating on the carrier, based on a waxy material and about one micron thick; a lacquer coating that protects the decorative coating that is to follow (the lacquer is metallized with aluminum or gold to a thickness of a few microns, having been previously printed, or is coated with a pigment without a metallic layer); and, a final heat- and pressure-sensitive adhesive layer to give maximum adhesion to the plastic to be printed. The adhesive-coated side of the film is pressed by a heated die to the object to be decorated, and the adhesive bonded to the plastic under pressure. After a short cooling period to allow the adhesive to solidify, the carrier film is stripped off, that part of the resin coating carrying the metal coating or pigment that corresponds to the die form adhering to the object.

Decorating thermoplastic articles

Polyester film as a carrier has the advantage of withstanding high temperatures, which is important because the die may be at a temperature as high as 130° C (270° F), though the usual temperature is about 110° C (230° F). Metal dies are usually steel, though softer metals can be employed for short runs. There is, however, a growing use of silicone rubber, the latest development being a metal–rubber sandwich, the rubber layer being about 1/16 inch (1.6 millimetres) thick, faced with 1/32 inch (0.8 millimetre) of copper, which can be photoengraved. Such a die gives flexibility sufficient to cope with surface irregularities on the plastic faces.

Printing on plastics. There are two principal factors involved in printing on plastics: the choice of ink and the type of printing process. Ink choice is influenced by the printing method. The printing method in turn is determined by the shape and the plastic used, usually flexible material such as polyethylene and polypropylene, thin polyvinyl chloride, nylon, or high-density polyethylene. For these materials flexography, which involves printing with a rubber printing plate, gravure, using engraved metal rollers, and lithography are widely employed, chiefly for printing on the plastic web. Dry offset printing or stamping is employed for molded bottles, jars, tubes, and tubs. For bold decoration, the silk-screen process, a form of stencil printing, is employed. Another process under rapid development is electrostatic printing, in which ink powder is expelled from an image screen by a difference in electrostatic potential. Ink formulation is specific to the material and process. Alcohol-soluble polyamides are used for polyolefins; oxidizing alkyd resins and oxidizing thermosetting systems are used for polyvinyl chloride, polystyrene, nylon and also polyolefins. When printed sheets such as cut film are stacked as they come off an offset press, they are interleaved with paper panels (until the ink is dry) to prevent ink smudging.

Heat, high-frequency, and ultrasonic welding. Polyvinyl chloride sheet, in its various forms, can be welded by a hot jet of nitrogen or carbon dioxide and a rod of lower melting polyvinyl chloride. Overlap joints in tank linings of polyvinyl chloride, polyvinylidene chloride, and polyisobutylene can be welded with a type of soldering iron, followed by a small pressure wheel. Polymethyl methacrylate with a hot jet welds through contact with the monomer released by heat decomposition.

Polyvinyl chloride sheet is also particularly suitable for electronic heat sealing, as is any plastic that will absorb radio-frequency energy. A heavy duty steel press with brass dies is employed. A radio frequency generator is required, with power output ranging from three to 25 kilowatts. Electronic techniques are used to control positioning, sealing, and the length of time the press stays closed (dwell time). Very strong joints are made, and the process has been much used for applique decoration.

Electronic heat sealing

Ultrasonic (above the range of human hearing) vibrations, at about 20,000 hertz (cycles per second) are transmitted into the plastic assembly, generating heat at the joint surfaces where melting takes place. The harder the plastic, the more effective are ultrasonic welding techniques. Ultrasonic welding can be used for spot welding; staking, in which a plastic stud is inserted into a hole in metal; and for molding in inserts by means of a hole slightly smaller than the insert, heat being generated at the point of contact between metal and plastic in a second or less.

Radiation processing. Two plastics industrial processes employ high-energy electrons, the first being the curing of certain types of resin, which become thermosets (causing them to take on a rigid form) at room temperature and the second, the cross-linking of thermoplastics, causing the molecules to form a network structure, thus making the plastic infusible. Radiation sources are either electron accelerators or radioactive cobalt. In the case of accelerators, the material is passed in front of a window of the accelerator, where it is briefly exposed to radiation; the cure, or cross-linking, occurs rapidly without any catalyst. Thermoplastics, such as polyethylene, which have been cross-linked in this way, if stretched while hot, can be frozen in the new dimension; subsequent heating causes rapid and strong shrinking. Thus, for example, a four-core electrical cable can be capped with a four-tubed glove of treated polyethylene and shrunk down throughout by heat to make tight joints at all points. The process can be applied to polyethylene and other wire insulations by exposure to an electron beam, thus providing increased thermal stability and improved stress-cracking properties. Similar exposure of film gives increased clarity when shrunk in place, with better resistance to chemical attack but little reduction in permeability to water vapour.

Vacuum metallizing. Vacuum metallizing, the earliest method of metal coating of plastics, is accomplished by evaporating a metal, usually aluminum, onto plastic surfaces within a high vacuum chamber, up to seven feet (2.1 metres) in diameter and containing hangers so arranged that the workpieces can be rotated. Rotation is necessary because the metal particles travel in straight lines. Alongside the work are tungsten heater filaments on which pieces of aluminum are suspended. The tungsten

filaments are electronically heated to melt the aluminum and the temperature then raised to evaporate it while the workpieces are rotated. For vacuum metallizing, very high vacuum is required; to achieve this, most plastics are pretreated to remove moisture and any volatile substances. The time required for this process can be reduced by lacquering and baking the article, then applying a coat of lacquer after metallizing to protect the metal surface and provide colour if necessary.

Continuous coating

Continuous coating from rolls of plastic of many types is accomplished by use of special crucible sources and winding mechanisms. Metallizing is used largely for decoration; metallized polyester film is used for electrical capacitors and, finely slit, for metallized yarn.

Electroplating. The use of plastics such as acrylonitrile–butadiene–styrene, polypropylene, and polysulfone for automotive parts has been enhanced by electroplating with metal. The process depends on etching, which is easiest with acrylonitrile–butadiene–styrene because the dispersed rubber particles can be removed by oxidizing. Other plastics depend on strong acid attack. Immersion in a tin salt solution, followed by palladium salt, results in the deposition of catalytic palladium that adheres to the etched holes. Further immersion in copper or nickel salt solutions causes a layer of metal to be deposited on the plastic through reaction with the palladium, thus providing a conductive surface on the plastic for electroplating with copper, nickel, and chromium. The copper deposition may be thick enough to serve for printed electronic circuits. A number of intermediate steps are required and there are many proprietary variations. It is important that the moldings be free from strain and the visible surfaces as perfect as possible. Areas up to 350 square inches (2,260 square centimetres) can be plated.

Finishing. *Painting and decorating.* Paint can be used to obtain multicoloured or pearly finishes, to reduce gloss, and to reduce the typical plastic appearance of an object. It can also give light-coloured finishes to dark resin moldings and objects made from reclaimed scrap. Paint is usually sprayed but can be roller coated, especially for raised letters.

Mold decoration. Printed foils can be located, either mechanically or by static electricity, in a mold; thermosets are decorated with printed melamine-impregnated paper, as for dinnerware, the foil being inserted after partial curing by interruption of the molding process. For thermoplastics, film, preferably of the plastic being molded, is inserted printed-side inward.

Inserts and fasteners. Inserts, placed in the female half of a thermoset mold, can be molded in. For subsequent insertion, self-tapping and thread-forming inserts can be used. Locking devices such as serrated rings are used to secure bushings (metal linings for a hole). The cheapest inserts are driven into place, using projections that fit in grooves (splines) or expansion devices instead of threads.

IV. Industrial plastics

STRUCTURAL FOAMS

Sandwich forms

Rigid foams. Rigid polyurethane foams in sandwich forms have wide applications as building components because of the stiffness imparted by the thick foam centre for a given weight. They are also the best insulants known today and so have wide application in refrigeration and in buildings, where they are applied in fitted slab form or are foamed into cavities at the building site. They can also be applied by spraying about one-quarter inch (six millimetres) thickness with each pass of the spray gun. The ability to spray a foaming mixture through a single nozzle is a great advantage in application. An alternative application method is to mix the foaming ingredients under pressure with fluorocarbons and run the froth into the cavity, where foaming takes place through vapourization of the fluorocarbons by the reaction heat.

A very important use of rigid foam is for furniture parts to reproduce wood structures; these can be injection molded. Since the polyurethane remains in the mold a rather long time to allow foaming and setting, molds can be mounted on a rotatable table, coming around in turn for a shot of foamable material. Rigid polyurethane foam can be screwed and nailed with a retention about equal to white pine lumber.

A major advance in the manufacture of sandwich structures is a new method of injection molding invented in Britain, in which a large machine is used to produce moldings up to four feet (1.2 metres) square. A double valve provides differential feeds to the mold, the first supplying a skin of selected plastic, the second a foamable core material that forces the first polymer to the surface of the mold; the process resembles the blowing up of a balloon. Moldings of great strength and any desired surface are obtained.

Flexible foams. Flexible foams, usually polyether urethane, are made in slab form up to eight feet (2.4 metres) in width and as much as five feet (1.5 metres) high; these are then cut to required shapes or sizes or are molded. The molded foams may be hot molded. This involves filling heated aluminum castings and gives a product having high resistance to compression, as for automotive seats; or they may be cold molded, a process used particularly for semiflexible foams with high load-bearing properties and densities from five to ten pounds (2.3–4.5 kilograms) per cubic foot. Used almost exclusively by the automobile industry for crash pads, armrests, and dashboard covers, the process involves machine mixing the ingredients and pouring them into aluminum molds lined with vinyl or acrylonitrile–butadiene–styrene skins, which become the cover material for the part. These skins are being replaced by integral skins, the formation of which depends upon high fluorocarbon content of the foam and special diisocyanates, foaming occurring from the centre of the mold outward, vapor pressure consolidating the material on the mold surface. The same process can be applied to rigid foams.

Polyester flexible foams with a special silicone surface active agent are used for textile interliners, with densities about one to seven pounds (450 grams to 3.2 kilograms) per cubic foot; these can be made down to 30 mils thick and used for lamination.

Polystyrene foams

Polystyrene foams are made in a wide range of densities, from expandable beads, either by extrusion through slot-shaped openings to 40 times the original volume to form boards directly or by foaming in steam chests to form large billets. Using small beads in stainless steel molds, cups can be molded with thin sections.

Thin sheet for embossed packaging can also be made by the tube extrusion technique. Though packaging is a major use for forms made in closed molds, the largest use is for building panels; they can be plastered directly. Acrylonitrile–butadiene–styrene can be expanded from pellets and is particularly suitable for wood-grain effects and for the production of heavy sections.

Expanded vinyls can be made from plastisols for flooring or textile linings by calendering with a blowing agent and laminating to a fabric base, and by injection molding for insulation and such articles as shoe soles. An improved material is now obtained from cross-linked polyvinyl chloride and competes with polyester in glass reinforced plastic. Syntactic polybenzimidazole owes its expanded properties to the incorporation of extremely small hollow spheres (microballoons) of glass or polyfluoride resins. It is stable up to 300° C (570° F); its heat resistance and light weight adapt it particularly for use in space vehicles.

SHEETS AND FILMS

These include vinyls, fluoroplastics, and cellulose acetate.

Vinyls. Plasticized polyvinyl chloride, made by a calendering process, can be sewn, heat-sealed, or electronically sealed; it is used for apparel, shower curtains, protective clothing, and the like. Made in any colour, transparent, translucent, or opaque, polyvinyl chloride can be coated with pressure sensitive adhesives and printed with decorative patterns. Thicker sheet is coloured and embossed for women's handbags, luggage, seat covers, and upholstery.

Thin film is also used for packaging, especially of meat and fruits; if biaxially stretched, it forms a shrink film that retracts up to 60 per cent. Another important use is as a laminate for printed paper.

Flooring tiles, largely made of polyvinyl chloride, are built up by lamination and decorated either by printing or by rolling in colour chips; the commonest tile is vinyl asbestos, pressed into sheets on calenders and then embossed and cut into tiles.

Rigid polyvinyl chloride sheet has high dimensional stability and flame retardancy and is often used in corrugated form for building construction. Partitions, rain gutters, downspouts, industrial tank linings, vacuum-formed signs, and lighting panels are other uses.

Styrene film is widely used for semirigid food containers, especially packaging, being heat formable if held on all four sides to prevent shrinkage.

Acrylonitrile–butadiene–styrene possesses a wide range of properties, notably scuff resistance, plus high impact strength at lower temperatures, making it suitable for high-quality luggage, refrigerator linings, and food and detergent containers because of its chemical resistance and freedom from stress cracking. Because it is easily formed by heat, thick acrylonitrile–butadiene–styrene sheet is used for sports-car bodies and automobile doors.

Uses of nylon films

Nylon films are mostly from nylon-6,6 and are ideal for food packaging because of strength, impermeability to oils and greases, and high melting point. As such films are steam sterilizable, they find many uses in hospitals. They are frequently laminated. Acrylic films have high resistance to ultraviolet light and external exposure; their prime use is in surfacing laminates.

Fluoroplastics. Fluorinated ethylene–propylene and chlorotrifluoroethylene are the principal fluoroplastics. Fluorinated ethylene–propylene resists extreme temperatures from that of liquid hydrogen to 275° C (525° F) and is extremely inert in the presence of chemicals. Since it can be bonded to metal with special adhesives, fluorinated ethylene–propylene is used in printed circuitry, to insulate flat cable used in the computer industry, in space vehicles, and for heat-sealed industrial and biological packaging.

Both fluorinated ethylene–propylene and chlorotrifluoroethylene are noncombustible and have very low moisture vapour transmission rates; the fluorohalocarbons also have excellent thermoforming characteristics. They are used in packaging of critical hardware, in aircraft insulation, encapsulation, and in other electrical objects.

Polyurethane film and sheet are available in thicknesses from ½ mil to 100 mils (2.5 millimetres), the outstanding characteristic being toughness and resistance to tearing. Tensile strength and elongation are both very high, leading to uses for awkward packaging and for inflatable sheet used to stabilize ship cargoes.

Cellulose acetate. Cast film up to ten mils thick is used for rigid packaging, especially for "blister" packaging, designed to protect small articles by inserting them in preformed shapes.

Acetate film can be printed or drawn upon and hence is used widely for visual aids and in engineering and architectural drafting.

Cellulose triacetate is more moisture resistant than ordinary diacetate and, until recently, plasticized with high-boiling plasticizers, has been pre-eminent as a photographic film base, being cast, for example, to make rolls of motion picture film base 3,000 feet (910 metres) long and over 40 inches (one metre) wide. After emulsion coating, these are slit into standard motion picture film widths for edge perforation and addition of the sound track. Cellulose triacetate is similarly used for amateur film bases at 3.5 mil thickness and for X-ray films at 7.8 mil. In the field of colour-separation films, however, it is being replaced by polyethylene terephthalate, which has greater dimensional stability. Cellulose acetate film has a wide range of other uses, the result of its great tensile strength (25,000 pounds per square inch, or 1,760 kilograms per square centimetre), its high dielectric strength (withstands high voltages), and resistance to heat. Thus it is extensively used for electrical insulation of motors and capacitors; for packaging, which accounts for three-quarters of its utilization; and for magnetic recording tapes. Polycarbonate sheet is heat-, odour-, and stain-resistant and practically unbreakable. Polyimide film has no melting point and so can be used at high temperatures; it maintains its flexibility at 4° above absolute zero. Its toughness, flame resistance, and radiation resistance make a valuable combination for electrical uses, especially in space technology.

Uses of polyimide film

LAMINATES, REINFORCED PLASTICS, AND COMPOSITES

High-pressure laminates with phenolic resin binders are available in many grades, from strong paper laminates with varying quantities of resin to fabric-reinforcements of cotton, asbestos, nylon fibre, and glass-fibre fabric. All are rigid, can be built up to required thicknesses, can be readily machined into required dimensions, and in many cases can be punched. They are chiefly characterized by excellent electrical properties and resistance to humidity, combined with high mechanical strength, all these properties depending on choice of resin content and reinforcement employed. Cotton-fabric-reinforced laminates having very high impact strength are used in a wide variety of mechanical applications, especially gears.

Composites, which incorporate a third layer in addition to the resin and reinforcement, have special applications. Very large quantities of copper-clad laminates are used for printed circuits, and there is an increasing use of plasticized polyvinyl chloride laminated to steel or, in some cases, to aluminum. The polyvinyl chloride protects the metal and also carries pigmentation of desired colours.

Decorative laminates are widely used on a base of phenolic paperboard by laminating the surface with a printed sheet of wood grain or specific designs and finished with a urea– or melamine–formaldehyde transparent protective surface layer. Melamine, silicone resins, and epoxides are used instead of phenolic resins in applications requiring electrical properties under wet conditions or flexural (bending) strength at high temperatures. Where reinforced shapes other than sheets are required, postforming laminates or prepregs are used. Postforming laminates are sheet assemblies in which the phenol–formaldehyde retains a degree of thermoplasticity, so that it can be molded into shapes such as kitchen trays and covers for electrical apparatus, the molded depth depending on the extensibility of the reinforcing fabric. Prepregs are glass-fibre mats impregnated with resin, fillers, colour, and catalyst, the resin being polyester, epoxides, phenolics, or silicones, partially cured, the final curing process being effected in the mold. Prepregs are particularly adapted to mass-production techniques.

Low-pressure (contact) laminates

Contact laminates are formed by placing reinforcing materials with polyester or epoxide resins, in viscous liquid form, on a mold. The major plastics material used is the polyester type previously described; the reinforcing material is glass fibre coated with a silicone or silyl compound to promote adhesion to the plastic. The fibres are used either as rovings (slightly twisted strands or rolls of textile fibres), mats, yarns, or woven fabrics, or, for reinforcing molding, as powders in the form of short strands cut in lengths up to two inches (five centimetres).

The desirable quality of glass fibres is their tensile strength, amounting to 250,000 pounds per square inch in commercial form.

Because of this great strength, glass-reinforced plastic can be used for such structures as small ships, footbridges, etc. A glossy finish can be given to the surface of these laminates by finishing them with a thin mat of staple filaments.

Because of its strength and lightness, glass-reinforced plastic has been much used for transport applications, and there is a small production of all glass-reinforced-plastic car bodies, made by a hot-press molding process. Automobile manufacturers are beginning to turn attention to compression-molded polyester glass composites for large area moldings, including body panels.

A different method of producing glass-reinforced plastic

is filament winding, in which glass-fibre filament is passed through a resin bath and wound on a former to produce pipe and tanks of great strength. Pipes of large diameter can be made in this way.

Many other fibres are in use or under development; polyvinyl alcohol fibres, for example, adhere better than glass to plastic, giving higher impact strength and lighter weight; but the greatest interest lies in materials that offer greater stiffness and strength. Boron fibres are about six times as stiff as glass, but no stronger, whereas carbon fibres made from acrylonitrile filament combine increased stiffness with very high tensile strength ranging from 300,000 to 400,000 pounds per square inch. Composites of carbon fibre and resin can have the same tensile strength as steel but weigh only a quarter as much. Wear rate and friction can be much reduced, and resistance to high temperatures can be greatly increased.

MISCELLANEOUS INDUSTRIAL PLASTICS

Extruded forms, made on an extruder with a special die, though commonly produced as rods or tubes, may also be manufactured in geometrical shapes to suit given tasks (curtain runners, for example), as interlocking strips for panels and window frames, and as a special interlocking strip that is wound into a spiral to form polyvinyl chloride pipes of large diameter finished by continuously welding the spiral joint.

A special application of extruded film, generally polypropylene, is the use of tapes, which are woven into simulated jute products for sacks and carpet backing. Special treatment of the tapes leads to manufacture of carpet yarns.

Engineering plastics, materials that can substitute for metals, require tensile strengths well above 5,000 pounds per square inch and flexural strengths (resistance to bending or flexing) at least 15,000 pounds per square inch. Plastics with these properties as a rule have softening points well above 100° C (212° F), so that their stability is unaffected by any ambient temperatures to which they are likely to be exposed; also, they can be sterilized. The earliest use of plastics in engineering was as gears cut from laminated phenolics and used for heavy duty with water lubrication. In current use are thermoplastics such as acrylonitrile–butadiene–styrene, polycarbonates, and nylon, admirably adapted for light mechanisms such as clocks and cameras as well as heavy parts such as fuel tanks and many smaller automotive parts. The use of chopped-glass-fibre filling, which can increase tensile and flexural strengths by about 7,000 pounds per square inch, has increased the scope for such uses.

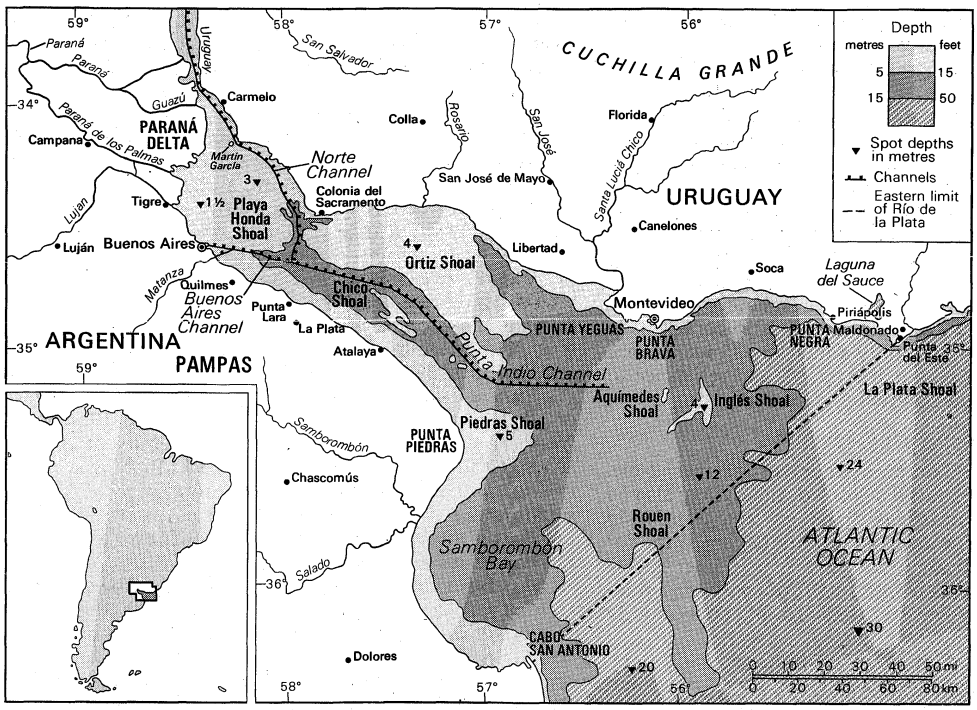
(E.G.C.)

Plata, Río de la

The Río de la Plata (literally River of Silver; in English often called the River Plate) is a tapering intrusion of the Atlantic Ocean occurring on the east coast of South America between Uruguay to the north and Argentina to the south. While some geographers regard it as a gulf, others even as a sea, and still others as a river, the majority regard it as the estuary of the Paraná and Uruguay rivers. As such, the Río de la Plata receives waters draining from the basin of these two rivers, which covers northern Argentina, the greater part of Uruguay, Paraguay, eastern Bolivia, and much of southern Brazil and represents an area of 1,600,000 square miles (4,144,000 square kilometres). Montevideo, the capital of Uruguay, is located on the northern shore, and Buenos Aires, the capital of Argentina, is on the southwestern shore.

The head of the Río de la Plata is where the delta of the Paraná and the mouth of the Uruguay meet; the eastern, or Atlantic, extremity lies about 180 miles seaward and would be represented by a line on a map drawn from Cabo San Antonio, Argentina, to Punta del Este, Uruguay. The breadth of the estuary increases from the head seaward: it is 31 miles from Punta Lara on the southern (Argentine) shore to the port of Colonia del Sacramento on the northern (Uruguayan) shore, and 136 miles from shore to shore at the Atlantic extremity of the estuary. To those who regard the Río de la Plata as a river, it is the widest in the world, with a total area of 13,500 square miles (35,000 square kilometres). (See also city articles on BUENOS AIRES; MONTEVIDEO; for an associated physical feature see PARANA RIVER).

The natural environment. *Physiography.* The two contributory rivers bring down about 2,000,000,000 cubic feet of silt every year. The muddiness of the water in the Río de la Plata itself is increased by the tides and winds that prevent the settling of the deposit on the bed. The deposit thus forms great shoals, banks, or bars of clay, sand, and organic matter: the Playa Honda Shoal is just off the Paraná Delta; the Ortiz and Chico shoals are further downstream; and the Rouen, the Inglés, the Alemán, and the Arquímedes shoals are still farther out. The depth of the water—varying from six feet above the shoals to 65 feet in the intervening channels—is reduced along the south coast by an offshore shoal. Silt and shoals



The Argentine coast of the estuary is low-lying; its banks are of marine debris and coarse sand, and the coast is subject to flooding in places. The Uruguayan coast stands quite high and consists largely of rocks and dunes. Off the Uruguayan coast there are several small islands, such as Hornos, San Gabriel, López, Lobos, Farallón, and—opposite the mouths of the Uruguay and Paraná Guazú rivers—Martín García.

Hydrology. The volume of water discharged by the Río de la Plata into the Atlantic is estimated at 776,925 cubic feet per second. Although the water of the tributary rivers is so widely distributed over the length and breadth of the estuary that variations in their volume do not affect the level of the water, the level is considerably affected by variations of the tides and, especially, of the winds reaching it. The ocean tides, weak though they may be, flow 120 miles up the Paraná and the Uruguay rivers from their mouths on the estuary. The average tidal range is six inches at Montevideo and two and a half feet at Buenos Aires. The pampero (the southwest wind) and the southeast wind both exert a great influence on the Río de la Plata: the pampero, when it is most powerful, drives the water on to the Uruguayan coast, so that the water level drops on the Argentine side; the southeast wind has the contrary effect, flooding parts of the Argentine shore, and causing the level to drop on the Uruguayan coast.

Climate. The Río de la Plata has a temperate climate and copious rainfall at all seasons, amounting to 39 inches a year. The mean annual temperature is 55° F (13° C), and monthly averages are always over 50° F (10° C). Humidity, at 70 percent, is notably high. The prevailing winds are the north, the pampero, and the southeast. Frosts are frequent in the winter months.

Fish. The estuary is very rich in fish; pejerrey (kingfish), corbina (white sea bass), patí (large scaleless river fish), surubí (the largest Argentinian river fish), dorado (a large golden fish resembling a salmon), and pacú (a large river fish almost as high as it is long) are among the edible species.

Human ecology. For the people living along its shores, the Río de la Plata has been useful as a waterway; for their essential livelihood they have looked inland to the

Río de la Plata.

pampas (grassy plains). Nevertheless, the estuary as a thoroughfare for trade is of major importance not only to the people of the coasts but also to the remotest inhabitants of the whole drainage basin.

Exploration. After the European discovery of the Pacific Ocean at the Isthmus of Panamá (1513), King Ferdinand II of Aragon commissioned the Spanish navigator Juan Díaz de Solís to look for a sea passage from the Atlantic to the Pacific. In 1516 Solís found his ship in freshwater at the mouth of the Río de la Plata estuary, which he named Mar Dulce (Freshwater Sea). Solís, however, was killed by Indians on the mainland. His Mar Dulce was subsequently renamed Río de Solís in his honour.

Early nomenclature

The Portuguese navigator Magellan reached the estuary in 1520 and explored it cautiously before continuing his voyage to the south. The Italian navigator Sebastian Cabot made a detailed exploration in the years 1526 to 1529, finding the Uruguay and the Paraná rivers and sailing up the Paraná River and a long way up the Paraguay River as well. It was his interest in the silver objects possessed by the local Indians that led in 1533 to the estuary's being named the Río de la Plata. The Spanish colonization of the shores was begun by Pedro de Mendoza, who founded Buenos Aires in 1536.

Navigation. The chief ports of the estuary are Montevideo, Colonia del Sacramento, and Maldonado on the left bank and Buenos Aires and La Plata on the right. While Montevideo has direct access to deep water, Buenos Aires requires the constant dredging of the Punta Indio Channel, which extends for 130 miles from the Ortiz Shoal to the Argentine mainland; 22,000,000 tons of deposit are taken from this channel every year in order to maintain a depth of 30 feet. Navigation upstream from Buenos Aires, likewise, requires the dredging of the Buenos Aires Channel (Martín García Channel), which, in its full length, runs between the Ortiz and Playa Honda shoals and forms a transverse link between the Punta Indio and Norte channels. The Norte Channel, north of the Ortiz Shoal, continues to the northwest, running between Martín García Island and the Uruguayan coast to the mouths of the Uruguay River and of the Paraná Guazú in the Paraná Delta. Martín García Island, which belongs to Argentina, stands less than two miles off the coast of Uruguay and commands the approach from the sea to the rivers and so to the whole basin of the Río de la Plata. The Paraná de las Palmas, the second mainstream of the Paraná Delta, has a bar at its mouth.

Channels

Economic resources. The shores of the Río de la Plata are the most densely populated areas of Argentina and of Uruguay alike. The great ports, Buenos Aires and Montevideo, where the density is highest, are primarily concerned with exporting meat from the hinterland; the refrigerators and shipyards required for this trade are located in the coastal zone, as are flour mills, factories for vegetable oils, textile industries, metallurgical plants, and petroleum refineries.

The port of Buenos Aires handles 80 percent of Argentina's imports by value and 70 percent of its exports. Of Paraguay's exports, 50 percent are destined for the ports of the Río le la Plata; nearly all the remainder goes down the estuary to overseas countries. Montevideo handles 75 percent of Uruguay's foreign trade. Buenos Aires is linked with Colonia del Sacramento and with Montevideo by daily boat services.

The water of the estuary is thus exploited for urban and industrial purposes as well as for navigation. Fishing is of little importance commercially, except that seals are caught around the Uruguayan islands. Some of the Uruguayan beaches—at Pocitos, Carrasco, Piriápolis, and Punta del Este—have been developed for vacationers.

Plateaus and Basins

Plateaus are high, flat-surfaced areas of the Earth's surface that typically are bordered on one or more sides by escarpments. Basins are low, flat-surfaced, elliptical or circular areas of the Earth's surface surrounded by mountains or highlands. Both terms are so loosely used that they cannot be defined rigidly. The term plateau, for example, is commonly applied to broad areas of hilly uplands that are plateau-like only in a most general sense. Nearly all of Africa is considered a plateau because it consists of a high, gently rolling region separated from a narrow, low coastal belt by an escarpment.

The term basin also has several different meanings. It is applied to drainage areas of large rivers, sediment-filled

structural downwarps of the Earth's crust (*e.g.*, the Paris Basin), and to major depressions of the ocean floor.

Plateaus and basins occur on every continent. About 30 percent of the Earth's land surface consists of plateaus (excluding ice plateaus), if the term is applied in its most general sense to include most of the continent of Africa. Topographic basins, however, constitute only about 3 percent of the land.

Kinds of plateaus

Plateaus develop in a variety of ways and occur in many different geologic settings. They can be classed as (1) low plateaus in stable ancient continental areas (shields) developed by differential erosion of flat-lying cover rocks (*e.g.*, the Brazilian Highlands) or by uplift of ancient crystalline rocks previously planed off by erosion (as in southern Africa); (2) low plateaus on flat-lying resistant rocks within sedimentary basins (plateaus in the Paris structural basin); (3) plateaus on flat-lying or gently folded strata on the flanks of major mountain systems (Appalachian Plateau); (4) plateaus developed within major mountain systems by uplift of previously developed erosion surfaces (plateaus in the eastern highlands of Australia); (5) intermontane plateaus high in mountain systems that occur over flat-lying or moderately deformed sedimentary rocks between flanking mountain ranges (Tibetan Plateau); (6) lava plateaus developed by the piling up of basaltic lava (Ethiopian Plateau); (7) volcanic plateaus high in mountain systems formed by the accumulation of vast quantities of volcanic materials such as lava and tuff (Altiplano and Puna of the Andes mountains); and (8) large continental ice plateaus (Greenland Ice Plateau).

Basins form by downwarping or downfaulting (vertical movement along fractures in the Earth's crust) and occur within mountain ranges, in areas of flat-lying sedimentary rocks, and in areas of ancient crystalline rocks.

This article describes the distribution of plateaus and basins by continent and presents specific examples of these landforms. For an overview of the Earth's surface features, see EARTH, PHYSIOGRAPHY OF; and for information on oceanic analogues, see OCEAN BASINS. See also the articles on the individual continents (*e.g.*, ASIA).

Occurrence and distribution. *North America.* Plateaus and basins are widespread in the intermontane region of the western cordillera (mountain system) of North America. In Alaska the area between the coastal mountains on the south and the Brooks Range on the north is called the Yukon Plateau. It consists of a vast, plateau-like rolling upland but also includes mountain ranges, river valleys, and irregular basins. In Canada the region between the coastal ranges and the Rocky Mountains consists of tablelands and low mountains and is referred to as the British Columbia Interior Plateau. It is generally 160 kilometres (100 miles) wide and has general summit elevations of about 1,100 metres (3,500 feet). In the United States the broad intermontane area between the coast ranges and the Rocky Mountains has a diverse topography including two typical plateau regions: (1) the Columbia Plateau, a Tertiary (2,500,000 to 65,000,000 years ago) lava plateau averaging 300 metres (1,000 feet) in elevation, and (2) the Colorado Plateau, composed mostly of flat-lying Mesozoic (65,000,000 to 225,000,000 years ago) sedimentary rocks lying at elevations of 1,200 metres (4,000 feet) or more. The remainder of the intermontane United States consists of mountain ranges separated by basins, forming the Basin and Range Province. The mountain ranges of North America extend southward into western Mexico, where most of the Sierra Madre Occidental is a volcanic plateau from 2,000 to 3,000 metres (6,000 to 10,000 feet) high flanked by regions of basin and range structure. East of the volcanic plateau in central Mexico is the "Central Mesa" (Central Plateau), which is more properly called a basin because it is a generally flat elliptical area surrounded by mountains or plateaus.

The Columbia and Colorado plateaus

In the eastern United States, a low, gently rolling region cut on crystalline rocks east of the Appalachian Mountains is commonly called the Piedmont Plateau, although it is a plateau only in the sense that a gentle slope separates it from the coastal plain to the east. West of the Appalachian Mountains, a region of plateaus 1,000 to 1,500 metres (3,000 to 5,000 feet) high underlain by resistant Paleozoic (225,000,000 to 570,000,000 years ago) sedimentary rocks is referred to as the Appalachian Plateau. Low plateaus on stratified (layered) rocks occur west of the Appalachian Plateau in Kentucky and Tennessee. Another high, hilly region (the Ozark Plateau) occurs in Arkansas and southern Missouri.

South America. Plateaus occur in five principal regions of South America: the Guiana Highlands, the Brazilian Highlands, the Paraná structural basin, the Patagonia region, and the Andes mountains. Topographic basins are not characteristic of South America.

The Guiana Highlands in the northern part of the South American continent and the Brazilian Highlands in the central part are broad interior regions of hilly uplands, low mountains, and tabular plateaus at a general elevation of 1,000 to 1,200 metres (3,000 to 4,000 feet). These plateaus are cut mainly on little deformed Paleozoic and Mesozoic sedimentary rocks and are within a stable continental block that has undergone little deformation since Precambrian (older than 570,000,000 years) time.

The low plateaus of the Paraná structural basin of southern Brazil, northern Argentina, Paraguay, and Uruguay are on relatively undeformed flood basalts much like those of the Columbia Plateau of North America.

Patagonia, along the east side of the Andes mountains in Argentina, is a relatively high, plateau-like region underlain by nearly horizontal sedimentary formations.

Extending for about 2,400 kilometres (1,500 miles) along the Andes from central Peru across western Bolivia to Argentina is a high intermontane volcanic plateau, called the Altiplano in Bolivia and the Puna in Argentina. It is generally 3,000 to 4,500 metres (10,000 to 15,000 feet) above sea level and is interrupted in places by high, intermittently active volcanoes. In Bolivia a segment of the plateau 800 kilometres (500 miles) long and 160 kilometres (100 miles) wide has been downdropped to form a basin of interior drainage containing Lake Titicaca, the world's highest large body of navigable water.

The Altiplano

Europe. In Europe plateaus occur in Spain, in a broad region north of the Alps, in Scandinavia, and in the western part of the Soviet Union. Basins occur within and adjacent to the Alps and in Spain.

The central part of Spain is occupied by the Meseta Central, a generally elevated plateau-like area formed by the irregular uplift of a flat-surfaced earth block composed of folded Paleozoic rocks. Part of the Meseta Central consists of broad basins drained by major rivers.

Some of the plateaus of central Europe north of the Alps, such as the Massif Central of southern France, the Vosges and Black Forest of France and Germany, and Bohemia in Czechoslovakia and Germany, are like the Meseta Central of Spain; they consist of uplifted blocks of folded Paleozoic rocks. The Massif Central of France, with large areas over 1,000 metres (3,000 feet) in elevation, is perhaps the most plateau-like.

Other plateaus in central Europe are developed in areas of flat-lying sedimentary rocks, where resistant formations have been uplifted bordering mountain ranges (*e.g.*, the Podolian Plateau, east of the Carpathian Mountains) or where sedimentary layers have been differentially eroded (*e.g.*, the low plateaus within the Paris structural basin).

Much of the southern part of the Scandinavian peninsula is a plateau-like area lying 1,000 to 1,200 metres (3,000 to 4,000 feet) above sea level. It has a glaciated surface developed on Precambrian crystalline and Paleozoic metamorphic rocks (those altered by high temperature and pressure). Also, most of the southern part of Finland can be considered a plateau, although it lies only 75 to 150 metres (250 to 500 feet) above sea level.

In the western part of the Soviet Union, plateaus occur within areas of relatively flat-lying rocks bordering mountain ranges (*e.g.*, the Ufa Plateau, west of the Ural Mountains) or within platform areas (long-stable structural plains).

Asia. The most spectacular plateaus and basins in the world occur in or adjacent to the great mountain chains

of Asia. These ranges are composed largely of complexly folded and faulted Paleozoic and Mesozoic sedimentary rocks that have had a varied geologic history.

The Anatolian Plateau

The Anatolian Plateau of central Turkey lies between two major ranges in the westernmost part of the mountain belt of Asia. It averages 1,000 metres (3,000 feet) in elevation and contains numerous depressions or basins, some of which hold salt lakes. The central part of Iran is also a high plateau containing a major basin of internal drainage. Farther east and lying north of the Himalayas in southern China is the world's most extensive high plateau, the Tibetan Plateau, covering an elliptical area of about 1,400,000 square kilometres (530,000 square miles) at a general elevation of 4,000 metres (14,000 feet). To the east and southeast, the highly dissected Yunnan, Kweichow, and Shan plateaus of China and Burma are in part a continuation of the Tibetan Plateau. North of the Tibetan Plateau in western China lies a vast region of mountains and basins. The basins have internal drainage and range in elevation from 300 metres (1,000 feet [Dzungaria]) to 2,700 metres (9,000 feet [Tsaidam]). Northeast of these basins is the Mongolian Plateau, varying from 1,000 to 1,500 metres (3,000 to 5,000 feet) in altitude. The highly diverse mountain region of the southern Soviet Union, extending almost continuously across Asia, contains many plateaus and a few basins. Some of the plateaus are developed in areas of relatively flat-lying rocks on the flanks of fold mountains; others are uplifted and dissected former erosion surfaces within fold mountains.

Extensive plateaus also occur in lowland areas of Asia. The Arabian Peninsula consists largely of an eastward-sloping plateau developed on uplifted Precambrian crystalline rocks and flat-lying Phanerozoic (younger than Precambrian) sedimentary rocks. The northwestern part of the peninsula of India is a lava plateau, the so-called Deccan Plateau, formed by the extrusion of large volumes of basalt during Late Mesozoic and Early Tertiary time. The Turgay area of the Soviet Union, south of the Siberian plain, and the Ustyurt area, within the Aralo-Caspian Basin in the southeast, contain low plateaus developed on generally flat-lying Cenozoic (of the last 65,000,000 years) strata. In addition, the central part of the Soviet Union consists of a broad plateau (the central Siberian plateau), formed on uplifted Precambrian crystalline rocks and flat-lying Paleozoic sedimentary rocks, that occurs at a general elevation of 500 metres (1,600 feet).

Africa. The entire African continent is considered to be a plateau because it contains huge areas of level or slightly undulating land that occur at moderate elevation. The continent is a rigid earth block composed of Precambrian metamorphic and crystalline rocks overlain by nearly flat-lying Phanerozoic sedimentary rocks.

The southern part of Africa contains an inner region of plateaus at an altitude of 1,000 to 1,200 metres (3,000 to 4,000 feet) above sea level. These plateaus are separated from coastal areas by the Great Escarpment, which can be traced, with some breaks, in an arc around southern Africa. The western and northern parts of Africa contain vast areas of low plateaus and broad topographic basins at elevations of 150 to 300 metres (500 to 1,000 feet). Some of the low plateaus are developed on flat-lying Mesozoic or Tertiary sedimentary rocks, whereas others are on uplifted Precambrian rocks. The Congo Basin, Chad Basin, and Qattara Depression are basins resulting from broad structural downwarps.

At the northern extremity of the African continent, high plateaus underlain by relatively flat-lying rocks separate two branches of the Atlas Mountains, the only Tertiary fold-mountain system on the continent.

East Africa is dominated by plateaus divided by a great rift-valley system that extends north to south for about 6,000 kilometres (4,000 miles). The rift valleys (*q.v.*) are grabens (downdropped blocks) formed along the crests of broad structural upwarps. In Ethiopia the plateaus are developed mostly on Tertiary flood basalts that occur in the area of the upwarp. Farther south, the plateaus are ancient surfaces developed mainly on the Precambrian and Paleozoic rocks bordering the downdropped rift valleys.

Australia. Australia is divided into three major landform regions: the western plateau, the central-eastern lowland, and the eastern highlands.

The western plateau, which occupies three-fifths of the continent, is much like Central Africa, as it is a shield area of Precambrian rocks 225 to 450 metres (750 to 1,500 feet) high and sloping gradually to narrow coastal plains. Its surface is monotonously flat and has developed through long periods of geologic time.

The central–eastern lowland is a wide belt of plains and basins occupying about one-third of the continent. It contains little land above 150 metres (500 feet), and it was completely covered by seas in Mesozoic time. The Great Artesian Basin in the central part of the region is one of internal drainage, ending below sea level at Lake Eyre.

The eastern highlands, which are mostly less than 1,500 metres (5,000 feet) high, consist of low mountains and plateaus. Their plateau-like character is a result of the Late Cenozoic uplift of a relatively flat erosion surface and subsequent erosion that has not advanced enough to destroy the fairly uniform summit elevations. In places, Tertiary basalt flows cap the surface, enhancing its plateau-like character.

Specific examples. *Lava plateaus.* The Ethiopian and Somalian plateaus of northeast Africa are typical lava plateaus built by the accumulation of vast quantities of basalt. Other plateaus of this type are the Columbia Plateau of the western United States, plateaus in the Paraná structural basin of South America, the plateau or tableland of Iceland, and the Deccan Plateau of India.

Ethiopian and Somalian plateaus

The Ethiopian and Somalian plateaus cover an irregular area of over 500,000 square kilometres (200,000 square miles) lying at an average elevation of about 2,000 metres (7,000 feet), higher than any other comparable region of Africa. The Ethiopian Plateau on the west and the Somalian Plateau on the east are separated by a north–south trending belt of rift valleys 60 kilometres (40 miles) wide, and their highest elevations are generally 1,000 metres (3,000 feet) above the valley floors. The limits of the plateaus are sharp in some areas and indistinct in others. Their upper surfaces are irregular and hilly, but summit elevations are generally concordant, and flat, lava-capped tablelands are characteristic. An exception, however, is the northern part of the Ethiopian Plateau, where mountain ranges rise to elevations of 3,700 to 4,600 metres (12,000 to 15,000 feet).

The oldest rocks of the plateau are Precambrian metamorphic and granitic rocks, and resting on them in places and on flat-lying Mesozoic strata elsewhere is a thick pile of basaltic rocks of Early Tertiary age that forms the upper surface of the plateaus. These lavas have a thickness exceeding 3,000 metres (10,000 feet) in places, and their volume is 170,000 cubic kilometres (40,000 cubic miles). The general uplift of the Ethiopian and Somalian plateaus took place in several phases extending to Quaternary time (the last 2,500,000 years). Some of the earliest lavas were extruded at or below sea level, but the region was considerably uplifted before the rift valleys started to form in Late Tertiary time.

According to modern theories, the eruption of the basalts, the uplift of the plateaus, and the formation of the rift valleys in Ethiopia are all genetically related. All these features are a consequence of events that are causing East Africa to separate and drift away from the remainder of the continent. During the initial phases of this separation, fractures develop in the Earth's crust, and these serve as conduits for the release of basaltic lava derived from the mantle (zone beneath the crust) far below. During and subsequent to these eruptions, other large quantities of the mantle-derived magma (molten silicate material) become entrapped below the crust, forming a pillow-shaped body that causes the overlying crust to dome or swell. The rift valleys are formed by later downdropping of crustal blocks (grabens) in the previously swollen arch.

Intermontane plateaus. Intermontane plateaus, broad high areas of diverse topography that are more or less

surrounded by mountains, occur within the boundaries of most of the major mountain ranges of the world. The Tibetan Plateau provides a typical example.

The Tibetan Plateau

The Tibetan Plateau is the largest high upland area in the world. It covers an irregular east–west trending elliptical area 2,400 kilometres (1,500 miles) long and 700 kilometres (430 miles) wide (about 1,400,000 square kilometres [530,000 square miles]) and lies at a general elevation of about 4,000 metres (14,000 feet). Extending parallel to the southern border of the plateau is a 72-kilometre- (45-mile-) wide tectonic trench (a deep trough produced by deformational forces in the Earth's crust) that controls the upper courses of the Indus and Brahmaputra rivers. South of this trench is the main part of the Himalayan mountain system, which has an average elevation of 6,000 metres (20,000 feet) and contains the highest peak in the world—Mt. Everest (8,848 metres [29,028 feet]). To the north of the plateau are the Kunlun Mountains, with peaks over 6,000 metres above sea level. To the west the plateau is enclosed by a group of mountains, and to the east it extends into the highland or plateau of Yunnan.

The surface of the Tibetan Plateau consists of broad plains and many easterly trending ranges rising from a few hundred to a few thousand feet above the general level of the plateau. Most of the drainage is internal: the streams lose themselves in innumerable salt lakes or salty swamps. The plateau is one of the most desolate areas of the world. It is cold, windy, and treeless; precipitation is generally less than ten centimetres (four inches) a year.

The Tibetan Plateau is underlain primarily by Mesozoic marine sedimentary rocks that were folded and faulted. The Himalayas to the south were formed by uplift, folding, and overriding during several orogenic (mountain-building) stages that started in Late Mesozoic time and continued throughout the Cenozoic. The most violent movements were in the Middle Tertiary, when granitic masses were intruded. The mountains have undergone great uplift, probably over 5,000 metres (16,000 feet) during the Cenozoic.

The events that formed the Himalayan mountain system are also responsible for the uplift of the Tibetan Plateau. The Himalayan mountain system is the result of the Cenozoic collision of two drifting Earth plates; the vast continental mass of Asia on the north is one plate, and the small continental mass of the Indian peninsula on the south is the other. The collision of these two plates caused the Earth's crust to buckle in a highly complex manner, forming the Himalayas. Because it was behind the Himalayas, the Tibetan Plateau was not so severely deformed, but the movement was great enough to cause the piling up of a great thickness of crustal and upper mantle material.

Western North America

Basin and range topography. Basin and range topography is best developed in the western United States and Mexico. It consists of closely spaced, parallel mountain ranges separated by elongate basins, some of which have internal drainage.

In western North America, basin and range topography occurs in an irregular area extending chiefly from northern Nevada and western Utah southward and southeastward for about 2,400 kilometres (1,500 miles) into northern Mexico. In the United States the region of basin and range topography is nearly 720 kilometres (450 miles) across. In Mexico the region of basin and range topography is divided into two parts by the Sierra Madre Occidental; the whole belt, including the medial mountains, is about 550 kilometres (350 miles) across. The most systematic development of basin and range topography is in Nevada and western Utah, where long north–south trending mountains about 16 kilometres (ten miles) wide that commonly crest at elevations of 2,500 to 3,000 metres (8,000 to 10,000 feet) separate valleys of comparable widths lying at elevations of 1,200 to 1,500 metres (4,000 to 5,000 feet). In the United States south of Nevada and Utah and in northern Mexico, the mountains and valleys are lower, and their distribution pattern is less systematic. There many of the mountains are isolated masses protruding from accumulated alluvium.

The mountains owe their origin to block faulting in which vertical uplift has occurred along extensive faults on one or both sides of the mountain block. Two different types of block faulting have been suggested: in one type, a giant crustal block is tilted, forming a mountain on the uplifted part and a valley on the downtilted part; in the other type, crustal blocks are alternately upthrown and downthrown—the upthrown blocks (horsts) forming the mountains, the downthrown blocks (grabens) forming the valleys. To form this structure by either method requires a considerable amount of extension of the Earth's crust. In Nevada and western Utah, this extension has been estimated to be about 70 kilometres (45 miles) in an east–west direction, or approximately 10 percent of the width of the basin and range region.

Ice plateaus. Most of Greenland and Antarctica are covered by thick sheets of ice that have relatively flat upper surfaces and high elevation. These ice regions are referred to as ice plateaus. The ice that forms them is over 1,500 metres (5,000 feet) thick in much of Greenland and Antarctica, and in both places their bases, where they are thickest, are below sea level. The ice is largely a relic of the Pleistocene ice age (10,000 to 2,500,000 years ago), when continental glaciers covered much of the Arctic, sub-Arctic, and even some temperate regions of the world (see further ICE SHEETS AND GLACIERS).

BIBLIOGRAPHY. Detailed information on plateaus and basins is available under descriptions of individual mountain ranges, countries, and continents. The following books contain information on specific continents and countries: W.D. THORNBURY, *Regional Geomorphology of the United States* (1965); M.G. RUTTEN, *The Geology of Western Europe* (1969); S.P. SUSLOV, *Physical Geography of Asiatic Russia* (1961; orig. pub. in Russian, 2nd ed., 1954). Details of the geology of the Ethiopian and Somalian plateaus are given by P.A. MOHR in "The Ethiopian Rift System," *Bull. Geophy. Obs. Addis Ababa*, no. 11 (1967); of the Himalaya mountains and the Tibetan Plateau by AUGUSTO GANSSER in "The Indian Ocean and the Himalayas: A Geologic Interpretation," *Eclog. Geol. Helv.*, 59:831–848 (1966); and of Basin and Range topography by J.H. STEWART in "Basin and Range Structure: A System of Horsts and Grabens Produced by Deep-Seated Extension," *Bull. Geol. Soc. Am.*, 82:1019–1044 (1971). Background information on plate tectonics related to the origin of plateaus and basins is in R.S. DIETZ and J.C. HOLDEN, "The Breakup of Pangaea," *Scient. Am.*, 223:30–41 (1970); and J.H. ILLIES, "Graben Tectonics As Related to Crust-Mantle Interaction," *Graben Problems: Proceedings of the International Rift Symposium*, pp. 4–27 (1970).

Platinum Metals, Products and Production of

Platinum and palladium are far more important commercially than the other members of the platinum-group metals, which also include iridium, osmium, rhodium, and ruthenium. The platinum metals are notable for their wide range of applications, many of which are based on their high melting points, resistance to corrosion, and catalytic properties.

History. The first platinum to reach Europe came from placers in the Chocó district of what is now Colombia, South America. Gold also was recovered from the same placers, which are still being worked. The new material was brought to England by Sir Charles Wood in 1741 and aroused widespread scientific interest as its complexities were gradually unravelled. A method for separating quite pure platinum from the ore was devised, and the metal was found to be ductile.

The high melting points of these metals were a limitation to their use, but researchers in England, France, Germany, and Russia devised methods for consolidating and working platinum into useful forms.

Ores and mining. Platinum ores usually contain more platinum than the other platinum metals, except for the relatively rare osmiridium.

Where deposits containing platinum minerals have been subjected to weathering, the high density of platinum and its corrosion resistance have led to its concentration in riverbeds. In a number of locations, gold also is present in the same placers, but the original sources differ. The

Chocó placers mentioned earlier were overshadowed by platinum from the Urals of Russia, which dominated the world supply from 1825 until about 1914.

Platinum was long known to exist as an arsenide, sperrylite, in Canadian copper–nickel–iron–sulfide deposits, and some recovery was made beginning in 1900. Not until the adoption of electrolytic methods for refining copper and nickel in Canada and the carbonyl process in England, however, did substantial production result. Platinum and palladium dominate in these deposits, but all of the platinum metals are present and are now recovered.

Before 1930, palladium was relatively rare, being derived from various platinum ores and from the electrolytic refining of copper, a situation that changed in 1930 when production by the International Nickel Company of Canada, Ltd., sharply increased and the metal became available in quantities adequate for industrial use. Production of palladium as well as platinum from copper nickel deposits in the U.S.S.R. began to increase in the 1960s.

Recovery from South African pyroxenite deposits. In working alluvial deposits, the high density of the platinum minerals is relied upon for recovery, as is the case with gold. In treating platinum ore from the pyroxenite deposits in the Merensky horizon in South Africa, now the largest sources of platinum, the ore is crushed, then finely wet-ground in ball mills. Then the pulp flows over corduroyed tables that recover free metallic particles and coarse platinum-bearing minerals. The recovered material is further concentrated and shipped to a refinery in England. The tailing from the table separation is thickened to remove much of the water and is then sent through a flotation cycle that recovers a concentrate of nickel, copper, and iron plus the remaining platinum minerals. The recovered material is dewatered, filtered, dried, and pelletized. The pellets are fed to blast furnaces, then converted into a copper–nickel matte containing substantial amounts of platinum metals, which can be treated to separate the copper and nickel sulfides and ultimately produce electrolytic copper and nickel. The platinum metals are recovered from the anode slimes from the nickel electrolysis. Alternatively, the Wise–Vines process can be employed, in which a small amount of silicon is added to the molten matte, followed by slow solidification. A nickel-rich bottom, which carries most of the platinum metals, separates and can be worked up promptly in a platinum metals refinery.

The Wise–Vines process

Recovery from Canadian copper–nickel ores. At the operations of the International Nickel Company of Canada, Ltd., the ore is selectively floated to yield fractions containing copper and nickel. The nickel fraction, after blast furnace and converter treatment, yields a nickel-rich matte, is cooled, crushed, ground, and passed over a magnetic separator to recover nickel-rich metallics, which contain most of the platinum metals. The remaining material is given further treatment and again selectively floated to yield a low-copper and a high-copper sulfide. The latter and the earlier copper concentrates are refined by the usual electrolytic methods, as is the nickel sulfide concentrate. Gold and silver are recovered from the copper electrolysis; any remaining platinum metals are recovered from the nickel electrolysis.

Some nickel matte is converted to oxide and shipped to Clydach, Glamorgan, where it is treated by the Mond carbonyl process, in which the nickel is converted into gaseous nickel carbonyl. The platinum metals remain behind, and this material, along with platinum metal concentrates from Canadian operations, is treated at Acton, England, to isolate the individual platinum metals.

In refining, it is essential that all the gold be precipitated and that no trace redissolves, as any gold will form the explosive fulminate when ammonia is added in the palladium recovery operation. Even a small amount of fulminate can cause a serious explosion when the palladium precipitate dries. It also should be noted that the rhodium compound $(NH_4)_2NaRh(NO_2)_6$ will explode if heated. Osmium is easily oxidized, forming volatile osmium tetroxide, OsO_4, which will seriously damage the eyes.

Applications of pure metals and alloys. The mechanical properties of the six platinum metals differ greatly. Platinum and palladium are rather soft and very ductile; these metals and most of their alloys can be worked hot or cold. Rhodium is initially worked hot, but cold working can be done later with rather frequent annealing. Iridium can be worked hot, as can ruthenium, but with difficulty. Neither metal can be cold-worked appreciably.

Pure platinum and pure palladium are too soft for many applications and so are hardened by alloying, generally with one of the other metals of the platinum group, usually iridium or ruthenium. Rhodium is a less potent hardener for platinum but confers special advantages for high-temperature and certain catalytic uses. Platinum–rhodium, platinum thermocouples are standard for the measurement of high temperatures. (A thermocouple is a junction of dissimilar metals, in this case pure platinum and a platinum–rhodium alloy. A voltage is generated when this junction is heated.) All of the platinum metals can be electrodeposited, palladium being the easiest to process. The deposited metal is much harder than the wrought metal.

Hardening by alloying

Platinum. Platinum alloyed with 3.5 percent of rhodium is the standard material for crucibles in the laboratory, where they are subject to a variety of corrosives, including molten salts. A large-scale use for platinum and platinum with 10 percent and 20 percent rhodium for lining tanks has developed in the production of high-quality glass. Even more important is the use of the platinum–10 percent rhodium alloy for the bushings through which molten glass flows in producing glass fibre, a new industry made possible by platinum.

Rayon fibre is produced by forcing a cellulose xanthate solution through hair-fine holes in a spinneret made of platinum–rhodium or a gold–platinum–palladium alloy.

Insoluble platinum-iridium anodes are essential to the production of perchlorates and persulfates, while platinum-coated titanium is used as an insoluble anode in some electroplating operations and in cells for producing chlorate as well as in cathodic corrosion protection systems. Titanium coated with ruthenium dioxide is used for chlorine production.

Platinum–10 percent rhodium in the form of gauze, operating at bright-red heat, serves as the catalyst in the reaction between ammonia and air to produce nitrogen oxide and ultimately nitric acid, a standard process throughout the world. By feeding in some methane along with the ammonia mixture, hydrocyanic acid can be produced.

Platinum has long been employed as the catalyst in many other processes, but the most important new application is in the petroleum industry to produce improved gasoline and other hydrocarbon products. In this and many other applications, most of the platinum in the spent catalyst can be recovered. Plant expansion accounts for most of the demand for the metal.

Use by petroleum industry

The use of platinum for fine jewelry began about 1906. It continues to be used in jewelry, but industrial demand has provided the impetus for opening new mines.

Platinum alloys have long been used as spark-resistant electrical contact materials, but for some years the largest electrical use was for lead-ins for incandescent lamps. Because of its resistence to spark erosion, platinum was used in spark plugs for combat aircraft in World War II.

Palladium. Pure palladium was found to be very desirable for contacts in the relays of telephone and other wire communications systems, because it provided long life and a high level of reliability. This use continues to be the major one.

Palladium in relay contacts

Hydrogen diffuses rapidly through palladium and some of its alloys at moderately elevated temperatures. Industrial application is made of this property by utilizing tubes with hair-thin walls of a palladium–25 percent silver alloy to separate high-purity hydrogen from mixed gases.

Palladium hardened with ruthenium is used in certain types of jewelry, and a number of palladium-content brazing alloys are in use in the aircraft industry.

The range of corrosives that can be handled with titanium can be widened by alloying it with small amounts of palladium; alloys containing about 0.2 percent palladium are of commercial importance.

Other platinum metals. Rhodium is the whitest of the platinum metals, a property responsible for its extensive

use as an electroplate in applications ranging from the finishing of jewelry to the production of 60-inch searchlight reflectors. Rhodium has useful catalytic properties that are receiving attention. It is also suitable for electrical contacts and is particularly useful as an electroplated surface on rubbing electrical contacts. The use of rhodium as an alloy with platinum for high-temperature use is important, and the platinum, platinum–10 percent rhodium thermocouple is standard for measurement of temperatures up to about 1,500° C. For higher temperatures, thermocouples made of platinum with 7 percent and 30 percent rhodium are available. Platinum–rhodium alloys also are used for the heating windings in laboratory furnaces. Pure rhodium as well as pure iridium crucibles are used in growing crystals for laser and related applications.

Iridium, the most corrosion-resistant of the platinum group metals, is a very effective hardener for platinum. Its extremely high melting point renders it useful in special situations where oxygen can be limited, as in growing special crystals. In addition to the small percentage of iridium found in most platinum deposits, natural alloys of iridium with osmium are found in a few locations around the world. In addition, a few thousand ounces of osmiridium are recovered yearly from the gold ores of South Africa. Iridium has outstanding resistance to lead compounds at high temperatures, one of the reasons for its use in ultra-long-life spark plugs.

Sources of iridium

Ruthenium is a good hardener for platinum, the 12 percent alloy being used for contacts in voltage regulators, thermostats, and magnetos. It is used to harden platinum and particularly palladium for use in jewelry. Ruthenium content alloys are also used for tipping the nibs of fountain pens. The electrodeposition of ruthenium is possible, and its hardness recommends it in instruments where a low-pressure rubbing contact is required.

Osmium is the rarest and hardest of the group and has the highest melting point, but its ready oxidation is a limitation. It has been employed in the synthesis of cortisone.

Purity. Traces of impurities in refined platinum metals can be estimated by the spectrography of the arc emissions. In the case of platinum, the measurement of the thermal electromotive force (EMF) against a sample of extremely pure wire often is employed, as is a measurement of the temperature coefficient of electrical resistivity between 0° and 100° C.

Within the temperature range of −183° C (the boiling point of oxygen) and 630° C, the platinum resistance thermometer defines the temperature on the International Practical scale. The range from 630° C to 1,064° C is covered with the platinum, platinum–10 percent rhodium thermocouple. In view of the importance of both the temperature coefficient and the thermal EMF against a sample of extremely pure platinum, a detailed study has been made of the effect of single impurities on these properties.

Production. The major sources of platinum metals are South Africa, the U.S.S.R., and Canada. Mining in South Africa is directed primarily to the production of the platinum metals; in the U.S.S.R., platinum metals as well as copper and nickel are involved; in Canada, nickel and copper are the primary goals.

BIBLIOGRAPHY. The history of the production of platinum is well covered in D. MCDONALD, *A History of Platinum from the Earliest Times to the Eighteen-eighties* (1960). The nickel ores that are the principal sources of platinum metals in the U.S. are discussed in J.R. BOLDT and P. QUENEAU, *The Winning of Nickel: Its Geology, Mining and Extracting Metallurgy* (1967). A large world source of platinum metal in South Africa is well described in "Platinum Mining at Rustenburg," *Platin. Metals Rev.*, 13:15–22 (1969). An excellent and current summary with a discussion of areas of future demand is given in L.B. HUNT and F.M. LEVER, "Availability of the Platinum Metals," *ibid.*, 13:126–138 (1969). The properties and uses of important platinum metal alloys and compounds are described in "Platinum Group Metals," *Kirk-Othmer Encyclopedia of Chemical Technology*, 2nd ed., 15:832–860 (1968); a pioneering summary of properties is presented in R.F. VINES and E.M. WISE (eds.), *Platinum Metals and Their Alloys* (1941). The properties of palladium and its alloys are presented in E.M. WISE, *Palladium* (1968). A bibliography dealing with the catalytic properties of metals other than platinum and palladium is A.E. REA and M. BEBBINGTON (comps.), *Annotated Bibliography on Ruthenium, Rhodium and Iridium as Catalysts* (1959). A good summary of the chemical analysis of platinum metals is in the *Treatise on Analytical Chemistry*, vol. 8, pt. 2, pp. 379–522 (1963). See also D.W. RHYS and P. TAIMSALU, "Effect of Alloying Additions on the Thermoelectric Properties of Platinum," *Engelhard Inds. Tech. Bull.*, 10:41–47 (1969).

(E.M.W.)

Plato

Plato was, with Socrates and Aristotle, one of the three philosophers of ancient Greece who between them laid the philosophical foundations of Western culture. Building on the life and thought of Socrates, whom his dialogues memorialized, Plato developed a profound and wide-ranging system of philosophy that was strongly ethical, and at times even mystical, in spirit, while remaining basically rationalistic. Through his foundational metaphysics of eternal Ideas or Forms, each answering to some changeless abstract concept (or universal), Plato sought to establish a realm of absolutes, which, by incorporating ethical as well as other concepts, could allay the moral confusion of his day.

THE LIFE OF PLATO

Plato was born, the son of Ariston and Perictione, in Athens, or perhaps in Aegina, in *c.* 428 BC, the year after the death of the great ruling statesman Pericles. His family, on both sides, was one of the most distinguished in Athens. Ariston is said to have traced his descent through Codrus, the last king of Athens, to the god Poseidon; on the mother's side, the family was related to the early Greek lawmaker Solon and traced its ancestry back to Dropides, archon (one of the nine principal magistrates of Athens) in 644 BC. His mother, Perictione, apparently married as her second husband her uncle Pyrilampes, a prominent supporter of Pericles; and Plato was probably brought up chiefly in his house. Critias and Charmides, leaders among the extremists of the oligarchic terror of 404, were, respectively, cousin and brother of Perictione; both were old friends of Socrates, and through them Plato must have known the philosopher from boyhood.

Distinguished family

His own early ambitions were political. A conservative faction urged him to enter public life under its auspices —at the age of 24—but he wisely held back until the faction's policy should be declared. He was soon repelled by its members' violent acts, particularly their attempt to implicate Socrates in the illegal execution of a victim. He hoped for better things from the restored democracy and

Plato, Roman herm probably copied from a Greek original, 4th century BC. In the Staatliche Museen, Berlin.

even clung to this hope for a considerable time after it condemned Socrates to death. Eventually, however, he became convinced that there was no place for a man of conscience in active politics. On the execution of Socrates in 399 BC, Plato and other Socratic men took temporary refuge at Megara with Euclid, founder of the Megarian school of philosophy. The next few years are said to have been spent in extensive travels in Greece, in Egypt, and in Italy. Plato's own statement is only that he visited Italy and Sicily at the age of 40 and was disgusted by the gross sensuality of life there but found a kindred spirit in Dion, brother-in-law of Dionysius I, the tyrant of Syracuse.

The Academy and Sicily. About 387, or soon after, Plato founded the Academy as an institute for the systematic pursuit of philosophical and scientific research. He presided over it for the rest of his life, making it the recognized authority also in mathematics and in jurisprudence. From allusions of Aristotle it would seem that Plato lectured without manuscript. "Problems" were propounded for solution by the joint researches of students. On the political side there are traces of tension between the Academy and the rival school of Isocrates.

Political action in Syracuse

The one outstanding event in Plato's later life was his intervention in Syracusan politics. On the death of Dionysius I in 367, Dion conceived the idea of bringing Plato to Syracuse as tutor to his successor, Dionysius II, whose education had been neglected. Plato himself was not optimistic about the results; but because both Dion and Archytas of Tarentum, a philosopher-statesman, thought the prospect promising, he felt bound in honour to risk the adventure. The plan was, by training Dionysius II in severe science, to fit him for the position of a constitutional king who might hold Carthaginian encroachment on Sicily at bay. The scheme was crushed by Dionysius' natural jealousy of the stronger Dion, whom he drove into virtual banishment. Plato later paid a second and longer visit to Syracuse in 361–360, still in the hope of effecting an accommodation; but he failed, not without some personal danger. Dion then captured Syracuse by a *coup de main* in 357. After the murder of Dion in *c.* 354, the philosopher drew up his important *Epistles* vii and viii, reviewing and justifying the policy of Dion and himself and making proposals, unsuccessfully, for a conciliation of the Sicilian parties. Plato is said to have died (in 348/347 BC) "at a marriage feast," or, while "writing," and to have been buried in the Academy.

As for Plato's personality, apart from the reflections of it in the *Epistles*, the most valuable light thrown upon it is that of Aristotle, who described him as a man "whom it is blasphemy in the base even to praise."

Influence of the Academy

To his readers through the ages, Plato has been important primarily as one of the greatest of philosophical writers; but to himself, the foundation and organization of the Academy must have appeared to be his chief work. In *Epistles* vii, he contrasts the impact of written works with that of the contact of living minds as a vehicle of "philosophy," and he utters on his own account the same comparatively unfavourable verdict on written works that he ascribes to Socrates in the *Phaedrus*. He apparently intended his dialogues in the main to interest an educated outside world in the more serious and arduous labours of his "school."

All of the most important mathematical work of the 4th century was done by friends or pupils of Plato. The first students of conic sections, and possibly Theaetetus, the creator of solid geometry, were members of the Academy. Eudoxus of Cnidus—author of the doctrine of proportion expounded in Euclid's *Elements*, inventor of the method of finding the areas and volumes of curvilinear figures by exhaustion, and propounder of the astronomical scheme of concentric spheres adopted and altered by Aristotle—removed his school from Cyzicus to Athens for the purpose of cooperating with Plato; and during one of Plato's absences he seems to have acted as the head of the Academy. Archytas, the inventor of mechanical science, was a friend and correspondent of Plato. The Academy can thus be viewed as the link between the mathematics of the 5th-century Pythagoreans and that of the geometers and arithmeticians of Alexandria.

Nor were other sciences neglected. Speusippus, Plato's nephew and successor, was a voluminous writer on natural history; and Aristotle's biological works have been shown to belong largely to the early period in his career immediately after Plato's death, before the breach between the younger philosopher and the Academy. The comic poets found matter for mirth in the attention of the school to botanical classification. The Academy was particularly active in jurisprudence and practical legislation. As the biographer Plutarch testifies,

> Plato sent Aristonymus to the Arcadians, Phormion to Elis, Menedemus to Pyrrha. Eudoxus and Aristotle wrote laws for Cnidus and Stagirus. Alexander asked Xenocrates for advice about kingship; the man who was sent to Alexander by the Asiatic Greeks and did most to incite him to his war on the barbarians was Delios of Ephesus, an associate of Plato.

The creation of the Academy as a permanent society for the prosecution of both exact and humane sciences was, some assert, the first establishment of a university.

Formative influences. The most important formative influence to which the young Plato's mind was exposed was that of Socrates. It does not appear, however, that Plato, whose first ambitions were political, belonged as a "disciple" to the innermost circle of Socrates' intimates. In *Epistles* vii he is careful to speak of Socrates not as a "master" but as an older "friend," for whose character he has a profound respect; and he has recorded his own absence (through indisposition) from the death scene of the *Phaedo*. It would seem that his own vocation to philosophy dawned on him only afterward, as he reflected on the treatment of Socrates by the democratic leaders.

Political setting of Plato's life

Plato was also connected with Pyrilampes, a Periclean politician, and Critias, known as a democrat until, after the collapse of the Periclean government, his moral balance was upset and he became one of the most unscrupulous of the ensuing Thirty Tyrants. Plato's early upbringing in a family of Periclean politics having connection with Solon may explain why Plato's own estimate of democracy in the *Statesman* and *Laws* is much less unfavourable than that which he earlier ascribed to Socrates.

Plato's early experiences covered the disastrous years of the Deceleian War, the shattering of the Athenian empire, and the fierce civil strife of oligarchs and democrats in the year of anarchy, 404–403. He was too young to have known anything by experience of the imperial democracy of Pericles and Cleon or of the tide of the Sophistic movement. It is certainly not from memory that he depicted Protagoras, the earliest avowed professional Sophist, or Alcibiades, a turncoat Athenian general, as they were in their great days.

GENERAL FEATURES OF THE DIALOGUES

The canon and text of Plato was apparently fixed at about the turn of the Christian era. By reckoning the *Epistles* as one item, the list contained 36 works, arranged in nine tetralogies. No genuine work of Plato has been lost, and there is a general agreement of modern scholars that a number of small items—*Alcibiades I*, *Alcibiades II*, *Theages*, *Erastae*, *Clitopho*, *Hipparchus*, and *Minos*—are spurious. Most, though not all, contemporary scholars also regard the *Epinomis* as an appendix to the *Laws*, added by the mathematician Philippus of Opus. The *Hippias Major* and the *Menexenus* are regarded as doubtful by some, though Aristotle seems to have regarded them as Platonic. Plato's will is pretty certainly authentic.

Order of composition. Plato's literary career extended over the greater part of a long life. *The Apology* must have been written early, while the memory of Socrates' trial was still fresh. The *Laws*, on the other hand, was the work of an old man, and the state of its text bears out the tradition that Plato never lived to give it its final revision. Since there is no evidence that Plato began his career with a fully developed "system" that had only to be exposed, and since there is every logical reason to believe that his mind developed, the order in which the various dialogues were written takes on importance. Only through it can the development of Plato's thought be adequately charted. Plato himself has given a few clues to the order:

he linked the *Sophist* and the *Statesman* with the *Theaetetus* externally as continuations of the conversation reported in that dialogue. Similarly, he seems to have linked the *Timaeus* with *The Republic*. And Aristotle noted that the *Laws* was written after *The Republic*.

Stylometric studies of the dialogues

Modern scholars, by the use of stylistic criteria, have established that the *Sophist, Statesman, Philebus, Timaeus* (with its fragmentary sequel *Critias*), and *Laws* form a distinct linguistic group, belonging to the later years of Plato's life. The whole group must be later than the *Sophist*, which professes to be a sequel to the *Theaetetus*, which, in turn, can be dated with some accuracy, since it commemorates the death of the eminent mathematician after whom it is named (probably in 369 BC). The dialogue may thus be ascribed to *c.* 368, the eve of Plato's departure for Syracuse.

The earlier group is generally believed to have ended with the *Theaetetus* and the closely related *Parmenides*. Besides this conclusion, perhaps all that can be said with certainty is that the great outstanding dialogues, *Symposium, Phaedo*, and *The Republic* (and perhaps also *Protagoras*), in which Plato's dramatic power was at its highest, mark the culmination of this first period of literary activity. The comparative decline of dramatic power, accompanied by a compensating maturity of critical acumen, is the most striking contrast between the dialogues of the second period and those of the first period.

Persons of the dialogues. The great difficulty that initially besets the modern student is that created by the dramatic form of Plato's writings. Since Plato never introduced himself into his own dialogues, he is not formally committed to anything taught in them. The speakers who are formally bound by the utterances of the dialogues are their protagonists—Socrates, the Rationalist Parmenides of Elea (who held that all is a static One), and the Pythagorean Timaeus—and all of these are real historical persons. It is, therefore, reasonable to question whether or not Plato was putting his own doctrines into the mouths of these characters, whether his purpose was dogmatic and didactic or mainly dramatic, and whether he should be held responsible for what is said.

Whether Plato gives his own views

George Grote, an English historian, held that Plato allowed himself to develop freely in a dialogue any view that interested him for the moment, without pledging himself to its truth. Thus, Plato can make Socrates tolerate hedonistic utilitarianism in the *Protagoras* and denounce it in the *Gorgias*. Others argued that some of Plato's characters, notably Socrates and Timaeus, are "mouthpieces" through whom he inculcates tenets of his own, without concern for dramatic or historical propriety. Thus it often has been held that the "theory of Ideas," the doctrine of "recollection," and that of the tripartite soul were originated by Plato after the death of Socrates and consciously fathered on the older philosopher. In fact, neither extremity seems a reasonable view.

Thought of the earlier and later dialogues. There is undeniably a real difference between the thought of the dialogues that are later than the *Theaetetus* and those that are earlier. But there are no serious discrepancies of doctrine between individual dialogues of the same period. Plato may have announced his own personal convictions on certain doctrines in a second group of dialogues by a striking dramatic device: in the *Sophist* and *Statesman* the leading part is taken by an Eleatic (one belonging to a school of monistic Rationalists) and in the *Laws* by an Athenian, who are the only anonymous, indeed almost certainly the only imaginary, personages of any moment in the whole of Plato's writings. It seems likely, therefore, that these two characters have been left anonymous so that the writer may be free to use them as mouthpieces for his own teaching. Plato thus takes on himself the responsibility for the logic and epistemology of the *Sophist* and of the *Statesman* and for the ethics and educational and political theory of the *Statesman* and of the *Laws* in a specially marked way, thus evoking the question of how far the earlier utterances of Socrates are to be taken as his own.

Doctrine of Forms. Scholars have definitely established that there is a specific philosophical doctrine running through the earlier dialogues that has as its main features a theory of Forms (or of Ideas), the theory that knowledge is "recollection," and the theory of the "tripartite soul." In the *Phaedo*, for example, Socrates is made to describe the theory of Ideas as something quite familiar that he has for years constantly canvassed with his intimates (nearly all of whom were certainly living when the *Phaedo* was circulated). In the dialogues of the second period these tenets appear only in the mouth of Timaeus, a 5th-century Pythagorean older than Socrates; and the most important of them all, the theory of Forms, is actually made the object of what looks like a refutation in the *Parmenides*. The question thus arises as to whether Plato himself had two distinct philosophies, an earlier and a later, or whether the main object of the first group of dialogues was to preserve the memory of Socrates, with the philosophy expounded being, in the main, that of Socrates—coloured, no doubt, but not consciously distorted, in its passage through the mind of Plato. Thus, on the second view, Plato had no distinctive Platonic philosophy until a late period in his life. This interpretation remained viable for many years in spite of objections from many scholars. In its favour were several considerations long viewed as weighty.

Whether Plato has two philosophies

Socrates and Plato. It is significant that the only dialogue later than the *Theaetetus*, in which Socrates takes a leading part, is the *Philebus*, the one work of the second group that deals exclusively with the ethical problems on which the thought of Socrates had concentrated. This is usually explained by supposing that Plato was unwilling to make Socrates the exponent of doctrines that he knew to be his own property. On the other hand, it is hard to understand his misgivings if he had already been employing him in that very capacity for years. It is notable, too, that Aristotle, who apparently knew nothing of an earlier and a later version of Platonism, attributed to Plato a doctrine that is quite unlike anything to be found in the first great group of dialogues. It was also the view of Neoplatonic scholars that the theory of Ideas of the great earlier dialogues really originated with Socrates; and the fact that they did not find it necessary to argue the point may show that this had been the standing tradition of the Academy.

Today, however, a modified view is regarded as much more likely. Though the theory of Forms, in this view, could not have arisen with Socrates, Plato nevertheless attributed it to him because he saw it as the theoretical basis and elaboration of what Socrates did teach.

THE EARLIER DIALOGUES

Three main areas of thought

In *The Republic*, the greatest of all the dialogues that precede the *Theaetetus*, there are three main strands of argument deftly combined into an artistic whole, the ethical and political, the aesthetic and mystical, and the metaphysical. Other major dialogues belonging to this period give special prominence to some one of these three lines of thought; the *Phaedo* to the metaphysical theme; the *Protagoras* and the *Gorgias* to the ethical and political; the *Symposium* and the *Phaedrus* to the aesthetic and mystical.

Dialogues of search. The shorter dialogues, dealing with more special problems, generally of an ethical character, mostly conform to a common type: a problem in moral science, often that of the right definition of a virtue, is propounded, a number of tentative solutions are considered, and all are found to be vitiated by difficulties that cannot be dispelled so that the reader is left, at the end of the conversation, aware of his discreditable ignorance of the very things that it is most imperative for a man to know. He has formally learned nothing but has been made alive to the worthlessness of what he had hitherto been content to take as knowledge and to the need of seeking further enlightenment.

The effect of these dialogues of search is thus to put the reader in tune with the spirit of Socrates, who had said that the one respect in which he was wiser than other men was in his keen appreciation of his own ignorance of the most important matters. He learns the meaning of Socrates' ruling principle that the supreme business of life is to "tend" the soul and his conviction that "goodness of

soul" means *knowledge* of good and evil. The three dialogues directly concerned with the trial of Socrates have manifestly a further purpose. They are intended to explain to a puzzled public, as a debt of honour to his memory, why Socrates thought it a matter of conscience neither to withdraw from danger before trial, nor to make a conciliatory defense, nor, after conviction, to avail himself of the opportunity of flight.

Themes of the shorter dialogues

In the *Hippias Major* Plato propounds the question "What is the 'fine' (or 'beautiful')?" In the *Hippias Minor* he deals with the paradox that "wrong-doing is involuntary." In the *Ion* he discredits the poets, who create not "by science" but by a nonrational inspiration. The *Menexenus,* which professes to repeat a funeral oration learned from Aspasia, a famous *hetaira,* or member of a class of highly educated concubines, is apparently meant as a satire on the patriotic distortion of history. The *Charmides, Laches,* and *Lysis* are typical dialogues of search. The question of the *Charmides* is what is meant by *sōphrosynē,* the virtue that is shown both in graceful command of the passions and in dutiful behaviour to parents and official "superiors," in balance and sanity amid the turns of fortune. It seems that this virtue can be identified with "knowledge of self"—the self-knowledge that Socrates had valued so highly—when man is confronted with an ambiguity. The *Laches* is concerned with valour, the soldier's virtue; and the *Lysis* examines in the same tentative way, friendship, the relation in which self-forgetting devotion most conspicuously displays itself.

The question of whether names are significant by nature or by convention is considered in the *Cratylus—i.e.,* whether there is some special appropriateness of the sounds of names to the objects called by them, or whether it merely reflects the "usage of the community." Thus Plato shows that language is an instrument of thought; that the test of its rightness is not mere social usage, but its genuine capacity to express true thought accurately. The dialogue *Euthydemus* satirizes the "eristics"—those who try to entangle a person in fallacies because of the ambiguity of language. Its more serious purpose, however, is to contrast this futile contradiction mongering with the "protreptic," or hortatory, efforts of Socrates, who urges that happiness is not guaranteed by the *possession* of things but by the right *use* of them—and particularly of the gifts of mind, body, and fortune.

Ethical and political dialogues. The *Gorgias,* the *Protagoras,* and several lesser dialogues give special prominence to ethical and political themes.

Gorgias. The *Gorgias* begins ostensibly as an inquiry into the nature and worth of rhetoric, the art of advocacy professed by Gorgias, and develops into a plea of sustained eloquence and logical power for absolute right—as against expediency—as the sovereign rule of life, both private and public. It ends with an imaginative picture, on Orphic lines, of the eternal destinies of the righteous and of the unrighteous soul. Literature contains no more impressive presentation of the claim of conscience to unqualified obedience and the impossibility of divorcing the politically right from the morally right.

Gorgias holds that "rhetoric" is the queen of all "arts." If the statesman skilled in rhetoric is clever enough, he will, though a layman, carry the day even against the expert specialist. Socrates, on the other hand, declares that "rhetoric" is not an "art" but a mere "empiric knack" of humouring the prejudices of an audience. There are two arts conducive to health of soul, those of the legislator and of the judge. The Sophist counterfeits the first, as the rhetorician does the second, by taking the pleasant instead of the good as his standard. The rhetorician is thus not the wise physician of the body politic but its toady. This severe judgment is disputed by Polus, an ardent admirer of Gorgias, on the ground that the successful rhetorician is virtually the autocrat of the community, and to be such is the summit of human happiness because he can do whatever he likes.

Autocratic power of rhetoric and its refutation

Socrates rejects this view. To suffer a wrong is an evil, but to inflict one is much worse. If rhetoric is of real service to men, it should be most of all serviceable to an offender, who would employ it to move the authorities to inflict the penalties for which the state of his soul calls. This is denied by Callicles of Acharnae, an otherwise unknown politician, who proceeds recklessly to develop the doctrine of the "will to power." It may be a convention of the herd that unscrupulous aggression is discreditable and wrong, but "nature's convention" is that the strong are justified in using their strength as they please, while the weak "go to the wall." To Socrates, however, the creators of the imperialistic Athenian democracy were no true statesmen; they were the domestic servants of the democracy for whose tastes they catered; they were not its physicians. That would be a condition like that of the fabled sinners who are punished in Hades by being set to spend eternity in filling leaking pitchers. The truly happy life is not, as Callicles supposes, to have vehement passions and be able to gratify them to the full; it is to have that measure in which the gratification of desire is strictly regulated by regard for justice and *sōphrosynē* (see above).

Meno. The *Meno* is nominally concerned with the question of what virtue is and whether it can be taught; but it is further interesting for two reasons: it states clearly the doctrine that knowledge is "recollection"; it also introduces as a character the democratic politician Anytus, the main author of the prosecution of Socrates.

Whether virtue can be taught

Whether virtue can be taught depends on what virtue is. Any definition, however, is futile because it is idle to inquire into what you already know, useless to inquire into what you do not know, for you could not recognize the unknown, even if you found it. But this difficulty would vanish if the soul were immortal and had long ago learned all truth, so that it needs now only to be reminded by sense experiences of truths that it once knew and has forgotten. Thus a youth who has never studied geometry can be brought to recognize mathematical truths. He produces the right answer "out of himself." The point is thus the presence of a priori elements in mathematical truth. But if virtue is knowledge, there must be professional teachers of it. But Anytus insists that the Sophists, who claim to be such professionals, are mischievous impostors; and even the "best men" have been unable to teach it to their own sons. If a man should arise who could actually teach statesmanship, he would be one who really *knew* what the Good is.

Protagoras. The *Protagoras,* a finely dramatic dialogue, gives the most complete presentation to be found in Plato of the main principles of the Socratic morality. In this dialogue, Socrates meets the eminent Sophist Protagoras, who explains that his profession is the "teaching of goodness"—*i.e.,* the art of making a success of one's own life and of one's city. Socrates urges, however, that public opinion and the practice of the eminent few, who have never taught "goodness" to their sons, alike suggest that the conduct of life is not teachable. But the problem arises as to whether the various commonly recognized virtues are really different or all one. Protagoras is ultimately ready to identify all of them but courage with wisdom or sound judgment. Socrates then attempts to show that, even in courage, goodness is meaningful inasmuch as, by facing pain and danger, one escapes worse pain or danger. Thus all virtues can be reduced to the prudent computation of pleasures and of pains, and virtue, according to Socrates, must then be one, namely, knowledge; and wrongdoing is thus involuntary. The true explanation of Socrates' doubts, however, is that, though true virtue, being knowledge, is teachable, what Protagoras is trying to teach is not true virtue. Success depends on personal tact, and tact cannot be learned from an instructor.

Euthyphro, The Apology, Crito. The main purpose of these three works, which deal with the bearing of Socrates before, during, and after his trial, is to obviate possible misunderstandings of his position and motives; their theme is the true meaning and importance of the care or tending of the soul. The problem of the *Euthyphro* is what is religion. The respondent Euthyphron is a kind of Orphic sectary. The central, though tacit, point is that the service of God, which in religion means cooperation with him, lies not in the fulfillment of purely arbi-

trary commands but in the production of a noble work, presumably that of the "tending of the soul." Consideration of *The Apology* and *Crito* in detail belongs to the study of Socrates (*q.v.*) rather than to that of Plato.

Metaphysical foundation of Plato's doctrine: "Phaedo." In the works so far considered, the foundation of a Socratic moral and political doctrine is laid, which holds that the great concern of man is the development of a rational moral personality and that this development is the key to man's felicity. Success in this task, however, depends on rational insight into the true scale of good.

Need for insight into absolute Good

The reason why men forfeit felicity is that they mistake apparent good for real, the conditionally for the absolutely Good. If a man ever knew with assurance what absolute Good is, he would in practice never pursue anything else; it is in this sense that "all virtue is knowledge." The philosophical moralist, who has achieved an assured insight into absolute Good, is thus the only true statesman, for he alone can tend to the national character. These convictions clearly imply a far-reaching metaphysic as their foundation and justification. The principles of this metaphysic are expounded more explicitly in the dialogues now to be considered, in which an explicit theory of knowledge and of scientific method are also discernible.

The object of the *Phaedo* is to justify faith in immortality by showing that it follows from a fundamental metaphysical doctrine (the theory of Ideas, or the doctrine of Forms), which seems to afford a rational clue to the structure of the universe. The writer has a passionate faith in "personal immortality." What is being maintained, in fact, is the divinity of the soul, of which its survival of death is a consequence. The argument is, briefly, that a true philosopher's whole life has been spent in trying to liberate the soul from dependence on her body. In life, the body is always interfering with the soul's activity. Its appetites and passion interrupt her pursuit of wisdom and goodness.

Arguments for immortality

There are three reasons for thinking that the soul survives death.

1. There is a belief that the soul has a succession of many lives. The processes of nature in general are cyclical; and it is reasonable to suppose that this cyclicity applies to the case of dying and coming to life. If this were not so, if the process of dying were not reversible, life would ultimately vanish from the universe. Secondly, the doctrine that what men call "learning" is really "recollection" suggests that men must have become acquainted with this knowledge before they were confined to their bodies.

2. The soul is relatively immutable, like the fixed ideal standards or eternal objects that she contemplates in her scientific thinking; and she, herself, has the likeness of that which she contemplates. Thus the divine element in man, the soul, can resist destruction. It is true that the soul could be an epiphenomenon, the tune (*harmonia*) given out by the body, which will vanish when the instrument is broken; but Socrates replies that what can be more or less in tune is clearly not itself a tune.

3. Socrates' thought was permeated by a fundamental unproved postulate, the theory of Ideas, which holds that there really is a single determinate and immutable something answering to every significant general, or abstract, term and apprehended only by pure thought. The sensible things of which a man predicates general terms temporarily partake in or communicate with the Idea or Form. When he says that a thing becomes beautiful, what he means is that the Form "beauty" begins to be present to that thing. This is the true account of the cause of "coming into and passing out of being." As applied to immortality, Socrates argues first that there are certain sensible things of which it is an essential character to partake of a given Form. Such things will never admit an incompatible Form. Similarly, it is an essential character of a soul to be alive, to partake of the Form life. It refuses to partake of the Form death. The proof of immortality is thus hypothetical; it is shown to be involved as a consequence of the doctrine of Forms. (For further discussion of the theory of Forms, see METAPHYSICS.)

Aesthetic and mystical dialogues. Both the *Symposium* and the *Phaedrus* present the Forms in a special light, as objects of mystical contemplation and as stimuli of mystical emotion.

Symposium. The immediate object of the *Symposium*, which records several banquet eulogies of *eros* (desirous love), is to find the highest manifestation of the love that controls the world in the mystic aspiration after union with the eternal and supercosmic beauty. It depicts Socrates as having reached the goal of union, and puts the figure of Alcibiades, who has sold his spiritual birthright for the pleasures of the world, in sharp opposition to him.

Ascent to the supreme Form of Good

The main argument may be summarized thus: *Eros* is a reaching out of the soul to a hoped-for good. The object is eternal beauty. In its crudest form, love for a beautiful person is really a passion to achieve immortality through offspring by that person. A more spiritual form is the aspiration to combine with a kindred soul to give birth to sound institutions and rules of life. Still more spiritual is the endeavour to enrich philosophy and science through noble dialogue. The insistent seeker may then suddenly descry a supreme beauty that is the cause and source of all the beauties so far discerned. The philosopher's path thus culminates in a supreme beatific vision of the "Form of Good," the supreme Form that stands at the head of all others.

Phaedrus. Though the immediate subject of the *Phaedrus* is to show how a really scientific rhetoric might be built on the double foundation of logical method and scientific study of human passions, Plato contrives to unite with this topic a discussion of the psychology of love, which leads him to speak of the Forms as the objects of transcendent emotion and, indeed, of mystical contemplation. The soul, in its antenatal disembodied state, could enjoy the direct contemplation of unbodied reality; *i.e.*, of the Forms. Sense experience can suggest the Form of beauty in an unusually startling way: through falling in love. The unreason and madness of the lover mean that the wings of his soul are beginning to grow again; it is the first step in the soul's return to its high estate.

The consummate dialogue: "The Republic." As earlier stated, it is in *The Republic* that Plato interweaves the ethicopolitical, the aesthetic and mystical, and the metaphysical strands of his thought. In *The Republic*, the immediate problem is strictly ethical. What is justice? Can it be shown that justice is always a boon, injustice a curse, apart from all consideration of consequences? Is there a rational and self-authenticating principle at the root of moral distinctions? Plato holds that there is. Each man has a specific contribution that he can make to a rational society. Morality, justice, is to discharge that vocation. For to live otherwise is to be spiritually diseased.

This leads to a sketch of the institutions of a society in which justice holds sway and, particularly, of its moral and religious education. To show, next, that the principles that regulate public life are also recognizably those of the great virtues of private life, Plato provides, through the doctrine of the tripartite soul, a psychology of voluntary action. Moral excellence is thus grounded in absolute loyalty to a sound moral tradition enforced by education —a goal to be assured through statesmen who are philosophers as well as kings.

But the way for the vision of the Good must be prepared by an intellectual discipline in hard thinking that leads through study of the exact sciences to that of their metaphysical principles. The central books of *The Republic* thus present an outline of metaphysics and a philosophy of the sciences. As the various stages of degeneration through which national and personal character pass when the true moral-ideal decays are reviewed, one is confirmed in his conviction that, in respect of happiness, the life of regard for right is immeasurably superior, and this conclusion is finally clinched by reaffirmation of the immortality of the soul, which makes the choice of infinite moment.

The virtues: in individual and state

In the ethical scheme of *The Republic*, "three lives" are distinguished: those of the philosopher, of the votary of enjoyment, and of the man of action. The end of the first is wisdom, of the second, the gratification of appetite,

and of the third, practical distinction. These reflect the three elements or active principles within a man: (1) considered rational judgment of good; (2) a multitude of clamant and conflicting appetites for particular gratifications; and (3) a factor of spirited higher ideal emotion, manifested as resentment against infringements both by others and by our own appetites.

The same three distinctions reappear in the structure of society; there are: (1) the statesmen; (2) the general civilian population, who provide for material needs; and (3) the executive force (army and police). These three orders are thus, respectively: the judgmental, appetitive, and spirited elements. The four cardinal virtues are thus: wisdom, the excellence of the thinking part; courage, that of the spirited part (loyalty to the rule of life laid down by judgment); temperance, that of the appetitive part (acquiescence of the nonrational elements to the plan of life prescribed by judgment); and justice—the state in which each of the elements is vigorously executing its own function and, in loyal contentment, confining itself within its limits. Such a society is a true aristocracy, or rule of the best. Successive deviations from the ideal are timocracy (the benign military state), oligarchy (the state dominated by merchant princes, plutocracy), democracy (the state run by the inexpert) and, worst of all, tyranny (the state subjected to an irresponsible or criminal will).

Philosophic rulers: their virtues and training

The tripartite psychological schema here reflected proves inadequate when applied to the moral life of the philosopher-king, of whom a higher level of moral goodness is demanded. His courage, for example, is declared to be no mere loyalty to right opinions but a high serenity arising from knowledge of the insignificance of man's brief individual life in a vast universe. For him, in fact, "all virtue is one thing, knowledge." In the ideal state itself, however, virtue is not a complete unity. A special demand may be made, for example, of the fighting force, which is the valour of the whole society. This is because their moral convictions arise not from personal insight but from opinions implanted by education and taken on trust. But the rulers must know with a personal knowledge, by their insight into a system of absolute values embodied in the very structure of the universe. The virtues are thus transubstantiated and can no longer be distinguished from one another; they fuse in knowledge of the Good.

In *The Republic* the Forms appear in the double character of objects of all genuine science and formal causes of events and processes. It is expressly denied that there can be knowledge, in the proper sense, of the temporal and mutable. In Plato's scheme for the intellectual training of the philosophic rulers, the exact sciences—arithmetic, plane and solid geometry, astronomy, and harmonics—are first studied for ten years to familiarize the mind with relations that can only be apprehended by thought. Five years are then further given to the still more severe study of dialectic, a study which proceeds "by means of Forms, through Forms, to Forms"—what in the 1970s would be called a critical metaphysic of the sciences, which examines the *hypotheses* seeking to discover some still more ultimate, really self-evident principle from which they follow as consequences.

The Form of Good

This principle is the Form of Good, which, like the sun in relation to visible things, is the source at once of the reality of all things and of the light by which they are apprehended, as well as of their value. As in the *Symposium*, the Good is the supreme beauty that dawns suddenly upon the pilgrim of love as he draws near to his goal. It is true that the Good holds the place taken in later philosophies by the God who is thought of as the "Light of the world." But it is not God. Though *The Republic* is permeated by religious faith, theism as a principle of metaphysical explanation only makes its appearance in Plato's latest dialogues.

Dialogues of critical reconstruction. The two works that probably anticipate the dialogues of Plato's old age, the *Parmenides* and *Theaetetus*, display a remarkable difference of tone, clearly the result of a period of fruitful critical reconstruction.

The theory expounded in the *Phaedo* and *The Republic* does not allow enough reality to the sensible world. They tell the reader that a sensible thing is a complex or meeting place of a plurality of Forms: what else it may be they do not say. Clearly, however, the relation between a thing and a Form (*e.g.*, beauty), which has been called participation, needs further elucidation. In these dialogues truths of fact, of the natural world, have not yet come by their rights.

Plato clearly had an external motive for the re-examination of his system as well. The *Parmenides*, the *Theaetetus*, and the *Sophist* all reveal a special interest in the Eleatic philosophy—of which Parmenides was the chief representative—and the first and third show an anxiety on Plato's part to maintain that, in spite of important divergences, he, and not the professed Eleatics, is the true spiritual heir of Parmenides. The doctrine of his friend Eucleides of Megara, like that of Parmenides, was that sensible appearances are illusions with no reality at all. Continued reflection on this problem thus led straight to the discussion of the meaning of the copula "is" and the significance of the denial "is not," which is the subject of the *Sophist*.

Parmenides. Formally, the *Parmenides* leads to an impasse. In its first half the youthful Socrates expounds the doctrine of the participation of things in Forms to the Eleatic philosophers Parmenides and Zeno as the solution of the problem of the one and the many. Parmenides raises what appear to be insoluble objections and hints that the helplessness of Socrates under his criticism arises from insufficient training in logic.

In the second half, Parmenides gives an example of the logical training that he recommends. He takes for examination his own thesis, "The one is," and constructs an elaborate set of antinomies, or contradictions, thus yielding a patently ironical conclusion.

Objections to the doctrine of Forms

The Eleatic objections to the doctrine of the participation of Form in thing are, first, that it does not really reconcile unity with plurality, since it leads to a perpetual regress. It says that the many things that have a common predicate, or characteristic, participate in or imitate a single Form. But the Form itself also admits of a common predicate, and therefore a second Form must exist, participated in alike by the sensible things and the first Form, and so on, endlessly. Secondly, a graver difficulty is that the relations between Forms must belong to the realm of Forms, and those between sensible things to the realm of things. Thus men, belonging to the second, can know nothing of the true realities, the Forms. The purpose of the objections is thus to suggest that the manifold of sense has not even a derivative reality; it is mere illusion. The inference is that Plato is reproducing Eleatic and Megarian criticisms of the doctrine ascribed by himself to Socrates. The purpose of the antinomies may be deliberate parody, to show that the methods of the Megarian logicians are even more damaging to themselves than to the doctrine of participation.

Theaetetus. The *Theaetetus* is a straightforward discussion of the question of how knowledge should be defined. Plato shows (1) that knowledge cannot be identified with sensation nor with any formless simple apprehension; and (2) that pure relativism is as impossible in epistemology as in metaphysics. The increasing value that Plato is coming to put upon natural knowledge is marked by the use of the word *doxa* (uncertain opinion) in the new sense of "judgment." The *Theaetetus* strikingly treats knowledge at length without making any reference to the Forms or to the mythology of recollection. It remains to this day the best of introductions to the problem of knowledge. The main argument is as follows:

Efforts at defining knowledge

1. It seems plausible to say that knowledge is sensation. "What seems to me is so to me; what seems to you is so to you" (Protagoras). This relativistic doctrine arrives at a point at which the only reality, both within and without, is motion—a view clearly derived from certain philosophers of change presumably influenced by Heracleitus. When the motions of both organ and environment impinge on one another, they give rise to the twin product, felt sensation–sensible quality.

There is thus no common perceived world and therefore no standard of truth or reality other than that of the individual percipient.

Even the relativists, however, do not hold that each man is the only and inerrant measure of his *future* sensations. A man's own opinion as to whether a certain course will be expedient or good for him is often far from being the soundest. What the soul perceives through bodily organs must be distinguished from what she apprehends by herself without organs—such as number, sameness, likeness, being, and good. Since these comprise the formal element in all knowledge, knowledge must be found not in sensations but in the judgment of the mind upon them.

2. Is knowledge, then, true judgment? The answer is "hardly," for the statement implies a knowledge of what is meant by error, for which Plato cannot give a satisfactory account.

3. Finally, is knowledge "true judgment accompanied by discourse, true judgment for which a man can give grounds"? This doctrine has difficulties of its own; and, in any case, the proposed definition amounts to saying that knowledge is true judgment about an object plus *knowledge* of its *differentia* and so is circular.

Because Plato's argument nowhere appeals to his favorite doctrine of Forms and because the dialogue ends so inconclusively, it is likely that Plato wanted to show that the problem of knowledge is insoluble without the Forms.

THE LATER DIALOGUES

Sophist and Statesman. Formally the important dialogues, the *Sophist* and the *Statesman*, are closely connected, both being ostensibly concerned with a problem of definition. The real purpose of the *Sophist*, however, is logical or metaphysical; it aims at explaining the true nature of negative predication, or denials that something is so, and thus at disposing of the Eleatic thesis that the sensible realm, containing, as it does, a negative moment, must be mere unreal illusion. The object of the *Statesman*, on the other hand, is to consider the respective merits of two contrasted forms of government, personal rule and constitutionalism, and to recommend the second, particularly in the form of limited monarchy. The *Sophist* thus lays the foundations of all subsequent logic, the *Statesman* those of all constitutionalism. A more temporary purpose in both dialogues is to illustrate the value of careful classification as a basis for scientific definition.

In the *Sophist*, the Sophistic criticism of any definition couched in terms of falseness is presented. The Sophists argued that there can be no such thing as a false statement or a false impression, for the false means "what is not," and "what is not" is nothing at all and can neither be uttered nor thought. Plato argues, on the other hand, that "what is not, in some sense also is," and "what is, in some sense is not"; there are, that is, significant negative propositions. Plato refutes Parmenidean monism by drawing the distinction between absolute and relative nonbeing. A significant denial, *A is not B*, does not mean that *A* is nothing, but that *A* is other than *B*; every one of the great categorical features of reality—being, identity, difference, motion, and rest—is other than every other feature, and the true business of dialectic is to treat the Forms themselves as an interrelated system, with relations of compatibility and incompatibility among themselves. Negation is a moment in the system of intelligible reality, and therefore its presence in the sensible realm does not stamp that realm as illusion.

Absolute versus relative nonbeing

In the *Statesman* the conclusion is reached that government by a benevolent dictator is not suitable to the conditions of human life, in which the direction is not that of a god. The surrogate for direction by a god is the impersonal supremacy of inviolable law. Where there is such law, monarchy is the best and democracy the least satisfactory form; but where there is no law, this situation is inverted. A sovereign democracy is preferable to an irresponsible autocrat.

Philebus. The *Philebus* contains Plato's ripest moral psychology. Its subject is strictly ethical—the question of whether the Good is pleasurable feeling (hedonism) or thought (the exercise of intelligence). Under the guidance of Socrates a mediating conclusion is reached: the best life contains both elements, but intelligence predominates.

Philosophically most important is a classification adopted to determine the formal character of the two claimants to recognition as the good. All components of the actual belong to one of four classes: (1) the infinite or unbounded, (2) the limit, (3) the mixture (of infinite and limit), (4) the cause of the mixture. Inasmuch as, in the *Philebus*, all of the good things of life belong to the third class, that is, are produced by imposing a definite limit upon an indeterminate continuum, this dialogue is the immediate source of the famous doctrine of the mean. The establishment of such a ratio is a genesis into being, and the cause in such a process is always intelligence, human or divine.

Timaeus. The *Timaeus* is an exposition of cosmology, physics, and biology. Timaeus first draws the distinction between eternal being and temporal becoming and insists that it is only of the former that one can have exact and final knowledge. The visible, mutable world had a beginning; it is the work of God, who had its Forms before him as an eternal model in terms of which he molded the world as an imitation. God first formed its soul out of three constituents: identity, difference, being. The world soul was placed in the circles of the heavenly bodies and the circles were animated with movements. Subsequently, the various subordinate gods and the immortal and rational element in the human soul were formed. The human body and the lower components of its soul were generated through the intermediacy of the "created gods" (*i.e.*, the stars).

The forming of the world and things

The *Timaeus* combines the geometry of the Pythagoreans with the biology of Empedocles, the founder of Sicilian medicine, by a mathematical construction of the elements, in which four of the regular solids—cube, tetrahedron, octahedron, and icosahedron—are assumed to be the shapes of the corpuscles of earth, fire, air, and water. (The fifth, the dodecahedron, comprises the model for the whole universe.)

Among the important features of the dialogue are its introduction of God as the intelligent, efficient cause of all order and structure in the world of becoming and the emphatic recognition of the essentially tentative character of natural science. It is also noteworthy that, though Plato presents a corpuscular physics, his metaphysical substrate is not matter but *chōra* (space). The presence of space as a factor requires the recognition, over and above God or mind, of an element that he called *anankē* (necessity), a name for the fact that there is always in the actual an irreducible remainder of brute datum that cannot be rationalized completely and that one has to be content to accept. Its function is everywhere to be instrumental to the intelligent and beneficent purpose of God. It is the expression, however, of a rational faith in Providence and in the supremacy of the moral order. The details of the cosmology, physiology, and psychophysics are of great importance for the history of science but metaphysically of secondary interest.

Laws and Epinomis. The *Laws*, Plato's longest and most intensely practical work, contains his ripest utterances on ethics, education, and jurisprudence, as well as his one entirely nonmythical exposition of theology. The immediate object is to provide a model of constitution making and legislation to assist in the actual founding of cities.

Plato's attempt to do work of this kind at Syracuse had given the Academy a recognized standing as a school of scientific politics and jurisprudence.

The practical level of the *Laws*

The problem is thus not the construction of an ideal state as in *The Republic*, but the framing of a constitution and code that might be successfully adopted by a society of average Greeks. Hence the demands made on average human nature, though exacting, are not pitched too high; thus the communism of *The Republic* is dropped.

Purely speculative philosophy and science are excluded from its purview; and the metaphysical interest is introduced only so far as to provide a basis for a moral theol-

ogy. In compensation, the *Laws* is exceptionally rich in political and juristic wisdom and appears, indirectly, to have left its mark on the great system of Roman jurisprudence.

The ethical ideal is still that familiar from earlier dialogues. All unnatural vices shall be completely suppressed and monogamous marriage with strict chastity shall be the rule. (In *The Republic*, however, at least the guardian class enters into temporary unions or "sacred marriages," with community of wives and children, to foster a concern for the common good.) In politics, Plato favours a mixed constitution, a balance between *eleutheria* (popular control) and *monarchia* (personal authority), and suggests a system to secure both genuine popular representation and the proper regard for personal qualifications. The basis of society is to be agriculture, not commerce. What amounts to a supertax of 100 percent is to be levied on incomes beyond the statutory limits. Education is regarded as the most important of all the functions of government. The distinction between the sexes is to be treated as irrelevant.

Careful attention is to be paid to the right utilization of the child's instinct for play and to the demand that the young shall be taught in institutions where expert instruction in all the various subjects is coordinated (the origin of the grammar school). Members of the supreme council of the state shall be thoroughly trained in the supreme science, which "sees the one in the many and the many in the one"; *i.e.*, in dialectics.

Plato instituted regulations that would ensure that trials for serious offenses would take place before a court of highly qualified magistrates and would proceed with due deliberation. Also, provision was made for appeals, and a foundation was laid for the discrimination between civil and criminal law.

There are passages showing that Plato believed in the Earth's motion. In the *Laws* it is said that the real orbit of each planet is a single closed curve; in the *Epinomis* the view that the circle of the stars communicates its motion to those of the planets is rejected. What Plato asserts is that each planet has only one proper revolution; the remaining revolutions are apparent, not real. The implication is that the latter are reflections of a motion of the Earth itself. The diurnal movement, however, would not be a rotation on an axis, but a diurnal revolution around a centre, apparently a Pythagorean "central fire."

Plato's natural theology

In the *Laws* Plato, for a practical purpose, creates a natural theology. There are three false beliefs, he holds, that are fatal to moral character: atheism, denial of the moral government of the world, and the belief that divine judgment can be bought off by offerings. Plato claims that he can disprove them all. His refutation of atheism turns on the identification of the soul with the "movement which can move itself." Thus all motion throughout the universe is ultimately initiated by souls. It is then inferred from the regular character of the great cosmic motions and their systematic unity that the souls that originate them form a hierarchy with a best soul, God, at their head. Since some motions are disorderly, there must be one soul that is not the best, and there may be more. (There is no suggestion, however, that there is a worst soul, a devil.) This is Plato's way of excluding pantheism, as incompatible with the reality of evil. The other two heresies can be similarly disposed of. Plato thus becomes the originator of the view that there are certain theological truths that can be strictly demonstrated by reason; *i.e.*, of philosophical theology. Plato goes on to enact that the denial of any of his three propositions shall be a grave crime. He is thus the inventor of the proposal to make an official creed for the state and to treat dissent from it as criminal. Plato's last word, then, on the problem of how the sensible comes to partake of form is that it does so through the agency of divine goodness and wisdom, as God molds the sensible upon the pattern of the intelligible Forms.

ARISTOTLE'S ACCOUNT OF PLATO'S THOUGHT

Since Plato refused to write his own metaphysic, knowledge of its final shape has to be derived from statements by Aristotle, according to whom Plato's doctrine of Forms was, in its general character, not different from Pythagoreanism, the Forms being actually called numbers. The two points on which Aristotle regards Plato as disagreeing with the Pythagoreans are: (1) that, whereas the Pythagoreans said that numbers have as their constituents the unlimited and the limit, Plato taught that the Forms have as constituents the one and the great-and-small; and (2) that, whereas the Pythagoreans had said that things are numbers, Plato intercalated between his Forms (or numbers) and sensible things an intermediate class of mathematicals.

Number-Forms: the one and the great-and-small

Light is thrown on the statement that the Forms are numbers if it is recalled that in the *Timaeus* the behaviour of bodies is explained by the geometrical structure of their corpuscles, and the corpuscles themselves are analyzed into complexes of elementary triangles, and a triangle may be regarded as a triplet of numbers. Moreover, according to Aristotle, the mathematicals that are intermediate between the Forms and sensible things, like the geometer's figure, differ from Forms because they are many (whereas the Form is one) and differ from sensible things in being unchanging. The relations of numbers are thus the key to the whole mystery of nature, as is actually said in the *Epinomis*.

There is also a difficulty about the notion of a number as a collection of units, which must have been forced on Plato's attention by his manifest interest in irrational numbers (not expressible as a fraction), which cannot possibly be reached by any process of forming collections of units. Thus numbers are determinations of a continuum (a great and small) by a limit. The one, however, can no longer be regarded as a blend of unlimited and limit but must be, itself, the factor of limit. Thus Plato's way of generating numbers is intended to permit the inclusion of rationals and irrationals in the same series.

The influence of Plato can be traced throughout Western culture from Aristotle through St. Augustine, from Pascal to A.N. Whitehead, an eminent 20th-century metaphysician who declared: "The safest general characterization of the European philosophical tradition is that it consists of a series of footnotes to Plato" (see PLATONISM AND NEOPLATONISM).

MAJOR WORKS

Apologia Sokratous (*c.* 399 BC).

THE DIALOGUES: *Hippias Elasson* (Major—doubtful); *Laches; Charmides; Ion; Protagoras; Euthyphron; Kriton; Gorgias; Menon; Lysis; Menexenos* (doubtful; *c.* 386 BC); *Euthydemos; Kratylos; Symposion* (*c.* 384 BC); *Phaidon; Politeia* (*The Republic*); *Parmenides* (*c.* 370 BC); *Theaitetos* (*c.* 368 BC); *Phaidros; Sophistes* (360 BC or later); *Politikos; Philebos; Timaios; Kritias; Nomoi* (*Laws*).

EPISTLES: There are 13 epistles, *Thirteen Epistles of Plato* (1925), attributed by some to Plato, but their authenticity is open to considerable doubt. The most important is *Epistles vii* concerning Plato's visit to Sicily (367 BC) and his relations with Dion and the tyrant Dionysius.

The Apology and the Dialogues are translated in the "Loeb Series." Several of the Dialogues are translated in the "Penguin Classics Series."

BIBLIOGRAPHY. Plato's role and context in the growth of Greek philosophy are concisely described by F.M. CORNFORD, *Before and After Socrates* (1932); and W.K.C. GUTHRIE, *The Greek Philosophers from Thales to Aristotle* (1950). His relations with the Sophists and Socrates are sketched in G.C. FIELD, *Plato and His Contemporaries* (1930); W.K.C. GUTHRIE devotes *A History of Greek Philosophy*, vol. 3, *The Fifth-Century Enlightenment* (1969), entirely to a detailed analysis of the Sophists and Socrates, as background for understanding Plato (vol. 4, forthcoming, concentrates on Plato). E.A. HAVELOCK, *Preface to Plato* (1963), traces the linguistic developments that furnished the terminological context of the dialogues.

Two still influential introductions are A.E. TAYLOR, *Plato: The Man and His Work*, 7th ed. (1960); and G.M.A. GRUBE, *Plato's Thought* (1935, reprinted 1958). More recent syntheses are G.C. FIELD, *The Philosophy of Plato* (1949); and R.S.H. BLUCK, *Plato's Life and Thought* (1949). PAUL FRIEDLANDER, *Platon*, 2 vol. (1928–30; Eng. trans., 3 vol., 1958–69), represents continental scholarship on Plato as myth-maker, cosmologist, and city planner. See also ALEXANDRE KOYRE, *Introduction à la lecture de Platon* (1945; Eng. trans., *Discovering Plato*, 1945); and J. STENZEL, *Studien zur*

Entwicklung der platonischen Dialektik von Socrates zu Aristotles (1917; Eng. trans., *Plato's Method of Dialectic*, 1940), a sound textual account; K.M. SAYRE, *Plato's Analytic Method* (1969), suggests an analogy between Plato and recent analysis. Stages of methodic development are distinguished in RICHARD ROBINSON, *Plato's Earlier Dialectic*, 2nd ed. (1953); the mature ontology and epistemology of the *Theaetetus* and the *Sophist* are presented in W.G. RUNCIMAN, *Plato's Later Epistemology* (1962). The strong mathematical component in Plato is examined formally by A. WEDBERG, *Plato's Philosophy of Mathematics* (1955); and in concrete applications by R.S. BRUMBAUGH, *Plato's Mathematical Imagination* (1954, reprinted 1968). Philosophy as a cure of souls is the theme of R.E. CUSHMAN, *Therapeia: Plato's Conception of Philosophy* (1958).

I.M. CROMBIE, *An Examination of Plato's Doctrines*, 2 vol. (1962–63), makes an in-depth analysis, furnishing the ethical-social-aesthetic-religious context for the more abstract issues of knowing and reality. W.F.R. HARDIE, *A Study in Plato* (1936), focusses on his evolving epistemology and metaphysics; W.D. ROSS, *Plato's Theory of Ideas* (1951), emphasizes the gradual transcendence of Forms; GILBERT RYLE, *Plato's Progress* (1966), criticizes the dialectic; and J.E. RAVEN, *Plato's Thought in the Making* (1965), gives balanced attention to the great middle dialogues. R.E. ALLEN (ed.), *Studies in Plato's Metaphysics* (1965); and R. BAMBROUGH (ed.), *New Essays on Plato and Aristotle* (1965), present collections of metaphysical and epistemological studies.

JOHN GOULD, *The Development of Plato's Ethics* (1955), furnishes a good conspectus; the religious aspects are studied by F. SOLMSEN, *Plato's Theology* (1942). A.W. GOULDNER, *Enter Plato* (1965), covers Plato's social analysis and legislation, with its tension between detachment and engagement. Plato's mixed influence on the history of freedom and authoritarianism is debated by KARL R. POPPER, *The Open Society and Its Enemies*, 5th ed. rev., 2 vol. (1966); and R.B. LEVINSON, *In Defense of Plato* (1953). Papers on the controversy are in R. BAMBROUGH (comp.), *Plato, Popper and Politics* (1967); and T.L. THORSON (ed.), *Plato: Totalitarian or Democrat?* (1963).

The Plato translations made by F.M. CORNFORD, R. HACKFORTH, and J. SKEMP also include commentaries. Other commentaries include: A. SESONSKE and N. FLEMING (eds.), *Plato's Meno: Text and Criticism* (1965), with essays on Socratic paradox, definition, and education; R.E. ALLEN, *Plato's "Euthyphro" and Earlier Theory of Forms* (1970), a thorough introduction to problems of the Forms; N.R. MURPHY, *The Interpretation of Plato's Republic* (1951), bringing out its many conceptual problems and pitfalls; A.E. TAYLOR, *A Commentary on Plato's Timaeus* (1928), which (together with Cornford's later commentary) examines his cosmology and myths; G.R. MORROW, *Plato's Cretan City* (1960), analyzes the social situation, internal organization, and general principles of Plato's *Laws;* a companion commentary on Plato's role in Sicilian politics appears in G.R. MORROW's translation of Plato's *Epistles* (1962).

See also the two studies by HAROLD F. CHERNISS on the influence of Plato upon the Academy: *The Riddle of the Early Academy* (1945, reprinted 1962); and *Aristotle's Criticism of Plato and the Academy* (1944, reprinted 1962), on Plato as critically interpreted by Aristotle. Plato's impact upon subsequent Greek philosophy is felt throughout *The Cambridge History of Later Greek and Early Medieval Philosophy*, ed. by A.H. ARMSTRONG (1967), especially in PHILIP MERLAN'S synthesizing view of "Greek Philosophy from Plato to Plotinus," pp. 14–132.

(Ed.)

Platonism and Neoplatonism

The term Platonism can be applied to any philosophy that derives its ultimate inspiration from the *Dialogues* of Plato. But these can be read in many different ways, often very selectively, and it may be that all that the various kinds of Platonism can be said to have in common is an intense concern for the quality of human life—always ethical, often religious, and sometimes political, based on a belief in unchanging and eternal realities, independent of the changing things of the world perceived by the senses. Platonism sees these realities as giving life value and meaning. It is this belief in absolute values rooted in an eternal world that distinguishes Platonism from the philosophies of Plato's immediate predecessors and successors and from later philosophies inspired by them—from the immanentist naturalism of most of the pre-Socratics (who interpreted the world monistically in terms of nature as such), from the relativism of the Sophists, and from the correction of Platonism in a this-worldly direction carried out by Plato's greatest pupil, Aristotle.

"Platonism" as construed in this article, however, does not include the work of Plato himself but covers, instead, that of his successors in the entire movement that issued from his work. As so defined, Platonism therefore begins with Aristotle.

GREEK PLATONISM FROM ARISTOTLE THROUGH MIDDLE PLATONISM: ITS NATURE AND HISTORY

Plato as construed by Aristotle

Aristotle's statements about the philosophy of his master seem at first sight to be very different from anything to be found in the *Dialogues*, though there are a few points of contact in some of the later ones. It was generally assumed in antiquity that Aristotle's main source was an unpublished lecture or course of lectures on "The Good" (or "On Goodness") delivered by Plato in his later years; and it seems likely that the doctrines criticized by Aristotle and developed by Plato's immediate successors in the leadership of his Academy, Speusippus (head from 347–339 BC) and Xenocrates (head from 339–314 BC), do in fact derive from the later oral teaching of their master.

The main feature of Plato's later thought seems to have been a certain mathematicization. The Ideas or Forms—the eternal realities that give existence, meaning, and value to everything else—were thought of somehow in numerical terms; between them and physical things there was an intermediate realm of mathematical objects, which are changeless like the Forms, but—unlike them—not unique; there can be many of each kind (*e.g.*, there is only one Idea of Circle, but there are many geometrical circles, which can intersect, etc.). This intermediate realm of "mathematicals" was connected in some way with Soul—perhaps by Plato, certainly by his immediate successors. The ultimate principles of the Forms, and so of all reality, were also described in mathematical terms as the One and the Indefinite Dyad. The One seems to have been thought of as a principle of limit, form, and order, and so of goodness; the Indefinite Dyad, though necessary if any plurality of realities were to exist, was the principle of vague, unbounded multiplicity, and so of evil. These doctrines, developed with individual variations by Plato's two successors, played an important part in later Platonism. Aristotle himself had little use for this sort of mathematical metaphysics and rejected Plato's doctrine of transcendent eternal Forms altogether. Nonetheless, something of Platonism survived in Aristotle's system in his belief (1) that the reality of anything lay in a changeless (though wholly immanent) form or essence comprehensible and definable by reason and (2) that the highest realities were eternal, immaterial, changeless self-thinking intellects that caused the ordered movement of the universe by a desire for their transcendent perfection that kept the heavenly spheres rotating and to which man's intellect at its highest was akin. This Aristotelian doctrine of Intellect (nous) was easily recombined with Platonism in later antiquity.

The Academy through the Hellenistic Age

Little is known about the contributions, if any, to the development of Platonism that were made by the three successors of Xenocrates in the headship of the Academy: Polemon, Crates, and Crantor. It is possible that the influence of Crantor (*c.* 330–270 BC) on later Platonism—at least as a transmitter of the ideas of the Old Academy—may have been considerable, as he is said to have been the first to write commentaries on Plato; and in particular he is said to have written one on the *Timaeus*, in which he maintained that its description of the creation of the universe in time was not to be taken literally and that Plato really believed that the physical world had always existed.

After Crantor the Academy passed through a Skeptical phase and was preoccupied for about two centuries with the serious questioning of man's knowledge claims. This began with Arcesilaus (*c.* 315–*c.* 240 BC), who is described as the founder of the Middle Academy. (The distinction between the Middle and the New Academies, though ancient, is artificial, since there was a real continuity of thought throughout the Skeptical period in the school's history.) The Skeptical Academics were probably inspired

both by a genuine desire to recover the critical, questioning, and Agnostic attitude of the Socrates of Plato's early dialogues—the Socrates who knew only that he did not know—and by philosophical exasperation with the crude dogmatism of contemporary Hellenistic philosophers, especially the Stoics. It is likely that Arcesilaus was influenced to some extent by Pyrrhon (*c.* 360–270 BC), founder of the tradition to which the name Skeptic was applied in antiquity. The Skeptical Academics developed a formidable critique of Stoic dogmatism. They denied that certainty on any subject was possible and worked out a sophisticated theory of probability as a guide to practical decision making. Their critical dialectic and probability theory were brought to their highest point of refinement by Carneades (214/213–129/128 BC), called the founder of the New Academy, who made a considerable impression at Rome when he went there on a diplomatic mission from Athens in 155 BC. The definitive and final return of the Academy from Skepticism to dogmatic and positive philosophical teaching was brought about by Antiochus of Ascalon, who was head of the school in 79–78 BC, when Cicero heard some lectures delivered by him.

Transition to Neoplatonism

The next important phase of Platonism, Middle Platonism or Pre-Neoplatonism, was significant through the influence that it exerted in more than one direction. In the direction of Semitic culture (further described in a later section), it formed the Greek philosophical background of the efforts of the Jewish philosopher Philo of Alexandria to create a philosophical system on the basis of the Old Testament heritage. Though the origins of Middle Platonism are obscure, the outlines of its main direction of development became clear in the 1st century AD. It seems to have been linked from the beginning with the closely related revival of Pythagoreanism (a philosophy holding that reality is number, and sometimes showing, after the revival, a tendency to superstitious occultism). The somewhat Platonized Stoicism of Poseidonius (*c.* 135–50 BC), whose dualism of matter and reason enhanced the roles of emotion and will, may have influenced its beginnings; and Stoic influence, especially in the ethical field, remained important in its later developments. There was sometimes a considerable influence of Aristotle, though there was also a strong anti-Aristotelian tradition. The general characteristics of this revised Platonic philosophy (and the closely related Neo-Pythagoreanism) were the recognition of a hierarchy of divine principles with stress on the transcendence of the supreme principle, which already was called occasionally "the One"; the placing of the Platonic Forms in the divine mind; a strongly otherworldly attitude demanding a "flight from the body," an ascent of the mind to the divine and eternal; and a preoccupation with the problem of evil, attributed either to an evil world soul or to matter. The best known of the Middle Platonists is the biographer and essayist Plutarch of Chaeronea (*c.* AD 46–120). Other important figures in the 2nd century AD were Albinus, Atticus, and Numenius of Apamea. It was from the thought of these and other Middle Platonists that the foremost Neoplatonist, Plotinus, started in developing his own interpretation of Platonism, which was both profoundly original and firmly rooted in an established school tradition.

NEOPLATONISM: ITS NATURE AND HISTORY

Neoplatonism is the modern name given to the form of Platonism developed by Plotinus in the 3rd century AD, which came to dominate the Greek philosophical schools in the 4th century and remained predominant till the teaching of philosophy by pagans ended in the second half of the 6th century AD. It represents the final form of pagan Greek philosophy. It was not a mere syncretism (or combination of diverse beliefs) but a genuine, if one-sided, development of ideas to be found in Plato and earlier Platonism—though it incorporated important Aristotelian and Stoic elements as well. There is little real evidence for Oriental influence. A certain Gnostic (ancient theosophical) tone or colouring sometimes may be discerned in the thought of Plotinus. But he was consciously a passionate opponent of Gnosticism; and in any case there was often a large element of popular Platonism in Gnosticism itself—*i.e.*, in the Gnostic systems then current. Moreover, the theosophical works of the Chaldean theologians (late 2nd century AD)—the *Chaldean Oracles*, which were taken as inspired authorities by the later Neoplatonists—seem to have been a hotchpotch of popular Greek religious philosophy.

Core concepts of Neoplatonism

Neoplatonism began as a complex (and in some ways ambiguous) philosophy and developed in a long, vigorous and varied growth; it is therefore not easy to generalize about it. But the leading ideas in the thought of philosophers who can properly be described as Neoplatonists seem always to have included the following:

1. There is plurality of spheres of being, arranged in hierarchical descending order, the last and lowest comprising the universe, which exists in time and space and is perceptible to the senses.
2. Each sphere of being is derived from its superior, a derivation that is not a process in time or space.
3. Each derived being is established in its own reality by turning back toward its superior in a movement of contemplative desire, which is implicit in the original creative impulse of outgoing that it receives from its superior; thus the Neoplatonic universe is characterized by a double movement of outgoing and return.
4. Each sphere of being is an image or expression on a lower level of the sphere above it. The relation of archetype and image runs through the whole of the Neoplatonic scheme.
5. Degrees of being are also degrees of unity; in each subsequent sphere of being there is greater multiplicity, more separateness, and increasing limitation—till the atomic individualization of the spatiotemporal world is reached.
6. The supreme sphere of being, and through it all of what in any sense exists, derives from the ultimate principle, which is absolutely free from determinations and limitations and utterly transcends any conceivable reality, so that it may be said to be "beyond being." As it has no limitations, so it has no division, attributes, or qualifications; it cannot really be named but may be called "the One" to designate its complete simplicity. It may also be called "the Good" as the source of all perfections and the ultimate goal of return; for the impulse of outgoing and return that constitutes the hierarchy of derived reality comes from and leads back to the Good.
7. Since this supreme principle is absolutely simple and undetermined (or devoid of specific traits), man's knowledge of it must be radically different from any other kind of knowledge: it is not an object (a separate, determined, limited thing) and no predicates can be applied to it; hence it can be known only if it raises the mind to an immediate union with itself, which cannot be imagined or described.

Plotinus and his philosophy. As far as is known, the originator of this distinctive kind of Platonism was Plotinus (AD 205–270). He had been the pupil at Alexandria of a self-taught philosopher called Ammonius, who also taught the Christian, Origen, and the latter's pagan namesake, and whose influence on his pupils seems to have been deep and lasting. But Ammonius wrote nothing, and so nothing is really known about his thought. A number of distinguished scholars have recently made attempts to reconstruct it, but their speculations go far beyond the evidence. Plotinus must thus be regarded as the first great Neoplatonist, and his collected works, the *Enneads* (Greek *ennea*, "nine"—six sets of nine treatises each, arranged by his disciple Porphyry), are then the first and greatest collection of Neoplatonic writings. (For further details about the life and works of Plotinus, see PLOTINUS.)

Plotinus, like other philosophers of late antiquity, was a religious and moral teacher as well as a professional philosopher engaged in the critical interpretation of a long and complicated school tradition. He was an acute critic and arguer, with an exceptional degree of intellectual honesty for his, or any, period; but philosophy for him was not so much a matter of abstract speculation as a way of life in which, through an exacting intellectual and moral self-discipline and purification, those who are capable of the ascent can return to the source from which they came. His written works explained how, from the eternal

Metaphysics: system of emanation

creative act—at once spontaneous and necessary—of that transcendent source, the One or Good, proceeds the world of living reality constituted by repeated double movements of outgoing and return in contemplation; and this account, showing the way for the human self—which can experience and be active on every level of being—to return to the One, was itself an exhortation to follow that way.

Plotinus always insisted that the One or Good is beyond the reach of thought or language; what he said about this supreme principle was intended only to point the mind along the way to it, not to describe or define it. But though no adequate concept or definition of the Good is possible, it was nonetheless for Plotinus a positive reality of superabundant excellence. Plotinus often spoke of it in extremely negative language, but his object in doing so was to stress the inadequacy of all of man's ways of thinking and speaking to express this supreme reality or to clarify the implications of the claim that the Good is absolutely one and undetermined, the source of all defined and limited realities.

The original creative or expressive act of the One is the first great derived reality, Nous (which can be only rather inadequately translated as "Intellect" or "Spirit"); from this again comes Soul, which forms, orders, and maintains in being the material universe. It must be remembered that, to Plotinus, the whole process of generation is timeless; Nous is eternal, and time is the life of Soul as active in the physical world, and there never was a time when the material universe did not exist. The "levels of being," then, though distinct, are not separate but are all intimately present everywhere and in everyone. To ascend from Soul through Intellect to the One is not to travel in space but to awake to a new kind of awareness.

Intellect, Soul, world

Intellect for Plotinus is both thought and object of thought; it is a mind that is perfectly one with its object. As object, it is the world of forms or ideas, the totality of real being in the Platonic sense. These forms, being one with Intellect, are not merely objects but are living, thinking subjects, each not only itself but, in its contemplation, the whole. They are the archetypes and causes of the necessarily imperfect realities on lower levels, souls and the patterns or structures that make bodies what they are. Men at their highest are intellects, or souls perfectly conformed to Intellect; they become aware of their intellectual nature when, passing not only beyond sense perception but beyond the discursive reasoning characteristic of the life of Soul, they immediately grasp eternal realities.

Soul for Plotinus is very much what it was for Plato, the intermediary between the worlds of Intellect and Sense and the representative of the former in the latter. It is produced by Intellect, as Intellect is by the One, by a double movement of outgoing and return in contemplation, but the relationship between the two is more intimate and the frontier less clearly defined. For Plotinus, as for Plato, the characteristic of the life of the Soul is movement, which is the cause of all other movements. The life of the Soul in this movement is time, and on it all physical movement depends. Soul both forms and rules the material universe from above; and in its lower, immanent phase, which Plotinus often calls nature, it acts as an indwelling principle of life and growth and produces the lowest forms, those of bodies. Below these lies the darkness of matter, the final absence of being, the absolute limit at which the expansion of the universe—from the One through diminishing degrees of reality and increasing degrees of multiplicity—comes to an end. Because of its utter negativity, such matter is for Plotinus the principle of evil; and although he does not really believe it to be an independent principle forming, with the good, a dualism, his language about it often has a strongly dualistic flavour.

He was not, however, really dualistic in his attitude toward the material universe. He strongly maintained its goodness and beauty as the best possible work of Soul. It is a living organic whole, and its wholeness is the best possible (though very imperfect) reflection on the space-time level of the living unity in diversity of the world of forms in Intellect. It is held together in every part by a universal sympathy and harmony. In this harmony external evil and suffering take their place as necessary elements in the great pattern, the great dance of the universe. Evil and suffering can affect men's lower selves but cannot touch their true, higher selves and so cannot interfere with the real well-being of the philosopher.

Ethics and religion: purification

As souls within bodies, men can exist on any level of the soul's experience and activity. (The descent of souls into bodies is for Plotinus—who had some difficulty in reconciling Plato's various statements on this point—both a fall and a necessary compliance with universal law.) Man can ascend in spirit to the level of universal Soul, become that whole that he already is potentially, and, in Soul, attain to Intellect; or he can isolate himself on the lower level, shutting himself up in the experiences, desires, and concerns of his lower nature. Philosophical conversion—the beginning of the ascent to the One—consists precisely in turning away, by a tremendous intellectual and moral effort, from the life of the body, dominating and rising above its desires, and "waking to another way of seeing, which everyone has but few use." This, Plotinus insisted, is possible while one is still in an earthly body and without neglecting the duties of his embodied state. But the body and bodily life weigh a man down and hamper him in his ascent. Plotinus' language when speaking of the body and the senses in this context is strongly dualistic and otherworldly. Platonists in general think much more dualistically about their own bodies than about the material universe as a whole. The physical world is seen positively as a noble image of the intelligible; the individual, earthly, animal body, on the contrary, tends to be regarded negatively as a hindrance to the intellectual and spiritual life.

When a man's philosophical conversion is complete and he has become Intellect, he can rise to that mystical union in which the One manifests his continual presence, carried on the surging current of the impulse of return to the source (in its strongest and final flow), the pure love of Intellect for the Good from which it immediately springs. There is no consciousness of duality in that union; one is not aware of himself; but neither is he destroyed or dissolved into the One—because even in the union he is still Intellect, though Intellect "out of itself," transcending its normal nature and activity. This mystical union for Plotinus was the goal of all his effort and the source of the continuing power of his teaching. Philosophy for him was religion, the effort to actualize in oneself the great impulse of return to the Good, which constitutes reality on all its levels; and religion for him was philosophy. There was no room in his thought and practice for special revelation, grace, and repentance in the Christian sense, and little for external rites or sacraments. For him the combination of moral purification and intellectual enlightenment, which only Platonic philosophy as he understood it could give, was the only way to union with the Good.

Porphyry and Iamblichus

The later Neoplatonists. Porphyry (*c.* AD 234–*c.* 305), a devout disciple of Plotinus and a careful editor of his works, occupied a special position in the development of later Neoplatonism. In some ways his thought paralleled that of the later pagan Neoplatonists, but in others it quite opposed them. The most distinctive features of his thought seem to have been an extreme spiritualism, an insistence, even sharper than that of Plotinus, on the "flight from the body" and—more philosophically important—a monistic interpretation of the Plotinian system; he tended, that is, to think that the One, Intellect, and Soul are ultimately only one reality. Soul in its true nature is for him practically identical with Intellect (which was already true in some of the writings of Plotinus), and Intellect is the self-determination of the life springing from the One, which is unknowable, infinite, pure being; the three—Being, Life, and Intellect—known as the "horizontal" triad, are phases in the eternal self-determination of the ultimate (and only) reality. This triad, which had its origins in the thought of Plotinus, became one of the most important elements in the complex metaphysical structures of the later Neoplatonists. But Iamblichus and his successors reacted strongly against Porphyry's monistic tendencies.

Iamblichus (*c.* AD 250–*c.* 325) was the real originator of the type of Neoplatonism that came to dominate the Pla-

tonic schools in the 5th and 6th centuries AD. This kind of Neoplatonism sharpened and multiplied the distinctions between the levels of being. The basic position underlying its elaborations is one of extreme philosophical Realism: it is assumed that the structure of reality corresponds so exactly to the way in which the mind works that there is a separate real entity corresponding to every distinction that it can make. In the fully developed late Neoplatonic system, the first principle of reality, the ultimate One, was removed to an altogether ineffable transcendence, mitigated by two factors: (1) the presence of the expressions or manifestations of its unifying power, the "henads"—identified with the gods of paganism—at every level of reality, and (2) the possibility of return to absolute unification through the henad with which one is linked. Below the One a vast structure of triads or trinities reached down to the physical world: this was constructed by combining Plotinus' "vertical" succession of the levels of Being, Intellect, and Soul (much complicated by internal subdivision and the interposition of mediating hypostases at every stage) with the horizontal triadic structure, giving a timeless dynamic rhythm of outgoing and return, such as that already encountered in Porphyry.

Neoplatonism as a pagan theology

This later Neoplatonism aspired to be not only a complete and coherent metaphysical system but also a complete pagan theology. The maintenance and defense of the old religion in a world more and more intolerantly dominated by its triumphant rival, Christianity, was one of the main concerns of the Platonists after Plotinus. By the study of Aristotle and of the religious metaphysics of Plato (above all in the *Parmenides* and the *Timaeus*), in which they employed remarkable processes of forced exegesis, they believed it possible to arrive at a complete understanding of divine truth cryptically revealed by the gods themselves through the so-called theologians—the inspired authors of the Orphic poems and of a strange theosophical farrago called the *Chaldean Oracles*, published in the second half of the 2nd century AD, to which Porphyry first gave some guarded and qualified recognition but which was inspired scripture to Iamblichus and his successors. Their view of the human soul was a humbler one than that of Plotinus: it was for them a spiritual being of low rank, which had descended altogether into the material world; they could not therefore aspire, like Plotinus, to that return to and unification with the divine that remained for them the goal of human life through philosophy alone. Help from the gods was needed, and they believed that the gods in their love for men had provided it, giving to all things the power of return in prayer and implanting even in inanimate material things —herbs and stones and the like—sympathies and communications with the divine, which made possible the secret rites of theurgy, through which the divine gave the needed spiritual help by material means. Theurgy, though its procedures were generally those of late Greek magic, was thus not thought of merely as magic; and the degree of attention paid to external rites varied considerably from philosopher to philosopher: there seem to have been men even in the last generation of pagan Neoplatonists who had little use for or interest in such things and followed a mystical way much like that of Plotinus.

Neoplatonic schools

The different schools of late Neoplatonism seem to have differed less from each other than has sometimes been supposed. The school of Pergamum, founded by Aedesius, a pupil of Iamblichus, made perhaps the least contribution to the philosophical development of Neoplatonism, but it was not entirely given over to theurgy. Its greatest convert was the emperor Julian, called by Christians the "Apostate." By the end of the 4th century AD, the Platonic Academy at Athens had become Neoplatonist in the manner of Iamblichus. It was particularly fervent and open in its paganism and attracted Christian hostility. Though maintaining itself for a surprisingly long time against this hostility, it eventually yielded to it and was closed by Justinian in AD 529. In the interim, however, it had produced the greatest and most influential systematic expositor of later Neoplatonism, Proclus (AD 410–485). The head of the school at the time of its closing, Damascius, was also a notable philosopher. The school of Alexandria in the 5th and 6th centuries does not seem to have differed very much in its fundamental philosophical outlook from that of Athens. Philosophers like Simplicius, the greatest of the Neoplatonic commentators on Aristotle, passed easily from one school to the other. But the Alexandrians seem to have been more discreet in their attitude toward Christianity and consequently devoted much time to the comparatively safe and neutral study of Aristotle. An openly pagan (and very inferior) philosopher, Olympiodorus, was still teaching at Alexandria well into the second half of the 6th century. Finally, in the 7th century, after philosophical teaching had passed peacefully into Christian hands, the last known Alexandrian philosopher, the Christian Stephanus, was called to teach in the University of Constantinople under Heraclius. Stephanus formed one of the most important links in the chain of transmission of Platonism to the Byzantine Middle Ages.

PLATONISM IN THE WORLD OF THE REVEALED RELIGIONS

Early Jewish Platonism. Well before the beginning of the Christian Era, Jews with some Greek education had begun to make casual use of popular Greek philosophy in expounding their revealed religion: there are traces of this in the Wisdom literature of the Old Testament. In Paul's speech to the Areopagus in Acts 17, commonplaces of Stoic philosophy were employed for apologetic purposes. But, as far as is known, the first Jew who was really well read in Greek philosophy and used it extensively in the exposition and defence of his traditional religion was Philo of Alexandria (*c.* 15 BC–after AD 40), an older contemporary of St. Paul. Philo expressed his philosophical religion in the form of lengthy allegorical commentaries on the Jewish Scriptures, especially on Genesis, in which he showed to his own satisfaction that the ancient revelation given to Moses accorded with the teaching of the best Greek philosophers, which, in his view, was later and derivative. The Greek philosophy that he preferred and found to be most in accordance with revelation was an early form of Middle Platonism (see above *Transition to Neoplatonism*). Philo was neither approved of nor read by later orthodox Jews, but his influence on Greek-speaking and Greek-educated Christians from the 2nd century AD was great; and in important ways he determined the tone of their religious speculation.

Philo of Alexandria

Ancient and medieval Christian Platonism. Like Philo, the Christian Platonists gave primacy to revelation and regarded Platonic philosophy as the best available instrument for understanding and defending the teachings of Scripture and church tradition. But, also like Philo, they did not believe that truth could conflict with truth and were confident that all that was rationally certain in Platonic speculation would prove to be in perfect accordance with the Christian revelation. Their unhistorical approach and unscholarly methods of exegesis of texts, both pagan and Christian, facilitated this confidence. The general attitude of Christian Platonists was one of relatively moderate and humane otherworldliness (the cruder sorts of Christian otherworldliness and hatred of the body seem to derive from non-Platonic and non-Greek sources). They stressed the transcendence of God though, by insisting that it is a transcendence that is also the deepest immanence, they acknowledged his intimate presence within the world as well. They took a dualistic view of soul and body (though accepting bodily resurrection) and emphasized the primacy of the spiritual, while insisting on the goodness of God's material creation.

Patristic Platonism. From the middle of the 2nd century AD, Christians who had some training in Greek philosophy began to feel the need to express their faith in its terms, both for their own intellectual satisfaction and in order to convert educated pagans. The philosophy that suited them best was Platonism. Though Stoicism had exerted a considerable influence on Christian ethical thinking (which has persisted till our own times), Stoic corporealism—the belief that God and the soul are bodies, of a subtle and peculiar kind—repelled most Christians, and Stoic pantheism was incompatible with Christianity. The Platonism that the first Christian thinkers knew was of

course Middle Platonism, not yet Neoplatonism. Its relatively straightforward theism and high moral tone suited their purposes excellently; and the influence of this older form of Platonism persisted through the 4th century, and beyond, even after the works of Plotinus and Porphyry began to be read by Christians.

Justin, Origen, the Cappadocians

The first Christian to use Greek philosophy in the service of the Christian faith was Justin Martyr (martyred *c.* 162–168), whose passionate rejection of Greek polytheism, combined with an open and positive acceptance of the essentials of Platonic religious philosophy and an unshakable confidence in its harmony with Christian teaching, was to remain characteristic of the Christian Platonist tradition. This was carried on in the Greek-speaking world by Clement of Alexandria (*c.* 150–*c.* 215), a persuasive Christian humanist, and by the greatest of the Alexandrian Christian teachers, Origen (*c.* 184–254), who was consciously more hostile to and critical of Platonic philosophy than either Justin or Clement but was nonetheless more deeply affected by it and produced a synthesis of Christianity and late Middle Platonism of remarkable originality and power, which is the first great Christian philosophical theology. In spite of subsequent condemnations of some of his alleged views, his influence on Christian thought was strong and lasting. The Greek philosophical theology that developed during the Trinitarian controversies over the relationships among the persons of the Godhead, which were settled at the ecumenical councils of Nicaea (325) and Constantinople (381), owed a great deal to Origen, on both sides, orthodox and heretical. Its greatest representatives on the orthodox side were the three Christian Platonist theologians of Cappadocia, Basil of Caesarea (*c.* 330–379), Gregory Nazianzus (*c.* 330–390), and Basil's brother Gregory of Nyssa (died 394). Of these, Gregory of Nyssa was the most powerful and original thinker (and the closest to Origen). He was the first great theologian of mystical experience, at once very Platonic and profoundly Christian, and he exerted a very strong influence on later Greek Christian thought.

Pseudo-Dionysius and others

At some time between the period of the Cappadocian Fathers and the early years of the 6th century, a new turn was given to Christian Platonism by the remarkable writer who chose to publish his works under the name of St. Paul's convert at Athens, Dionysius the Areopagite. The kind of Platonism that the Pseudo-Dionysius employed for his theological purposes was the 5th-century Neoplatonism that is best represented by Proclus (see above). Almost everything about this mysterious author is vigorously disputed by scholars. But there can be no doubt about the influence that his system of the hierarchic universe exerted upon later Christian thought; his vision of man's ascent through it—carried up by divine love, to pass beyond all hierarchy and all knowledge into the darkness of the mystical union with God—had its impact both in the East, where one of the greatest of Greek Christian Platonist thinkers, Maximus the Confessor (*c.* 580–662), was deeply influenced by the Dionysian writings and commented extensively upon them, and in the West, where they became known and were translated into Latin in the 9th century. In the Latin West there was more than one kind of Christian Platonism. An impressive and extremely difficult philosophical theology, employing ideas approximating Porphyry's version of Neoplatonism to explain and defend the orthodox doctrine of the Trinity, was produced in the second half of the 4th century by the rhetorician and grammarian Marius Victorinus. A strong and simple Platonic theism and morality, which had a great influence in the Middle Ages, was nobly expressed in the final work of the last great philosopher-statesman of the ancient world, Boethius (*c.* 480–524). This was the *Consolation of Philosophy*, written in prison while its author was under sentence of death. But the Christian Platonism that had the widest, deepest, and most lasting influence in the West was that of St. Augustine.

Augustinian Platonism. Each of the great Christian Platonists understood Platonism and applied it to the understanding of his faith in his own individual way; and of no one of them was this more true than of Augustine, with his extremely strong personality and distinctive religious history. Augustine's thought was not merely a subspecies of Christian Platonism but something unique—Augustinianism. Nonetheless, the reading of Plotinus and Porphyry (in Latin translations) had a decisive influence on his religious and intellectual development, and he was more deeply and directly affected by Neoplatonism than any of his contemporaries and successors.

Teachings of Augustine

In his anthropology, Augustine was firmly Platonist, insisting on the soul's superiority to and independence of the body. For him, as for Plotinus and Porphyry, it was axiomatic that body could not act on soul, for soul was superior in the hierarchy of reality, and the inferior cannot act on the superior. This affected both his ethical doctrine and his epistemology. On the other hand, he differed from the philosophers who influenced him in his insistence that not only man but higher spiritual beings as well are mutable and peccable, liable to sin and fall, and in his consequent stress on the necessity of divine grace. His crucial doctrine that man's destiny is determined by the right direction of love, though profoundly original, was a development rather than a contradiction of Platonism. His very original theology of history and his view of human society, however, owed little to Plotinus and Porphyry, whose interests lay elsewhere.

In his epistemology, Augustine was Neoplatonic, especially in the subjectivity of his doctrine of illumination —in its insistence that in spite of the fact that God is exterior to man, men's minds are aware of him because of his direct action on them (expressed in terms of the shining of his light on the mind, or sometimes of teaching) and not as the result of reasoning from sense experience. For a Platonist, as has been said, body cannot act upon soul. Sense experience, therefore, though genuinely informative on its own level, cannot be a basis for metaphysical or religious thinking. This must be the result of the presence to the soul of higher realities and their action upon it. In Plotinus the illumination of the soul by Intellect and the One was the permanent cause of man's ability to know eternal reality; and Augustine was at this point very close to Plotinus, though for him there was a much sharper distinction between Creator and creature, and the personal relationship between God and the soul was much more strongly stressed.

In his theology, insofar as Augustine's thought about God was Platonic, he conformed fairly closely to the general pattern of Christian Platonism; it was Middle Platonic rather than Neoplatonic in that God was not the One beyond Intellect and Being but the supreme reality in whose creative mind are the Platonic Forms, the eternal patterns or regulative principles of all creation. Perhaps the most distinctive influence of Plotinian Neoplatonism on his thinking about God was in his Trinitarian theology. He started with the unity of God and continually insisted upon it, unlike Greek Christian thinkers, who started with the Three Persons perfectly united, and because he thought that something like the Christian doctrine of the Trinity was to be found in Plotinus and Porphyry, he tended to regard it as a philosophical doctrine and tried to make philosophical sense of it to a greater extent than the Greek Fathers did. His last and most important and influential attempt to do so was in his treatise *On the Trinity*, with its discovery of analogies to the divine mystery in the self-directed, internal activities of the soul.

Medieval Platonism. With the gradual revival of philosophical thinking in the West that began in the Carolingian period (late 8th–9th centuries), the history of Platonism becomes extremely complex. Only a kind of sketch map that distinguishes the main streams of more or less Platonic tradition can be given here.

Influence of the *Timaeus*

In the 4th century the Christian exegete Calcidius prepared a commentary on Plato's *Timaeus*, which exerted an important influence on its medieval interpretation. A Christian Platonic theism of the type of which Boethius is the finest example thus arose, based on a reading of the *Timaeus* with Christian eyes, and continued to have a

strong influence in the Middle Ages, especially in the earlier period. This kind of theism, issuing in a strongly positive view of God's creation and a nobly austere but humane view of man's duty and destiny, was particularly apparent in the Christian humanism of the School of Chartres (12th century).

The widest, deepest, and most persistent Christian Platonist influence in the Latin West was that of Augustine (see above *Augustinian Platonism*). Augustinianism in a variety of forms—often stiffened, exaggerated, or distorted—persisted throughout the Middle Ages and survived the "recovery of Aristotle" (see below). In the later Middle Ages Augustine's influence was particularly strong in the Franciscan school, though not confined to it. But the greatest and most influential of medieval thinkers deeply influenced by Augustine was Anselm of Canterbury (1033–1109), the originator (probably on the basis of suggestions in Augustine) of the still much discussed "ontological argument" for the existence of God (see RELIGION, PHILOSOPHY OF) and a philosopher whose humility, openness, and readiness to consider objections had a genuinely Socratic quality.

John Scotus Erigena

One of the boldest and most original thinkers of medieval Europe was John Scotus Erigena (2nd half of the 9th century AD), who introduced to the West the Greek Christian Platonist tradition (see above *Patristic Platonism*), as it had been developed by the Pseudo-Dionysius and Maximus the Confessor. His views were much disapproved of by the Western Church; and his great philosophical work, the *Periphyseon* (usually known as *De divisione naturae*), was not much read and ceased to be copied after his condemnation in 1210. But a considerable part of the text circulated in the form of anonymous glosses to the Latin translations of the Pseudo-Dionysius (of which the first adequate translation was by Erigena himself); and in this way his thought influenced both the tradition of Western mysticism, which derived from the Pseudo-Dionysius, and 13th-century Scholasticism, for which St. Paul's supposed disciple was still a major authority.

The Platonism in "Aristotelian" Scholasticism

There is no more superficial and misleading generalization in the history of philosophy than that which sharply opposes "Christian Platonism" and "Christian Aristotelianism." To be sure, the recovery of the authentic thought of Aristotle through Latin translations of his works in the 12th and 13th centuries was indeed a major event in the history of philosophy. But Platonism and Aristotelianism have never been tidily separated in the history of European thought. There was already a strong Aristotelian element in Middle and Neoplatonism. Byzantine theologians (in the East) from the 6th century AD onward were as Aristotelian as anybody in western Europe in the 13th century. Thirteenth-century "Aristotelian" Scholastics, though much preoccupied with the new translations of Aristotle and their philosophical and theological implications, were still deeply influenced by Augustine, Boethius, and the Pseudo-Dionysius (with glosses derived from Erigena). And the Islāmic philosophy, to be mentioned below, with which they had to grapple, was as much Neoplatonist as it was Aristotelian. Further, they also were influenced by the *Liber de causis*, compiled by an Arab author from Proclus and attributed to Aristotle, as well as by Latin translations of some of the shorter works of Proclus (see above). It has been said that "Aquinas is closer to Plotinus than to the real Aristotle," and there is some truth in this judgment.

Islāmic and medieval Jewish philosophy. After the Muslim conquest of Syria and Egypt, there began a great work of translation of the texts that had been studied in the late Greek philosophical schools—including a number of dialogues of Plato and Neoplatonic treatises, as well as the works of Aristotle and a number of the Alexandrian Neoplatonist commentaries on them. The translations—partly from Greek, partly from Syriac versions of the Greek texts—were made between about 800 and 1000. On the basis of these translated texts an impressive development of Islāmic theology and philosophy (*q.v.*) took place, strongly influenced by Neoplatonism, though Aristotelian influence also became increasingly important. An interesting feature of this Islāmic philosophy, which distinguished it sharply from the familiar Neoplatonism, was its much greater interest in the political and social side of Plato's thought and its attempts to adapt Platonic political ideas to the conditions of the contemporary Muslim world. The tradition culminated in two great Muslim philosophers who deeply influenced the medieval West, Avicenna (Ibn Sīnā, 980–1037) from Persia and Averroës (Ibn Rushd, 1126–98) from Muslim Spain. Of these, Avicenna was perhaps the more Platonist, and Averroës, whose fame and influence rested primarily on his commentaries on Aristotle, was the more Aristotelian. But both knew, were influenced by, and developed in their own way both Platonic and Aristotelian ideas. Medieval Jewish philosophy (*q.v.*), which also developed within this Muslim intellectual tradition, especially in Spain, reflected—at least in its earlier phases—strong Neoplatonic influence. This is especially true of the thought of the first great Jewish philosopher of Muslim Spain, Ibn Gabirol (born *c.* 1021).

PLATONISM FROM THE RENAISSANCE TO MODERN TIMES

From the 15th century onward the *Dialogues* of Plato and a large number of Middle Platonist and Neoplatonist works, above all the *Enneads* of Plotinus, became available in the original Greek in western Europe and were studied by scholars, philosophers, and theologians. As a result of this new acquaintance with the original texts, Platonic influences on Renaissance and post-Renaissance thought became even more complex and difficult to recognize than those on medieval thought. Older Neoplatonically influenced traditions (notably Augustinianism) persisted, and new ones developed from the direct reading of the Neoplatonic texts. And, at least from the time of Leibniz (1646–1716), European thinkers realized that the Neoplatonic interpretation of Plato was in some ways a distorted and one-sided one; hence they sometimes developed their own allegedly more authentic understandings of Plato on the basis of direct readings of such of his varied works as they found to be philosophically congenial. Only a few of the more interesting Platonic influences can be indicated here.

The persistence of Christian Platonism

In spite of its deep influence on Greek Christian thinkers, Platonism was regarded with profound suspicion by the Byzantine Orthodox Church. The suspicion reflected its association in the Byzantine ecclesiastical mind with the militant paganism of the Athenian Neoplatonists (see above). Nonetheless, it survived in the Byzantine world—generally underground but with a notable overt revival in the 11th century, in which the most notable figures were the broadly erudite Michael Psellus, who did much to enhance the prestige of philosophy, and his rival, the syncretistic Aristotelian commentator John Italus. In the 15th century the last known Byzantine philosopher, George Gemistus Plethon, a passionate pagan Platonist in the manner of Proclus, travelled to Italy (1438–39) and persuaded Cosimo de' Medici to sponsor a Platonic Academy at Florence, of which the greatest figures to emerge were its founder, the Platonic commentator Marsilio Ficino, and the humanist Pico della Mirandola, author of the influential *Oration on the Dignity of Man*. In spite of the paganism of Plethon, the Platonism of the Florentine Academy was a Christian one of humane and liberal kind. This was probably at least partly due to the influence in Italy of the thought of Cardinal Nicholas of Cusa (1401–64), who at about the same time (the period of the short-lived reunion between Eastern and Western churches at the Council of Florence), worked out his own very original version of Christian Platonism, influenced by the Pseudo-Dionysius, Erigena, and the German mystical tradition (as in Meister Eckehart).

The influence of the Christian Platonism of the Florentine Academy was quite extensive and was particularly marked in England. Perhaps the most impressive development of this post-Renaissance movement lay in the works of the Cambridge Platonists (late 17th century). Since their time a tradition of liberal Christian Platonism has persisted in England, predominantly, though not exclu-

sively, among Anglican thinkers; and though at present unfashionable, it is by no means dead. Moreover, there have been other notable traditions of Platonically influenced Christian thought in Europe. One that deserves to be better known is that of the outstanding French philosopher of "action" Maurice Blondel (1861–1949), who found a prominent place in his system for the formation of ideas—interpreted as an important species of action that faithfully reflects the eternal order of reality. Blondel's philosophy has had a widespread influence, mainly among Catholic philosophers dissatisfied with Neoscholasticism.

Pagan Neoplatonic influence on German Idealism and on English literature

The rediscovery of Proclus by the great German Idealist G.W.F. Hegel (1770–1831) had an important influence on his thought and so on the whole history of 19th-century Idealist philosophy. The German Idealists, of course, understood Neoplatonism much in their own way; and Idealism should not be interpreted as revived Neoplatonism, nor Neoplatonism as an anticipation of Idealism. But the historical influence of a direct reading of the Neoplatonists on Idealist thought is indisputable. There was a strong reaction against Hegel's influence in some quarters in 19th-century Germany, and this reaction led to a corresponding depreciation of Neoplatonism. But 20th-century German (and French) scholars have been readier than English scholars to take a serious interest in Neoplatonism. The latter, with some notable exceptions, have maintained a traditionally rationalist attitude toward that philosophy, which, in all its forms, they have regarded as "decadent" and "mystical."

The influence of the sort of Christian Platonism mentioned above on English literature, and especially on English poetry, has been wide and deep. But there has also been a strongly anti-Christian Neoplatonic influence, that of Thomas Taylor "the Platonist" (1758–1835), who published translations of Plato, Aristotle, and a large number of Neoplatonic works in the late 18th and early 19th centuries. Taylor was as militant in his pagan Platonism as Gemistus Plethon. His ideas had a strong influence on the poetry of William Blake, one of the fathers of "visionary" British Romanticism, who eventually succeeded in reconciling Taylor's paganism with his own very original version of Christianity: much of the symbolism in Blake's poetry is Neoplatonic. The Platonism of the English Romantic poet and political radical Shelley also derives from Taylor. Thomas Taylor also deeply influenced Emerson and his circle in America. Later, in the early 20th century, the influence of Taylor's writings was again apparent in the Irish poet and dramatist, Yeats, especially in his later poems.

The foremost process philosopher A.N. Whitehead (1861–1947), perhaps because of his original and abiding concern with mathematical philosophy, was interested in Plato (though not, apparently, in the Neoplatonists); and the reading of the *Timaeus* in particular contributed something to the metaphysical system of his last period and especially to his concept of a God who does not timelessly transcend process but is in some way involved in it. Whitehead is an excellent example of a Platonically influenced thinker whose development of Plato's own thought proceeds along lines completely opposed to Neoplatonism.

EVALUATION OF PLATONISM

The essential point at issue between Platonists and their opponents through the centuries has been the existence (in some sense) of spiritual or intelligible reality, which is independent of the sense world, is normative, and is the source of values. This is a very rough generalization, which does not apply to the skeptical Academy (see above *Greek Platonism from Aristotle through Middle Platonism*) nor do full justice to the thought of the modern skeptical Platonist George Santayana. Platonists have understood this central doctrine in a great variety of ways and defended it with a great variety of arguments. But whenever it has been strongly held, it seems to have been by a faith depending on some sort of experience rather than simply as the conclusion of an argument. Its opponents have generally followed the lines of attack laid down by Aristotle (and to some extent anticipated by Plato in the first part of his *Parmenides*): that the doctrine involves an illegitimate duplication of reality and the postulation of entities for the existence of which no sufficent evidence or arguments can be offered and the relationship of which to the world of sense experience cannot be intelligibly stated.

The argument still continues and will perhaps never finally be settled, but there can be no doubt about the central importance of Platonism in the history of European thought. It has been a continual stimulus to philosophical discussion, and it has provided the central tradition of Western religious philosophy and so has deeply influenced Christian theology. Finally, it has done more than any other philosophy of ancient Greek origins to stimulate new developments in physical science, literature, and art.

BIBLIOGRAPHY. A good source of information on the Platonic and Neoplatonic philosophers up to and including Anselm is the *Cambridge History of Later Greek and Early Medieval Philosophy*, ed. by A.H. ARMSTRONG (1967; reprinted with revised bibliographies, 1970). The bibliographies of this work include a list of the editions of ancient and medieval sources (complete and fragmentary), with the more important translations and modern works. For medieval Platonism, see B. GEYER, *Die patristische und scholastische Philosophie*, in F. UEBERWEG, *Grundriss der Geschichte der Philosophie*, pt. 2, 12th ed. (1951); ETIENNE GILSON, *History of Christian Philosophy in the Middle Ages* (1955), with valuable bibliographical material; D. KNOWLES, *The Evolution of Mediaeval Thought* (1962); G. LEFF, *Mediaeval Thought: St. Augustine to Ockham* (1960); and W. BEIERWALTES (ed.), *Platonismus in der Philosophie des Mittelalters* (1969), a collection of important articles published in German. All these works to some extent cover the later medieval period not dealt with in the *Cambridge History*. For medieval Jewish philosophy, see I. HUSIK, *A History of Mediaeval Jewish Philosophy* (1946). For Neoplatonic movements in Jewish Hellenistic and medieval philosophy, see J. GUTTMANN, *Philosophies of Judaism: The History of Jewish Philosophy from Biblical Times to Franz Rosenzweig*, trans. from the Hebrew by D.W. SILVERMAN (1964). There is no adequate and up-to-date account of Renaissance and post-Renaissance Platonism; reference must be made to general histories of philosophy. P. SHOREY, *Platonism, Ancient and Modern* (1938), still remains the best general introduction. On Byzantine Platonism, see J.M. HUSSEY, *Church and Learning in the Byzantine Empire, 867–1185* (1937); and B.N. TATAKIS, *La Philosophie byzantine* (1949). The most satisfactory short general account of Renaissance Platonism in English is that by F.C. COPLESTON, *History of Philosophy*, vol. 3, ch. 12 and 15 (1953). A good short introduction to Renaissance Platonism in England is ERNST CASSIRER, *Die Platonische Renaissance in England und die Schule von Cambridge* (1932; Eng. trans., *The Platonic Renaissance in England*, 1953). G.R. CRAGG (ed.), *The Cambridge Platonists* (1968), is an excellent anthology, with good introductions and notes. On English Christian Platonism, see also W.R. INGE, *The Platonic Tradition in English Religious Thought* (1926). On the influence of Thomas Taylor, see *Thomas Taylor the Platonist*, selected writings ed. by K. RAINE and G.M. HARPER (1969); and F.A.C. WILSON, *W.B. Yeats and Tradition* (1958).

Platyhelminthes

The flatworms constitute the phylum Platyhelminthes, a group of invertebrate animals that are free-living as well as parasitic—*i.e.*, living on or in another organism and securing nourishment from it. They are bilaterally symmetrical (*i.e.*, the right and left sides are similar), usually flattened, and lack respiratory, skeletal, and circulatory systems; no body cavity (coelom) is present. The body is not divided into true segments; spongy connective tissue (mesenchyme) constitutes the so-called parenchyma and fills the space between organs. Flatworms, generally hermaphroditic—functional reproductive organs of both sexes occurring in one individual—are the lowest invertebrates to possess three embryonic layers—endoderm, mesoderm, and ectoderm—and to have a head region containing concentrated sense organs and nervous tissue (brain).

The phylum consists of five classes: Trematoda (flukes), Cestoda (tapeworms), Turbellaria, Monogenea, and As-

pidocotylea (or Aspidobothria). Members of all classes except Turbellaria are parasitic during all or part of the life cycle. Most turbellarians are exclusively free-living forms. About 13,000 species of flatworms have been described.

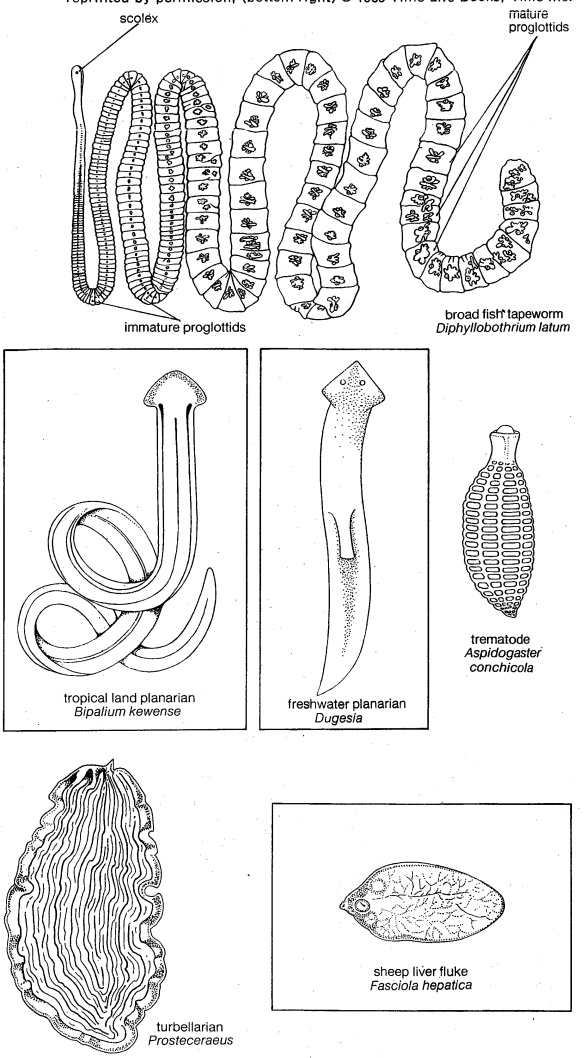

Figure 1: Representative body types of Platyhelminthes.

GENERAL FEATURES

Tapeworm, fluke, and trematode infestations

Importance. Platyhelminthes are of particular economic interest because many species of flukes are parasitic in man, in domestic animals, or in both. In Europe and in North and South America, tapeworm infestations of man have been greatly reduced as a consequence of routine meat inspection. But where sanitation is poor and meat eaten undercooked, the incidence of tapeworm infestations is high. In the Baltic countries much of the population is infested with the broad tapeworm (*Diphyllobothrium latum*); in parts of the southern United States a small proportion of the population may be infested with the dwarf tapeworm (*Hymenolepis nana*). In Europe and the United States the beef tapeworm (*Taenia saginata*) is not uncommon due to the habit of eating undercooked steaks or other beef products.

Immature stages (larvae) can seriously damage the host. A larval stage of the gid parasite of sheep (*Multiceps multiceps*) usually lodges in the sheep brain. Fluid-filled hydatid cysts (*i.e.*, sacs containing many cells capable of developing into new individuals) of *Echinococcus* may occur almost anywhere in the body of sheep. Hydatids of the liver, brain, or lung of man are often fatal. Infestation occurs only where man lives in close association with dogs, and the dogs have access to infested sheep for food.

Thirty-six or more species of flukes have been reported as parasitic in man. Endemic (local) centres of infection occur in virtually all countries; widespread infections occur in the Far East, Africa, and tropical America. Many species are ingested as cysts, called metacercariae, in uncooked food—*e.g.*, the lung fluke *Paragonimus westermani* found in crayfish and crabs, the intestinal flukes *Heterophyes heterophyes* and *Metagonimus yokogawai* and the liver fluke *Opisthorchis sinensis* in fish, and the intestinal fluke *Fasciolopsis buski* on plants. Free-swimming larvae (cercariae) of blood flukes penetrate the human skin directly. In man, these parasites and others listed below cause much misery and death. Control of certain flukes through the eradication of their mollusk hosts has been attempted but without much success.

Schistosomiasis (bilharziasis) is a major human disease caused by three species of the genus *Schistosoma*, known collectively as blood flukes. Africa and western Asia (*e.g.*, Iran, Iraq) are endemic centres for *S. haematobium; S. mansoni* also is found in these areas, as well as in the West Indies and South America. In the Far East, *S. japonicum* is the important blood fluke.

Among domestic animals, the sheep liver fluke (*Fasciola hepatica*) may cause debilitating and fatal epidemics (liver rot) in sheep. These animals become infected by eating metacercariae encysted on grass. Monogenea are common pests on fish in hatcheries and home aquariums (see also DISEASES OF ANIMALS).

Size range and diversity of structure. Most of the Turbellaria are less than five millimetres (one-fifth inch) long, and many are microscopic in size. The largest of this class are the planarians, which may reach 0.5 metre (about 20 inches) in length. Trematoda are mostly five to 100 millimetres (about one-fifth to four inches) long; some species, however, may grow to several centimetres. The smallest Cestoda are about one millimetre long, but some exceed 15 metres (50 feet) in length. The Monogenea range in length from 0.5 to 30 millimetres. Aspidocotylea are from a few millimetres to 100 millimetres in length.

Distribution and abundance. In general, free-living flatworms can occur wherever there is moisture. Except for one group of turbellarians, the temnocephalids, flatworms are cosmopolitan in distribution. They occur in both freshwater and salt water and occasionally in terrestrial habitats that are moist, especially in tropical and subtropical regions. The temnocephalids, which are parasitic on freshwater crustaceans, occur primarily in Central and South America, Madagascar, New Zealand, Australia, and islands of the South Pacific.

Some flatworm species occupy a very wide range of habitats. One of the most cosmopolitan and most tolerant of different ecological conditions is the turbellarian *Gyratrix hermaphroditus*, which occurs in freshwater at elevations from sea level to 7,000 feet (2,000 metres) as well as in saltwater pools. Adult forms of parasitic flatworms are confined almost entirely to specific vertebrate hosts; the larval forms, however, occur in vertebrates and in invertebrates, especially in mollusks, arthropods (*e.g.*, crabs), and annelids (*e.g.*, marine worms). They are cosmopolitan in distribution, but their occurrence is closely related to that of the intermediate host or hosts.

NATURAL HISTORY

Life cycle. *Reproduction.* With very few exceptions, platyhelminthes are hermaphroditic, and their reproductive systems are generally complex. Numerous testes but only one or two ovaries are usually present. The female system is unusual in that it is separated into two structures: the ovaries and the vitellaria, often known as the vitelline glands or yolk glands. In contrast, in most higher animals the yolk is part of the egg. The cells of the vitellaria form yolk and eggshell components. In some groups, particularly those that live primarily in water or have an aqueous phase in the life cycle, the eggshell consists of a hardened protein known as sclerotin, or tanned protein. Most of this protein comes from the vitellaria. In other groups, especially those that are primarily terrestrial or

Separation of the female reproductive system

have a terrestrial phase in their life cycle, the eggshells are composed of another protein, keratin, a tougher material that is more resistant to adverse environmental conditions.

The general structure of the reproductive system may be seen in Figure 2. In the tapeworms, the tapelike body is generally divided into a series of segments, or proglottids, each of which develops a complete set of male and female genitalia. A rather complex copulatory apparatus consists of an evertible (capable of turning outward) penis, or cirrus, in the male and a canal, or vagina, in the female. Near its opening the female canal may differentiate into a variety of tubular organs. Fertilized eggs are often stored in a saclike uterus, which may become greatly distended; in tapeworms, it may fill a whole segment.

Each male and female reproductive system may have its own external opening, or gonopore, or the terminal regions of each system may join to form a common genital atrium (Figure 2), or passage, and a genital pore.

Modes of fertilization

Either cross-fertilization (*i.e.*, involving two individuals) or self-fertilization may occur; self-fertilization is probably more common. Some free-living flatworms perform a type of copulation known as hypodermic impregnation, whereby the penis of one animal pierces the epidermis of another and injects sperm into the tissues. Some forms reproduce asexually—*i.e.*, they produce chains that eventually separate to form individuals.

Development. The life cycles of the free-living forms are relatively simple. Eggs are laid singly or in batches. Frequently they are attached to some object or surface by an adhesive secretion. After a period of embryonation (*i.e.*, the formation of the first larval stage) minute worms emerge, feed, develop genitalia, and become adult.

Parasitic platyhelminths undergo very complex life cycles, often involving several larval stages in other animals —the intermediate hosts; these hosts may be invertebrate or vertebrate.

The simplest cycle in parasitic platyhelminths occurs in the Monogenea, which have no intermediate hosts. The majority of the Monogenea are ectoparasitic (externally parasitic) on fish. The eggs hatch in water. The larva, known as an oncomiracidium, is heavily ciliated (has hairlike projections) and bears numerous posterior hooks. It attaches to a host, grows, and matures. In some species (*e.g.*, *Polystoma integerrimum*) parasitic in frogs, maturation of the genitalia is synchronized with maturation of the host and apparently is controlled by the endocrine system of the latter.

In the life cycle of flukes of the subclass Digenea, mollusks serve as the intermediate host. Eggs of Digenea usually hatch in water or in a snail host. The first larval stage, the miracidium, generally is free-swimming and penetrates a freshwater or marine snail, unless it has already been ingested by one. Within this intermediate host, the parasite passes through some or all of a series of further larval stages known as sporocysts, rediae, and cercariae. Cercariae are essentially young flukes with tails. They either penetrate the host or are ingested by it. Tapeworms of the subclass Eucestoda are generally transmitted from host to host by direct ingestion of eggs; by ingestion of intermediate hosts containing larval stages; and, very rarely, by passage of a larva from an intermediate host through a skin wound into another intermediate host.

Transmission to a human host through a skin wound is most likely to occur in Asia, where frogs infested with tapeworm larvae are sometimes used to treat wounds. The tapeworm, *Hymenolepis nana*, parasitic in rodents and man, can complete its life cycle without an intermediate host. Certain species of trematodes and cestodes show a tendency toward progenesis, in which adult features—such as the appearance of genital rudiments—appear in the larva. In some cases of progenesis the worm achieves sexual maturity in the intermediate host.

Regeneration. The ability to undergo tissue regeneration, beyond simple wound healing, occurs in two classes of Platyhelminthes: Turbellaria and Cestoda.

Turbellaria. Turbellarians, planaria particularly, have been commonly used in regeneration research. The greatest regenerative powers exist in species capable of asexual reproduction. Pieces from almost any part of the turbellarian *Stenostomum*, for example, can reorganize into completely new worms. In some cases regeneration of very small pieces may result in the formation of imperfect (*e.g.*, headless) organisms.

Polarity

In other Turbellaria, regeneration of the head is limited to pieces from the anterior region or to tissues containing the cerebral ganglion (brain). The region anterior to this ganglion is incapable of regeneration, but if cuts are made posterior to it, many species can replace the entire posterior region, including the pharynx and the reproductive system. In the cut pieces, polarity is retained; *i.e.*, the anterior zone of the cut piece regenerates the head and the posterior region regenerates the tail. If a region in front of the pharynx is transplanted into the posterior region of another individual, it influences that region to form a pharyngeal zone that eventually differentiates a pharynx. This new pharyngeal zone is now said to be determined and, if removed, will regenerate again into a new pharynx.

There is evidence that a special type of cell, a neoblast, is concerned in planarian regeneration. Neoblasts, rich in ribonucleic acid (RNA), which plays an essential role in cell division, appear in great numbers during regeneration. Similar cells, apparently inactive, occur in the tissues of whole organisms (see also REGENERATION, BIOLOGICAL).

Cestoda. Regeneration, although rare in the parasitic worms in general, does occur in the cestodes. Most tapeworms appear to be capable of regeneration from the head (scolex) and neck region. This property often makes it difficult to treat man for tapeworms; treatment may eliminate only the body, or strobila, leaving the scolex still attached to the intestinal wall of the host and thus capable of producing a new strobila, which re-establishes the infestation. Several species of cestode larvae can regenerate themselves from cut regions. A branched larval form of *Sparganum prolifer*, a human parasite, may undergo both asexual multiplication and regeneration.

Ecology. Turbellaria are adapted to a wide range of environments, and many species are resistant to extreme environmental conditions. Some occur in coastal marine habitats—in sand, on or under rocks, and in or on other animals or plants. Some marine species occur at relatively great depths in the sea; others are pelagic (*i.e.*, living in the open sea). Freshwater species are found in ponds, lakes, rapidly flowing rivers, and streams. Temporary freshwater pools may contain adult forms that survive periods of dryness in an encysted state. Some aquatic species exhibit considerable tolerance to osmotic changes —*i.e.*, to differences in salt concentrations of the water; a marine species *Coelogynopora biarmata*, for example, has also been found in freshwater springs.

Terrestrial species of Turbellaria occur in soil, moist sand, leaf litter, mud, under rocks, and on vegetation. Some have been found in pools in the desert and in caves. Cave-dwelling species tend to show loss of eyes and pigment.

Tolerance of temperature extremes

Some species are able to stand considerable temperature ranges; for example, *Crenobia alpina*, which occurs in alpine streams, apparently can survive temperatures of −40° to −50° C (−40° to −58° F). Remarkable heat tolerance is exhibited by *Macrostomum thermale* and *Microstomum lineare*, which are found in hot springs at 40°–47° C (104°–117° F). *M. lineare* can also tolerate temperatures as low as 3° C (37° F).

Many Turbellaria live in association with plants and animals. Marine algae, for example, frequently harbour many species, often in large numbers. Turbellarians most commonly associate with animals such as echinoderms (*e.g.*, starfish), crustaceans (*e.g.*, crabs), and mollusks. Less commonly, associations occur with sipunculids (tiny marine invertebrates), annelid worms, arachnids (*e.g.*, spiders), coelenterates (*e.g.*, jellyfish), other turbellarians, and lower vertebrates. An interesting feature of these associations is that species within a turbellarian family tend to associate with one type of organism; for example,

almost all members of the family Umagillidae associate with echinoderms.

In a few cases, the association is considered parasitic; *i.e.*, the turbellarians obtain all nourishment from the host. Most of these species belong to the order Rhabdocoela, in which the alimentary canal is either absent or reduced. In a few hosts they cause so-called parasitic castration—*i.e.*, suppression of gonad maturation in the host organism.

Among the turbellaria that are parasitic or commensal (*i.e.*, living in close association with but not harmful to another organism) the Temnocephalida are best adapted for attachment to other organisms. They have a large saucer-shaped posterior adhesive organ and anterior tentacles that are also used for adhesion. All temnocephalids occur on freshwater hosts, mainly crustaceans but also mollusks, turtles, and jellyfish.

The tendency to associate with other animals apparently represents a definite evolutionary trend among the platyhelminths; permanent associations essential to the survival of a species could develop from loose associations, which could also give rise to parasitic forms, such as the Trematoda and Cestoda. The free-living larval stages that frequently occur in these groups play a major role in the dissemination of the species.

The ecology of the parasitic groups (*i.e.*, Cestoda and Trematoda) is particularly complex, because as many as four hosts may be involved in the life cycle. In the case of the broad tapeworm, for example, man serves as the final (or definitive) host, various species of fish as one intermediate host, and species of a small water crustacean (*Cyclops*) as another intermediate host. It is clear that the broad tapeworm (*Diphyllobothrium latum*) can occur only where an intimate ecological association exists among the three host groups.

Adaptation to the microenvironment of the host

In addition to adapting to the general external environment, individuals at each stage of the life cycle of a parasite must adapt to the micro-environment provided by the host. Adaptations include not only obvious features, such as suckers or hooks for attachment, but also those associated with the biochemical and physiological conditions imposed by the host. Parasites frequently utilize the physiological and biochemical properties of a new host, especially those that differ markedly from the external environment, in order to trigger the next developmental stage—*e.g.*, several species of cestodes are stimulated to mature sexually by the high body temperature (40° C) of their bird host, which contrasts sharply with the low body temperature of the cold-blooded fish host of the larval stage. The unusually intimate association of certain flukes (subclass Digenea) with mollusks suggests that flukes were originally parasites of mollusks and that they later developed an association with other hosts.

Knowledge of the ecology both of a platyhelminth parasite and of its intermediate host(s) is essential if control measures against the pest are to be effective. Man's alterations of the environment sometimes increase the occurrence of platyhelminth diseases. The Aswan High Dam in Egypt, for example, has produced conditions especially favourable for the breeding of the snail that serves as the intermediate host of the blood fluke (*Schistosoma mansoni*). In this case, as with many trematode infestations, man exposes himself to the disease by bathing in water containing infective larvae (cercariae) released from infested snails; the cercariae enter directly through the skin. Certain other human diseases of platyhelminth origin—such as hydatid (cyst) disease, caused by the tapeworm *Echinococcus granulosus*—owe their survival and dissemination to man's close ecological association with dogs.

In the parasitic platyhelminth groups (*e.g.*, the Monogenea) that do not normally utilize intermediate hosts, there is a close ecological association between egg release and production of young of both the parasite and its host; infection of the next generation of host could not otherwise occur.

Many platyhelminths show highly specific adaptations to internal host environments. Many monogeneans, for example, show a marked preference for a particular gill arch in a fish. The scolex (head) of certain tapeworms of elasmobranch fishes (*e.g.*, sharks, skates, and rays) is highly specialized and can satisfactorily attach only to the gut of a fish possessing a complementary structure.

FORM AND FUNCTION

External features. Some Turbellaria are gray, brown, or black, with mottled or striped patterns. Others, which contain algae in the mesenchyme, are green or brown. Parasitic flatworms usually have no pigment, but cestodes may be coloured by food (*e.g.*, bile, blood) in their gut. Some parasitic forms may show masses of dark eggs through a translucent, creamy, or whitish tissue.

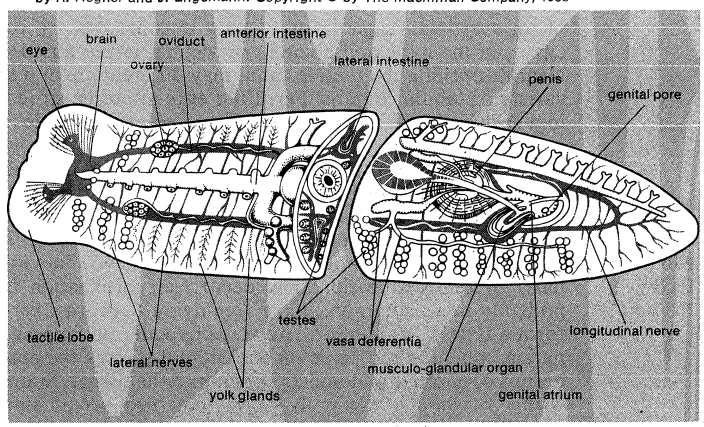

Figure 2: General structure of a platyhelminth, as exemplified by a freshwater turbellarian, *Procotyla fluviatilis*.

The flatworm body plan

The typical flatworm body is flatened and leaflike or tapelike (Figure 2). The head may be set off from the body or grade imperceptibly into it. The anterior (head) end can usually be distinguished from the posterior end in free-living forms by the presence of two pigment spots, which are primitive eyes. In the case of the tapeworm, the scolex is usually conspicuous for its breadth. The strobila (body) typically consists of proglottids, each of which is usually a self-sufficient reproducing unit with all of the sexual organs necessary to reproduce. The number of proglottids may vary from three in some species to several hundreds in others. Organs of attachment on the scolex may, in addition to suckers, consist of hooks, spines, or various combinations of these.

The structure and function of the body covering, or tegument, differs markedly between free-living and parasitic forms. In free-living forms, the body covering is typically an epidermis consisting of one layer of ciliated cells—*i.e.*, cells with hairlike structures—the cilia being confined to specific regions in some species. In the parasitic groups—flukes, tapeworms, and monogeneans—the tegument shows striking modifications associated with the parasitic way of life. It once was thought that the tegument is a nonliving secreted layer; it is now known, however, that the tegument of parasites is (Figure 3) metabolically active and consists of cells not separated from

From (Left) R. Hegner and J. Engemann, *Invertebrate Zoology*, (Right) J. Smyth, *The Physiology of Cestodes*

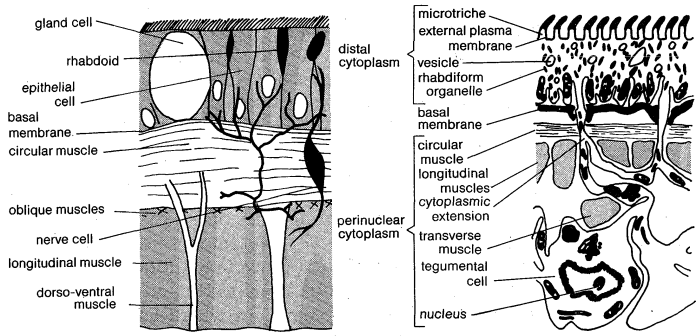

Figure 3: Comparison of the body wall in a (A) free-living and a (B) parasitic platyhelminth. A is a turbellarian, B is a tapeworm.

one another by cell walls (*i.e.*, a syncytium). The tegument itself consists of cytoplasmic extensions of tegumental cells, the main bodies of which lie in what may be described as the "subcuticular" zone, although a true cuticle is not present. A membrane separates the inner zone of the tegumental cells, the so-called perinuclear cytoplasm, from the surface syncytium, or distal cytoplasm (Figure 3).

The surface of tapeworms and monogeneans is drawn out into spinelike structures called microtriches, or microvilli. The microtriches probably help to attach the parasite to the gut of the host, absorb nutritive materials, and secrete various substances. In the flukes, microtriches are lacking, but spines are frequently present.

Embedded in the epidermis of turbellarians are ovoid or rod-shaped bodies (rhabdoids, see Figure 3) of several sorts; of uncertain function, the bodies frequently are concentrated dorsally or may be clustered anteriorly as rod tracts opening at the apex. Rhabdoids are absent in flukes and tapeworms.

Internal features. Beneath the epidermis of turbellarians is a homogeneous or lamellated basal membrane. Club-shaped mesenchymal gland cells, opening externally, generally are present in all flatworms. In turbellarians two major types of mesenchymal glands occur: one produces a slimy material upon which the organisms creep; the other secretes an adhesive substance for capture of prey, for adhesion, and for cementing egg capsules to a suitable surface. The larvae of parasitic forms generally possess similar glands whose secretions are used for adhesion, for producing cyst walls around resting stages, and for penetrating hosts; some adult parasites have glands for adhesion and, in trematodes, for softening and digesting host tissues.

Mesenchyme

The mesenchyme consists of fixed and free cells as well as a fibrous matrix. A fluid occupies the minute open spaces and serves for distribution of nutrients and wastes. The mesenchymal cells in certain groups may differentiate during growth to become sex cells or may function in asexual reproduction in repair or in regeneration.

Nervous system. The main ganglia, or nerve centres, of the nervous system and the major sense organs are generally concentrated at the anterior end. Typically, the primitive brain of the flatworm consists of a bilobed mass of tissue with lateral longitudinal nerve cords connected by transverse connectives, thus forming a rather ladderlike structure or grid running the greater length of the organism (Figure 2). Free-living forms commonly have two longitudinal cords, but some tapeworms have as many as ten. Sensory receptors occur in all groups.

Musculature. The well-developed muscular system present in flatworms is comprised of a subcuticular musculature consisting of layers of circular, longitudinal, and diagonal muscles close to the epidermis, and a mesenchymal musculature consisting of dorsoventral, transverse, and longitudinal fibres passing through the mesenchyme. In general, platyhelminths are capable of extensive body contraction and elongation.

Digestive and excretory systems. The blind-ending intestine of trematodes consists of a simple sac with an anterior or midventral mouth or a two-branched gut with an anterior mouth; an anus is usually lacking, but a few species have one or two anal pores. Between the mouth and the intestine are often a pharynx and an esophagus receiving secretions from glands therein. The intestine proper, lined with digestive and absorptive cells, is surrounded by a thin layer of muscles that effect peristalsis; *i.e.*, they contract in a wavelike fashion down the length of the intestine. In many larger flukes lateral intestinal branches, or diverticula, bring food close to all internal tissues. Undigested residue passes back out of the mouth.

The digestive system of Turbellaria typically consists of mouth, pharynx, and intestine. In the order Acoela, however, only a mouth is present; food passes directly from the mouth into the parenchyma, to be absorbed by the mesenchymal cells. Tapeworms lack digestive systems.

The excretory system consists of protonephridia. These are branching canals ending in so-called flame cells—hollow cells with bundles of constantly moving cilia.

Nutrition. *Free-living forms.* Free-living platyhelminths (Turbellaria), mostly carnivorous, are particularly adapted for the capture of prey. Their encounters with prey appear to be largely fortuitous, except in some species that release ensnaring mucus threads. Because they have developed various complex feeding mechanisms, most turbellarians are able to feed on organisms much larger than themselves, such as annelids, arthropods, mollusks, and tunicates (*e.g.*, sea squirts). In general, the feeding mechanism involves the pharynx which, in the most highly developed forms, is a powerful muscular organ that can be protruded through the mouth. Flatworms with a simple ciliated pharynx are restricted to feeding on small organisms such as protozoans and rotifers, but those with a muscular pharynx can turn it outward, thrust it through the tegument of annelids and crustaceans, and draw out their internal body organs and fluids. Turbellaria, with a more advanced type of pharynx, can extend it over the captured prey until the animal is completely enveloped.

Complex feeding mechanisms

Digestion is both extracellular and intracellular. Digestive enzymes (biological catalysts), which mix with the food in the gut, reduce the size of the food particles. This partly digested material is then engulfed (phagocytized) by cells or absorbed; digestion is then completed within the gut cells.

Parasitic forms. In the parasitic groups with a gut (Trematoda and Monogenea), both extracellular and intracellular digestion occur. The extent to which these processes take place depends on the nature of the food. When fragments of the host's food or tissues other than fluids or semifluids (*e.g.*, blood and mucus) are taken as nutrients by the parasite, digestion appears to be largely extracellular. In those that feed on blood, digestion is largely intracellular, often resulting in the deposition of hematin, an insoluble pigment formed from the breakdown of hemoglobin. This pigment is eventually extruded by disintegrating gut cells.

Despite the presence of a gut, trematodes seem able to absorb certain materials, such as glucose, through the metabolically active tegument covering the body surface. The tapeworms, which have no gut, must take in all foods through the tegument. The entry of amino acids (the structural units of proteins) and small molecules of carbohydrate (*e.g.*, sugars) through this tegument occurs by a mechanism known as active transport, in which molecules are taken up against a concentration gradient. This process, similar to that in the vertebrate gut, requires the expenditure of energy. There is also some evidence that cestodes may be able to digest materials in contact with the tegument by means of so-called membrane digestion, a little-understood process.

Metabolism. Both free-living and parasitic platyhelminths utilize oxygen when it is available. Most of the parasitic platyhelminths studied have a predominantly anaerobic metabolism (*i.e.*, not dependent upon oxygen). This is true even in species found in habitats—such as the bloodstream—where oxygen is normally available.

Parasitic platyhelminths are made up of the usual tissue constituents—protein, carbohydrates, and lipids—but, compared to other invertebrates, the proportions differ somewhat; *i.e.*, the carbohydrate content tends to be relatively high and the protein content relatively low. In larval and adult cestodes, carbohydrate occurs chiefly as animal starch, or glycogen, which acts as the main source of energy for species in low oxygen habitats. The level of glycogen, like other chemical constituents, can fluctuate considerably, depending on the diet or feeding habits of the host. In some species, more than 40 percent of the worm's dried weight is glycogen.

Because carbohydrate metabolism is important in parasitic flatworms, a substantial amount of carbohydrate must be present in the host diet to assure normal growth of the parasite. Hence the growth rate of the rat tapeworm, *Hymenolepis diminuta*, is a good indicator of the quantity of carbohydrate ingested by the rat. Experiments have shown that most parasitic worms can utilize only certain types of carbohydrate. All tapeworms studied thus far utilize the sugar glucose. Many can also utilize

galactose, but only a few can utilize maltose or sucrose.

An unusual constituent of both trematodes and cestodes is a round or oval structure called a calcareous corpuscle; large numbers of them occur in the tissues of both adults and larvae. Their function has not yet been established, but it is believed that they may act as reserves for such substances as calcium, magnesium, and phosphorus.

The chief proteins in cestodes and trematodes are keratin and sclerotin. Keratin forms the hooks and part of the protective layers of the cestode egg and the cyst wall of certain immature stages of trematodes. Sclerotin occurs in both cestode and trematode eggshells, especially in those that have larval stages associated with aquatic environments.

Requirements for egg hatching

Platyhelminth eggs hatch in response to a variety of different stimuli in different hosts. Most trematode eggs require oxygen in order to form the first larval stages and light in order to hatch. Light is thought to stimulate the release of an enzyme that attacks a cement holding the lid (operculum) of the egg in place. A similar mechanism probably operates in cestodes (largely of the order Pseudophyllidea) whose life cycles involve aquatic intermediate hosts or definitive hosts, such as birds or fish.

In many cestodes, especially those belonging to the order Cyclophyllidea, the eggs hatch only when ingested by the host. When the host is an insect, hatching sometimes is apparently purely mechanical, the shell being broken by the insect's mouthparts. In vertebrate intermediate hosts, destruction of the shell depends largely on the action of the host's enzymes. Activation of the embryo within the shell and its subsequent release depend on other factors, including the amount of carbon dioxide present, in addition to the host's enzymes. Factors involving a vertebrate host are also important in establishing trematode or cestode infections after encysted or encapsulated larval stages have been ingested. Under the influence of the same factors, tapeworm larvae are stimulated to evaginate their heads (*i.e.*, turn them inside out, so to speak), a process that makes possible their attachment to the gut lining.

EVOLUTION AND CLASSIFICATION

Evolutionary hypotheses. The origin of the platyhelminths and the evolution of the various classes have not been positively settled. There are, however, two main lines of thought. According to the more widely accepted view, the Turbellaria and an aberrant group, the Ctenophora, have been derived independently from the lower Coelenterata. In the alternative view, the Turbellaria are derived from the Ciliata and the Ctenophora from the Turbellaria.

Origin of Turbellaria

It is generally believed that the parasitic groups are derived from the Turbellaria, many of which form close associations with other animals. These associations often show host specificity, a characteristic of truly parasitic forms. There are a number of views regarding the evolutionary relationships among the various parasitic groups. One school of thought proposes that rhabdocoel turbellarians gave rise to monogeneans; these, in turn, gave rise to digeneans, from which the cestodes were derived. Another view is that the rhabdocoel ancestor gave rise to two lines; one gave rise to monogeneans, who gave rise to digeneans, and the other line gave rise to cestodes. A further modification of the latter view, based largely on the study of the larval forms, proposes that cestodes were derived from monogeneans.

In considering the evolution of the parasitic groups, the digeneans should be mentioned in particular. The life cycle of digeneans is dominated by mollusks, which invariably act as intermediate hosts. This condition has led to the widely accepted view that digeneans were originally parasites of mollusks and later formed an association with vertebrates; the vertebrates, in turn, became incorporated into the life cycle as definitive hosts.

Classification. *Distinguishing taxonomic features.* The phylum Platyhelminthes is grouped with several other phyla (Nemertea, Rotifera, Nematoda, Gastrotricha, Acanthocephala, and Nematomorpha) as acoelomate triploblasts—*i.e.*, lacking a body cavity and with three embryonic layers: endoderm, mesoderm, and ectoderm. These phyla also represent animals that are unsegmented and whose body space tends to be occupied by mesenchyme. In Platyhelminthes, mesenchyme cells completely fill this space.

In the classification of platyhelminths the principal criteria are: habitat of organism (*i.e.*, free-living or parasitic); the characteristics of the body covering; the form and position of organs for attachment to host (when present); the presence or absence of segmentation; the form of the reproductive system, especially with respect to vitellaria (yolk glands) and the number of testes; the presence or absence of an alimentary canal; the characteristics of the pharynx (when present); and the nature of protective egg membranes.

Annotated classification. There is no unanimity concerning the classification of platyhelminths. The following classification is based partly on that of Grassé, Hyman, Yamaguti, and La Rue (see below *Bibliography*).

PHYLUM PLATYHELMINTHES (flatworms)

Flat, unsegmented worms; gastrovascular cavity and respiratory, skeletal, and circulatory systems absent; excretion by means of flame-bulb protonephridia; mesenchyme fills all spaces between organ systems; a variable number of longitudinal nerve cords with transverse connectives; body structure triploblastic (*i.e.*, 3 embryonic layers); reproductive system hermaphroditic and complex.

Class Turbellaria

Epidermis usually ciliated at least in part, provided with rhabdoids (minute rodlike structures); body unsegmented; gut present except in order Acoela; life cycle simple; mostly free-living, some ectocommensal, endocommensal (*i.e.*, living, respectively, outside or inside another organism without harming it), or parasitic; about 3,000 species.

Order Acoela. Exclusively marine; mouth present; pharynx simple or lacking; no intestine; without protonephridia, oviducts, yolk glands, or definitely delimited gonads.

Order Rhabdocoela. Saclike intestine; protonephridia and oviducts usually present; gonads few, mostly compact; nervous system generally with 2 longitudinal trunks.

Order Alloecoela. Pharynx simple, bulbose or plicate (many ridges); intestine may have short diverticula, or pockets; protonephridia paired; testes usually numerous; penis papilla generally present; nervous system with 3–4 trunks.

Class Monogenea

Oral sucker lacking or weakly developed; posterior end with large posterior adhesive disk (opisthaptor) usually provided with hooks; excretory pores paired, anterior and dorsal; parasites of the skin and other superficial locations, especially on the gills of fish; life cycle simple, no alternation of hosts; about 1,350 species.

Class Aspidocotylea (Aspidobothria)

Oral sucker absent; main adhesive organ occupying almost the entire ventral surface and consisting of suckerlets arranged in rows; excretory pore single and posterior; endoparasites of vertebrates (especially turtles and fish), mollusks, and crustaceans; about 100 species.

Class Cestoda (tapeworms)

Elongated endoparasites with alimentary canal lacking; epidermis modified for absorption and secretion; usually divided into segments (proglottids); adhesive organs limited to anterior end; except in Cestodaria, adult stages almost entirely parasites of vertebrates; life cycles complicated with 1 or more intermediate hosts; about 3,500 species.

Subclass Cestodaria

Unsegmented tapeworms containing 1 set of genitalia; parasites of the body cavity or intestine of annelid worms or fish.

Order Amphilinidea. Uterus long and N-shaped; genital pores at or near posterior extremity; intestinal parasites of teleosts (bony fish).

Order Caryophyllidea. Uterus a coiled tube; genital pore well separated from posterior extremity; intestinal parasites of teleosts, occasionally in annelids.

Order Gyrocotylidea. Testes confined to anterior region; genital pores near anterior end; parasitic in intestine of fish of the genus *Chimaera*.

Subclass Eucestoda

Polyzoic tapeworms with scolex (head) of varying structure; body usually with distinct external segmentation; parasitic in intestine of vertebrates.

Order Tetraphyllidea. Scolex with 4 bothridia (leaflike muscular structure); vitellaria located in lateral margins of proglottids; genital pores lateral; parasites of elasmobranchs.

Order Lecanicephalidea. Reproductive system similar to

Tetraphyllidea, but scolex divided into an upper disklike or globular part and a lower collar-like part bearing 4 suckers; mainly parasites of elasmobranchs.

Order Proteocephalidea. Scolex with 4 suckers, sometimes a 5th terminal one; vitellaria located in lateral margins; genital pores lateral; mainly parasites of cold-blooded vertebrates.

Order Diphyllidea. Two bothridia, each sometimes bisected by a median longitudinal ridge; large rostellum (cone-shaped or cylindrical projection) armed with dorsal and ventral groups of large hooks; cephalic peduncle (fleshy stalk on head) with longitudinal rows of T-shaped hooks; genital pore median, parasitic in elasmobranchs; 1 genus, *Echinobothrium.*

Order Trypanorhyncha. Scolex with 2 or 4 bothridia; vitellaria in continuous sleevelike distribution; parasites of elasmobranchs.

Order Pseudophyllidea. Scolex with 2 elongated, shallow bothria, 1 dorsal and 1 ventral; genital pore lateral or median. Vitellaria lateral or extending across proglottid and encircling other organs; parasites of teleosts and land vertebrates.

Order Nippotaeniidea. Scolex bears 1 apical sucker; parasites of freshwater fish; 1 genus, *Nippotaenia.*

Order Cyclophyllidea. (Taenoidea) Scolex with 4 suckers; no uterine pores; 1 compact vitellarium behind ovary; mainly parasites of birds and mammals.

Order Aporidea. No sex ducts or genital openings; parasites of swans.

Order Spathebothriidea. Scolex without true bothria or suckers; strobila with internal segmentation but no external segmentation; parasites of marine teleosts.

Class Trematoda (flukes)

Ectoparasites or endoparasites; no ciliated epidermis; body undivided; adhesive organs well-developed; life cycles generally complex with 2 or more hosts, about 6,250 species.

Subclass Aspidogastrea

Oral sucker absent; main adhesive organ occupying almost the entire ventral surface, consists of suckerlets arranged in rows; excretory pore single and posterior; endoparasites of vertebrates, mollusks, and crustaceans.

Subclass Digenea

Oral and ventral suckers generally well-developed; development involves at least 1 intermediate host; usually endoparasites of vertebrates.

Superorder Anepitheliocystidia. Excretory bladder thin walled (*i.e.*, not epithelial in any stage); excretory pores open to exterior in tail; stylet always lacking.

Order Strigeatoidea. Cercaria (immature form) fork-tailed; penetration glands present; 1-2 pairs of protonephridia.

Order Echinostomida. Cercaria with simple tail and many cyst-producing glands; life cycle with 3 hosts.

Superorder Epitheliocystidia. Cercaria completely lacking caudal excretory vessels at any stage of development; stylet (piercing structure) present or lacking.

Order Plagiorchida. Cercaria typically armed with a stylet; encystment in invertebrates, rarely vertebrates; excretory vessels not open to the exterior.

Order Opisthorchiida. Cercaria never armed; excretory pores open on margins of tail.

Critical appraisal. There is considerable disagreement on many aspects of the taxonomy of Platyhelminthes, especially regarding class divisions. Among the free-living or semiparasitic forms, the temnocephalids are placed as an order among the class Turbellaria (as here) by some authorities but are treated as a separate class by others. It is now generally recognized that the monogeneans, previously placed in a class of the Trematoda, are sufficiently divergent from the digeneans, nearer to the cestodes and turbellarians, to be placed in a separate class (Monogenea). The classification of the digeneans that has been used here is based on the development of the excretory bladder and associated structures. Such a scheme, however, clearly raises taxonomic problems of identification for species whose life cycles are not yet fully known.

Plautus

Little is known for certain about the life and personality of Plautus, who ranks with Terence as one of the two great Roman comic dramatists. His work, moreover, presents scholars with a variety of textual problems, since the manuscripts by which his plays survive are corrupt and sometimes incomplete. Nevertheless, his literary and dramatic skills make his plays enjoyable in their own right, while the achievement of his comic genius has had lasting significance in the history of Western literature and drama.

According to the grammarian Festus (2nd or 3rd century AD), Plautus was born at Sarsina, Umbria, in northeastern central Italy. He is customarily assigned the dates *c.* 254–184 BC. These dates, however, are largely based on statements made by later Latin writers, notably Cicero in the 1st century BC. Even the three names usually given to him—Titus Maccius Plautus—are of questionable historical authenticity. Internal evidence in some of the plays does, it is true, suggest that these were the names of their author; but it is possible that they are stage names, even theatrical jokes or allusions ("Maccus," for example, was the traditional name of the clown in the "Atellan farces," a long-established popular burlesque, native to the Neapolitan region of southern Italy: "Plautus," according to Festus, derives from *planis pedibus, planipes* (flat-footed) being a pantomime dancer. There are further difficulties: the poet Accius (170–*c.* 86 BC), who made a study of his fellow Umbrian, seems to have distinguished between one Plautus and one Titus Maccius. Tradition has it that Plautus was associated with the theatre from a young age. An early story says that he lost the profits made from his early success as a playwright in an unsuccessful business venture, and that for a while afterward he was obliged to earn a living by working in a grain mill.

Approach to drama. The Roman predecessors of Plautus in both tragedy and comedy borrowed most of their plots and all of their dramatic techniques from Greece. Even when handling themes taken from Roman life or legend, they presented these in Greek forms, setting, and dress. Plautus, like them, took the bulk of his plots, if not all of them, from plays written by Greek authors of the late 4th and early 3rd centuries BC (who represented the "New Comedy," as it was called), notably by Menander and Philemon. Plautus did not, however, borrow slavishly; although the life represented in his plays is superficially Greek, the flavour is Roman, and Plautus incorporated into his adaptations Roman concepts, terms, and usages. He referred to towns in Italy; to the gates, streets, and markets of Rome; to Roman laws and the business of the Roman law courts; to Roman magistrates and their duties; and to such Roman institutions as the Senate. Not all references, however, were romanized: Plautus apparently set little store by consistency, despite the fact that some of the Greek allusions that were left may have been unintelligible to his audiences. Terence, the more studied and polished playwright, mentions Plautus' carelessness as a translator and upbraids him for omitting an entire scene from one of his adaptations from the Greek (though there is no criticism of him for borrowing material, such plagiarism being then regarded as wholly commendable). Plautus allowed himself much other freedom in adapting his material, even combining scenes from two Greek originals into one Latin play (a procedure known as *contaminatio*).

Sources of the plays

Language. But even more important was Plautus' approach to the language in which he wrote. His action was lively and slapstick, and he was able to marry the action to the word. In his hands, Latin became racy and collo-

quial, verse varied and choral. Whether these new characteristics derived from now lost Greek originals—more vigorous than those of Menander—or whether they stemmed from the established forms and tastes of burlesque traditions native to Italy, cannot be determined with any certainty. The latter is the more likely. The result, at any rate, is that Plautus' plays read like originals rather than adaptations, such is his witty command of the Latin tongue—a gift admired by Cicero himself. It has often been said that Plautus' Latin is crude and "vulgar," but it is in fact a literary idiom based upon the language of the Romans in his day.

Themes of the plays

Plot. The plots of Plautus' plays are sometimes well-organized and interestingly developed, but more often they simply provide a frame for scenes of pure farce, relying heavily on intrigue, mistaken identity, and similar devices. Plautus is a truly popular dramatist, whose comic effect springs from exaggeration, burlesque, often coarse humour, rapid action, and a deliberately upside-down portrayal of life, in which slaves give orders to their masters, parents are hoodwinked to the advantage of sons who need money for girls, and the procurer or braggart soldier is outwitted and fails to secure the seduction or possession of the desired girls. But Plautus can also recognize the virtue of honesty (as in *Bacchides*), of loyalty (as in *Captivi*), and of nobility of character (as in the heroine of *Amphitruo*).

Verse. Plautus' plays, almost the earliest literary works in Latin that have survived, are written in verse, as were the Greek originals. The metres he used included the iambic six foot line (*senarius*) and the trochaic seven foot line (*septenarius*), which Menander had also employed. But Plautus varied these with longer iambic and trochaic lines and more elaborate rhythms. The metres are skillfully chosen and handled to emphasize the mood of the speaker or the action. Again, it is possible that now lost Greek plays inspired this metrical variety and inventiveness, but it is much more likely that Plautus was responding to features already existing in popular Italian dramatic traditions. The *Senarii* (conversational lines) were spoken, but the rest was sung or chanted to the accompaniment of double and fingered reed pipes. It could indeed be said that, in their metrical and musical liveliness, performances of Plautus' plays somewhat resembled musical comedy of the 1950s and '60s.

Influence. Plautus' original texts did not survive. Even by the time that Roman scholars such as Varro, a contemporary of Cicero, became interested in the playwright, only acting editions of his plays remained. These had been adapted, modified, cut, expanded, and generally brought up-to-date for production purposes. Critics and scholars have ever since attempted to establish a "Plautine" text, but 20th-century editors have admitted the impossibility of successfully accomplishing such a task. The plays had an active stage life at least until the time of Cicero and were occasionally performed afterward. Whereas Cicero had praised their language, the poet Horace, writing in the early years of the empire under its founder, the emperor Augustus, is a more severe critic and considered the plays to lack polish. There was renewed scholarly and literary interest in Plautus during the 2nd century AD, but it is unlikely that this was accompanied by a stage revival, though a performance of *Casina* is reported to have been given in the early 4th century. St. Jerome, toward the end of that century, says that after a night of excessive penance he would read Plautus as a relaxation; in the mid-5th century, Sidonius Apollinaris, a Gallic bishop who was also a poet, found time to read the plays and praise the playwright amid the alarms of the barbarian invasions. During the Middle Ages, Plautus was little read—if at all—in contrast to the popular Terence. By the mid-14th century, however, the humanist scholar and poet Petrarch knew eight of the comedies. As the remainder came to light, Plautus began to influence European domestic comedy after the Renaissance poet Ariosto had made the first imitations of Plautine comedy in the Italian vernacular. His influence was perhaps to be seen at its most sophisticated in the comedies of Molière (whose play *L'Avare*, for instance, was based on *Aulularia*), and it can be traced up to the present day—witness such adaptations as Jean Giraudoux's *Amphitryon 38* (1929) or Cole Porter's musical *Out of This World* (1950). Plautus' stock character "types" have similarly had a long line of successors: the braggart soldier of *Miles Gloriosus*, for example, became the "Capitano" of the Italian commedia dell'arte, is recognizable in Nicholas Udall's *Ralph Roister Doister* (16th century), in Shakespeare's Pistol, and even in his Falstaff, in Rostand's *Cyrano de Bergerac* (1897), in Bernard Shaw's Sergius in *Arms and the Man* (1894), while a trace of the character perhaps remains in Bertolt Brecht's Eilif in *Mother Courage and her Children* (1941). Thus, Plautus, in adapting Greek "New Comedy" to Roman conditions and taste, also significantly affected the course of the European theatre.

Influence on European domestic comedy

MAJOR WORKS

Twenty-one comedies (most dates uncertain) have survived: *Amphitruo* (*Amphitryon*); *Asinaria* (*The Comedy of Asses*); *Aulularia* (*The Pot of Gold*); *Bacchides* (*The Two Bacchises*); *Captivi* (*The Captives*); *Casina; Cistellaria* (*The Casket Comedy*); *Curculio; Epidicus; Menaechmi* (*The Two Menaechmuses*); *Mercator* (*The Merchant*); *Miles Gloriosus* (*The Braggart Warrior*); *Mostellaria* (*The Haunted House*); *Persa* (*The Persian*); *Poenulus* (*The Little Carthaginian*); *Pseudolus* (first produced 191 BC); *Rudens* (*The Rope*); *Stichus* (first produced 200 BC); *Trinummus* (*Three Bob Day*); *Truculentus; Vidularia*, fragmentary (*The Tale of a Travelling Bag*).

There is an English translation of all the extant plays in the "Loeb Series" (1916–38) and a French translation in the "Budé Series" (1932–40). Several of the plays have been translated in the "Penguin Classics Series." Many other translations of specific plays are available.

BIBLIOGRAPHY. Full bibliography is in G.E. DUCKWORTH, *The Nature of Roman Comedy*, pp. 447–464 (1952); a more recent but selective one may be found in MASON HAMMOND, ARTHUR M. MACK, and WALTER MOSKALEW, *Plautus: Miles Gloriosus*, rev. ed. pp. 59–66 (1970). Still fundamental are the collections of ancient evidence and the discussions in MARTIN SCHANZ, 4th ed. by CARL HOSIUS, *Geschichte der römischen Literatur I: Die römischen Literatur in der Zeit der Republik*, pp. 55–86 (1927); and the article "Maccius" by A.F. SONNENBERG in *Pauly–Wissowa Realencyclopädie*, vol. 14, col. 95–126 (1928). Useful is the briefer article "Plautus" by G.W. WILLIAMS in the *Oxford Classical Dictionary*, 2nd ed., pp. 843–844 (1970). In addition to Duckworth (above), a good account is in WILLIAM BEARE, *The Roman Stage*, 3rd ed. (1964). A standard text is that by M.W. LINDSAY, 2 vol. (1904 and reprints). The Loeb edition with English translation by PAUL NIXON, 5 vol. (1916–38 and reprints), unfortunately used the text of FRIEDRICH LEO, 2nd ed. (1895–96).

Playas, Pans, and Saline Flats

Playas, pans, and saline flats are the flattest of all landforms. Each owes its almost perfect flatness to periodic past and present inundation by water, and their surfaces appear similar for this reason. The processes that control their individual development vary greatly, however. They are ubiquitous features of arid and semi-arid environments, where evaporation greatly exceeds precipitation; consequently they are dry most of the time. Storm runoff or the flooding of coastal lowlands occasionally fills playas, pans, and coastal saline flats to shallow depths. Groundwater levels beneath them actively affect surface properties, especially the amount of saline minerals accumulated by evaporative concentration.

Definitions and general distinctions

A playa occupies the lowest area in a basin of interior drainage, usually consists of fine-grained sediment, and is dry most of the time. When flooded it is called a playa lake. Playa is the Spanish word for shore or beach, but in the English-speaking world it is now applied in a general sense to a wide range of topographic depressions and desiccated former lakes. Playa nomenclature is highly variable, often because of a range in both individual and regional characteristics. In North America, "salt flat," "salt marsh," "salt pan," "alkali flat," and "salina" may be used to describe a saline playa; a salt-free playa may be termed a clay pan, hardpan, dry lake bed, or an alkali flat. Playas are called lakes and pans in Australia, *takyr*s in the U.S.S.R., *sabkha*s in Arabia, and *kavīr*s in Iran. All are playas, but the terms used do not necessarily repre-

sent identical features, because geology and climate have varied with time in each locale, and the effects of these variations usually create distinctive attributes. Thus, terminology varies from place to place and within specific regions.

In South Africa, topographic depressions that periodically collect water and subsequently evaporate are called pans. Pans are generally smaller than playas, but the larger ones are equal to or greater in area than playas occurring elsewhere and that have had similar origins. Thus the terms pan and playa are used interchangeably by many authorities. Although differences do exist in playas in South Africa, they are essentially no greater than the variations that occur in other arid regions. Thousands of small depressions in the southern High Plains of Texas and New Mexico, and in Western Australia, are also termed pans by many.

Saline flats are located adjacent to coasts, shrunken inland lakes, and deltas and are usually topographically higher than the zone of tidal or lake fluctuation. They are flooded infrequently by storms or may fill to shallow depths from wave surges associated with storms. Saline crusts on the surfaces of such flats are very similar in appearance to those on saline playas. Barrier ridges often separate coastal saline flats from the open sea. These ridges have been formed by dune accumulation and, in some places, by the lowering of sea level. Saline flats extend for hundreds of miles along the coastal zones of North Africa, India and Pakistan, and the Persian Gulf.

Importance to man

Man has used playas and saline flats to his benefit for centuries. His need for salt in many areas has been satisfied only because of the existence of saline playas and coastal salt flats. Brine from several saline playas in California and Nevada contains potassium, borax, lithium, sodium, and magnesium, and these elements are extracted in commercially useful quantities. Following storms, playas and pans hold water and some ranchers in North America have constructed catchment channels and ponds for livestock watering. Persons hunt wild game that congregate at water-filled pans in Africa and Australia. The hard salt crust at Bonneville Salt Flats, Utah, has made possible construction of an automobile speed course, and several clay playas are designated as alternate aircraft landing fields. Playas have been considered for spacecraft recovery areas as well as sites for installing large phased-array antenna systems and for solar energy collectors. Numerous attempts have been made to use playas for agriculture but few successfully, usually because of excessive clay or salinity in the soil.

This article treats the physical characteristics and modes of origin of playas, pans, and saline flats and describes type examples from the western U.S., the Kalahari, the Persian Gulf area, and the Rann of Kutch in the Indian subcontinent. For further information on factors important in the development of these landforms, see WEATHERING; RIVERS AND RIVER SYSTEMS; CLIMATIC CHANGE; LAKES AND LAKE SYSTEMS; and WIND ACTION. See also EVAPORITES; and GEOCHEMICAL EQUILIBRIA AT LOW TEMPERATURES AND PRESSURES for relevant information on the kinds of surficial minerals that are formed by evaporative processes and the conditions of formation of these minerals.

PHYSICAL CHARACTERISTICS

Size, shape, and distribution. The smallest pans are measured in tens of feet, whereas the largest playas that were once permanent lakes measure tens of miles across and sometimes contain secondary depressions within a larger basin. Saline flats may be rather localized, extending across only a few hundred yards, but at their maximum development an uninterrupted length of several hundred miles, with widths of 20 miles (32 kilometres), is not uncommon.

There are probably about 50,000 playas and pans in the world, the greater majority being small deflation (wind-eroded) pans. Although large in number, they are small in area. Conversely, the largest playas are few in number and large in area. The number of playas in the world that exceed 25 square miles (65 square kilometres) in area is probably less than 1,000, and fewer than 100 are larger than 200 square miles (520 square kilometres).

The shape of playas is variable. Larger playas generally are oriented with the trend of the basin in which they occur. Smaller playas tend to be more nearly circular, but many of the smaller playas and pans have originated from deflation, and this may cause an orientation parallel to the strongest wind direction. It is highly unusual for playas to have length–width ratios that exceed 10:1; more typically a 2:1 or 3:1 ratio is observed. Playas resting on horizontal rocks tend to be more irregular in their shape, reflecting in part the regional drainage patterns. Saline flats are characteristically elongated parallel to shorelines, but this depends upon topographic and other variations.

Relation to flooding

Playas, pans, and saline flats owe their unique properties and geographic location to climate—specifically to flooding and to long periods of drought in between. They are almost exclusively situated in arid and semi-arid climates, but a small percentage are located in the dry side of adjacent climatic zones including tropical savanna, Mediterranean, and humid subtropical climates. Drained and desiccated lakes and elevated tidal flats are known to occur in polar regions, but they are not considered to belong in the same category of features. Distinction can be based on flooding ratios, wherein basins that contain water less than one-fourth of the time (and usually less than one-tenth) should be called playas. Lakes should contain water more than three-fourths of the time, and those intermediate between playas and lakes can be termed intermittent lakes. It is not unusual for average evaporation–precipitation ratios in the world's arid zones to exceed 10:1; this is the chief factor producing low flooding ratios and, in consequence, playas.

Host rock and thickness of deposits. Most playas, pans, and saline flats are floored with alluvium or unconsolidated sediment, but a few are rock-floored and some contain rock islands. Bedrock beneath playa surfaces is more likely to be sedimentary because flat-lying or gently undulating sedimentary deposits often favour playa formation. In a few areas, such as Jordan, basalt flows have served as dams and these have aided shallow-basin formation. The amount and thickness of sediments in playas and saline flats depend largely on whether the dominant formational processes and history have been depositional or erosional and on the position of the groundwater table.

Sediment thickness is not necessarily related to the age of the basin or to the rate of deposition. The 3,700-square-mile (9,600-square-kilometre) Lake Eyre (playa) in Australia, for example, contains silts and sands and evaporite deposits that are no more than 15 feet (4.5 metres) thick in places, and it has received sediment for about 80,000 years. High relief in adjacent highlands and the amount of precipitation are probably responsible for the greatest playa thicknesses. The total sedimentary fill in the basins of some former lakes in the western United States is more than 5,000 feet (1,500 metres) thick, and the Pleistocene (from about 2,500,000 to 10,000 years ago) lacustrine thickness can be as much as 1,000 feet (300 metres). Deflation pans in western Texas and southern Africa are typically shallow; many contain only a few feet of sediment, and bedrock is exposed in others. Because of the lack of a widespread pluvial (Pleistocene moist period) climate combined with a general lack of relief, the sedimentary sequences in the basins of North Africa are usually not deep. Areas of sand accumulation may be several hundred feet thick; interdune playas are often situated at the water table in these sand plains.

Surficial minerals, brines, and other materials. Playa surfaces display a range of composition and physical properties that is largely dependent on the basin origin and the hydrologic framework (precipitation, evaporation, and runoff). The depth and degree of circulation of groundwater controls the amount of capillary discharge (loss) occurring through the surface. The accumulation of evaporite minerals at the playa surface results from dissolved solids in the groundwater. The amount of clastic sediment (transported particles of sand, silt, and clay)

Importance of groundwater

is a result of prior lake sedimentation or of more recent infilling in the present environment. Clastic materials in playas are chiefly fine grain clays, silt, and sand, and these may contain carbonate that serves to bind them together.

Groundwater in arid basins follows several patterns. In northern and southern Africa, Australia, Central Asia, and Arabia it is common to have many playas or pans situated within regional basins that may cover thousands of square miles. In the United States, Iran, and Chile, smaller basins predominate, and the groundwater divides usually occur within the topographic basins. If the basin has no outlet, or if groundwater is near the surface, discharge will occur through the surface by evaporation and by transpiration from plants. Most playas and saline flats discharge some groundwater, but there are many places where there is no evidence for it; at these locations the groundwater depth is usually more than 50 feet (15 metres). These playas often contain admixtures of clay, silt, and carbonate, and there is evidence that fine-grained sediments inhibit groundwater movement.

The chemical quality of groundwater in arid basins varies greatly. Even though brines associated with saline-crusted playas are often saturated at the surface, potable water can usually be found underlying the alluvial fans and other sedimentary deposits not far from the playa. In some areas entire basins have no potable water, however.

Dissolved solid constituents have their sources in rock weathering, volcanic emanations and thermal springs, and pre-existing lake beds. It is possible to classify groundwater basins on the basis of the dominant anion (negatively charged ion)—*e.g.*, chloride, sulfate, carbonate. More attention has been given to saline mineralogy and solution geochemistry than any other aspect of playa geology, undoubtedly because of the value of agricultural, industrial, and household chemicals. Searles Lake, California (a playa), is well known for its 25 evaporite species, 10 of which were first discovered there in a natural state.

Evaporite zonation

Evaporite precipitation in a desiccating (drying) saline lake follows a solubility ordering and zonation; chlorides are the most soluble and preferentially occur in the pan or playa centre, followed by sulfates under and outside the chlorides, and carbonates deeper still and fringing the sulfates and chlorides. Other zonations that involve minor minerals also occur.

Saline flats have mineral assemblages similar to saline playas but can receive much of their brine directly from flooding by seawater during storms or unusually high tides. Saline flats receive an additional sediment source in the form of fecal pellets and guano, derived chiefly from nearshore bird populations. In a number of places this material is harvested for fertilizer.

Many authorities have attempted to classify playas according to their several characteristics; predominant sediment composition and basin hydrology have been used most often. It is desirable to know whether a basin discharges groundwater because this affects the surface properties of playas. Surfaces that appear on nondischarging playas also can appear on discharging playas, however, and this creates confusion. For this reason it is desirable to describe most playas individually and to qualify the more generalized, regionally occurring classes or types.

Surficial structures and textures. Hard, dry crusts result from the drying of fine-grained sand, silt, and clay admixtures and have little microrelief except for the occurrence of mud cracks, which are widespread. These surfaces are nearly always hard enough to support automobiles but when wet they become slippery, sticky mud. Because of the compact clay structure, floodwater is sometimes unable to penetrate more than a few inches downward. Drying mud often flakes and curls and is then more susceptible to deflation—removal by wind. The characteristic colour of these crusts is very pale tan, sometimes with tinges of pink. They are usually barren, but coarser sediments in or adjacent to them permit vegetative growth. A tendency for grasses to grow occurs in the cooler fringes of the semi-arid climatic zone.

Mud cracks and desiccation polygons

Mud cracks are widespread in desiccated fine-grained playa soil and form in saturated mud. Cracks intersect essentially at right angles to form a polygonal network that varies in size from a few inches to a foot across individual polygons. In some clay-rich playas that have undergone long-term drought periods, the depth of drying and sediment contraction is great enough to permit larger mud-crack polygons to form; the term giant desiccation polygon describes those up to 300 feet (90 metres) across, a yard wide, and 50 feet (15 metres) deep in individual cracks.

Soft, friable surfaces contain some salt at the surface as a result of evaporative concentration of groundwater that rises by capillary action. These surfaces normally have groundwater within 10 or 15 feet (3 or 4.5 metres) of the surface, but the important factor is salinity rather than depth of the water. Microrelief generally ranges from two to six inches, creating a puffy appearance resembling a plowed field. These surfaces have been termed self-rising ground in the U.S. and are called *solonchaks* in the U.S.S.R. Upon flooding, these surfaces can release much of their salt by dissolution and, upon drying, can form relatively salt-free surfaces.

Salt crusts and salt karst topography

Evaporite crusts are usually associated with near-surface groundwater levels and result from rigorous evaporative concentration. These glistening white crusts range from less than an inch to many feet in thickness. Some

authorities believe that the thicker crusts do not develop solely by evaporative concentration but may derive their salinity from the desiccation of pre-existing (pluvial) lakes. Where salt is thin the usual condition immediately beneath the crust is one of dark-brown sticky-wet mud. When salt is thick it may form rugged crusts, such as the "Devils Golf Course" on the playa floor near Badwater, Death Valley, California, or if flooded at regular intervals a smooth "racecourse" will form, such as the Bonneville Salt Flats, Utah. The crusts of saline coastal flats often originate from a combination of seawater flooding and of the evaporative concentration of saline groundwater adjacent to coasts. The thickness of salt is gradational in playas and saline flats; the greatest thicknesses tend to occur in the lowest portion of the depressions.

Salt crusts form expansion ridges that intersect in polygonal outlines that normally do not exceed a few feet, but giant forms have been noticed in unusually thick crusts, where the ridges are 2 feet (0.6 metre) high and 75 feet (23 metres) apart.

In the thicker salt crusts downward percolation of groundwater occurs where water tables are several feet below the surface or which fluctuate seasonally. Because of the high solubility of these crusts, dissolution occurs during percolation and a "salt karst" topography (a surface that is pitted by solution cavities) can develop on a small scale, leaving minor depressions as a result.

All of these surfaces are subject to change during flooding, and more than one, and sometimes all, may occur on a single playa. A distinct boundary between the surface types does not always exist and a considerable variety of surface types occurs. Despite these facts, they are much the same everywhere in the world.

Surface drainage occurs on playas, often in the form of small birdfoot deltas that extend inward from the periphery, and spread outward approaching the interior. Shallow channelways called grooves are common and at their maximum development are 50 miles (80 kilometres) long, for instance, at the Warburton Groove, Lake Eyre, Australia. Because of the flushing action of water the grooves are often salt free and hard most of the time and provide trafficable routes across many of the soft-surfaced playas.

Artesian (free-flowing) spring discharge on playas is common because the water table frequently slopes toward playas and because the relatively less permeable playa sediments cause the subsurface water to rise and flow near the playa margin. Both hot and cold springs occur and sediment and travertine frequently are deposited around them. Some of these spring mounds are relict features, but a number of them are still actively forming today.

MODES OF ORIGIN

Role of climate and climatic change. Climatic variation that occurred during the Quaternary Period (the last 2,500,000 years, approximately) of geologic time had great influence on the hydrologic regimen in the areas that contain playas, pans, and saline flats. Although continental glaciation during this period extended only to latitude 47° N in Europe and 38° N in North America, the effects from climatic change that caused the glaciation were noticeable far beyond the margins of maximum ice advance. Increased precipitation and cooler temperatures are generally thought to be responsible for the development of hundreds of pluvial lakes that existed in many parts of present-day arid zones. A pluvial lake is one that has had considerable, and usually periodic, fluctuation in lake level, and which may or may not contain water today. The pluvial lakes are restricted to arid region basins throughout the world, and all of them are believed to be of Quaternary age.

Pluvial lakes and the occurrence of playas today

Among the better known pluvial lakes are Lake Baikal and the combined Caspian-Aral seas in the U.S.S.R., the Dead Sea bordering Israel and Jordan, and Lakes Bonneville and Lahontan in Utah and Nevada. At its maximum extent, Lake Bonneville was nearly the size of Lake Michigan, but the modern remnant, Great Salt Lake, is only about 10 percent of its former size. South of Salt Lake City, Utah, Pleistocene glacial moraines (sedimentary deposits that formed at the margins of a glacier) that originated in the Wasatch Mountains extend beyond the old shorelines of pluvial Lake Bonneville. This suggests that some of the glacial intervals were synchronous with pluvial periods. Interpluvial periods existed with interglacial periods, and the climatic conditions of the intervals may have been similar to the modern climate.

Many playas and some saline flats that are adjacent to present-day lakes were the sites of these pluvial lakes, and the sedimentary record beneath several of them has been studied and dated by radiocarbon methods (see DATING, RELATIVE AND ABSOLUTE). Searles Lake, California, is among 120 pluvial lakes in the western United States, and it has been intensively cored and studied. Alternating layers of mud and salt correspond to pluvial and interpluvial periods and Recent (the last 10,000 years, approximately) time. These units record the former presence of two deep lakes followed by at least near-desiccation and evaporite precipitation. Radiocarbon dates on samples from these layers show that the more recent of the two pluvial periods lasted from before 23,000 to about 10,000 years BP (before present), and it was therefore contemporary with the Wisconsin stage of glaciation in the central and eastern U.S. The older pluvial sequence was well es-

tablished by about 46,000 BP and started to wane before about 32,000 BP.

A somewhat similar sequence of salt and mud layering has been discovered at the Masileh Kavīr, Iran, suggesting an alternating pluvial and interpluvial climate, but the layers have not been dated. It is possible that this occurrence represents more local conditions adjacent to the Elburz and Zagros mountains because there is little evidence for a marked pluvial period in most of Iran. The numerous playas in pluvial lake basins in western North America at one time prompted speculation on similar correlations in other regions. Studies of pluvial lakes and past climates in other regions have failed to show a general scheme of climatic fluctuation that is acceptable in more than one region.

Meteorological variations in North America

The worldwide occurrence of pluvial lakes did not depend entirely upon runoff or on glacial meltwater but rather on the combined effects of local and secular variation of temperature, precipitation, wind, and the seasonal distribution of each, which together regulate the hydrologic balance. Most of the world's pluvial lakes were situated beyond the drainage of glaciers and were thus hydrologically unrelated, although exceptions did exist. Precipitation and temperature variation during the pluvial periods change considerably from one region to another. Studies of pluvial lake environments in western North America have suggested precipitation increases of about seven to nine inches (18 to 24 centimetres) and temperature reductions of 5° to 9° F (3° to 5° C), relative to modern values. The last true pluvial period occurred during Wisconsin time, reaching maximum development about 20,000 years BP. Minor climatic fluctuations have occurred since the last major phase and will continue to occur in the future. About 5,000 years BP a period of slightly higher temperature and increased wind activity is thought to have occurred. Many deflation pans in western Texas probably formed at this time.

During the last hundred years glacier advances have been observed in the western U.S., concurrent with a rise in levels of some enclosed lakes in Oregon and Washington. Climates since 1850 are thought by many to have become warmer, with less precipitation and greater evaporation. The drying up of several permanent lakes during the past 100 years may be related to arid conditions that followed the "little ice age," a widespread period of renewed glacial activity that lasted from about 1650–1850. These short-term fluctuations are not true pluvial episodes, but nonetheless they have important local effects on basin hydrology and geologic processes. Playas and pans are sensitive to meteorological variations of even small magnitude, and the longer term events associated with and following the Pleistocene glaciations have profoundly affected their emplacement.

Role of tectonism. Tectonism, or movements of the earth's crust, affects proportionately few playas as a dominant playa-forming process, but those that are affected include the larger ones; thus the total area involved is great. There are noticeable effects of tectonism that probably influence all playas to some extent. The very existence of many regional desert basins depends on mountain barriers, which essentially reflect the global tectonic framework. Individual basins in Nevada, Iran, Chile, and elsewhere are down-dropped, fault-block basins or grabens, and in some places they are associated with volcanism. It is the relief of the adjacent mountains combined with precipitation that provides the sedimentary framework for the thick lacustrine (lake bed) sequences in many of these basins. Large regional basins in North Africa, Central Australia, and the Dasht-e Kavīr of Iran have resulted from regional downwarping and faulting and folding. Coastal warping and uplift undoubtedly have been responsible for the initial formation of some coastal saline flats.

Association of faults, earthquakes, and springs

Faults transect numerous structurally controlled playas in the western U.S., Iran, Chile, and Australia and are represented by low scarps (ledges) and hydrologic effects in the form of springs and wet zones marked by vegetation. Earthquakes and active faulting occur in Nevada, and hot springs deposit travertine at several locations.

Pleistocene Lake Bonneville reveals tilted shorelines today, showing that the weight of water in the largest pluvial lakes was capable of depressing the crust of the earth. Isostatic rebound, the recovery of the crust from this load following lake desiccation, is still going on today, and it is estimated that it is 75 percent complete after some 12,000 years. The crustal depression of Lake Bonneville was more than 200 feet (61 metres) in the basin centre, where the water was about 1,100 feet (335 metres) deep. This process demonstrates that large basins can effectively perpetuate themselves by further deepening their basin once they have achieved a certain size.

Role of wind action. Wind has an important role in at least four aspects of playa and saline-flat development: (1) the initial depression-forming processes; (2) modification and orientation of the shapes of basins; (3) removal of sediments by deflation; and (4) depositional features leeward of deflated playas and saline flats.

Wind is a universal agent that seems to have affected all playas to some degree. It may be the principal agent of small basin formation in West Texas and the Kalahari. There are more than 20,000 of these basins—large in number, but small in total area compared with larger playa basins. Many of the larger basins in the Sahara, South Africa, and Australia are thought to have had considerable material removed by deflation, perhaps at an early stage in their development.

A principal role of wind that occurs during flooding on playas and saline flats lies in assisting water as a levelling agent. It agitates the water and increases its capacity to hold and move suspended sediment. It moves water in sheets and piles it up in local concentrations, regardless of level. Dissolved salts can be removed from playas by this process; Harper Playa, California, was effectively washed clean in this manner. Prior to flooding its surface was soft and friable and contained substantial amounts of salt, but upon drying a hard, dry crust appeared.

Dispute regarding the importance of deflation

There is lack of agreement in many regions on the relative importance of deflation on playas. It is known that the amount of wind erosion ranges widely over the world and that it is controlled by aridity and the intensity of local winds. Danby Playa, California, has been described as an example of a playa that has had approximately ten feet (three metres) of sediment removed by deflation. Estancia Valley, New Mexico, contains numerous deflation pans that experienced wind erosion in the past. In the Sahara the evidence is often more direct and widespread.

Once barrier ridges are formed and tidal salt flats are isolated from the sea, wind becomes an important agent of change. As material is deposited by sedimentation and evaporative concentration of groundwater, wind serves to carry it away, thus destroying marine constructed features.

Sand dunes in the Kara-Kum and Kyzyl-Kum deserts of Turkistan are interspersed with depressions (playas) that are frequently saline and that are similar to widespread areas of interdune playas in many other areas, including the Algerian Sahara, the Dasht-e Lut desert of Iran, and western Rhodesia. They usually have a linear orientation and are small, but a few are a mile long and a half mile wide. Wind action is essential in the formation of these playas, but a near-surface water table is present in many of them, serving as a base level (lower limit) of deflation.

Many playas in Australia and the United States exhibit transverse crescentic foredunes called lunettes on their leeward side and may contain substantial amounts of silt and clay. Similar features are forming today along the saline flats of the Gulf Coast of Texas and have been termed clay dunes. Their widespread occurrence in association with playas and saline flats, and yet general inactivity at present, has caused several researchers to believe that many are relict features, possibly representative of a drier and windier period during earlier Quaternary time.

Some elongated lakes can be oriented perpendicular to the winds that produce them. In the development process, winds blowing across shallow circular lakes produce 90° longshore currents that have maximum erosive power at the lake ends.

At many playas vegetation serves as a windbreak and sand accumulates on the lee of the plants. Often the

vegetation will continue growing, thereby perpetuating the sand-accumulation process and forming conical mounds up to 20 feet (6 metres) high. The roots of the plants frequently extend downward to phreatic (subsurface) water; thus the term phreatophyte mounds has been coined to describe these features.

Summary of occurrences and origins. Playas, pans, and saline flats have similar surface characteristics; they are extremely flat because of flooding and usually consist of fine-grained sediment, or evaporite minerals. The resemblance is superficial because great variation exists in basin origin, sediment thickness, and hydrologic balance, each lending individual or regional character to them.

Larger playas usually were associated with pluvial periods during Pleistocene time; the runoff often depended on nearby mountain precipitation sources, and it was responsible for increased basin sedimentation. Structural warping and faulting created the basins for many of these lakes. Ancient river systems have been responsible for the initial location of numerous playas and pan systems. Past climatic fluctuation has affected nearly all playas and pans to some degree. Most important were the pluvial and interpluvial periods of the Wisconsin stage, and subsequent postglacial events. Deflation occurred on many pans and small playas at this time. A combination of processes, including solutioning and animal wallowing, is locally important. The amount of capillary discharge and the depth and salinity of groundwater are especially significant in controlling the evaporite buildup in all playas. Coarser grained playa sediments tend to increase capillary discharge.

Coastal saline flats have originated as depositional features that have been cut off from the sea by sand-barrier ridges, by reef building, or by coastal uplift. The slight elevation of some coastal flats, such as the Sirte Gulf of Libya, is believed to have resulted from recent sea-level oscillations, where at high-water stands these features were shallow bays or lagoons. Although similar to playas in many respects, saline flats are much less stable features of the landscape because of their precarious location.

Current uncertainties and gaps in knowledge

Several aspects of playas, pans, and saline flats remain poorly understood. Very few of these features have been explored beneath the upper few feet. Knowledge of the depositional sequence and chronology contained in the sedimentary record would provide detailed knowledge of past and present climates and ultimately help to predict future trends. Age dating of sediments and analysis of evaporites is required to correlate absolute age with the depositional environment and to reconstruct late Pleistocene history and the worldwide variation in climatic change. More regional information on playa basins, surface conditions, and hydrologic factors would help in understanding changes through time and their cause.

TYPE EXAMPLES

Playas of the western U.S. Arid-land specialists have remarked that the U.S. arid zone is atypical in comparison to other deserts of the world. A chief reason for this difference is that mountain precipitation sources are so close to the arid basins that runoff is greater, lessening the geologic impact of aridity. Consequently, western North America had the greatest concentration of pluvial lakes during Pleistocene time. It has much less sand than most deserts and less evidence of wind activity. During the Pleistocene, south of about latitude 34° N, the amplitude of climatic change showed a marked decrease because of increased distance from the belt of westerly storm tracks. This fact, in combination with higher temperatures at more southerly latitudes, resulted in reduced pluvial lake fluctuation. For this reason the Mojave Desert shows less evidence of pluvial lake development than Nevada, but at the same time more sand and consequent wind activity. Searles Lake derived its pluvial lake water from overflow of the Owens River system, which originates in the high Sierra Nevada. There are some 300 playas exceeding five square miles (13 square kilometres) in the Basin and Range Province, which covers western Utah, Nevada, southern Oregon, Idaho, and Wyoming and extends into California, Arizona, and New Mexico. Because the majority of these playas were formerly pluvial lakes, the thickness of sediments is great. The pluvial history of Searles Lake shows that more than 800 feet (240 metres) of sediment were deposited over a period of some 100,000 years.

More than half of the U.S. playas contain hard, dry crusts, which is a higher ratio than that occurring elsewhere. This is partly the result of thick lacustrine sediment sequences that help retard capillary discharge, because of interbasin circulation of groundwater in some places, and because of periodic flooding that helps wash away saline accumulations. Man's intensive use of groundwater has affected playa surfaces in many basins; lowered groundwater levels and reduced capillary discharge have been one result. Subsidence of basins and the occurrence of giant desiccation polygons are other effects that have been observed.

The thousands of deflation pans on the southern High Plains are different in origin than Basin and Range playas and are more similar to the pans of the Kalahari. A number of workers believe that U.S. playas are essentially in equilibrium, with deposition and deflation being nearly equal.

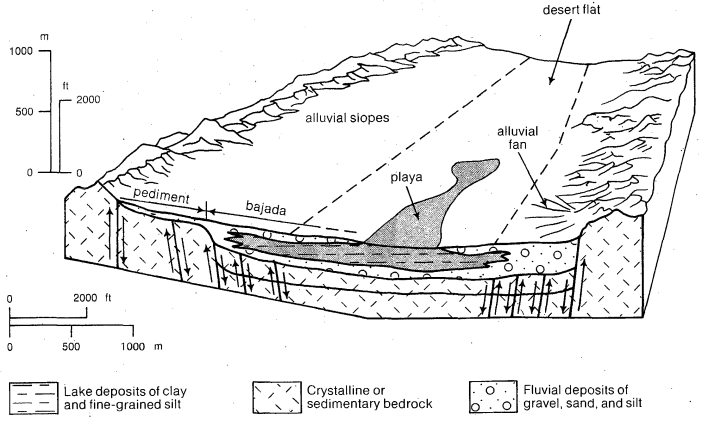

Figure 1: A typical playa in the Basin and Range region showing the nature of the deposits and related features.

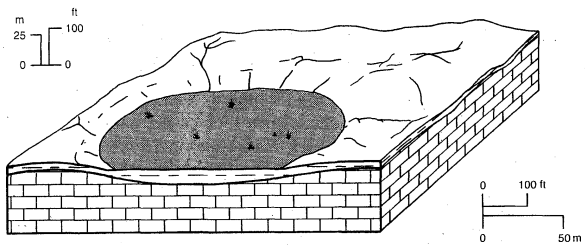

Figure 2: Deflation pan, representative of the Kalahari, southern Africa, and of western Texas.

Kalahari pans. The Kalahari region of southern Africa is a gently undulating plain, elevated 3,000 to 3,600 feet (900 to 1,100 metres) above sea level. Much of it is covered with sand and has a vegetative cover of trees, grasses, and scrub. Sand dunes are inactive, and movement occurs only where vegetation has been destroyed.

There are some 10,000 pans over 100 yards (90 metres) across in the Kalahari south of the Okavango and Zambezi rivers. The flat-floored depressions vary considerably in their extent and may lie 50 feet (15 metres) or more below the surrounding plain. They are not peculiar to the Kalahari but more are located there than in the rest of South Africa. There are several varieties of pans: (1) large pans like Haakschein Vley that are 80 square miles (210 square kilometres) and more; (2) sand pans a mile (1.6 kilometres) or more across, but often smaller; and (3) smaller limestone pans. The first group contains shallow sandy mud situated on sandstone or shale bedrock, whereas the sand pans in sandy terrain may overlie several hundred feet of sand. Limestone pans are apparently

Varieties of pans and relation to former drainage systems

peculiar to the Kalahari and are smaller than the others; sandy limestone is usually encountered within a few feet of the surface. A considerable amount of variation exists in all of these pans; many are saline, or grass covered where salinity is low.

Wind erosion is thought to have played a prominent role in the formation of the larger pans, and sand and interdune pans, but it is also essential that an initial topographic depression existed. It is believed that the majority of these Kalahari pans are aligned along sand-covered ancient drainage systems. Limestone pans are generally smaller and may originate in animal wallows where groundwater fluctuates near the surface during alternating wet and dry seasons. A combination of processes seems to be involved in the formation of most of the Kalahari pans.

The Makgadikgadi Depression in Botswana is not a single basin but rather a series of salt pans within a larger basin that measures some 110 by 60 miles (117 by 96 kilometres). The larger region of internal drainage covers about 200,000 square miles (517,998 square kilometres) and includes the basin of the Okavango River. Numerous fossil river valleys, termed *mokgacha* locally, lead into the depression. The margins of the basin pass gradually from grassland and isolated pans to panland with grassy islands, and finally to unbroken pan in the interior. The main floor is not completely level, and the interior pans occupy the lowest part of an area of internal drainage. Artesian springs are seen in the depression and probably originate in higher ground to the north. The depression is structural in origin and is deflated to some extent by easterly winds during the dry season. Little deposition is occurring at present because the Okavango River deposits its sediment in the marshes of Ngamiland.

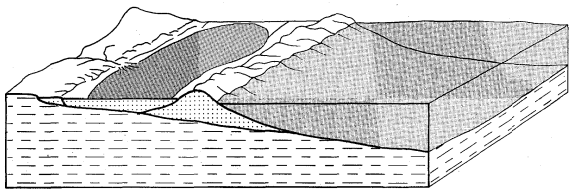

Figure 3: A coastal saline flat separated from the open ocean by a barrier ridge of dune sand.

Saline flats of the Persian Gulf and the Rann of Kutch. The saline flats that border most of the Persian Gulf coast of Abu Dhabi, a sheikhdom of the Trucial States, are known locally as *sabkhas*. These flats extend a distance of almost 200 miles (322 kilometres) and are nearly 20 miles (32 kilometres) across at their widest part. The flats stand just above the normal high-tide level and are everywhere bordered on their landward side by low bluffs of Tertiary (2,500,000 to 65,000,000 years ago) and Quaternary rock exposures. On the seaward side the *sabkhas* face broad intertidal flats, and in some places lagoons. Outside the outer beach ridge, the upper parts of the intertidal flats resemble the *sabkha* surface. Storms may create new beach ridges and cut these *sabkha* flats off from the sea. Low linear ridges cut much of the *sabkha* plain and provide vehicle routes across an otherwise treacherous surface. They are undoubtedly old beach ridges and often consist largely of gastropod shells, similar to many of the present outer beach ridges. Some parts of the outer coastal ridge system are capped by low dunes; when these are breached during storms with concurrent high tides, much of the *sabkha* plain can be covered with water.

The barren *sabkha* surface is often encrusted with salt up to several inches thick, and gypsum crystals and anhydrite nodules can be seen projecting from the surface, indicating that deflation is operative. In places Quaternary limestone is exposed just beneath the surface, but elsewhere the sediment is much thicker. The Tertiary and Quaternary limestone inland provides the source of the unconsolidated sediment, which is predominantly carbonate, with minor amounts of quartz.

Some authorities believe that the *sabkha* plain is very young and, because it shows no major breaks in level across its width, that it has not experienced a change in sea level during its development. Its outward growth is the result of extensive and prolonged intertidal flat sedimentation, together with chemical deposition and the growth of calcareous organisms. The Rann of Kutch in northwestern coastal India (Gujarāt state) is an area of extensive tidal mud flats and salt flats that are periodically inundated by seawater. It extends inland from the coast for a distance of about 250 miles (400 kilometres), with an average width of about 50 miles (80 kilometres). Much of the "Great Rann" and the extensive lowland at the eastern end of the Gulf of Kutch known as the "Little Rann" contain local saline efflorescences and salt crusts that range in elevation from sea level to 10 or 12 feet (3 or 4 metres) above sea level. Together, the Great Rann and the Little Rann comprise a saline flat desert 9,000 square miles (23,300 square kilometres) in area. The Rann of Kutch is a remnant of an arm of the sea that previously connected the Narmada Rift with Sind and separated Kutch from the mainland.

The Rann is mostly covered with water and is virtually impassable to any type of vehicular traffic during the southwest monsoon, but when dry much of it will allow some traffic by drivers who are aware of its dangers. These routes must generally follow the higher elevations, as the lowest parts of the Rann remain flooded throughout the year. Saline areas are usually avoided, but when a salt crust is thick or dry enough it may be trafficable. Everywhere groundwater is within a few feet of the surface and it is saline. Vegetation is practically absent, except in a few areas that are slightly raised and less saline, or which are naturally favourable for mangrove growth or salt-tolerant plants.

Pleistocene Epoch

The sixth of the seven epochs that constitute the Cenozoic Era of geologic history (the last 65,000,000 years), the Pleistocene immediately antedates the most recent or Holocene Epoch (*q.v.*). The time boundaries are not fixed precisely, but the Pleistocene is believed to have begun about 2,500,000 to 3,000,000 years ago and to have ended about 10,000 years before the present time. Although originally defined in 1839 as the time when certain marine strata containing fossil mollusks were deposited, the Pleistocene Epoch also was a time during which extensive ice sheets and other glaciers formed repeatedly on the lands. For that reason it was long informally called the Ice Age. It is now evident, however, that large glaciers formed on the Antarctic Continent, Arctic North America, and possibly other areas as early as 10,000,000 to 13,000,000 years ago, in the later part of Miocene time. Following an unknown number of fluctuations of these "early" glaciers, ice sheets developed over vast areas of northern and middle-latitude North America and northwestern Eurasia. This invasion of middle latitudes seems to have occurred within the Pleistocene Epoch proper. It was followed by the melting away of the ice sheets and their later renewal, an oscillating process that occurred several times. These events, evidently responses to fluctuation of the earth's climate, are widely known as glacial ages and interglacial ages. The Pleistocene Epoch is frequently referred to as the Glacial Age, and the usage is reasonably accurate when large ice sheets extending into middle latitudes are implied. Earlier gla-

Glacial and interglacial ages

cial ages, however, resulted from earlier climatic fluctuation and were characterized by the presence of numerous glaciers in higher latitudes.

Although the spreading of glaciers, including large ice sheets, was a conspicuous result of climatic fluctuation during the Pleistocene, it was accompanied by other results of great importance. Among these were notable fluctuations of the level of the world ocean, the creation of temporary lakes in regions that today are dry, and changes in the composition and areal ranges of plants and animals, both on the lands and in the ocean. In addition, the earth's crust subsided to considerable depths beneath the loads created by the spreading ice sheets. In high latitudes the ground froze deeply and remained frozen through entire glacial ages. The great natural process of erosion of rocks and deposition of sediment was temporarily altered in a number of ways. All these changes were directly or indirectly the result of changes in the world's climate during the Pleistocene. This article describes these direct and indirect effects of Pleistocene glaciation and climatic change. For additional detail on the earth processes and features involved, see CLIMATIC CHANGE; ICE SHEETS AND GLACIERS; GLACIATION, LANDFORMS PRODUCED BY; PERMAFROST; LAKES AND LAKE SYSTEMS; RIVERS AND RIVER SYSTEMS; COASTAL FEATURES; WIND ACTION; SOILS. See also TERTIARY PERIOD and HOLOCENE EPOCH for allied information on the previous and subsequent intervals of geological time, and CENOZOIC ERA for a general overview of the last 65,000,000 years of earth history.

PLEISTOCENE CHRONOLOGY

The framework of Pleistocene events has been determined primarily from sequences of strata, deposited in many different environments, that contain assemblages of fossils and bear absolute dates measured by a variety of methods (see DATING, RELATIVE AND ABSOLUTE). The study and dating of Pleistocene strata is in progress in all countries but is farthest advanced in parts of North America and Europe. An example of the accumulated information is the generalized succession of Pleistocene tills (direct glacial deposits) recognized in the Sierra Nevada, California (Table 1), each till representing a glacial episode. Some of the tills are separated from adjacent ones by ancient soils, and others by volcanic sediments. They have been dated by various means and the dates given represent varying degrees of uncertainty. Each indicates an episode, or a longer period, when glaciers in the Sierra Nevada region were much larger and more extensive than they are today.

Table 1: Chronology of Glacial Deposits in the Sierra Nevada, California

glacial till	approximate date in years BP* (uncertainty increases downward)
Hilgard Till	10,000
Tioga Till	
Tenaya Till	20,000
Tahoe Till	50,000
Mono Basin Till	80,000
Donner Lake Till	200,000 to 500,000
Sherwin Till	750,000
McGee Till	1,500,000
Deadman Pass Till	3,000,000

*Before present.

North American sequences

In central North America, from the Appalachians through the Great Lakes region to the Great Plains, extensive and detailed sequences of strata have been studied and described. These strata represent a succession of major glaciations by an ice sheet; the glaciations have been identified, and each is named after the state in which it was first clearly recognized (Table 2).

The Wisconsin major glaciation occurred in at least three pulses or stades, separated by interstades during which the ice sheet shrank. Each of the three earlier major glaciations was likewise multiple and so consisted of stades, but less is known of their number and their dates; hence, their local names are not included in the Table. The sediments representing each major glaciation are separated from the layers overlying them by ancient soils or by sediments of nonglacial character, some of them containing fossil organisms that imply temperate rather than glacial climate. The intervals corresponding to such features are interglaciations or, simply, interglacials.

The late Wisconsin Stade in central North America began some 25,000 years ago, reached its maximum some 15,000 to 20,000 years ago, and ended around the end of Pleistocene time, although remnants of the ice sheet persisted in Canada until after 7000 BP (before present, where present means AD 1950). During this glaciation most of the deposits and other features were formed that led 19th-century geologists to recognize the extent of glaciation in North America. The middle Wisconsin Stade can be placed near 50,000 to 40,000 BP in round numbers, and the early Wisconsin Stade around 70,000 to 60,000 BP, although with more uncertainty. Between the times of these glacial events, climates were cooler than those of today, as indicated by the fossil pollen of plants that constituted the vegetation.

In the central region there has been no direct measurement of the age of any of the older glacial sediments, so that time comparison of the sequence as a whole with that in the Sierra Nevada is not yet possible. In most places Nebraskan sediments unconformably overlie much older rocks, no strata from the preceding epoch, the Pliocene, being present, so that direct evidence of the position of the Nebraskan relative to the Pliocene is lacking. On indirect evidence, however, the Nebraskan Glaciation is supposed to belong within the Pleistocene Epoch, and on very indirect reasoning a tentative age of around 700,000 years has been suggested for it.

The Pleistocene units in central North America are grouped, on the basis of their content of fossil mammals, into the three mammal ages, shown in Table 2. These

Table 2: Chronology of Glacial and Interglacial Episodes in Central North America

approximate date (years BP)	glaciations		interglaciations	mammal age
10,000				
20,000		late

	Illinoian			
			Yarmouth	Irvingtonian
	Kansan			
			Aftonian	
700,000?	Nebraskan			Blancan

same ages have been identified in Pacific North America, although not in the Sierra Nevada, because the tills are not in contact with strata that contain fossil mammals. The Blancan Mammal Age reaches much farther back in time than the Nebraskan Glacial Age is thought to do. The latter age may have begun less than 1,000,000 years ago. Potassium-argon dates suggest that the Blancan Mammal Age may have begun perhaps as long aso as 4,000,000 years BP.

European sequences

Sequences representative of those developed in Europe are set forth in Table 3, in which interglaciations and temperate-climate layers are italicized. A somewhat similar sequence of glacial deposits is recognized in the Alps region in Europe but is insufficiently well known and insufficiently controlled by dates to be represented in a comparable table. These sequences are more complicated than those in North America. Most of the units designated as cold-climate units include glacial sediments and therefore clearly indicate glaciation. Some, however, record merely low temperature, through the kinds of fossils (mostly of plants) they contain. The temperate-climate units are identified principally through their fossils.

In the two western European columns in Table 3, the lowest units directly overlie, in places, strata of Pliocene age, and so are clearly of lower Pleistocene age. Based on

fossil evidence, chiefly fossil mammals, the units are grouped into lower, middle, and upper Pleistocene categories. Indeed, fossil mammals are a chief means of correlating the temperate and even the glacial units between one part of Europe and another.

*Correlations, particularly in the lower part of the sequence, are uncertain and provisional. †Marine units.

The dates of the youngest major cold-climate unit, the Weichsel/Valdai, fall within the last 70,000 years and so are comparable with the Wisconsin unit in North America. Like that unit, the Weichsel/Valdai includes repeated periods of low temperature, although the details of its earlier part are still obscure. The time relationships are inadequately fixed by absolute dates, although the relationship of the base of the sequence to the Pliocene strata is more evident than it is in central North America.

Although lower Pleistocene and Villafranchian are regarded by some authors as synonymous, the latter is properly a mammal age, like the Blancan in North America. Radiometric dates, however, suggest that the Villafranchian does not reach as far back in time as the Blancan does. It may have begun only some 3,000,000 years ago.

PLEISTOCENE CLIMATES AND CLIMATIC CHANGE

Snow lines and lake levels. Although the former presence of great glaciers in middle latitudes is perhaps the most obvious evidence of cold Pleistocene climates, less conspicuous indications likewise show convincingly that cold climates prevailed. One of the most widespread concerns the snow line, the elevation above which snow and ice remain on the ground throughout the year. Plots of the altitude of the snow line during glacial ages, measured in various ways, reveal that it was everywhere lower than is the snow line of today. The plots indicate further that the two snow-line positions are broadly parallel, although the vertical distance between them is greater in middle than in very high latitudes, and is greater in moist rather than dry regions. In moist middle latitudes the vertical interval between former and modern snow lines amounts to between 1,000 and 1,500 metres (3,300–4,900 feet).

Temperature differences

Although there exists no precise way of determining the related temperature difference, the opinion that the glacial-age summer temperatures were 5° to 7° C, or more, below those of today is rather widely held. If today's temperatures in southern Norway were lowered by only half that amount over a long period, it is believed that the resulting growth of glaciers would again cover that country with an ice sheet.

Another indication of the colder climates of glacial ages is provided by the existence of former lakes. Saline lakes and saline flats that today occupy basins in the world's dry regions are surrounded by abandoned beaches and other shoreline features. Such features demonstrate that larger lakes formerly occupied the basins, some of them to great depth, and that a different climate must have prevailed when the lakes existed.

Oxygen isotope ratios. Further indication of Pleistocene climatic fluctuation has been derived from a core of glacier ice, bored from the Greenland Ice Sheet in 1969. The water vapour in the atmosphere contains two isotopes of oxygen, ^{16}O and ^{18}O. The ratio between these two isotopes depends on the temperature at which atmospheric moisture condensed to form falling snow. In the region where the snow fell, changes in this ratio, from layer to layer in fallen snow preserved through many years, should therefore reflect changes in atmospheric temperature through those years. The isotope ratios from the core of the whole thickness of the northern part of the Greenland Ice Sheet yield a curve with variations that are similar to those constructed from other climatic data from North America and Europe. In 1970 analogous measurements in a core from the Antarctic Ice Sheet produced compatible results. Although these measurements demonstrate fluctuation of climate in very high latitudes, they do not reveal the absolute amount of fluctuation at any given place.

Measurement of the $^{18}O/^{16}O$ isotope ratio in sediment cores obtained from beneath the ocean floor in low latitudes gave results from which curves were plotted as early as 1955. The substance measured was carbonate, from the shells of planktonic Foraminifera that accumulated year by year on the ocean bottom. The ratio depends on both temperature and the isotopic composition of the seawater from which those organisms secrete carbonate. The curve shows changes between warm and cold times, and in that respect it resembles broadly the curves developed from the ice cores. It does not, however, discriminate between changes in temperature of seawater and changes in isotopic composition of the water. Isotopic measurements of sediment cores, therefore, do not give independent temperature data.

Faunal and floral evidence. Another indication of Pleistocene climatic change, likewise derived from analysis of cores from beneath the ocean floor, consists of changes in the proportions of constituents of fossil microfaunas between one layer of sediment and another. Many groups of planktonic species can be labelled warm, transitional, or cold according to their areal distribution in the oceans today. When cold faunas systematically occur as fossils in a particular layer, in cores from lower latitudes in which only warm elements live today, it can be inferred that when the fossil fauna was living the temperature was lower than it is now. Applied with proper techniques, this principle has yielded results that agree broadly with temperature data derived from other sources.

Microfauna as index of climatic change

A different kind of temperature indication is obtained from counting and estimating the absolute numbers of individual fossil planktonic organisms in particular layers within a core. In many parts of the ocean the numbers of such organisms decrease with decreasing temperature, and a decrease therefore indicates a colder climate. In certain areas, however, numbers increase with increased nutrients, brought to the surface in greater amount by more rapidly upwelling cold water during glacial ages. A curve developed from a series of such measurements on a seven-metre core from the eastern equatorial Pacific shows pronounced fluctuations, which are of greater amplitude in the upper than in the lower part of the section. The fluctuations probably were climatically caused, but because they are not dated radiometrically they cannot yet be compared closely with climatic changes inferred from features on land. When such comparison can be made, curves from long sea-floor cores will be especially useful, because in many of them the sediments were deposited continuously. Continuous sedimentation represented in cores taken from land areas is less likely because the processes of erosion on land are everpresent.

The Pleistocene sediments of the land as well as those of the ocean contain fossils from which important climatic data are extracted. The fossils include both plants and animals, but the data most suitable for the interpretation of former climates are derived from fossil pollen that

Analysis of fossil pollen

accumulated in lakes and bogs. The kinds of vegetation that flourished in the vicinities of such places, compared with the distribution of similar kinds that are living today, supply sensitive information about former climates. It has been found that in glacial ages, in Eurasia and North America at least, distinctive groups of middle-latitude plants lived somewhat nearer the Equator than their counterparts do today, and in mountainous terrain they lived at lower altitudes. The inference that temperatures were then generally reduced is obvious. Where the inference can be quantified, it appears that the amplitude of temperature reduction is roughly comparable with that calculated independently from snow-line altitudes—specifically, a few degrees Celsius.

In the regions overrun by former ice sheets, many of the pollen data come from exposures of interstadial and interglacial sediments sandwiched between layers of till or other sediments of glacial character. Beyond the limits of the former ice sheets, data have been obtained from long cores taken from thick sediments deposited in lakes and bogs. Such sediments, unlike those in the glaciated regions, may represent deposition that was continuous throughout the latest major glaciation, and perhaps through an even longer time. The longest cores of this kind have been taken from lake sediments in southern Spain and in Macedonian Greece and are dated radiometrically, back through about the last 50,000 years.

The most basic result of the comparison of curves derived from pollen data is that most of the curves are similar. This similarity strengthens the inference that changes of climate have occurred in similar succession throughout wide regions—at least in the Northern Hemisphere, where most of the existing data have been derived.

Another important source of climatic inference consists of fossil land mammals, collected systematically since the 18th century. In the 19th century it was realized that the nature of some of them implied climatic differences. Pleistocene fossil mammals furnish a routine basis for climatic inferences today, however, and much has been learned from them. Land mammals are a less sensitive indicator of environment than plants because they are able to withstand a wider variety of environmental influences. In consequence the value of fossil mammals largely lies in confirming the environmental data provided by the more sensitive fossil plants, especially in the form of pollen. Such confirmation is abundant, and few conflicts in testimony from the two sources have appeared.

Fossil invertebrate land animals also have played a part in the reconstruction of Pleistocene environments. Nonmarine mollusks, for example, have proved important in the discrimination between forest and steppe in central and eastern Europe, a distinction closely related to the change between interglacial and glacial climate. Insects, too, are useful, partly because they are very sensitive to temperature and respond promptly to a change of climate by migration.

Relict frost-climate features. Among other kinds of widespread evidence from which Pleistocene climates have been inferred are frost-action effects. In many areas such features are comparatively obscure; nevertheless close study of them has produced informative results.

Frost-wedged debris and cave rubble

Debris created by frost wedging of rocks is one widespread effect. The debris forms taluses (sloping masses of unconsolidated fragments), block fields, and other patchy mantles on the land surface, especially in moist climates in which freeze-and-thaw occurs frequently. Although forming today at high latitudes and altitudes, frost-wedged debris occurs also in an inactive state in lower positions. Its relict character is attested by direct measurement as well as by its state of weathering and by the growth of lichens on it. In Europe relict taluses occur as far south as Gibraltar. In the western United States most taluses in the south are inactive, but toward the north taluses increase in size and abundance. It is thought that former colder, moister, glacial-age climates, reflected in the pluvial lakes of that region, promoted frost wedging that today is decadent.

Relict debris formed in this way, but now found interlayered in the floor sediments of caverns, is particularly significant because in some caverns it is associated with artifacts, bones of fossil mammals including man, and radiometrically dated material. Two layers of rubble derived from the cave roof at different times are included in floor sediments of a cavern in coastal Libya. The layers correspond in radiometric age with two glacial stades in northern Europe. Therefore, they support evidence from fossils that European glaciations were marked, in some places at least, by frost climates in a belt of country that extended far beyond the glaciers themselves.

Other features indicative of former frost climate are relict mantles of solifluction (soil-flowage) sediment. Common in moist Arctic areas today, such sediment is activated by spring thawing and moves downslope over frozen ground as thin tongues and sheets. Wide areas of relict solifluction sediment are common in such regions as western Europe, the central Appalachians, and southeastern Australia and testify to glacial-age frost climates.

Still another kind of frost-action effect that occurs in relict form in middle latitudes consists of ice-wedge casts, which today are observed in higher latitudes in all stages of active development. Sudden winter cold snaps cause permafrost (permanently frozen ground) to crack at the surface. Frost accumulating in the crack, over the years, fills the crack with a wedgelike body of ice and continually widens it. When the climate warms sufficiently, the wedge melts and the vacated space gradually fills with washed-in or blown-in sediment. Patterned ground and frost-stirred ground are additional frost-climate features that occur commonly as relicts. Networks of patterned ground occur at high altitudes on ridge tops in the middle Appalachians but are inactive today.

Some of the frost-action effects mentioned above are related to permafrost; others are not. Permafrost is widespread in Arctic regions today and during glacial ages certainly extended to lower latitudes. Its former extent, however, is difficult to fix. In general, permafrost occupied belts of country bordering the major ice sheets. Indications of its former presence seem to be most abundant in continental central Europe, where winter temperatures were much lower than in the maritime climates of western Europe. Apparently the permafrost belt across the eastern half of North America was narrow and discontinuous, possibly because warm air from the Gulf of Mexico was carried northward with little hindrance, thus maintaining a less rigorous climate than that of central Europe.

Soils and eolian sediments. Soils, which result basically from processes of weathering of pre-existing materials, constitute distinctive markers (layers) in a sequence of Pleistocene sediments. Thus two layers of till may be separated by a soil or zone of weathering, developed on the surface of the lower till under a nonglacial climate and later overridden by the glacier that deposited the upper till. Hence the soil records a nonglacial interval between two colder times. The maturity and thickness of some such soils suggest that interglacial times were rather long but do not in themselves indicate how long they were.

Loess as a paleoclimatic indicator

Eolian sediments, such as dunes of wind-blown sand and broad blankets of the wind-blown silt known as loess (*q.v.*), occur as relicts over wide regions. Much of the loess is of glacial age, having been derived from the bare ribbons of sand and silt deposited in the valleys of major rivers by streams of meltwater as these flowed away from the ice sheets. Such loess, in itself, tells little of former temperatures; neither do the patches of relict sand dunes of glacial age that are widespread in North America and Europe. Some types of dunes, however, record wind directions; some of them indicate that effective winds were northwest in regions where today the prevailing winds are southwest. Although this relationship says nothing about temperature, it does suggest that in glacial ages the belts of westerly winds that characterize middle latitudes were somewhat nearer the Equator than they are today.

Runoff and carbonate dissolution. The behaviour of streams in nonglaciated regions through parts of Pleistocene time has been studied in an effort to learn the climatic history of such regions. Persistent study has been given especially to streams in the dry southwestern quarter of

the United States. Repeated fluctuation in the regimens of such streams, expressed in alternating cutting and filling, has been discerned. Very likely some such changes have resulted from climatic changes related to the glacial–interglacial sequence in higher latitudes. The factors that determine the regimen of a stream are so complex, however, that it is difficult to extract uncomplicated data on former climate from studies of this kind.

Dissolution and precipitation of carbonates appear to offer a means of determining former fluctuation of rainfall. The features of some caverns in carbonate rocks indicate former alternations between dissolution and refilling with either chemically or mechanically deposited sediments. Stalactites and other cave deposits (speleothems) in caverns have been measured for their temperature implications. In one attempt, $^{18}O/^{16}O$ isotopic ratios were measured at short intervals along radii of stalactites in order to determine the fluctuation of temperature during deposition through the last 30,000 years or more. In another, caverns throughout a wide region were examined for the crystal systems to which the calcium carbonate in their speleothems belongs. Calcium carbonate crystallizes as aragonite at temperatures above 17° C; below that temperature it crystallizes as calcite. In the northern part of the western United States speleothems consist of calcite, whereas in the southern part they consist of aragonite, and in an intermediate belt they include both. The development of such measurements could lead to useful data on the thermal history of a region.

Temperature and precipitation fluctuation. Many attempts have been made to learn the extent to which temperatures at the height of a glacial age differed from those prevailing today. The differences were much greater in some areas than in others, and knowledge is still very much generalized. Calculations based on the altitude of the inferred glacial-age snow line compared with that of today suggest that mean summer temperatures in high places were lower than they are now by some 5° to 9° C. Inferences drawn from the distribution of fossil plants are broadly comparable. Inferences from frost-action effects in European areas of continental climate suggest that mean annual temperatures there may have been more than 12° C below today's values in some places. Scattered data based on areal distributions of planktonic microfaunas in the ocean suggest that temperatures of surface seawater differed from those of today by amounts comparable with those derived from terrestrial sources.

Mean temperatures and precipitation

Data of the same kinds, based on features of interglacial rather than glacial age, seem to indicate mean temperatures comparable with, or at most no more than about 2° C higher than those of today. From this the conclusion is drawn that at present the earth's climates are closer to interglacial than to glacial conditions. In this connection it is worth noting that the entire range of mean temperatures cited is much less than today's range of mean annual values over the earth as a whole.

Precipitation, likewise, underwent changes during the Pleistocene. Physical and organic data suggest that in some areas it was greater than modern values for long periods; in other areas it was less. Nothing, however, compels the supposition that precipitation increased or decreased overall, although overall change is not excluded. Nor does increased precipitation seem necessary to explain the building of the Pleistocene glaciers. On reasonable assumptions it appears that all of the ice in the Northern Hemisphere, at its greatest extent, could have been built in a period of 50,000 years from only about 3 percent of today's annual precipitation on lands in the Northern Hemisphere. In this calculation the Southern Hemisphere can be neglected, because the Antarctic Ice Sheet was already in existence before the beginning of the Pleistocene.

Some authorities believe world precipitation during a glacial age is likely to have been as much as 20 percent less than that of today, but others believe that it may have been greater than modern values. Some evidence points to relatively dry glacial ages, but it is scattered and has not been fully evaluated; for this reason, the matter remains unresolved.

DIRECT EFFECTS OF GLACIATION

Pleistocene glaciers. Glaciers have existed on mountains and other highlands at many times during geologic history, and both the Antarctic Ice Sheet and other extensive glaciers are known to have existed in high latitudes during the last 10,000,000 years or so. But the Pleistocene seems to have been distinguished principally by a rather rare event, the building of large ice sheets in middle latitudes (Figure 1). The largest of these, the Laurentide

From R.F. Flint, *Glacial and Quaternary Geology* (1971); John Wiley and Sons

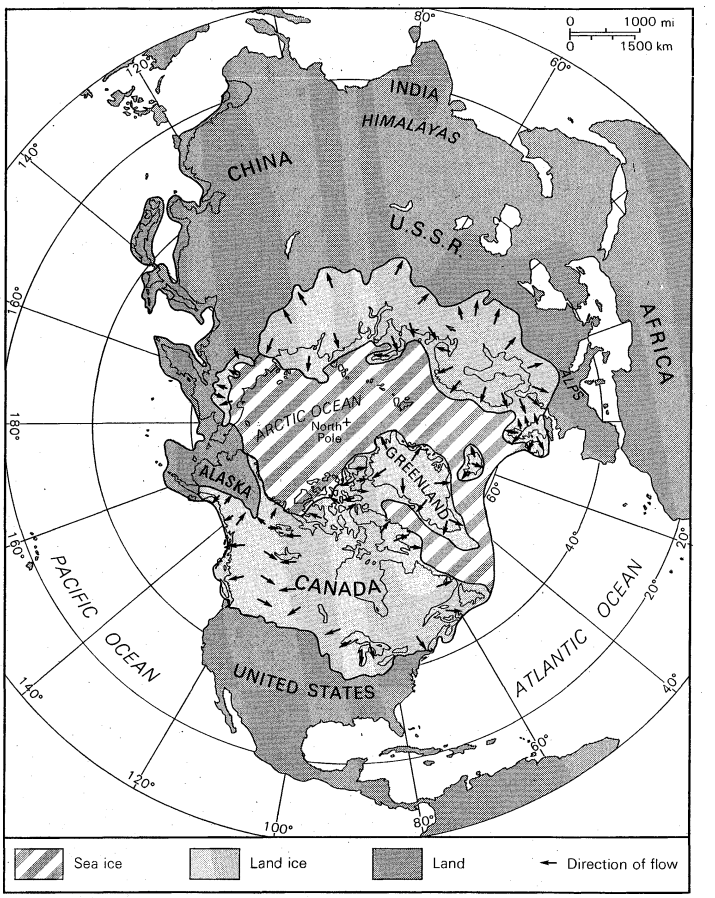

Figure 1: Northern Hemisphere showing areas glaciated during glacial ages.

Ice Sheet, covered an area of more than 13,000,000 square kilometres (5,000,000 square miles) and in terms of area was larger than the existing Antarctic Ice Sheet. Its thickness, unknown through direct measurement, may have attained a maximum of 3 kilometres (1.9 miles) or more. This ice sheet stretched from the Atlantic Ocean at New York City to the Rocky Mountains in Montana, and from the Arctic Ocean southward as far as latitude 37° N in the vicinity of the Mississippi River. Its southern margin stood near Cincinnati, Ohio; St. Louis, Missouri; Kansas City, Missouri; and Pierre, South Dakota. This great ice mass flowed outward in all directions, except where buried mountains distorted its flow. The rate at which its margin crept over the Ohio–Indiana region has been measured by means of the carbon-14 dates of spruce trees it knocked over; the rate averaged between 100 and 200 feet (30–60 metres) per year.

Laurentide and Scandinavian ice sheets

Second in order of area covered, the Scandinavian Ice Sheet (including all British glaciers) spread over about 6,600,000 square kilometres (2,500,000 square miles) according to present interpretation. There is fairly good reason to believe, however, that the ice sheet spread northward across the shallow sea floor to merge with the glaciers of Spitsbergen. If that did in fact happen, the maximum area covered probably would have exceeded 7,000,000 square kilometres (2,700,000 square miles). The southern margin of the Scandinavian Ice Sheet, at its maximum extent, reached the vicinities of London,

Amsterdam, and central Germany. Continuing through southern European Russia, it swung northward to the Arctic Ocean. Like its American counterpart, this ice body attained a probable maximum thickness of 3 kilometres (1.9 miles) or more. It was adjoined on the east by smaller ice sheets, while in eastern Siberia, China, and the rest of Asia all major high mountain ranges were capped with smaller glaciers of various sizes and shapes.

Conditions in North America were broadly similar. Although the Laurentide Ice Sheet did not overtop the Rocky Mountains in Canada, it was adjoined by, and in places connected with, a smaller ice sheet (some 2,300,000 square kilometres [890,000 square miles] in area) that extended from the Rocky Mountains to the Pacific Ocean, and from northern Alaska to Washington, Idaho, and Montana. South of it, as in Asia, high mountains as far south as southern California were dotted with local glaciers. The Arctic Ocean was covered with floating sea ice that surrounded glacier-covered Greenland and Iceland. The southern limit of sea ice stretched across the Atlantic from Newfoundland to Britain.

Ice in the Southern Hemisphere

In the Southern Hemisphere the Antarctic Ice Sheet was the only glacier of comparable size, mainly because a large part of that hemisphere consists of water. The southern Andes, however, were covered by a narrow ice sheet that subdivided northward into many separate groups of glaciers reaching right to the Caribbean Sea. Together, the South American glaciers covered an area of around 800,000 square kilometres (300,000 square miles). The South Island of New Zealand likewise was extensively covered with ice.

Apart from these large bodies of ice, a host of smaller glaciers occupied mountains in southern Europe and Africa, Japan, Tasmania, and other areas, some of them directly on the Equator. The combined area of all Pleistocene glaciers totals nearly 45,000,000 square kilometres (17,000,000 square miles), equivalent to about 30 percent of the world's land area, and more than three times the area occupied by glaciers today. A striking feature of formerly glaciated areas on mountains is that their asymmetry (slope locations) with respect to the mountains has the same orientations as the asymmetry of today's glaciers on the same mountains. This similarity implies in part that the wind systems bringing snowfall to the glaciers reach the mountains from broadly the same direction today as during the glacial ages.

Much of the terrain that formerly was covered by glaciers displays changes wrought by the glaciers themselves. Huge areas, including much of Canada and Fennoscandia (Norway–Sweden–Finland), were laid bare by the removal of regolith (rock mantle), and the underlying bedrock was ground down, smoothed, scratched, or polished by stones embedded in the bases of the glaciers, in a manner recognized by geologists as peculiar to glaciers. Other types of terrain, including areas of erodible bedrock and areas near the margins of former glaciers, were covered with heterogeneous deposits of earth, stones, and boulders, together known as glacial drift, spread rather thinly over the surface or heaped into prominent curving ridges at the terminus of a given glacier, in which case it is known as an end moraine. Such drift constitutes the basis for some of the best agricultural soils in the north central United States, but where its content of boulders is very great, as in most parts of New England, the soil developed in it is probably much poorer than the soil that existed in that region before glaciation. Glacial erosion and deposition likewise created the basins of the Great Lakes and most of the other lakes in northern North America and northern Europe.

Meltwater flowing away from the great ice sheets and the smaller glaciers followed pre-existing valleys and transported enormous quantities of gravel and sand through them to the sea. The Mississippi River was preeminent as a carrier of such glacial outwash, with which it built a massive delta into the Gulf of Mexico, a delta still being added to by the modern river.

Not only have rivers carried huge amounts of glacial sediment to the sea but the floors of the northeastern Pacific and the northern Atlantic oceans (to mention only two wide regions) have been liberally spread with sediments, including boulders, dropped to the bottom from floating ice shelves, or icebergs and pack ice (*q.v.*). In some of the cores taken from beneath the sea floor, two or more layers of such sediment have been recovered, separated by layers of normal, nonglacial origin. This reflects the alternation of cold climates with more temperate ones.

Glacial retreat and crustal recovery. The building up of thick glaciers on the earth's surface during glacial ages creates new, heavy, yet temporary loads, which the earth's crust is not rigid enough to sustain. The weak material of the substratum below the rocky crust flows plastically outward from beneath the overloaded areas as they subside, in basin-like fashion, to depths theoretically equal to about one-third the thickness of the overlying glacier. When the climate changes and the glacier begins to melt, the load on the crust is reduced, the direction of plastic flow of the subcrust material is reversed, and the rocky crust "recovers." It bulges upward as the overlying glacier melts away. The rate of uplift is very rapid at first, and then decreases nearly exponentially. Eventually, long after the ice has wasted away completely, the original, preglacial condition is restored. Such basin formation and later recovery of the crust is of the kind called isostatic.

Isostatic basin formation

Two classical examples of large-scale isostatic basin formation followed by rebound or recovery are Fennoscandia and glaciated eastern North America, where large ice sheets first depressed the crust and then permitted upward movement when they melted away. In both regions the updoming is still in progress many thousands of years after the ice sheets disappeared. The recent part of the movement is recorded by tide gauges along coasts. The earlier part is indicated by instrumental measurement of beaches and other shorelines that have been lifted above sea level and deformed. In Fennoscandia the outer limit of movement is a line that trends from southern Scandinavia northeastward toward Leningrad. South of that line the crust was not deformed isostatically. North of it, any strandline that represents a water plane made during or after deglaciation is tilted up in the northward direction. The tilt is clearly shown by contours that represent the altitude of the sea (Figure 2). It is predicted that a further 11 metres

From *Atlas over Sverige*

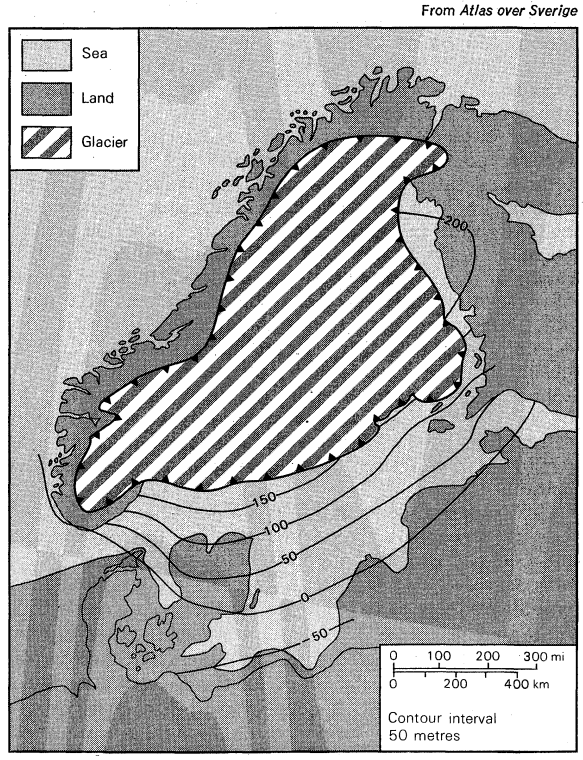

Figure 2: Distribution of former shorelines (contours) around the wasting Scandinavian ice sheet.

(36 feet) of the uplift still in progress will convert the Baltic Sea into a lake, which will gradually shrink to very small size, occupying only the northern part of the Gulf of Bothnia.

A similar history is reflected in the glaciated eastern part of North America. The dome in this region is much larger than the one in Fennoscandia, reflecting the larger size of the Laurentide Ice Sheet, but it has not yet been studied as thoroughly. It, too, is recorded both in the tide-gauge records and in measurements of deformed strandlines. The southern limit of deformation swings through a wide, irregular arc from Nova Scotia southwest to New Jersey. It is unknown across the Appalachians but is identified across the southern part of the Great Lakes region, where it trends northwest, passing near Cleveland, Detroit, and Milwaukee. Thereafter it continues northwestward and passes across northeastern South Dakota. Inside this limit, contours on various strandlines form a generally concentric pattern, with the centre of the pattern lying in the general region of Hudson Bay.

The parallelism between the outer limits of deformation and of glaciation is striking, both in North America and in the Baltic region. In both regions the concentric contours on deformed strandlines are related to areas, in North America to the Hudson Bay region and in the Baltic region to the Gulf of Bothnia, in each of which the related ice sheet is believed to have been centred during deglaciation.

In both regions continuing deformation is causing lakes to encroach on their southern shores and to recede from their northern shores. It has been predicted that in the future Hudson Bay, like the Baltic Sea, will disappear almost completely, although in the process it is not expected to become a lake. This is because of the fact that Hudson Bay's connection with the ocean is both deeper and differently placed.

Uplift similar to the examples described, although less spectacular, has been identified in the British Isles, East Greenland, the coastal region of British Columbia, and Patagonia. Indeed it is to be expected in any region in which former glaciers were massive enough to depress the crust beneath them.

INDIRECT EFFECTS OF GLACIATION

Fluctuation of sea level. The aggregate quantity of water at or near the earth's surface varies but little. Nearly 98 percent of it resides in the ocean, and a little more than 2 percent resides on land in the form of streams, lakes, ice, and snow; only a trace resides in the atmosphere. Hence, because most of the water on land resides in glaciers, the critical elements in the exchange between ocean and land are seawater and glaciers. Under today's climates with 10 percent of the land area covered with ice, the two elements are in equilibrium. In a glacial age they were in equilibrium, with the aggregate area of glaciers, and probably also their volume, increased by a factor of three. The glacial-age sea level, therefore, must have been much lower than today's sea level. Estimates vary, but according to an estimate that takes into account several complex factors, including isostatic adjustment, glacial-age sea level stood 100 metres (330 feet), in round numbers, below that of today. In essence, an ocean-wide layer of water was withdrawn by evaporation to build glaciers, and this water was later returned to the ocean, mainly through rivers, during the process of deglaciation.

Glacial-age sea level

The process of deglaciation has not rid the lands of glacier ice; 10 percent of the lands are still ice covered. Complete deglaciation of the lands would return to the ocean a volume of water that, after all factors are accounted for, would probably cause the level of the sea to rise a little more than 40 metres (130 feet). It appears, however, that the land has not been completely deglaciated during at least the last 10,000,000 years, for the Antarctic Ice Sheet seems to have been in existence during that much time. It is likely that at the interglacial maxima glaciers were less extensive than they are now. In that case, the sea at such times would have contained more water than it does now and its surface would have stood higher against land that was "stable." One reasonable estimate that has been made has placed a limiting height for interglacial sea levels at a figure of +20 metres (66 feet).

The difficulty here is that any part of a continent might move upward or downward through forces that have nothing to do with exchange of water between ocean and land. Hence a sinking coast could become submerged or a rising coast could emerge from the sea even while such exchange was in equilibrium. This is a principal reason why ideas as to the fluctuation of sea level are based only on estimates. Fluctuation cannot be determined closely at any locality along a coast where movement of the crust cannot be measured also.

Most broad movements of the crust, however, seem to be much slower than was the last great rise of sea level, evidence of which is found around most of the world's coasts. The evidence consists of a variety of features that were formed at or near sea level and that are now submerged to various depths. They include physical features such as beaches as well as fossils of many kinds. Where such things are datable by the radioactive carbon method it becomes possible to construct curves of time versus depth (Figure 3).

From F.P. Shepard, *Science*, vol. 143, pp. 574—76, figs. 1 and 2, Feb. 7, 1964

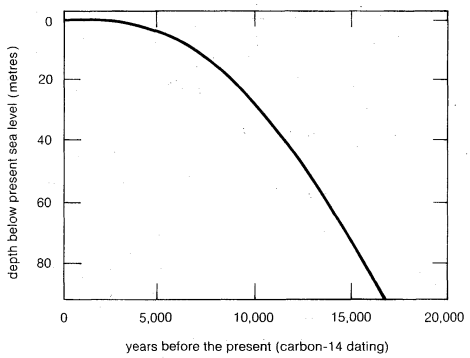

Figure 3: Generalized curve showing position of sea level, relative to land, since peak of last glaciation.

Curves of time versus depth, mostly spanning the last 10,000 years or so, agree broadly with each other where they pertain to coasts believed to be "stable." They indicate that the rise of sea level was rapid at first, then gradually slowed with the passage of time. The rise seems to have continued to the present. Authorities are not agreed as to whether a worldwide time–depth curve would be smooth or marked by fluctuation. Some, indeed, favour the view that the rising sea level reached above its present position at some time or times during the last few thousand years, although this concept is not readily supported by unequivocal evidence and consequently has few advocates.

Land bridges during glacial stades

If, as seems probable, the level of the sea was lowered during glacial ages by as much as 100 metres (330 feet), the effect on the positions of coasts would have been conspicuous. Along all coasts the area of the land would have been increased. The increase would have been slight along a steep, mountainous coast, but along a coast fringed by a continental shelf the increase of land would have been spectacular. The land area of the world might have been increased temporarily by as much as several percent.

An additional effect in parts of the world would have been the conversion of former islands into parts of mainlands, and even the connection of one continent with another. Thus, during one or more glacial ages, England was connected with France, Alaska with Siberia, Japan with Korea and perhaps also with Siberia, Borneo and Sumatra with the mainland of southeast Asia, Australia with Tasmania and with New Guinea, and Ceylon with India, to cite only a partial list. Such connections are postulated on a basis of the depths (less than 100 metres [330 feet] of the shallow shelves that now separate these pairs of land areas, and they are confirmed by certain striking

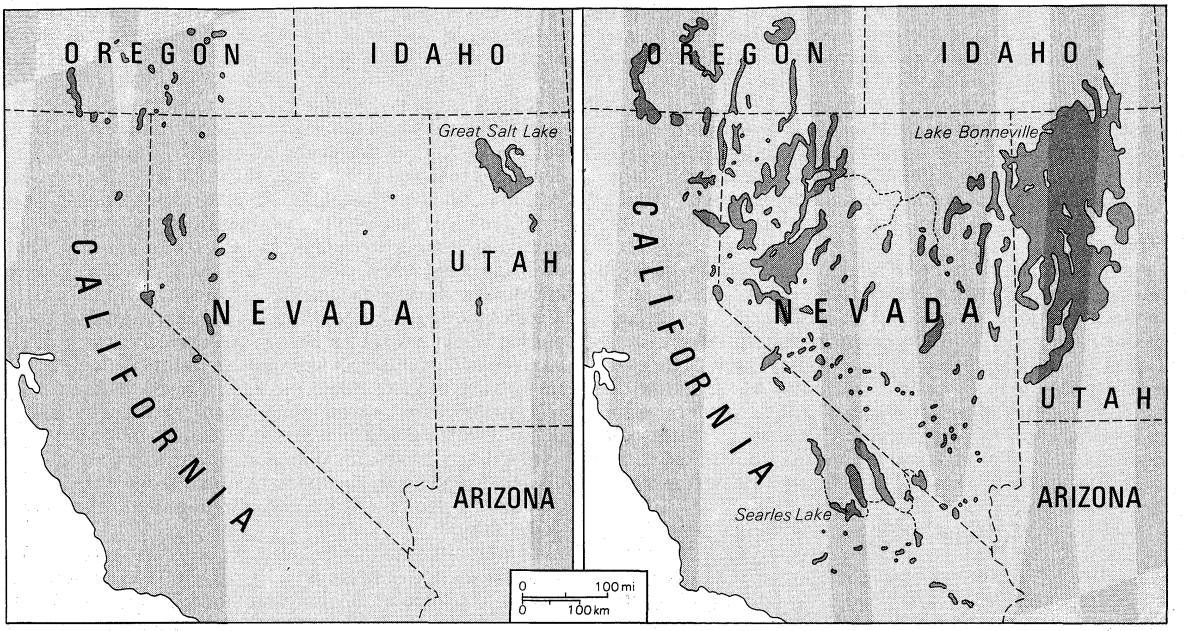

Figure 4: Distribution of (left) existing lakes and (right) pluvial lakes in the western United States. Dashed lines indicate probable drainage connections.

similarities in the fossil faunas as well as by similarities in the living faunas of the land areas.

One of the largest and best known of the former "land bridges" is that now represented by the Bering Strait, which separates Siberia from Alaska. It was not merely a bridge, but a broad land nearly as wide as Alaska itself, that was created and re-created again and again, first by movement of the crust and later by glacial lowering of sea level. The evidence that animals travelled across it from one continent to the other, in both directions, is conclusive (see below *Pleistocene life: Migration of plants and animals*).

Even where no bridge was involved, the addition of a wide strip to an existing land mass influenced organisms in a significant way. The falling sea level in glacial ages may have added land as much as 170 kilometres (100 miles) wide to the Atlantic coastal region of the United States. This afforded an enlarged refuge for plants and animals driven southward by the encroaching ice sheet, as well as a convenient north–south migration route for various organisms.

Fluctuation of lake levels. The water economy of a lake is determined chiefly by precipitation and evaporation—in other words, by climate. In a moist climate the water level of a lake is controlled by the level of the outlet. Any increase in the water received by the lake simply increases the volume of the outlet stream. In a warm, dry climate, however, most lakes lack outlets. Under such conditions water level is controlled by the ratio of water received to water lost by the processes of evaporation and by leaking into the ground.

Because climates fluctuate, the balance between water received and water lost is rarely maintained for long; hence the levels of lakes in dry regions continually change. The Great Salt Lake in Utah, for example, has fluctuated in level through a range of about 18 feet (6 metres) since 1850, and the changes are known to correspond with measured changes of air temperature and rainfall.

Lakes responded to the changed climate in a glacial age in different ways, according to their environment. Most lakes in moist climates already possessed outlets, and those that received increments of meltwater from glaciers, particularly ice sheets, responded by passing the excess water along and discharging it through these outlets. The increased discharges eroded the outlets and lowered them somewhat, thus causing an enduring reduction of lake levels. Meanwhile, the meltwaters entering the lakes deposited much of their load of glacial sediment in the lake basins, thus creating depositional records of the glacial event.

In contrast, lakes in dry climates, which largely lack outlets, experienced a dual change. Under lowered glacial-age temperatures, evaporation diminished. At the same time the rainfall on many such lakes increased, as is shown by the kinds of plants, evident in the fossil record, that grew near the lakes. The increased rainfall, accompanied by decreased evaporation, caused lake levels to rise until they came into balance with the new climatic conditions.

Pluvial lakes in North America and Africa

In the basin of the Great Salt Lake, a water body that is very shallow today, the water rose to form a lake (called Lake Bonneville) at least 300 metres (985 feet) deep in its deepest part and nearly 500 kilometres (310 miles) in greatest length. It spilled over temporarily through a mountain pass. Subsequently it fell and rose again repeatedly, in response to changes in temperature and rainfall, before reaching its present shrunken condition. Its various levels are recorded by beaches and other strandlines that can be traced along the slopes of the enclosing mountains. Its fluctuations are reflected also in fine-grained sediments that are recovered from cores bored from the floor of the former lake.

Another striking example is Searles Lake, now a dry salt-encrusted flat, between high mountains in southeastern California. In the latest glacial age the changed precipitation–evaporation ratio permitted a lake to form and rise to a height of at least 230 metres (755 feet) above its floor. At that height it overflowed through a mountain pass into an adjacent basin. Subsequently, it too diminished, leaving many strandlines along the mountainsides. Many core borings, one of them more than 250 metres (820 feet) deep, reveal layers of two kinds. One consists of clay and silt, deposited in a deep lake and in places containing fossil fishes. The other consists of mixtures of fine sediment with salts precipitated on the lake floor by evaporation of the water. Radioactive carbon dates of these deep-lake and dry-lake sediments agree closely with those of glacial and nonglacial deposits in other parts of North America and demonstrate that the deep, pluvial lakes existed during times of glaciation. Records of pluvial lakes are abundant in the western United States (Figure 4), northern Mexico, and the dry Pacific slope in middle South America. One of the pluvial lakes that existed in Bolivia was nearly as large as the American Lake Bonneville.

The former Dead Sea in Jordan and Israel, 200 metres (656 feet) deep in the latest glacial age, was the first plu-

vial lake to be recognized as such; it was identified in 1865. One of the largest known pluvial lakes is the former Lake Chad, now a shallow saline lake (latitude 13° N, longitude 14° E) in the southern Sahara. In its pluvial phase the lake is thought to have attained an area of some 300,000 square kilometres (115,800 square miles; roughly three times the area of Lake Bonneville); it may have been the largest pluvial lake in the world. Other pluvial lakes have been recorded in northern Africa, western and central Asia, and central and southern Australia.

Pluvial lakes seem to be related in time to glacial ages in most regions for which information exists. There appear to be exceptions among the several lakes that occupy basins in the Rift Valley system in eastern Africa, however. Certain lakes seem to have remained at high levels much longer than those in other parts of the world, indeed until after the great ice sheets in the Northern Hemisphere had wholly disappeared. The cause of this difference is not presently known but may be related to peculiarities in the history of the climates of northern and eastern Africa.

Fluctuation of stream regimen. Although the fluctuation of lakes in Pleistocene time gives a fairly clear indication of the relationship to changing climates, changes in the regimens of streams are more difficult to identify and to interpret in climatic terms. Two stream parameters in particular that probably changed with changing climate are (1) discharge and (2) rate of transport of sediment. Both of these parameters are known to depend on a number of factors, of which rainfall is one. But no known direct relationship exists between either one of these parameters and the quantity or time distribution of rainfall.

Although today's discharge in a stream can be measured, former discharge is very difficult to determine. A means by which attempts have been made to approximate former discharge is measurement of the geometry (principally width, depth, and gradient) of stream channels. When discharge increases, the geometry of the channel changes accordingly. In some streams glacial-age changes were apparently so great, and have been so well preserved, that inferences as to former discharge could be attempted.

Terraces and stream meanders

One example is the Valley of the Nile in Nubia. Studies of ancient alluvium left as terraces along the sides of the river show that through a time corresponding with the latest glaciation of northern Europe the Nile repeatedly aggraded its valley floor with alluvium, building up its floodplain to as much as 30 metres (98.4 feet) above its present position. At the same time local tributaries, whose discharges today are zero, brought to the Nile Valley abundant sediment. Evidently both the Nile and its tributaries in Nubia were formerly characterized by greater discharge, and probably also by a more rapid rate of transport of sediment.

An example of a different kind consists of streams that meander in valleys that are themselves meandering on a larger scale. The ratio of wavelength of the former (valley) meanders to existing meanders is large, being as much as 10:1. Still other streams meander on floodplains beneath which are buried meandering channels; again the wavelength ratio between the two is large. Because wavelength is related systematically to channel width, and hence to discharge, it is held that in the streams mentioned above, discharge (at least at flood peaks) was formerly greater. Calculations based on wavelength ratios in valleys of the kind mentioned have yielded former (peak) discharges as great as 50 times existing discharges. In some cases the geologic relationships point to the later part of the latest glacial age as the time of last great discharge. Such large discharges may have been attained in only a few very exeptional floods and may have been aided by the existence, beneath the stream, of frozen ground that prevented a loss of water from the stream by infiltration. Although calculations of this kind provide very interesting material for speculation, they have thrown little light on the problem of rainfall during glacial ages.

Attempts to determine glacial-age rates of transport of sediment by streams likewise encounter difficulties. Streams that originated at the margins of ice sheets during glacial ages consisted mainly of meltwater and carried large volumes of outwash sediment. Such sediment was deposited continuously and so diminished in both volume and grain size in the downstream direction. The deposited material is generally thick, at least in upstream positions. In the Mississippi River drainage basin it extends from Montana on the west and Pennsylvania on the east continuously to the Gulf of Mexico. In this and other drainage basins, the streams have trenched deeply into outwash sediments in postglacial time, leaving them as terraces along valley sides. Such trenching, however, was not the direct effect of a change from glacial-age climate to postglacial climate. It was only an indirect effect, and a remote one at that, because in each stream the change in regimen occurred at the time when melting reached a point at which glacier ice ceased to deliver meltwater and sediment to the stream. With consequent changes in both discharge and load, regimens changed from one of predominant upbuilding to one of predominant erosion of valley floors.

Sediment transport in glacial streams

In summary, analysis of outwash sediment in a stream valley does not indicate whether glacial-age stream discharge was greater or less than today's nonglacial discharge. It does, however, suggest that rates of transport and deposition of sediment were greater in a glacial age than they are today.

Whether such changes in rates of transport characterized all streams, even those that were not influenced directly by glaciers, is not known with certainty. Sediment cores raised from beneath the floor of the Atlantic Ocean, which receives the drainage from about two-thirds of the world's watershed area, throw some light on this matter. The part of the sediment that was derived from the land rather than from the activities of marine organisms, and which is so situated as not to have been interfered with by sediment brought in by bottom currents, seems to have been deposited at considerably more rapid rates during glacial than during nonglacial times as calculated from radioactive carbon dates. This relationship suggests that transport of sediment from land to sea (mostly the work of streams) increased during glacial ages, although the cores reveal nothing about discharge.

Fills and cuts are common in the valleys of streams of nonglacial origin, particularly those in dry regions, and some of them are dated by means of radioactive carbon. Such features reflect changes in the regimens of the streams, but the changes are difficult to interpret in climatic terms. Factors in climate, such as amount of precipitation, distribution of precipitation through the year, and annual and seasonal temperature cannot easily be singled out. Other factors that affect stream regimen include (1) drainage area, range of altitude, and slopes in the watershed; (2) topographic texture; and (3) character of the soils and vegetation. A change in only one of the factors in climate might lead to different responses in two different streams, and even in two different segments of a single long stream. Because of this complexity, it has not yet become possible to establish a general relationship between Pleistocene changes of climate and the regimens of streams.

Wind action and wind direction. Just as the snow line, the extent of glaciers, and the volumes of lakes in dry regions fluctuated between glacial and nonglacial ages, so the direction of winds changed, at least in some regions. The changes are recorded in windblown sediments that accumulated in former times, and that since those times have been protected from erosion.

Winds move grains of sand by saltation (bouncing contact) close to the ground, and particles of silt in suspension through much greater heights. These sediments are picked up from sandy and silty surfaces not protected by vegetation, are carried downwind, and are deposited. The sand normally is deposited close to its source, in the form of dunes or, less commonly, in thin blankets; the silt accumulates in broad sheets that extend a much greater distance from the source area. Common sources include

ocean and lake beaches, alluvium in stream valleys, and basins in dry regions.

Eolian deposits and wind direction

Fields of modern windblown sand and silt are comparatively small. Most if not all of the large fields originated in Pleistocene time or even earlier. Among the large fields that consist primarily of sand is the one called the Nebraska Sand Hills in the Great Plains region of North America. In it sand covers an aggregate area of more than 35,000 square kilometres (13,500 square miles) to an average depth of about eight metres (26 feet), and includes at least three groups of dunes of different late Pleistocene ages. A far larger field, or group of fields, is represented by the great dune systems that cover most of central Australia. Still others are the several fields that occupy basins in northern Africa.

Many of the fields of windblown sediment contain indications as to the direction of the predominant winds under which they accumulated. Windblown silt, when sampled systematically and analyzed, shows a remarkably orderly decrease of both thickness and grain size in the direction downwind from the source. Windblown sand, most of which occurs in the form of dunes, some of them more than 100 metres (330 feet) in height, reflects wind direction in two ways. One is the direction of slope of the stratification within the downwind faces of dunes. The other is the external form of the dune itself. Dunes have several characteristic shapes, most of which are related systematically to the direction of the prevailing wind.

Few Pleistocene dune groups have been studied closely, but in some instances the indicated wind directions are different from those of today's winds in the same areas. In middle latitudes in both North America and Europe, where prevailing winds generally have a westerly component, some Pleistocene dunes built close to former ice sheets indicate effective winds of north and even northeast direction. Others indicate northwest winds where prevailing winds are southwest today. The indicated former directions generally are compatible with a glacial-age pattern in which wind belts occupied positions somewhat nearer the Equator than today, and ice sheets generated local winds having northerly components along the southern margins of the glaciers. Observations are still too few for good synthesis, but this method is likely to help substantially in the reconstruction of glacial-age wind belts.

Windblown silt (loess) occurs mainly in two situations: (1) In the lee of arid basins. The extensive loess in China is chiefly of this kind. The source material consists mainly of alluvium washed onto basin floors from the erosion of rocks that form the sides of the basins. Most such loess is unrelated to glacial outwash; probably most of it accumulated at times when the regional climate was dry. (2) In the lee of valleys that were being actively filled with glacial-outwash sediments during glacial ages. Floods of meltwater added annual increments of sediment that overwhelmed the local vegetation and thus maintained extensive bare surfaces of sediment subject to erosion by winds. Most of the extensive loess of the central United States is of this kind; it accumulated only as long as glaciers were present in the drainage basins of the source streams. Thereafter vegetation gained the upper hand on valley floors and so inhibited further wind erosion. Related wind directions are determined in the manner mentioned above.

Soil formation. Soils of Pleistocene age are widely preserved by burial beneath coverings of glacial drift, loess, or volcanic rocks, and others lie unburied at the present surface. Because soils have characteristics impressed on them by the environments in which they were formed, these ancient soils afford clues to the former environment. Factors in the environment that have been recognized in some ancient soils include topography, vegetation, and climate.

Characteristics of Pleistocene soil

If an ancient buried soil can be traced through closely spaced exposures, the topography at the time of burial can be inferred. Such a soil that today is confined to hills and is lacking in the intervening valleys indicates that cutting of the valleys occurred after the soil developed. The change could have resulted from movement in the earth's crust or alteration of the climate, particularly as regards rainfall; either change could have caused valley cutting.

A different sort of change is represented by a soil of one zonal type superposed on or partly obliterating a soil of another zonal type, in a relationship referred to as degraded. An ancient middle-latitude soil, for example, may be partly converted to a soil with remnants of secondary carbonate that is characteristic of the first type. The relationship would suggest a change of climate from semiarid to humid, with invasion of grassland by forest, such as might occur at the beginning of a glacial age. Another example consists of red and yellow soils, on the fringes of the subtropics, that have been podzolized. This degradation, too, suggests change to a cooler climate accompanied by the incursion of trees into grassland.

In parts of central North America and central Europe there are exposed stratigraphic sequences in which layers of loess alternate with ancient soils. Such occurrences represent the fluctuation of climate between glacial times of loess deposition and less cold times of relative stability of the surface, when loess was not accumulating. Several such fluctuations could occur within a single glacial age. Interglacial ages are marked in many areas by the presence of thick, mature, ancient soils.

It is not easy to generalize on the time required for soil making, both because many variable factors are involved and because few reliable dates between which measurements can be made are available. Indirect evidence suggests that some chernozem soils have developed to maturity within less than 200 years, that a thin podzolic soil in New England developed in about 1,500 years, and that many podzolics in moist-temperate environments have matured in less than 4,000 years. The dated stratigraphy of one buried soil in Illinois indicates that it formed between 22,000 and 28,000 years BP, although the proportion of the intervening 6,000 years that was involved in its development is not known.

In North America, soils developed in Wisconsin time differ, as a general rule, from those developed earlier. The latter are considerably more mature, with thicker horizons and greater development within them, including the formation of red and yellow iron oxides. In Europe, similar differences exist between soils related to young drift and those related to older drift.

Distribution of permafrost

Under the climatic regimen of today, permafrost in the Northern Hemisphere extends southward, even in discontinuous patches to only 52° N in North America and to 66° N in Europe, positions at which mean air temperatures are a little above 0° C. In the latest glacial age permafrost is believed to have extended much farther south. This statement is based principally on the following reasoning. Frost cracks, and the ice wedges created from them, are active today, not in the peripheral part of the permafrost region but only in the more central part where the mean air temperature is −6° C or lower. Ice-wedge casts, a relict form of ice wedges, are present in drift of the latest glaciation in central Europe, penetrating to depths as great as eight to ten metres. Because mean temperatures at least as low as −6° C seem to be required for the development of such structures, glacial-age mean temperatures in parts of central Europe are thought to have been lower than they are now by 15° to 18° C, and the southern limit of permafrost is thought, by analogy, to have stood farther south than central Europe. In central North America, likewise, relict ice-wedge casts of glacial age are known. They imply former mean temperatures 10° to 15° C below those of today. Permafrost probably did not extend as far beyond the southern limit of glacier ice as it did in Europe, however, because the configuration of the North American continent results in warmer climates than those of Europe.

PLEISTOCENE STRATIGRAPHY

Pleistocene strata represent sediments of the same kinds as those that are accumulating today. They differ from today's sediments principally in their areal distribution. Sediments deposited during glacial ages, for example, include more widespread glacial strata, and at the same

time more restricted marine strata on continental shelves, than those now accumulating. Such differences constitute primary clues to changes in environment. Pleistocene strata differ from Pliocene and older strata in being generally much thinner and little consolidated, mainly because of the comparatively short segment of geologic time they represent.

Like modern sediments, Pleistocene strata are commonly very discontinuous. The discontinuity increases the difficulty of correlating strata from one place to another. Correlation is effected through traceable physical features and relationships, through similarities in the fossils the strata contain, and through similarities in geopolarity and in radiometric dates. Extensive, sound correlation yields the relationships necessary for the construction of paleogeographic maps of regions in particular units of time. The small map that accompanies this article is essentially such a map, though with little detail. More detailed examples can show the distribution of natural features, environments, and groups of organisms at a given time. The former distribution can thus be compared with that of today.

Stratigraphic data are likewise the means of reconstructing historical sequences, in which are shown changes in natural environment through time. Both maps and developmental changes are, of course, best known from the youngest and highest strata, which are least subject to loss through erosion and to concealment through subsequent burial, and most amenable to dating by means of radioactive carbon. Thus the events of the last 25,000 years, which include the latest great glaciation, are those that are understood in greatest detail.

PLEISTOCENE LIFE

Pleistocene plants and animals differed in some respects from those of today, although many were identical with living forms. The differences are the result of at least three factors: (1) the unending process of organic evolution, (2) changes of range because environments changed, and (3) mass extinctions. Each of these factors will be considered in turn.

Evolution and adaptation to cold climates

Pleistocene evolutionary changes in living things represent an unbroken continuation that had been taking place throughout earlier geologic history. Under the influence of continuously changing environments, existing species became extinct and new species evolved. Among mammals, for example, only 6 of the 119 species that now live in Europe and adjacent Asia are present as fossils in Pliocene strata. All the others first appeared in the Pleistocene, or even later. The Pleistocene evolutionary history of plants is more conservative. Some 80 percent of the plant species now living in northwestern Europe were already in existence at the beginning of the Pleistocene Epoch.

Changes in environment that were principally responsible for the evolutionary changes stemmed in large part from uplifts of the earth's crust and from localized mountain building that together have been conspicuous since the middle part of the Cenozoic Era. These movements resulted in generally lowered temperatures and in physical compartmentation of the land. Uplifts and the creation of mountain barriers to rain-bringing winds in turn enhanced the continentality of climates. Apart from these changes arising from earth movements, there seem to have been other changes in temperature and rainfall that are thought to have been caused independently. Both, however, affected evolution by promoting extinctions, adaptations, and speciation.

Mammalian fauna. Specific adaptations to cold climate, as represented in large mammals, have attracted much attention because they are conspicuous. Most of these, however, affected fleshy and other soft parts and did not necessarily affect the skeleton. Examples include the development of wool (a thermal insulator) in elephants, rhinoceroses, and musk-oxen; of blubber (an insulator and a source of energy in winter) in polar bears; and of food- and water-storage structures in some camels. Apart from such adaptations, which in any case did not appear until rather late in the Pleistocene, the majority of the changes in mammals are not related to low temperature in an evident way. The repeated changes of temperature that characterized the later part of Cenozoic time could, however, have stirred and mixed populations by forcing many changes of range and thus might have induced evolutionary changes of other kinds.

Villafranchian fauna

The earliest Pleistocene fauna of land mammals in Europe, widely termed Villafranchian, differed from the preceding Pliocene fauna in that it included new groups such as true elephants, zebrine horses, and cattle, but it contained no known elements that were obviously or exclusively of cold-climate character. It endured through a long time, possibly amounting in the aggregate to more than 2,000,000 years. A somewhat comparable fauna in North America took form even earlier and so endured even longer.

Within the time between the Waal and the Cromer Interglaciations, the Villafranchian fauna was so greatly modified by extinctions and new additions that a new fauna can be said to have appeared, one generally labelled middle Pleistocene. It included mammals of "Arctic" affinity such as reindeer, musk-oxen, and lemmings, followed after a time by woolly mammoths, woolly rhinoceroses, and moose.

Following the Saale Glaciation another marked change occurred among European mammals. Certain large, non-"Arctic" mammals, including the straight-tusked elephant and the hippopotamus, became extinct and the saiga antelope appeared among the existing "Arctic" forms. The result was the late Pleistocene fauna.

In North America the earliest Pleistocene fauna was the Blancan, which resembled the European Villafranchian fauna in some respects but which seems to have begun earlier, dating from some 4,000,000 years BP (as compared with perhaps 3,000,000 years BP for the Villafranchian). The Blancan included many relict Pliocene forms but was marked by the appearance of zebrine horses from Asia and by modern camel-like forms.

The succeeding Irvingtonian fauna seems to have appeared late in the Kansan Glaciation. Its most distinctive characteristic was the presence of a large number of immigrants from Asia, including mammoths, caballine horses, woodland musk-oxen, antelopes, and many rodents. During the succeeding glaciation, the Illinoian, further extinctions and new arrivals created the Rancholabrean fauna. Among the new elements were bison, skunks, bats, and many other rodents. Decimation of that fauna occurred near the end of the Wisconsin Glaciation.

Migration of plants and animals. More conspicuous than evolutionary changes, yet springing mainly from the same causes, were alterations in the ranges occupied by species and indeed whole populations of animals and plants. These consisted of the displacement of populations from their accustomed areas, mainly through the agency of changing climate. When a glacial age set in, organisms were displaced downward on the sides of mountains and plateaus and moved toward the Equator in broad regions of lesser relief. The process was one of slow spreading toward more hospitable areas. The result for the organisms was minimal disturbance of their environment, a result that for many organisms was critical for their survival. The displacements were accompanied by little apparent evolutionary change, but this may have been only because glacial ages were comparatively short, permitting the early return of most organisms to their normal ranges.

Both the spreading of organisms at the beginning of a glacial age and their return at its end would have been very irregular. Some elements of a community would spread while others remained behind, depending on their particular tolerances. Ranges would overlap and mixing of populations would occur. That these things happened is indicated by the observation that local floras and faunas were not alike in successive glacial and interglacial ages, even where there is little reason for believing that the successive climates differed from each other.

Apart from plants and land animals, marine organisms underwent similar displacements. Planktonic microfaunas display this history particularly clearly because they

can be recovered as fossils in ocean-floor sediments by means of coring and because their large numbers are well adapted to statistical treatment. Boreal species, for example, have been repeatedly displaced toward the Equator at times of reduced temperature, and vice versa.

Displacement of marine organisms

In the vicinities of large ice sheets, shifting of plant and animal populations was the result of invasion by the ice as well as of general cooling of the earth's atmosphere. In regions unaffected by ice sheets, amplitude of shifting was generally less and was the result wholly of secular rather than local causes. The distribution of glacial drift, together with fossil pollen and fossil mammals, yields the following rough sketch of environments south of the ice sheet in the region below the existing Great Lakes, 17,000 to 20,000 years ago: The margin of the ice lay across southern Ohio, central Indiana, and central Illinois, with streams of meltwater flowing away toward the south. Cloudy weather was common, with much snow and rain resulting from interactions between warm, moist air masses from the Gulf of Mexico and the high, cold body of ice. In a narrow zone close to the glacier, intense frost activity occurred, and the vegetation cover consisted of barren, tundra-like grassland with scattered clumps of spruce trees. Toward the south this vegetation merged rapidly into spruce forest with birch, alder, and tamarack. A boreal forest of this kind extended far southward, but with ever increasing proportions of deciduous trees characteristic of temperate climate. The stations at which fossil mammals of that time have been collected are not spaced closely enough to reveal animal distribution in detail but show clearly enough that the relatively barren zone close to the ice sheet was inhabited by, among others, woolly mammoths, caribou, and collared lemmings, while the forest south of it was occupied by mastodons, ground sloth, and moose. In addition there were horses, bison, woodland musk-oxen, snowshoe hares, and many kinds of smaller mammals.

Mass extinctions. The remarkable difference between today's fauna of large land mammals and the far richer fauna that existed at the height of the latest glaciation is the direct result of a series of extinctions. These were both limited in time and apparently without precedent in earlier glacial ages, and they left many ecological niches unfilled, a most unusual phenomenon. Estimates of the proportion of large-mammal genera that became extinct in North America toward the end of the latest glacial age run as high as 70 percent, although so high a number is not accepted universally. The number in Eurasia is considerably smaller, as is the case also in Africa and South America. The extinctions involved not only large mammals but also large flightless birds, as in New Zealand, and small mammals, particularly on islands. Most of the activity occurred between 15,000 and 9,000 BP, although in New Zealand it occurred much later.

Causes of faunal extinction

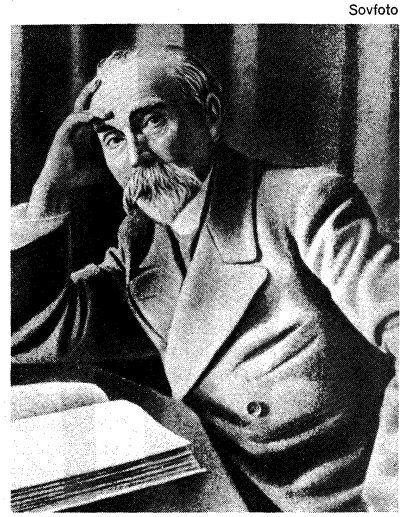
The two most likely causes of the mass extinctions, which have been much debated, are (1) changing environment with changing climate and (2) the direct or indirect influence of early man. In its common form the climatic hypothesis specifies that the warming and drying of middle-latitude climates that accompanied deglaciation brought with it changes in ecology, especially vegetation. These changes are presumed to have created crises in the kinds and abundance of available food, with which large herbivores could not cope.

Three arguments urged against the climatic hypothesis, mainly in connection with the North American scene, are as follows: (1) independent evidence is lacking that the climatic warming in late Wisconsin time was greatly different from the warming that introduced earlier interglaciations, in which extinctions were fewer; (2) the change of climate involved more time overall than did the majority of extinctions, which clustered near 11,000 BP; (3) application of the hypothesis to a number of the mammals that became extinct is not clear: desert herbivores such as camels and desert ground sloths, for example, should have flourished in consequence of the enlargement of arid lands, instead of becoming extinct; steppe grazers such as bison had only to move northward in order to keep within their favoured environment, yet only one species survived; with few exceptions browsers such as mastodons and forest musk-oxen should have been able to do likewise, yet both succumbed.

The hypothesis of human influence embraces not only the direct slaughter of large mammals by Paleolithic hunters but also the pressure exerted by man as part of the whole ecologic pattern. Human disturbance of the environment might have included selective killing of young individuals and of genera having exceptionally long periods of gestation.

The most sweeping and frequently heard arguments against the hypothesis of human influence is that man was not sufficiently numerous to have caused such extensive extinction, despite the evidence of stone-tipped, high-velocity projectiles and of group drives in which hundreds of large mammals at a time were stampeded and driven over cliffs.

Probably no single cause can explain the known data on the extinctions, and probably the circumstances differed from one region to another. Overall, however, it seems likely that human influence was a significant factor in these remarkable events.



BIBLIOGRAPHY. Summary works on the Quaternary, with extensive bibliographies, include: R.F. FLINT, *Glacial and Quaternary Geology* (1971); P. WOLDSTEDT, *Quartär* (1969); and J.K. CHARLESWORTH, *The Quaternary Era*, 2 vol. (1957). All place emphasis on physical features. R.G. WEST, *Pleistocene Geology and Biology* (1968), emphasizes biologic features, with special attention to the history of plants as revealed by fossil pollen, and with the discussion confined mainly to Britain. B. FRENZEL, *Die Klimaschwankungen des Eiszeitalters* (1967), is concerned primarily with the glacial-age distribution of plants in Eurasia. For both physical and biologic aspects of the subject, see H.E. WRIGHT and D.G. FREY (eds.), *The Quaternary of the United States* (1965). P.S. MARTIN and H.E. WRIGHT (eds.), *Pleistocene Extinctions*, (1968), is confined entirely to the extinctions of mammals that occurred in many parts of the world at the end of the Pleistocene Epoch.

(R.F.F.)

Plekhanov, Georgy Valentinovich

The founder and for many years the leading exponent of Marxism in Russia, G.V. Plekhanov was born into a family of the minor gentry on November 29 (according to the Russian old style calendar, then 12 days behind the Western Gregorian calendar), 1856, in Gudalovka, in Tambov province. In 1873, after completing his studies at the Voronezh Military Academy, he enrolled in St. Petersburg's Konstantinovskoe Military School, with the intention of becoming an army officer.

Sovfoto

Plekhanov.

He soon transferred to the Mining Institute, and then, during his second year there, abandoned his studies to devote himself entirely to a populist revolutionary movement. Although this movement aimed to foment a peasant upheaval and to establish an agrarian socialist society,

Plekhanov's activity involved him particularly with urban factory workers. After becoming a leader of the populist organization Land and Freedom in 1877, he engaged in underground political agitation. His writings appeared in Land and Freedom's publication of the same name; some of them showed Marxist influence. When Land and Freedom turned increasingly to terrorist methods, Plekhanov formed an antiterrorist splinter group to continue mass agitation. This faction was, however, short-lived, and in 1880 Plekhanov went abroad to avoid arrest. He did not return to Russia until 1917.

For the greater part of his exile Plekhanov resided in Geneva, Switzerland. In 1883, with several friends, he established the first Russian Marxian revolutionary organization, Liberation of Labour. In two major works, *Socialism and Political Struggle* (1883) and *Our Differences* (1885), he launched a destructive critique of populism and laid the ideological basis of Russian Marxism. Russia, he argued, had been caught up in a capitalistic development that was altering its social structure and creating the conditions for the overthrow of Russian autocracy and the establishment of a bourgeois-democratic regime. The Marxists, according to Plekhanov, were obliged to organize the emerging industrial proletariat for the struggle against autocracy. After its overthrow further capitalistic development would multiply the numbers of the proletariat; and, under the leadership of a social democratic labour party, the working class would ultimately liberate itself through a socialist revolution. This two-phase revolutionary scheme lay at the centre of Russian Marxian thought through several decades.

Birth of Russian Marxism

During the ten years or so after the publication of *Socialism and Political Struggle*, Plekhanov's group produced a mass of socialist literature, but the Marxists remained isolated from the Russian working class. Toward the mid-'90s, however, after a renewal of antigovernment activity, the group won some notable followers, including Vladimir Lenin. Revolutionaries from the intelligentsia established relationships with workingmen to promote labour struggles against management. Plekhanov and his friends joined with these groups, whose activities culminated in 1898 in the formation of the Russian Social Democratic Workers' Party.

In the '90s Plekhanov continued his polemics against the populists, most importantly with his book *On the Development of the Monistic Conception of History*. In 1898 he began publishing a series of tracts defending Marxian orthodoxy from those who proposed modifications or deviations. His principal targets were the reformist revisionism propounded by the German Social Democrat Eduard Bernstein, and a Russian tendency called "economism," which purportedly deprecated the importance of the direct political struggle and, rather, encouraged efforts to improve the position of the working class through labour pressure on the factory owners. These campaigns were waged in concert with Lenin and some others, who, in 1900, had joined hands to publish the militant journal *Iskra* ("The Spark"). By 1903 their foes in the Russian movement had apparently been routed, and the second congress of the Russian Social Democratic Workers' Party was held. Unexpectedly, a controversy over the character of the party split the congress into what became known as the Bolshevik and Menshevik factions. Plekhanov initially sided with Lenin, the Bolshevik leader, but soon drew away and joined the Mensheviks in attacks upon him. For the remainder of his political life, and especially between 1906 and 1914, he strove in vain to reunite the party.

Break with Lenin

In the last two decades of his life, Plekhanov was deeply absorbed in philosophical, artistic, literary, and historical studies. In all these fields he made significant contributions. But he did not completely retire from political life. A prominent member of the Second International, he assumed a "defeatist" stance toward his country in the Russo-Japanese War of 1904–05. By contrast, he supported the Entente during World War I, as he believed that the victory of German militarism would unquestionably spell disaster for the progressive workers' movement in Russia and elsewhere.

The Revolution of 1905 tested the revolutionary scheme Plekhanov had devised in the 1880s and found it wanting. The bourgeoisie did not act as he had anticipated they would. The peasantry, whose role he had underestimated, proved to be a potent revolutionary force. Yet he did not modify his theory in any fundamental respect. His influence declined noticeably between the two revolutions.

In 1917 Plekhanov greeted the February upheaval as the long-awaited "bourgeois" revolution. Returning to Russia in 1917, he urged continuation of the war to victory. The soldiers heeded him no more than did the peasants and workers whom he urged to subordinate their political demands to the more pressing need for national survival. Though critical of the Provisional Government, he supported many of its key policies. He was impotent to stop the Bolsheviks' march to power, and as a consequence of his attacks on them he was harassed by overzealous Red Guards as "an enemy of the people." He died on May 30, 1918, in Terioki, Finland.

BIBLIOGRAPHY. For biographical information, see S.H. BARON, *Plekhanov: The Father of Russian Marxism* (1963). The most complete edition of Plekhanov's works is his *Sochineniya*, 24 vol. (1923–27). Among Plekhanov's works translated into English are: *Art and Social Life* (1953), *The Development of the Monist View of History* (1947), *Fundamental Problems of Marxism* (1929), and *History of Russian Social Thought* (1938, 1967).

Pleuronectiformes

Members of the fish order Pleuronectiformes, commonly called flatfishes, flounders, or soles, are unique among fishes in being asymmetrical (strongly compressed, with both eyes on one side); other fishes and vertebrates in general are bilaterally symmetrical. The asymmetry is believed to have evolved from a generalized, symmetrical percoid (sea bass) body pattern in a fish that habitually rested on its side. Larval flatfishes have an eye on each side of the head, but during a period of rapid body change (metamorphosis) one eye migrates to the other side, after which the larvae settle to the bottom. Osteological changes resulting from the eye migration are responsible for the asymmetry in the flatfish skull.

Flatfishes of the family Pleuronectidae are commercially important in northern waters, and members of other families are taken in limited quantities. Some Bothidae and Soleidae (soles) are exploited in tropical and temperate waters, but no other flatfishes are utilized to the extent that Pleuronectidae are. In 1969, 1,400,000 tons of flatfishes were landed by the world's fisheries, and 85 percent of these were Pleuronectidae.

Natural history. Flatfishes generally spawn offshore, but some spawn in estuaries. Fecundity is high, females generally releasing at least several hundred thousand eggs (large female halibut have between 2,500,000 and

Body plan and sexual dimorphism in the flounder.

3,000,000 eggs). The eggs are small and float freely (pelagic) or sink to the botton (demersal), with or without oil globules. Newly hatched larvae are 1.5 to three millimetres long (0.06 to 0.12 inch). Active feeding begins shortly after hatching, and mortality of newly hatched larvae is extremely high. Larvae drift with currents (planktonic) until metamorphosis, or shortly afterward, and then settle to the bottom to assume their adult bottom-living (benthic) existence.

Habitat

Flatfishes lie on the bottom, generally covered by sand or mud, with only their eyes protruding. The eyes can be raised or lowered and moved independently. Flounders feed primarily on crustaceans, other bottom invertebrates, and small fish. When feeding they remain motionless until their prey ventures too close and then literally leap off the bottom in pursuit. Flatfishes in turn fall prey to a variety of large fish and cetaceans (whales, porpoises, etc.), but the primary predator of flatfishes is man.

Swimming is accomplished by undulating movements of body and fins, rather than by sculling with the caudal fin as in most other fish.

Flatfishes are primarily found in temperate and tropical seas, with some species extending northward into the Arctic. Sizes range from about 100 millimetres (four inches) to the large Atlantic halibut, which attains a length of more than two metres (nearly seven feet) and a weight of about 325 kilograms (716 pounds). Most species are marine, but some spend all or part of their life in freshwater. Flatfishes are found in depths up to 1,000 metres (3,300 feet), but most occur on the continental shelf in less than 200 metres of water.

Form and function. Many species display sexual dimorphism, with the male having one or several of the following characteristics: elongated pectoral-fin rays, wider interorbital bones, spines on the head, tentacles on the eyes, more elaborate pigmentation. Flounders have a long dorsal fin extending from the head to caudal (tail) fin and an anal fin extending from vent (anus) to caudal fin in most species. Pectoral fins are present on all larval flatfishes but are lost or reduced in adults of the families Soleidae and Cynoglossidae. Caudal-fin rays and their supporting structures are variable. Scales are ctenoid (rough edged) or cycloid (smooth). Dentition is variable and corresponds to feeding habits of the species. Active predators have large, well-developed teeth in both jaws, whereas those living primarily in mud and feeding on bottom invertebrates have teeth only on the lower jaw of the blind side. Sexes are easily distinguished because the ovaries extend posteriorly from the body cavity beneath the skin and a thin layer of muscle immediately above the muscles of the anal-fin rays. Testes cannot be seen without dissection. The stomach and intestines curl within the body cavity to form a loop.

Migration of the eye during metamorphosis

The main feature of metamorphosis is the migration of the eye around or through the head. This is accomplished as a movement either over the middorsal ridge or through the head, in a depression between the supraorbital bars (over the eye) and ventral edge of the dorsal fin. The supraorbital bars extend forward from the cranium to the ethmoid region of the skull (the area in front of the eye), gradually shifting ventrally and coming to lie next to one another. As the eye migration begins, the dorsal edge of the supraorbital bar is reabsorbed to make room for the eye moving through the head. The supraorbital bars ossify and become the interorbital bone after the eye has completed its migration. The blind- (bottom-) side frontal bone shifts to the ocular (upper) side and forms a portion of the optic-capsule floor for the upper eye. Torsion (twisting) of the frontals, ethmoid, and mouthparts is the essential feature of the flatfish skull.

Normal pigmentation on adult flatfishes consists of a coloured ocular side and an unpigmented (white) blind side. The ocular side is variable in pigment pattern and intensity. Flatfishes can mimic their background by assuming a similar coloration. Partial or complete albinism is known in some species, but a more common colour variation is ambicoloration (coloration on both sides). Ambicoloration can be partial or complete and is often associated with incomplete migration of the eye (in which the migrating eye stops on middorsal ridge) and a hooked appearance, caused by the unattached origin of the dorsal fin. Reversal (eyes and pigmentation on the side that normally is unpigmented) is fairly frequent in some species but quite rare in others.

Classification. Flatfishes are divisible into three suborders and seven families.

ORDER PLEURONECTIFORMES

(Heterosomata of some authors)

Allied to Perciformes but asymmetrical, compressed, both eyes on one side of head; pelvic bones attached directly to cleithrum. Swim bladder absent in adults. Fossil records for this group of fish are limited, extending from Paleocene to Recent, about 65,000,000 years.

Suborder Psettodoidei

The least specialized (most primitive) flatfish. Spines present in dorsal, anal, and pelvic fins; dorsal fin not extending onto head; eyes on either right (dextral) or left (sinistral) side; maxillary (upper-jaw) bone with well-developed supplemental bone; vertebrae 24–25 (10 precaudal, 14–15 caudal).

Family Psettodidae (primitive flatfishes)

Same characters as given for the suborder. Two species, one from Indo-Pacific and one from Africa; attain a length of about 2 ft.

Suborder Pleuronectoidei

No spines in fins (one spine in pelvic fin of Citharidae); dorsal fin extending forward onto head; usually no supplemental bone on maxillary (may be present or absent in Citharidae); vertebrae 27–70 (generally numbering 34 or more); preopercular margin free; lower jaw prominent; nostrils asymmetrical (that on blind side being near edge of head).

Family Citharidae

Eyes either dextral or sinistral; anus on ocular side; gill membranes widely separated; dorsal- and anal-fin rays not shortened posteriorly. Five monotypic genera found in the Indo-Pacific and Mediterranean and off Africa and Japan; attain a length to about 12 in.

Family Scophthalmidae

Eyes sinistral; anus on blind side; gill membrane widely separated; dorsal- and anal-fin rays shortened posteriorly; pelvic-fin bases long (both extending forward onto the urohyal). Four genera and 10 species found in North Atlantic and Mediterranean Sea; attain lengths to about 3 ft. and weights to about 50 lb.

Family Bothidae (left-eyed flounders)

Eyes sinistral; anus generally far up on blind side; gill membranes connected; dorsal- and anal-fin rays shortened posteriorly; pelvic-fin bases on ocular side short, on blind side may be short or long, 6-fin rays in all but 1 species. Thirty genera with about 200 species, found primarily in the tropical and temperate seas of the world; generally small.

Family Pleuronectidae (right-eyed flounders)

Eyes dextral; anus on blind side, commonly on or near midline; gill membranes connected; dorsal- and anal-fin rays shortened posteriorly; pelvic-fin bases of ocular side short or long, on blind side short, 3–13 pelvic-fin rays. Forty-three genera with about 100 species, found primarily in northern and Arctic seas, but some occur in tropical and temperate seas.

Suborder Soleoidei

Same as Pleuronectoidei, but preopercular margin not free (covered by skin and scales); lower jaw not prominent; nostrils nearly symmetrical, that on blind side not near edge of head.

Family Soleidae (soles)

Eyes small, dextral; mouth curved downward; sensory or tactile papilla on head (primarily on blind side); caudal fin with numerous rays. Over 100 species found in tropic and temperate seas; many true soles are small and found along the shore, somes species inhabiting freshwater.

Family Cynoglossidae (tongue soles)

Eyes small, sinistral; head large; mouth curved downward, head lacking sensory or tactile papilla; dorsal and anal fins confluent with caudal fin; caudal fin with only about 12 fin rays; generally small, slender fishes, found in tropical seas.

(E.J.G.)

Pliny the Elder

Gaius Plinius Secundus is usually called Pliny the Elder to distinguish him from his nephew and biographer, Gaius Plinius Caecilius Secundus. In his energy, public spirit, and culture, the elder Pliny typified upper class Roman society. He influenced the intellectual development of western Europe no less than did Cicero, Horace, and Virgil; unlike Virgil, however, Pliny's influence was not stylistic and literary but scientific and historical. Because of the enormous amount of material he collected, edited, and arranged under the then uncommon title *Historia naturalis* (*Natural History*), Pliny became one of the chief authorities on scientific matters in the Middle Ages. His encyclopaedic coverage and picturesque descriptions far outweigh his lack of critical discrimination and knowledge of technical details. By preserving the best of Greek science, the *Natural History* long remained a source for both correct and incorrect scientific information. The history of early science cannot be understood properly without recognizing Pliny's role, both in establishing a new type of scientific literature—the encyclopaedia—and in supplying the content that would be accepted for over 1,500 years.

Pliny was born in Novum Comum (modern Como), in northern Italy, in AD 23. Descended from a prosperous family, he was enabled to complete his studies in Rome. At the age of 23, he began a military career by serving in Germany, rising to the rank of cavalry commander. He returned to Rome, where he possibly studied law. Until near the end of Nero's reign, when he became procurator in Spain, Pliny lived in semi-retirement, studying and writing. His devotion to his studies and his research technique were described by his nephew. Upon the accession in AD 69 of Vespasian, with whom Pliny had served in Germany, he returned to Rome and assumed various official positions.

Seven writings are ascribed to him, of which only the *Natural History* is extant. There survive, however, a few fragments of his earlier writings on grammar, a biography of Pomponius Secundus, a history of Rome, a study of the Roman campaigns in Germany, and a book on hurling the lance. These writings probably were lost in antiquity and have played no role in perpetuating Pliny's fame, which rests solely on the *Natural History*.

The *Natural History*, divided into 37 *libri*, or "books," was completed, except for finishing touches, in AD 77. In the preface, dedicated to Titus (who became emperor shortly before Pliny's death), Pliny justified the title and explained his purpose on utilitarian grounds as the study of "the nature of things, that is, life" ("Preface," 13). Heretofore, he continued, no one had attempted to bring together the older, scattered material that belonged to "encyclic culture" (*enkyklios paideia*, the origin of the word encyclopaedia). Disdaining high literary style and political mythology, Pliny adopted a plain style—but one with an unusually rich vocabulary—as best suited to his purpose. A novel feature of the *Natural History* is the care taken by Pliny in naming his sources, over 100 of which are mentioned. Book I, in fact, is a summary of the remaining 36 books, listing the authors and sometimes the titles of the books (many of which are now lost) from which Pliny derived his material.

The *Natural History*

The *Natural History* properly begins with Book II, which is devoted to cosmology and astronomy. Here, as elsewhere, Pliny demonstrated the extent of his reading, especially Greek texts, which he read fluently. By the same token, however, he was sometimes careless in translating details, with the result that he distorted the meaning of many technical and mathematical passages. In Books III through VI, on the physical and historical geography of the ancient world, he gave much attention to major cities, some of which no longer exist.

Books VII through XI treat zoology, beginning with man (VII), then mammals and reptiles (VIII); fishes and other marine animals (IX); birds (X); and insects (XI). Pliny derived most of the biological data from Aristotle, while his own contributions were concerned with legendary animals and unsupported folklore.

In Books XII through XIX, on botany, Pliny came closest to making a genuine contribution to science. Although he drew heavily upon Theophrastus, he reported some independent observations, particularly those made during his travels in Germany. Pliny is one of the chief sources of modern knowledge of Roman gardens, early botanical writings, and the introduction into Italy of new horticultural and agricultural species. Book XVIII, on agriculture, is especially important for agricultural techniques such as crop rotation, farm management, and the names of legumes and other crop plants. His description of an ox-driven grain harvester in Gaul, long regarded by scholars as imaginary, was confirmed by the discovery in southern Belgium in 1958 of a 2nd-century stone relief depicting such an implement. Moreover, by recording the Latin synonyms of Greek plant names, he made most of the plants mentioned in earlier Greek writings identifiable.

Books XX through XXXII are concerned with medicine and drugs. Like many Romans, Pliny criticized luxury on moral and medical grounds. His random comments on diet and on the commercial sources and prices of the ingredients of costly drugs provide valuable historical evidence relevant to contemporary Roman life. The subjects of Books XXXIII through XXXVII include minerals, precious stones, and metals, especially those used by Roman craftsmen. In describing their uses, he referred to famous artists and their creations and to Roman architectural styles and technology.

Pliny's last assignment was that of commander of the fleet in the Bay of Naples, where he was charged with the suppression of piracy. Learning of an unusual cloud formation—later found to have resulted from an eruption of Mt. Vesuvius—Pliny went ashore to ascertain the cause and to reassure the terrified citizens. He was overcome by the fumes resulting from the volcanic activity and died on August 24, 79, according to his nephew's report. Pliny was unmarried and was survived by his only sister.

Assessment

In retrospect, Pliny's influence is based on his ability to assemble in a methodical fashion a number of previously unrelated facts; his perceptiveness in recognizing details ignored by others; and his readable stories, with which he linked together both factual and fictional data. Along with unsupported claims, fables, and exaggerations, Pliny's belief in magic and superstition helped to shape scientific and medical theory in subsequent centuries. Perhaps the most important of the pseudoscientific methods advocated by him was the doctrine of signatures: a resemblance between the external appearance of a plant, animal, or mineral and the outward symptoms of a disease was thought to indicate the therapeutic usefulness of the plant. With the decline of the ancient world and the loss of the Greek texts on which Pliny had so heavily depended, the *Natural History* became a substitute for a general education. In the Middle Ages, many of the larger monastic libraries possessed copies of the work; these and many abridged versions ensured Pliny's place in European literature. His authority was unchallenged, partly because of a lack of more reliable information and partly because his assertions were not and, in many cases, could not be tested.

The first attack on Pliny's work—Niccolò Leoniceno's *De erroribus Plinii* ("Concerning the Errors of Pliny")—was published in Ferrara in 1492. Thereafter, Pliny's influence diminished, as more writers dared to question

his statements. By the end of the 17th century, the *Natural History* had been rejected by the leading scientists. Up to that time, however, Pliny's influence, especially on nonscientific writers, was undiminished; he was, for example, almost certainly known to Shakespeare and Milton. Although Pliny's work was never again accepted as an authority in science, 19th-century Latin scholars conclusively demonstrated the historical importance of the *Natural History* as one of the greatest literary monuments of classical antiquity. It is still of value to those who wish an honest résumé of 1st-century Rome.

BIBLIOGRAPHY. *Natural History*, 10 vol., ed. and trans. by H. RACKHAM *et al.* ("Loeb Classical Library," 1938–63), Latin text has facing English translation, which is accurate, readable, with helpful notes and indexes. KONRAT ZIEGLER, WILHELM KROLL *et al.* "C. Plinius Secundus der Ältere," in *Pauly-Wissowa Realencyklopädie*, vol. 21, col. 271–439 (1951), is the best overall treatment. H. LE BONNIEC, *Bibliographie de l' "Histoire naturelle" de Pline l'Ancien* (1946), contains over 900 items, arranged according to the books of the *Natural History*. See also JERRY STANNARD, "Pliny and Roman Botany," *Isis*, 56:420–425 (1965).

(Je.St.)

Plotinus

Plotinus, the great philosopher and religious genius of the 3rd century AD, who transformed the revival of Platonism in the Roman Empire into what modern scholars call Neoplatonism, exercised a wide-ranging direct and indirect influence on European thought that lasted until the late 17th century. Neoplatonism has been enthusiastically studied and has provided inspiration for the thought of particular individuals and groups down to the present time. Neoplatonic philosophy has also deeply influenced the thought of the Islāmic world (see PLATONISM AND NEOPLATONISM).

Porphyry's "Life of Plotinus." The only important source for the life of Plotinus is the biography that his disciple and editor Porphyry wrote as a preface to his edition of the writings of his master, the *Enneads*. Other ancient sources add almost no reliable information to what Porphyry relates. This must be mentioned because, though Porphyry's "Life of Plotinus" is the best source available for the life of any ancient philosopher, it has some important deficiencies that must necessarily be reflected in any modern account of the life of Plotinus that does not use a great deal of creative imagination to fill in the gaps. The "Life" is the work of an honest, accurate, hero-worshipping, and serious-minded friend and admirer. Apart from a few fascinating scraps of information about the earlier parts of the life of Plotinus, Porphyry concentrates on the last six years, when he was with his master in Rome. Thus, a fairly complete picture is available only of the last six years of a man who died at the age of 65. It is the elderly Plotinus, as it is the elderly Socrates, who alone is known.

Early life. Plotinus' own writings contain no autobiographical information, and they can give no unintentional glimpses of his mind or character when he was young; they were all written in the last 15 years of his life. Nothing is known about his intellectual and spiritual development.

Origin. Plotinus was born in the year AD 205. Porphyry states that he never spoke about his parents, his race, or his country. Eunapius, a late-4th-century writer, and later authors wrote that his birthplace was Lyco or Lycopolis in Egypt, either the modern Asyūt in Upper Egypt or a small town in the Nile Delta. Though this may be true, there is no real evidence in the "Life" or in his own writings to suggest that Plotinus had any special knowledge of or affinity with Egypt; the fact that he later studied philosophy in the great cosmopolitan city of Alexandria is not necessarily evidence that he was an Egyptian. His name is Latin in form, but, in the 3rd century AD, this gives no clue to his ethnic origins. All that can be said with reasonable certainty is that Greek was his normal language and that he had a Greek education. For all his originality, he remains Hellenic in his way of thinking and his intellectual and religious loyalties.

Study under Ammonius Saccas. In his 28th year—he seems to have been rather a late developer—Plotinus felt an impulse to study philosophy and thus went to Alexandria. He attended the lectures of the most eminent professors in Alexandria at the time, which reduced him to a state of complete depression. In the end, a friend who understood what he wanted took him to hear the self-taught philosopher Ammonius "Saccas." When he had heard Ammonius speak, Plotinus said, "This is the man I was looking for," and stayed with him for 11 years.

Study of philosophy at Alexandria

Ammonius is the most mysterious figure in the history of ancient philosophy. He was, it seems, a lapsed Christian (yet even this is not quite certain), and the one or two extant remarks about his thought suggest a fairly commonplace sort of pre-Neoplatonic Platonism. A man who could attract such devotion from Plotinus, and who may also have been the philosophical master of the great Christian theologian Origen, must have had something more to offer his pupils; but what it was is not known. That Plotinus stayed with him for 11 years is in no way surprising. One did not enter an ancient philosophical school to take courses and obtain a degree, but rather to join in what might well be a lifelong cooperative following of the way to truth, goodness, and the ultimate liberation of the spirit.

Expedition to the East. At the end of his time with Ammonius, Plotinus joined the expedition of the Roman emperor Gordian III against Persia (242–243), with the intention of trying to learn something at first hand about the philosophies of the Persians and Indians. But the expedition came to a disastrous end in Mesopotamia, when Gordian was murdered by the soldiers and Philip the Arabian was proclaimed emperor. Plotinus escaped with difficulty and made his way back to Antioch. From there he went to Rome, where he settled at the age of 40. That a Greek philosopher, especially at this period, should be interested in Oriental thought is not extraordinary. Plotinus' own thought shows some striking similarities to Indian religious philosophy, but he never actually made contact with Eastern sages because of the failure of the expedition. Though direct or indirect contact with Indians educated in their own religious-philosophical traditions may not have been impossible in 3rd-century Alexandria, the resemblances of the philosophy of Plotinus to Indian thought were more likely a natural development of the Greek tradition that he inherited. That Plotinus was able to join the expedition of the senatorial emperor Gordian, that he went to Rome (an unusual place for a philosopher to settle), and that Porphyry found him, 19 years later, at the centre of a circle of friends and disciples—many of whom were members of the senatorial aristocracy—has been interpreted (probably erroneously) as meaning that he or his family had strong personal connections with Roman senators.

Life as an established philosopher in Rome. Whatever may have been the circumstances of Plotinus when he first came to Rome, by the time Porphyry made his acquaintance in AD 263 he was living in dignified and comfortable conditions, though maintaining a considerable degree of personal austerity. His reputation in society was excellent and earned by practical activity as well as by teaching. He acted as an arbitrator in disputes, without ever being known to make an enemy. And many of his aristocratic friends, when they were approaching death, appointed him guardian of their children. "His house," Porphyry says, "was full of young lads and maidens," and he most conscientiously fulfilled his obligations under Roman law as their guardian, taking care of their education and their property. Like other great contemplatives, he had plenty of time for other people and could attend to their worries (sometimes quite trivial) without losing his inward concentration. He heard a boy's lessons, found who had stolen a lady friend's necklace, or noticed that Porphyry was in a state of depression and contemplating suicide, and so sent him away for a change of scenery and companionship. "Present at once to himself and others" and "gentle and at the disposal of all who had any sort of acquaintance with him" are ways in which Porphyry described him. He was, it seems, a man who gave the im-

Practical and scholarly activities

pression of being in touch with the eternal without losing awareness of the earthly needs of his many friends.

His circle of friends was cosmopolitan, including men from the eastern half of the empire as well as Roman senators, their wives, and widows. Among those who venerated Plotinus, according to Porphyry, were the emperor Gallienus (reigned 253–268) and his wife Salonina, and this led Plotinus on one occasion to attempt practical activity on a larger scale. He asked the Emperor to restore a ruined city in Campania and endow it with the surrounding land; the restored city was to be called Platonopolis, and its citizens were to live according to the laws and customs of Plato's ideal states. Plotinus promised that he would go and live there himself with his friends. That a philosopher who shows in his writings such a total lack of interest in the political side of Plato's thought, and who preached withdrawal from public life, should have made such a proposal is interesting. He may well have thought it his duty as a Platonic philosopher to attempt the foundation of a Platonic city, if opportunity offered —however personally disinclined he might have been to such activity. The Emperor refused his request, and in the political circumstances of the time there was no chance of its being granted. Gallienus and the Senate were not on good terms. He had excluded members of the senatorial order from all military commands, and they took their revenge by successfully blackening his memory after his death. However much he might have respected Plotinus personally, the Emperor would inevitably have regarded Platonopolis as a most undesirable senatorial strongpoint and a centre of intrigue against his authority.

Teaching and writing for his school

The main activity of Plotinus, to which he devoted most of his time and energy, was his teaching and, after his first ten years in Rome, his writing. There was nothing academic or highly organized about his "school," though his method of teaching was rather scholastic. He would have passages read from commentaries on Plato or Aristotle by earlier philosophers and then expound his own views. The meetings, however, were friendly and informal, and Plotinus encouraged unlimited discussion. Difficulties, once raised, had to be discussed until they were solved. The school was a loose circle of friends and admirers with no corporate organization. It was for these friends that he wrote the treatises that Porphyry collected and arranged as the *Enneads*. Some, it seems from their complexity, were destined for an inner circle of his closest friends and philosophical collaborators, such as Porphyry, Amelius Gentilianus from Tuscany (the senior member of the school), and Eustochius, who was Plotinus' physician and who may have produced another edition of his works, now lost.

Some stories in the "Life," and some passages in the *Enneads*, give an idea of Plotinus' attitude to the religions and superstitions of his intensely religious and superstitious age, an attitude that seems to have been unusually detached. Like all men of his time, he believed in magic and in the possibility of foretelling the future by the stars, though he attacked the more bizarre and immoral beliefs of the astrologers. His interest in the occult was philosophical rather than practical, and there is no definite evidence that he practiced magic. A person called Olympius is reported to have once tried to use magic against Plotinus, but he supposedly found that the malignant forces he had evoked were bouncing back from Plotinus to himself. Plotinus was once taken to the Temple of Isis (a Greco-Egyptian mystery goddess) for a conjuration of his guardian spirit; a god, Porphyry stated, appeared instead of an ordinary guardian angel but could not be questioned because of a mishandling of the conjuring process which broke the spell. What Plotinus himself thought of the proceedings is not known, but apparently he was not deeply interested.

Attitude toward pagan cults and Gnostics

His attitude toward the traditional pagan cults was one of respectful indifference. Amelius, his closest friend and co-worker in philosophy, was a pious man, addicted to attendance at sacrifices. Plotinus refused to join him in his devotions but seems to have thought none the worse of him. Despite his rather aggressive piety, Amelius remained Plotinus' friend and collaborator. Some members of his circle of friends were Gnostics (heretical Christian dualists who emphasized esoteric salvatory knowledge), and they provoked him not only to write a vigorous attack on their beliefs but to organize a polemic campaign against them through the activities of Porphyry and Amelius. The reasons of Plotinus for detesting Gnosticism also would have applied, to some extent, to orthodox Christianity—though there is no evidence that he knew anything about it or that he had any contact with the church in Rome. Gnosticism appeared to him to be a barbarous, melodramatic, irrational, immoral, un-Greek, and insanely arrogant superstition. Plotinus' own religion, which he practiced and taught with calm intensity, was the quest for mystical union with the Good through the exercise of the pure intelligence.

Last years. In his last years Plotinus, whose health had never been very good, suffered from a painful and repulsive sickness that Porphyry describes so imprecisely that one modern scholar has identified it as tuberculosis and another as a form of leprosy. This made his friends, as he noticed, avoid his company, and he retired to a country estate belonging to one of them in Campania and within a year died there (270). The circle of friends had already broken up. Plotinus himself had sent Porphyry away to Sicily to recover from his depression. Amelius was in Syria. Only his physician Eustochius arrived in time to be with Plotinus at the end. His last words were either "Try to bring back the god in you to the divine in the All" or "I am trying to bring back the divine in us to the divine in the All." In either case, they express very simply the faith that he shared with all religious philosophers of late antiquity.

BIBLIOGRAPHY. The text of PORPHYRY'S *Life of Plotinus* may be found prefixed to most of the editions of the *Enneads* of Plotinus. *Plotins Schriften*, vol. 5c, ed. and trans. by R. HARDER (1958), is a critical edition of the Greek text with German translation and notes. A Greek text with English translation and short notes is in *Plotinus*, vol. 1, trans. by A.H. ARMSTRONG (1966). An English translation is in *The Enneads*, trans. by STEPHEN MACKENNA, 4th ed. rev. by B.S. PAGE, pp. 1–20 (1969). The best character study of Plotinus, and also an excellent introduction to his thought, is PIERRE HADOT, *Plotin, ou la simplicité du regard* (1963). See also A.H. ARMSTRONG in the *Cambridge History of Later Greek and Early Mediaeval Philosophy*, pt. 3, "Plotinus," ch. 12, "Life," and 13, "Teaching and Writing" (1967), with bibliography.

(A.H.A.)

Plumbing

In general, plumbing refers to the system of pipes, fixtures, and other apparatus used inside a building for supplying water and removing liquid and waterborne wastes. In practice, the term includes storm water or roof drainage and exterior system components connecting to a source such as a public water system or a point of disposal such as a public sewer system or a domestic septic tank or cesspool.

The purpose of plumbing systems is, basically, to bring into, and distribute within, a building a supply of safe water to be used for drinking purposes and to collect and dispose of polluted and contaminated wastewater from the various receptacles on the premises without hazard to the health of occupants. Codes, regulations, and trade practices are designed to keep the water system separated from drainage systems; to prevent the introduction of harmful material such as chemicals, micro-organisms, and dirt; and to keep the water system safe under all operating conditions. These protective codes also are designed to prevent flooding of drainage lines, provide venting of dangerous gases, and eliminate opportunities for backflow of dangerous waste water into the water system. It is essential that disease-producing organisms and harmful chemicals be confined to the drainage system.

Since the time of Moses man has been cautioned to dispose of his wastes safely, and cleanliness has been related to the availability of water and associated with social custom. Early man often lived near a water source that served as his water supply and drainage system in one. It was also his bath. Latrine-like receptacles with

Water system of King Minos

crude drains have been found in excavations in the Orkney Islands of Neolithic stone huts at least 10,000 years old. Both a water system and piping used as drainage fashioned of terra-cotta pipe were part of the royal palace of Minos in Crete, about 2000 BC. The palace also had a latrine with water-flushing reservoir and drainage. Nothing comparable to it was developed in Europe until the 18th century. Even the equipment of the modern bathroom, though much improved with hot and cold water under pressure and less crude provisions for drainage, is in concept little different from the Minoan version. It was not until the end of the 19th century that advances in plumbing practice were given serious attention as an integral part of housing.

A building plumbing system includes two components, the piping that brings potable water into the building and distributes it to all fixtures and water outlets and the piping that collects the water after use and drains it to a point of safe disposal.

Water systems. When a building is served by a public water system, the plumbing begins at the service connection with the public supply. It includes all meters, pumps, valves, piping, storage tanks, and connections required to make water available at outlets serving the fixtures or equipment within the building.

Many premises in rural areas are not served by public water supply. These may include private dwellings, apartment houses, hotels, commercial centres, hospitals, institutions, factories, roadside stands, and restaurants.

Public water supplies have surface water or groundwater as their source. Large water systems are almost entirely supplied with surface water (see WATER-SUPPLY SYSTEMS). In smaller communities and in certain areas groundwater is obtained from wells or springs. Independent semipublic, industrial, and private-premise water systems frequently take water from wells on the premises but may, under certain conditions, draw water from a spring, lake, or stream.

Public water systems supply treated water meeting public water-supply drinking-water standards. Private-premise systems are expected to provide water of equal quality, and to do so the private system requires a water-treatment plant including chlorination as a minimum and possibly sedimentation (settling out of solid particles) chemical treatment, primarily for softening, and filtration.

Pressure pumps

Water is supplied to fixtures and outlets under pressure provided by pumps or elevated storage tanks or both. In some installations a pump controlled by a pressure-activated switch on a pressurized storage tank takes water from a well and pumps until the upper limit of pressure for the system has been reached. If water is being used at the rate it is being pumped, the pump operates continuously. Elevated storage tanks are usually equipped with high- and low-level-float control switches to activate the pump. When the tank gets low the pump starts and continues pumping until the tank is full. A storage tank may be constructed as illustrated in Figure 1, or it may be located

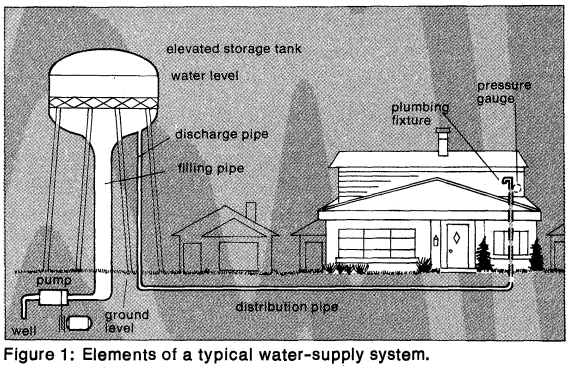

Figure 1: Elements of a typical water-supply system.

on the roof of a high building. Water from the tank feeds the distribution system by gravity. Water flowing through pipes causes a loss of head due to friction. Since building piping systems are designed to deliver water at the required outlet pressure, pipe size is a critical variable.

Plumbing codes have tables and graphs to show typical water demands of fixtures and outlets in a building. If the required water demand is not met because of undersized piping or underpowered pumping, the pressure drops and some outlets may have little or no water flow. Plumbing codes usually specify pressures and rates of flow for the fixtures in a building. The total amount of water that may be needed to supply the demand can be calculated from tables of fixture water demand. Minimum pipe sizes for different fixtures in a building are specified in plumbing codes.

Since it is uneconomical to design a water piping system that would provide flow with all outlets open simultaneously, judgment and experience are used to determine the probable maximum simultaneous demand.

Average daily water requirements vary according to the type of premises being served. A single-family dwelling unit averages from 20 to 100 gallons (80 to 400 litres) per capita per day. Apartment house occupants use less. Special users such as hospitals and industries usually require far greater allowances.

Fixtures and equipment. Most bathrooms of dwelling units comprise lavatory, water closet, and tub or shower (or both). These may be varied by including two lavatory fixtures and a stall shower. In some countries a bidet is also included. Washing and bathing units are normally supplied with both hot and cold water taps. Designs vary; some have separate faucets, while others have mixer valves or common outlets to regulate water temperature.

Kitchen plumbing

Normal kitchen plumbing provides for a single or double sink. Dishwashers, permanently installed or mobile, are finding greater use. In many communities where the drainage is connected to a separated, or sanitary, sewer system, waste food grinders may be installed under the kitchen sink. In small apartments provision may also be made for a mobile laundry facility with an automatic washing machine. Water is taken from sink taps, and wastewater is discharged to the sink through flexible hoses.

The laundry or utility room is usually equipped with a double laundry tub with hot and cold water taps. Clothes washing machines and vented dryers are also part of the laundry equipment. Flexible drains discharge water from the washer to the sink. Metal venting to the outside is usually required on dryers, particularly gas-fired models, but is desirable for all to avoid polluting room air with minute pieces of lint not caught on dryer screens.

Larger apartment houses, hospitals, commercial buildings, and institutions may be equipped with utility sinks in custodian's closets.

Water-system piping and fittings are made of a variety of materials, including copper, brass, bronze, plastic, galvanized iron, wrought iron, malleable iron, and cast iron. Exterior pipe of larger capacity may be constructed with asbestos cement, steel, or plastic materials. In all plumbing it is necessary to have a variety of fittings such as couplings, elbows (angular pipe fittings), wyes (pipe fittings shaped like the letter Y), tees (pipe fittings shaped like the letter T), and caps in order to transport the liquids within piping that must be concealed in walls and floors and provide service to fixtures. Pressure relief valves are required on all hot water tanks as a safety measure. Fittings are made with screw thread, flange (fitted rims), bell and spigot (formed by the insertion of the spigot or male end of one pipe into the bell or female end of another), and slip joint (a telescopic joint). Connections are required to be gastight and watertight for pressures specified for testing purposes by plumbing codes.

Special equipment and safety problems. Hospitals are designed with special fixtures for washing, scrubbing, surgical cleaning, instrument sterilization, housekeeping, disposal of dangerous liquids and solids, and special laundry facilities; kitchen equipment such as vegetable scrubbers, potato peelers, waste food grinders; and the various pieces of water-using equipment found in laboratories such as aspirators, chemical sinks, and autoclaves (pressure cookers).

Industrial plants have individual requirements for plumbing that are contingent on the sanitary facilities for

employees and the process needs of the industry. The sanitary needs are related to ordinary washing facilities and special protection requirements such as eyewash fountains and deluge showers for personnel, clothes, and equipment. Although processing operations involve plumbing, these are generally treated separately. The building process waste piping is, however, part of the plumbing system.

Water-softening systems

In regions where the water is hard and in special quality requirement situations in laboratories and industrial plants, water-softening systems may be installed. Such systems remove calcium and magnesium ions from the water. The typical unit of the past has been a chemical exchange unit in which sodium ions replace calcium ions (base exchange process). Other units employ resins and a few use filter membranes. Softening units require maintenance and either replacement or recharge of the chemical. Care must be taken to avoid contamination of the water system while maintaining the unit.

Sanitary hazards. These are of three kinds: those that endanger the water system, those that may pollute or contaminate the closed space (room) air environment, and those that expose premises to unclean water through leakage or flooding.

The most general and overall danger is related to the water supply, and the most common means of affecting the potability of the water system is by backflow or back siphonage. Liquids under pressure flow from a zone of higher pressure to a zone of lower pressure. Dangerous backflow is produced when a contaminated or polluted liquid under a higher pressure is connected to a potable water system under lower pressure. Back siphonage merely extends this principle to a condition in which the pressure is negative (*i.e.*, a vacuum condition) on the low-pressure side of the connection. Backflow connections endanger not only the building system but may affect the public water supply. If an industrial-fire water system of nonpotable quality pumping at 200 pounds per square inch (14 kilograms per square centimetre) is connected to a public water system operating at 100 pounds per square inch (seven kilograms per square centimetre), for example, the nonpotable fire water supply will flow to the public waterlines. Another type of backflow can be created in the event of a fire if fire engine pumpers draw more water from the mains than can be supplied to them, thus putting a negative pressure on the mains. In this case, water will flow from buildings adjoining the pumping centre and drain the building system by placing a negative pressure on lines in the building. Any connection within this building such as a water-softening unit, corrosion-control unit, laboratory sink, custodial sink, or toilet with submerged water connections will then flow to the building system and possibly to the public system, thereby contaminating both the building water supply and the public water supply.

Various devices are placed in plumbing systems to prevent backflow. Air gaps with a free air opening distance of two to three times the diameter of the fixture or pipe outlet are the only positive means of separating a nonpotable liquid from the water system. Other means of preventing backflow include manually supervised devices consisting of gate valves, check valves, and pressure indicators designed to prevent flow from a zone of higher pressure to one of lower pressure; vacuum breakers, providing a direct opening to air when vacuum or negative pressure occurs in the waterline; and swing connections that must be manually connected to a line to permit water flow.

Gases. In drainage systems, gases result from biological action on organic matter contained in wastes. Evolution gases, generated by chemical reactions, may be found in laboratories of industry, hospitals, and institutions. Sewer gases are present in the house drainage system as well as in the public sewer. Gases from the public sewer are prevented from entering the building drainage system by traps installed at or near the lower end of the building drainage system. House drainage gases are vented through pipes or vent stacks leading from the various fixture drainage lines to the outside air as in Figure 2.

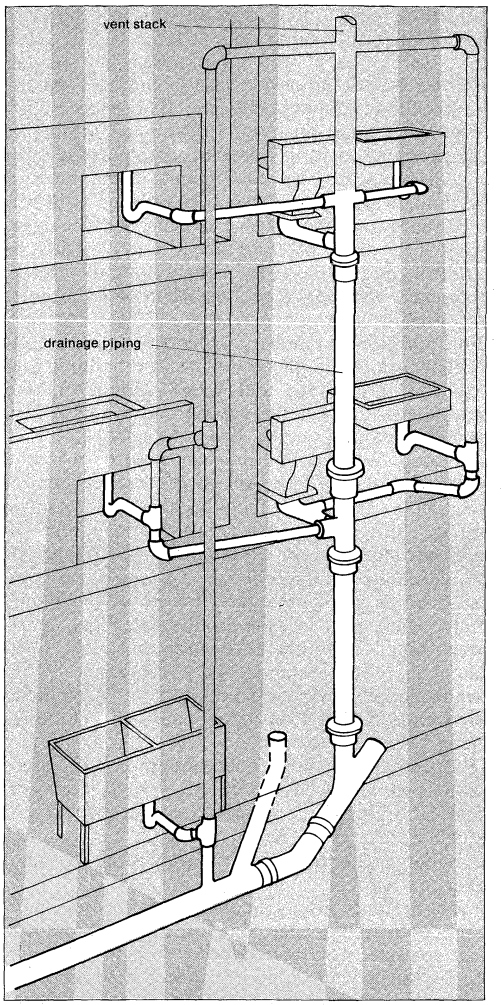

Figure 2: Building drainage and venting system.

Venting gases

Plumbing codes provide for uniform venting of residence fixtures through stacks ranging from two to four inches (five to ten centimetres) in diameter. In complicated and extensive plumbing systems, relief vents are provided to insure air circulation and keep the drainage system at atmospheric pressure. Vents are never less than one-half the diameter of the drain line being vented and at least 1.25 inches (3.3 centimetres) in diameter for individual fixture venting. Vent sizes vary with the length of vent and the fixture units connected. Plumbing codes contain tables from which the size of vent relative to the number of fixtures, size of waste drain, and length of vent may be

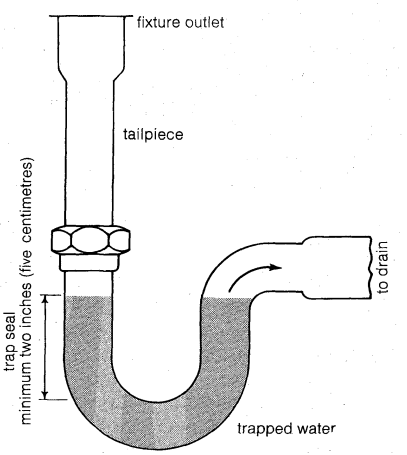

Figure 3: Sanitary fixture trap showing water column that seals the fixture from sewer gases, bacteria, and vermin.

determined. All fixtures require traps of the type shown in Figure 3. The trap places a water seal between the fixture and the drain line so that gases cannot escape into room air. The venting system (Figure 2) prevents a siphon action that would remove the seal. Though stoppage in a drain line at some lower point in the system causes liquids to back up into a fixture, the liquid seal is not broken. Refrigerator drains, commercial food-preparation equipment, and any other equipment in which backup of waste water could cause serious contamination are connected to the drainage system through an indirect waste pipe with adequate air-gap protection.

Under unusual conditions, laboratories may discharge flammable or toxic materials to the drainage system. In this case, precautions are taken to detect leaks or the presence of gases with special instruments. Under normal circumstances regular checks for leakage are performed as required by codes. Occasionally the gases discharged by vents may pollute the outside or ambient air unless special air-cleaning devices are installed on vents (see also POLLUTION CONTROL).

Plumber's equipment. Plumber's equipment is designed to handle the construction and repair of both water and drainage piping and installation of fixtures. A complement of wrenches, including adjustable crescent, monkey, chain, and Stillson, or pipe, wrenches is required. The plumber also needs gasoline or propane fuel torches, hacksaws, tubing and pipe cutters, reamers, chisels, files, pipe threaders, force cups for clearing clogged pipes or facilities ("plumber's helper"), soldering equipment, caulking tools, caulking materials (oakum, lead, and special compounds), fluxes, sealers, valve packing, washers, gaskets, and pressure and vacuum gauges (see also HAND TOOLS). For drain maintenance the plumber must have flexible wire or rods called "snakes" to go through traps and bends. Small snakes are used by hand while large ones are operated by electric or gasoline-powered equipment that rotates the flexible rod and forces it into the pipe obstruction. Special cutters may be attached to this equipment to cut plugging materials such as roots from house sewers.

Drainage systems. Drainage of residential buildings includes the collection of sanitary wastes and roof drainage (see also SEWAGE SYSTEMS; POLLUTION CONTROL). The sanitary wastes are collected in soil pipes and stacks usually made of cast iron, although certain portions of connecting pipe may be galvanized iron. When corrosive liquids are collected, as in laboratories and industrial plants, the system may include plastic or glass pipes or coated piping. The joints, bends, tees, elbows, wyes, and many other special fittings are designed to carry away wastes without having obstructions in the pipe or creating conditions that will cause clogging if some large object is dropped into a fixture or a receptacle. Cleanouts and receptacle outlets are provided with screens or gratings to prevent the entry of clogging materials. The entire piping system is sized so that the smallest size is at the fixture outlet. Plumbing codes specify the minimum sizes for drainage connections and the standards applicable to all pipe and fitting materials.

Normally all building drainage is constructed so that waste water flows by gravity to the main house drain. The house drain is usually connected outside the building to a gravity flow house sewer that leads to a public sewer or a point of treatment. In large buildings such as apartment houses, commercial buildings, hospitals, and industrial plants, the house drain may be lower than the point of discharge. Wastes are then discharged to a sump, or storage pit, and all of the building drainage is lifted by pumps or pneumatic ejectors to a point of discharge to the exterior sewer system. These lifting devices empty water from the storage sump on a cycling basis activated by float controls that prevent flooding of the storage area. Such units are usually installed in duplicate and often have alternate sources of power such as a diesel- or gasoline-powered generator for emergency pumping.

Roof drainage is collected in gutters and leaders and taken by appropriate piping to a point of discharge permitted by law. Isolated dwellings may drain to surrounding ground, while larger buildings have a drainage system similar to the sanitary system that connects into a public storm-water sewer system.

Home disposal systems

Home disposal systems are used in rural areas. The house drain is connected to a septic tank with a tile drainage field or to a cesspool. The septic tank removes heavy solid materials from the waste, and the effluent or treated water is allowed to percolate into the soil through buried, specially constructed, rock-filled trenches over which tiles with open joints are laid. Enough trench must be constructed to allow percolation without flooding the surface of the ground. The effluent from septic tanks contains disease-causing bacteria and cannot be allowed to flow directly into streams or underground waters. Health codes and regulations specify the sizes of home disposal units and control the discharge of effluent.

Premises often have other water uses including swimming pools (both outdoor and indoor), ornamental pools, fish pools, and fountains. These require water and are part of the plumbing system. Since swimming-pool water is easily contaminated by bathers, it must either be replaced frequently or filtered, chlorinated, and recirculated.

Pools constructed for private family use are subject to regulation to prevent backflow of pool water into the building water system. Hotels and motels frequently have swimming pools; provisions for handling the water and waste water are made in designing the plumbing system.

The practice of installing permanent lawn-sprinkling systems has grown. A piping system of plastic or metal is placed beneath the lawn and spray headers that pop up when water pressure is applied are placed according to the desired sprinkling pattern. As the sod forms, pockets around these headers hold water and provide a submerged connection that might, under backflow conditions, carry contaminated water back into the building supply system. Such systems need a vacuum breaker or other means of backflow prevention.

A mobile home—a vehicular, portable structure built on a chassis and therefore without a permanent foundation—must be provided with and connected to suitable utility services when in use as a dwelling. Conditions of transport and use are such that plumbing standards for permanent buildings are not always applicable. The same principles of plumbing practice for safety and protection must be preserved, however. Special codes have been developed for such homes.

Plumbing modules

Another variant in buildings is the prefabricated structure or prefabricated plumbing module. In such structures units such as wall panels are made at a factory and shipped to a site for erection. The plumbing (both water and drainage) is systematized, and modules with appropriate matched connection points in panels and floor sections and the like can be connected quickly on site. Prefabricated plumbing systems must comply with building and plumbing codes and must be tested after erection to insure against leakage.

BIBLIOGRAPHY. L. WRIGHT, *Clean and Decent* (1960), traces the bathroom and its development from Neolithic times to the 20th century. A.J. MATTHIAS, JR., *How to Design and Install Plumbing*, 3rd ed. rev. by E. SMITH, provides a practical treatise on the parts of a plumbing system and how they are put together. V.M. EHLERS and E.W. STEEL, "Plumbing," in *Municipal and Rural Sanitation*, 6th ed., ch. 11 (1965), offers a general exposition on water supply and wastewater systems and on public health hazards for both rural and urban conditions. AMERICAN NATIONAL STANDARDS INSTITUTE, *National Plumbing Code, ASA-40.8* (1955), is the standard reference on plumbing regulations and standards and has been adopted by many agencies for control purposes. PUBLIC HEALTH SERVICE TECHNICAL COMMITTEE ON PLUMBING STANDARDS, *Proposed Revision of ASA-40.8-1955* (1962), is often used as a supplement to the ANSI code. AMERICAN PUBLIC HEALTH ASSOCIATION, AMERICAN SOCIETY CIVIL ENGINEERS, WATER POLLUTION CONTROL FEDERATION JOINT EDITORIAL BOARD, *Glossary, Water and Wastewater Control Engineering* (1969), is a standard reference and a compendium of terms used in the field including terms related to plumbing, house drainage, water systems, and wastewater systems.

(W.T.I.)

Plutarch

Between the 16th century and the early 19th one of the most popular of classical authors in Europe was Plutarch, a 1st-century Greek biographer and miscellaneous writer. Admired for their wisdom as well as for their information, his writings were long used as source books for anecdotes and moral *exempla;* they influenced the origins and development of the essay, the biography, and the writing of history; and it was from his *Parallel Lives* that the generally accepted images of the great historical figures of Greece and Rome were derived.

Plutarch was born *c.* AD 46 at Chaeronea in Boeotia, an ancient district in east central Greece. He was the son of Aristobulus, himself a biographer and philosopher. In 66–67, Plutarch was studying mathematics and philosophy at Athens under the Peripatetic philosopher Ammonius. Public duties later took him several times to Rome, where he lectured on philosophy, made many friends, and perhaps enjoyed the acquaintance of emperors Trajan and Hadrian. According to the Suda lexicon (a Greek dictionary dating *c.* AD 1000), Trajan bestowed the high rank of an ex-consul upon him. Although this may be true, a report of a 4th-century church historian, Eusebius, that Hadrian made Plutarch governor of Greece is probably apocryphal. A Delphic inscription reveals that he possessed Roman citizenship; his *nomen* or family name, Mestrius, was no doubt adopted from his friend Lucius Mestrius Florus, a Roman consul.

Plutarch travelled widely, visiting central Greece, Sparta, Corinth, Patrae (Patras), Sardis, and Alexandria, but he made his normal residence at Chaeronea, where he held the chief magistracy and other municipal posts and directed a school with a wide curriculum in which philosophy, especially ethics, occupied the central place. He maintained close links with the Academy at Athens (he possessed Athenian citizenship) and with Delphi, where, from *c.* 95, he held a priesthood for life; he may have won Trajan's interest and support for the then renewed vogue of the oracle. The size of Plutarch's family is uncertain. In the *Consolatio* to his wife Timoxena on the death of their infant daughter he mentions four sons; of these at least two survived childhood, and he may have had other children. He died sometime after 119.

Plutarch's literary output was immense. The 227 titles in the so-called catalog of Lamprias, a list of Plutarch's works supposedly made by his son, are not all authentic, but neither do they include all he wrote. The order of composition cannot be determined.

Lives. Plutarch's popularity rests primarily on his *Bioi parallēloi (Parallel Lives)* of Greek and Roman soldiers, legislators, orators, and statesmen. These, dedicated to Trajan's friend, Sosius Senecio, who is mentioned in the lives "Demosthenes," "Theseus," and "Dion," were designed to encourage mutual respect between Greeks and Romans. By exhibiting noble deeds and characters they were also to provide model patterns of behaviour.

Plan of the *Lives*

The first pair, "Epaminondas and Scipio," and perhaps an introduction and formal dedication, are lost. But Plutarch's plan was clearly to publish in successive books biographies of Greek and Roman heroes in pairs, chosen as far as possible for their similarity of character or career, and each followed by a formal comparison. Internal evidence suggests that the *Lives* were composed in Plutarch's later years, but the order of composition can be only partially determined; the present order is a later rearrangement based largely on the chronology of the Greek subjects, who are placed first in each pair. In all, 22 pairs survive (one pair being a double group of "Agis and Cleomenes" and the "Gracchi") and four single biographies, of Artaxerxes, Aratus, Galba, and Otho.

The *Lives* display impressive learning and research. Many sources are quoted, and, though Plutarch probably had not consulted all these at first hand, his investigations were clearly extensive, and compilation must have occupied many years. For the Roman *Lives* he was handicapped by an imperfect knowledge of Latin, which he had learned late in life; for, as he explains in "Demosthenes," political tasks and the teaching of philosophy fully engaged him during his stay in Rome and Italy. The form of the *Lives* represented a new achievement, not closely linked with either previous biography or Hellenistic history. The general scheme was to give the birth, youth and character, achievements, and circumstances of death, interspersed with frequent ethical reflections; but the details varied with both the subject and the available sources, which include anecdote mongers and writers of memoirs as well as historians. Plutarch never claimed to be writing history, which he distinguished from biography. His aim was to delight and edify the reader, and he did not conceal his own sympathies, which were especially evident in his warm admiration for the words and deeds of Spartan kings and generals; his virulent and unfair attack on Herodotus, the great Greek historian of the 5th century BC, probably sprang from his feeling that he had done Athens more and Boeotia less than justice.

Attack on Herodotus

Moralia. Plutarch's surviving writings on ethical, religious, physical, political, and literary topics are collectively known as *Ethica* (Latin *Moralia*), and amount to more than 60 essays cast mainly in the form of dialogues or diatribes. The former vary from a collection of set speeches to informal conversation pieces set among members of Plutarch's family circle; the date and dramatic occasion are rarely indicated. The diatribes, which often show the influence of seriocomic writings of the 3rd-century BC satirist Menippus, are simple and vigorous. The literary value of both is enhanced by the frequent quotation of Greek poems, especially verses of Euripides and other dramatists.

Two educational works, "How a young man ought to hear poetry" (which moderated an old Platonic objection to poetry) and "How to listen," together with a pseudo-Plutarchean treatise, "On the education of children," were popular and influential during the Renaissance. In the treatise on moral virtue Plutarch considered how virtue must subordinate unreason to reason within the soul, a theme developed in many other of the works dealing with popular ethical problems; these adduced examples from the lives of famous men, and contain sound but unoriginal moralizing. Among them are "Vice and Virtue," "How to recognize progress in virtue" (dedicated, like the *Lives*, to Sosius Senecio), "How to distinguish a flatterer from a friend," "On having many friends," and "On Fortune." Another group includes the highly rhetorical historical essays "On the fortune of Alexander," "On the fortune of the Romans," and "Whether the Athenians were more famous in war or in wisdom"; these resemble the traditional topics of declamation, and parallel to them are "Whether water or fire is more useful," "Whether virtue can be taught," and "Whether mental or bodily afflictions are the worse."

Plutarch's interest in animals and their minds emerged in two books "On eating flesh," in "Whether land or sea animals are more intelligent" (a question which receives no clear answer), and "Gryllus" or "Do animals reason?" an entertaining dialogue set on Circe's island in which a pig, one of Odysseus' transformed companions, attacks the Stoic argument denying reason to animals and convinces Odysseus of the moral superiority of many animals over man. The tenets of the philosophical schools are the subject of several essays, including "Platonic questions," "On the creation of the soul in the Timaeus" (expounding Plutarch's views about Plato's teaching on the soul), "Against Colotes" (attacking Epicurean views), and "On the impossibility of living pleasurably according to Epicurus' teaching"; several other essays criticize Stoic doctrines. Physical and medical problems are discussed in "Precepts on health," "On the face of the moon's disk," and "On primary cold" (which argues that cold is something real, not the mere absence of warmth).

The treatises dealing with political issues are of especial interest. "Political precepts" is an enlightening account of political life in contemporary Greece; in "Whether a man should engage in politics when old" Plutarch urged his friend Euphanes to continue in public life at Athens; Stoic ideas appear in the short work "To the unlearned ruler" and the fragmentary argument that "The philoso-

pher should converse especially with princes"; in "The one, the many, and the few in government" the author (who may not be Plutarch) favours monarchy. The virtues of family life are treated in "On brotherly love," "On the love of one's offspring," and "Conjugal precepts"; with the *Consolatio* to his wife goes the fine essay "On exile"; the *Amatorius* is a consideration of love, which favours normal heterosexual relationships.

Religious interests

Plutarch's interest in religious history and antiquarian problems can be seen in a group of striking essays, the early "Daemon of Socrates," and three later works concerning Delphi, "On the failure of the oracles," in which the decline of the oracle is linked with the decline in the population, "On the E at Delphi," interpreting the word EI at the temple entrance, and "On the Pythian responses," seeking to re-establish belief in the oracle. Contemporary with these is "On Isis and Osiris," with its mystical tones; the dialogue "On the late vengeance of God," staged in Delphi, argued that the postponement of divine vengeance is to give time for repentance. "Convivial questions" (nine books) and "Greek and Roman questions" assembled a vast collection of antiquarian lore; "On the malignity of Herodotus" displayed the local patriotism of a Boeotian; and the "Comparison of Aristophanes and Menander" prefers Menander for moral reasons.

Among the more important works no longer accepted as authentic are the *Consolatio* to Apollonius for his son, the "Lives of the Ten Orators," "On Fate," the "Short sayings of kings and commanders," the "Short sayings of Spartans," and "Proverbs of the Alexandrines."

Assessment. Plutarch's perennial charm and popularity arise in part from his treatment of specific human problems in which he avoids raising disquieting solutions. He wrote easily and superficially, with a wealth of anecdote. His style is predominantly Attic, though influenced by the contemporary Greek that he spoke; he followed rhetorical theory in avoiding hiatus between words and was careful in his use of prose rhythms. He is clear, but rather diffuse. Plutarch's philosophy was eclectic, with borrowings from the Stoics, Pythagoreans, and Peripatetics (but not the Epicureans) grouped around a core of Platonism. His main interest was in ethics, though he developed a mystical side, especially in his later years; he reveals that he had been initiated into the mysteries of the cult of Dionysus, and both as a Platonist and as an initiate he believed in the immortality of the soul. He believed too in the superiority of Greek culture and in the meritoriousness and providential character of the Roman Empire. Personally, he preferred a quiet and humane civic life as a citizen of a small Boeotian town, where his writing and teaching did much to illuminate the darkness of provincial life in 1st-century Greece.

Reputation and influence. Plutarch's later influence has been profound. He was loved and respected in his own time and in later antiquity; his *Lives* inspired a rhetorician, Aristides, and a historian, Arrian, to similar comparisons, and a copy accompanied the emperor Marcus Aurelius when he took the field against the Marcomanni. Gradually, Plutarch's reputation faded in the Latin West, but he continued to influence philosophers and scholars in the Greek East, where his works came to constitute a school book. Proclus, Porphyry, and the emperor Julian all quote him, and the Greek Church fathers, Clement of Alexandria and Basil the Great, imitate him without acknowledgment. His works were familiar to all cultivated Byzantines, who set no barrier between the pagan past and the Christian present. It was mainly the *Moralia* which appealed to them; but in the 9th century the Byzantine scholar and patriarch Photius read the *Lives* with his friends.

Plutarch's works were introduced to Italy by Byzantine scholars along with the revival of classical learning in the 15th century, and Italian Humanists had already translated them into Latin and Italian before 1509, when the *Moralia*, the first of his works to be printed in the original Greek, appeared at Venice published by the celebrated Aldine Press. The first original Greek text of the *Lives* was printed at Florence in 1517, and by the Aldine Press in 1519. The *Lives* were translated into French in 1559 by Jacques Amyot, a French bishop and classical scholar, who also translated the *Moralia* (1572). The first complete edition of the Greek texts by a French Humanist in 1572 marked a great improvement in the text.

That Rabelais knew Plutarch well is proved by the frequency with which he quotes from both the *Lives* and the *Moralia*. It was Montaigne, however, who read Plutarch in Amyot's version, who first made his influence widely felt. The style of Montaigne's *Essays* (1580–88) owed much to the *Moralia*, and from the *Lives* he adopted Plutarch's method of revealing character by illustrative anecdote and comment, which he applied to self-revelation. Moreover, the *Essays* made known the ideal, derived from Plutarch's presentation of character and openly expressed opinion, of "high antique virtue and the heroically moral man" which became the Humanist ideal of the Renaissance period.

The *Lives* were translated into English, from Amyot's version, by Sir Thomas North in 1579. His vigorous idiomatic style made his *Lives of the Noble Grecians and Romans* an English classic, and it remained the standard translation for more than a century. Even when superseded by more accurate translations, it continued to be read as an example of Elizabethan prose style. North's Plutarch was Shakespeare's source for his Roman plays and influenced the development of his conception of the tragic hero. The literary quality of North's version may be judged from the fact that Shakespeare lifted whole passages from it with only minor changes.

Influence on Shakespeare

In 1603 the complete *Moralia* was first translated into English directly from the Greek. Its influence can be seen in the 1612 edition of Bacon's *Essays*, which contain counsels of public morality and private virtue, recognizably derived from Plutarch. Francis Bacon was more attracted by Plutarch the moralist than by Plutarch the teller of stories or painter of character, but to the Renaissance mind it was the blend of these elements that gave him his particular appeal. His liking for historical gossip, for the anecdote, and the moral tale, his portrayal of characters as patterns of virtue or vice (in the manner of the morality play and the "character"), his emphasis on the turn of fortune's wheel in causing the downfall of the great, all suited the mood of the age, and from him was derived the Renaissance conception of the heroic and of the "rational" moral philosophy of the ancients.

Historians and biographers in the 16th and 17th centuries followed Plutarch in treating character on ethical principles. The 17th-century English biographer Izaak Walton knew Plutarch well, and his own *Lives* (collected 1670, 1675) imitated him in dwelling on the strength, rather than the weakness, of his subjects' characters.

Influence in 17th and 18th centuries

Plutarch was read throughout the 17th and 18th centuries. The English poet and dramatist John Dryden edited a new translation of the *Lives* first published in 1683–86, and abridged editions appeared in 1710, 1713, and 1718. The *Moralia* was retranslated in 1683–90 and also frequently reprinted. In France, Amyot's translations were still being reprinted in the early 19th century, and their influence on the development of French classical tragedy equalled that of North's version on Shakespeare. Admiration for those heroes of Plutarch who overthrew tyrants, and respect for his moral values, inspired the leaders of the French Revolution; Charlotte Corday, who assassinated the revolutionary leader Jean Paul Marat, spent the day before that event in reading Plutarch.

In Germany, the first collected edition of Plutarch's works was published in 1774–82. The *Moralia* was edited by Daniel Wyttenbach in 1796–1834, and was first translated in 1783–1800. The *Lives*, first edited in 1873–75, had already been translated in 1799–1806. The German classical poets—Goethe, Schiller, and Jean Paul (Johann Paul Richter) especially—were influenced by his works, and he was read also by Beethoven and Nietzsche.

In the 19th century, Plutarch's direct influence began to decline, in part as a result of the reaction against the French Revolution, in part because the rise of the Romantic movement introduced new values and emphasized the free play of passions rather than their control, in part because the more critical attitude of scholars to historical

accuracy drew attention to the bias of his presentation of fact. He was still admired, however, notably by the U.S. poet, philosopher and essayist Ralph Waldo Emerson, and although in the 20th century his direct influence was small, the popular ideas of Greek and Roman history continued to be those derived from his pages.

BIBLIOGRAPHY. R.H. BARROW, *Plutarch and His Times* (1967), is a good general introduction that lists further reading. An excellent study (in German), with comprehensive bibliography, is K. ZIEGLER in *Pauly-Wissowa's Real-encyclopädie der classischen Altertumswissenschaft*, vol. 41, col. 636–962 (1951). The dating of the works is discussed by C.P. JONES in "Towards a Chronology of Plutarch's Works," *Journal of Roman Studies*, 56:61–74 (1966). T.J.B. SPENCER, *Shakespeare's Plutarch* (1964), prints North's *Lives* of Caesar, Brutus, Antony, and Coriolanus, with the relevant parts of Shakespeare.

Editions and translations: (*Lives*): *Vitae Parallelae* by C. LINDSKOG and K. ZIEGLER in the "Teubner Series" (1914–39), is being revised (1957–); *Plutarch's Lives* by B. PERRIN in the Loeb edition, 11 vol. (1914–26), gives a text and translation. (*Moralia*): *Moralia* by G. BERNADAKIS in the "Teubner Series," 7 vol. (1888–96), is being revised by various authors and is nearly complete (1925–). *Plutarch's Moralia* in the Loeb edition, with text and translation, is also being revised by several authors, 16 vol. (1928–).

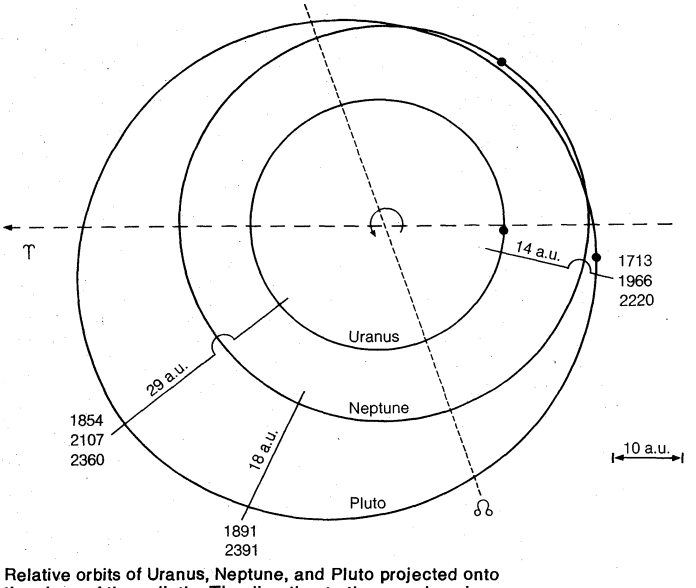
Pluto

Pluto, symbol ♇ in astronomy, is the ninth planet in the solar system. Long considered the solar system's most distant planet, Pluto is now believed to have an even more distant neighbour, known as Planet X. The principal orbit and physical data are shown in the accompanying table.



Discovery. Before Pluto's discovery in 1930 several astronomers, making calculations similar to those that led John Couch Adams and Urbain Leverrier to predict correctly the position of Neptune before its discovery, had interpreted the motions of Uranus and Neptune as revealing gravitational perturbations beyond those accountable for by all the planets known at that time. Among those who thus predicted a planet beyond Neptune was Percival Lowell, to whom credit for a successful prediction was generally given. Not only were his predicted orbital elements close to those of Pluto but he also initiated the effort that led ultimately to its discovery by his successors at the Lowell Observatory, Flagstaff, Arizona. Although Lowell's famous *Memoir on a Trans-Neptunian Planet* (*Memoirs of the Lowell Observatory*, vol. 1) was not published until 1915, the year before his death, he and his colleagues carried out intermittent searches between 1905 and 1916 with a variety of telescopes of limited capability. On the basis of experience gained in these early efforts, a fast wide-field telescope was designed specifically for the trans-Neptunian planet search.

After the telescope was completed in 1929, the project was placed in the hands of Clyde William Tombaugh. He painstakingly compared pairs of photographic plates of selected sky regions, taken several days apart, looking for images of moving objects. The project was carefully planned so that, in examining millions of stellar and starlike images, other moving bodies such as the numerous asteroids could be easily recognized and not be misidentified as the sought-for planet. On Feb. 18, 1930, Tombaugh discovered the trans-Neptunian planet on plates that he had taken on Jan. 21, 23, and 29, 1930. Announcement of the successful discovery was not made until March 13, 1930, the anniversary of Lowell's birth date, but in the interval the Lowell Observatory astronomers were able to assemble further supporting evidence and confirm the discovery. After a long deliberation over many suggested names for the new planet, the name Pluto was chosen, as it could be denoted by the symbol ♇, made up of Percival Lowell's initials.

Even while the announcement of this significant discovery was drawing the attention of the entire astronomical world to the new planet, certain grave doubts were being expressed as to whether it indeed was Lowell's trans-Neptunian planet. The difficulty was that Pluto was much fainter than had been expected (about one-tenth as bright) and it had no observable disk. It was therefore difficult to resist the conclusion that it was altogether too small and, hence, of insufficient mass to have caused the large perturbations in Uranus' and Neptune's motions that had led Lowell and others to predict its existence and orbital motion. Soon after Pluto's discovery, the noted celestial mechanician E.W. Brown showed that Lowell's prediction was, in fact, dynamically invalid. Then, E.C. Bower of the Lick Observatory, Mt. Hamilton, California, among others, convincingly demonstrated that Pluto's mass was probably less than one-half that of the Earth and that the resulting perturbations to the motions of Uranus and Neptune must have been significantly smaller than the probable errors of the earliest observations of these bodies. Modern data have since confirmed this conclusion. Thus Pluto, at first considered as the second planet, after Neptune, to have been discovered through prediction, is actually the second planet, after Uranus, to have been discovered by accident. Rather it is the first planet to have been discovered through a systematic and comprehensive search.

The orbit. Pluto moves in a markedly eccentric orbit about the Sun with a period of about 248 years. The orbit is more eccentric than that of any other planet and has a very high inclination, about 17°, to the mean plane of the solar system. The ellipse designated as Pluto's orbit in the figure is the projection of the true orbit onto the ecliptic plane; a proper representation of the true orbit would intersect this plane in the line of nodes marked ☊ and lie below it to the left, above it to the right.

The near commensurability of the periods of revolution of the three outermost planets brings the planets into successive conjunctions at about the same places in space. At intervals of approximately 500 years, during which Pluto makes two revolutions and Neptune three, these two planets come closest to each other and are then separated by only 18 astronomical units (1 a.u. = 1,496 × 10^5 km); this last occurred in 1891 and will occur again in 2391, as indicated in the figure. Similarly, Pluto and Uranus have close conjunctions although in two series. For example, in the years 1854, 2107, and 2360, Pluto and Uranus are approximately 29 a.u. apart, and in the years 1713, 1966, and 2220 only 14 a.u. apart.

Relative orbits of Uranus, Neptune, and Pluto projected onto the plane of the ecliptic. The direction to the vernal equinox is indicated by ♈. The line of nodes between Pluto's orbital plane and the ecliptic plane is indicated by ☊. The orbital motion is counterclockwise and the positions of the three planets in 1967 are indicated by dots. Approximate locations of conjunctions at the dates shown are indicated by the lines joining the orbits.

The surface of the planet. Pluto has no observable disk and is so faint that it has not been profitable to look for surface detail or to employ the more customary visual and spectroscopic techniques used in studying other planets. As early as 1933, however, W. Baade, in determining

Orbital and Physical Data for Pluto
(osculating elements for Epoch JD 2,430,000.5)

Mean distance from Sun	39.53 a.u.
Least distance from Sun	29.81 a.u.
Greatest distance from Sun	49.26 a.u.
Eccentricity	0.246
Inclination to ecliptic	17.123°
Period of revolution	248.5 years
Time of perihelion	1989.8
Visual magnitude at mean opposition	15.0
Period of axial rotation	6.3867 days
Diameter	probably between 5,000 and 6,000 kilometres
Mass	very uncertain; estimated to lie between 0.03 and 0.1 terrestrial mass
Satellites	none known
Atmosphere	unknown; traces of helium and neon probably present

Pluto's brightness at the Mount Wilson Observatory, Pasadena, California, found some evidence that it might be variable.

About 20 years later the postwar development of photoelectric techniques in astronomical photometry made possible much greater sensitivity and accuracy. Photoelectric observations of Pluto's brightness made between 1952 and 1965 by G.P. Kuiper, M.F. Walker, and R.H. Hardie at the McDonald, Mount Wilson, Lowell, and Dyer observatories confirmed Baade's suspicion. Pluto varies by about 15 percent in brightness with a period of 6.39 days. The periodic variation in reflected light is interpreted as due to the combined effects of axial rotation and of surface features of differing brightness. As yet there are insufficient data for determining the direction of the spin axis in space; but ultimately, as Pluto is observed over a larger portion of its orbit, this determination should become possible as the observed light curve goes through gradual changes in amplitude or shape with time.

Mass, diameter, and density. Because Pluto is not known to have a satellite of its own, the only direct means of determining Pluto's mass is through its perturbations on other bodies. To date the only other bodies available have been Uranus and Neptune, although in the future artificial space vehicles may provide a much more sensitive means for determining the mass of Pluto. Very slight adjustments among the orbital elements and masses of Saturn, Uranus, and Neptune can have a substantial influence on the determination of Pluto's mass, so that even the most reliable direct determination carried out by applying perturbation theory to Uranus' and Neptune's motions must be regarded as only approximate. Such a determination made at the U.S. Naval Observatory in 1970 by R.L. Duncombe, W.J. Klepczynski, and P.K. Seidelmann resulted in a mass for Pluto of 0.17 that of the Earth. Other considerations, noted below, lead astronomers to believe that this is overestimated by at least a factor of 2.

Bearing on the problem of Pluto's mass is that of its diameter. A direct observation made in 1950 by G.P. Kuiper with the 200-inch telescope at the Palomar Observatory revealed a diameter of close to 6,000 km, although a value of about 5,000 km was not ruled out. In later astrometric observations of an appulse, or near-occultation, of a faint star by Pluto, it was determined by O.G. Franz, J.B. Priser, and L.W. Sanders at the U.S. Naval and Lick observatories, that Pluto's diameter could not exceed 5,800 km for it would then have occulted the star's light, a circumstance ruled out by numerous observers. A lower limit to the diameter of about 2,000 km can be fixed from the knowledge of Pluto's brightness and distance and the assumption of perfect reflection, but on the basis of a more reasonable and typical estimate of the albedo, a diameter between 4,000 and 6,000 km is indicated. It would thus appear that taking Pluto's diameter to be about 5,500 km cannot be far wrong.

The dynamically determined mass, 0.17 of the Earth's mass, taken at face value, together with a diameter of 5,500 km, implies a mean density for Pluto of about 11.7 grams per cubic centimetre, a highly unlikely value. On the other hand, if the mean density were only as high as that of Earth (that is, 5.5 grams per cubic centimetre) a diameter of 7,000 km would be required to account for a total mass of 0.17 of the Earth's mass. As this value of diameter lies outside of the recognized possible range, one must conclude that either the mean density is higher than that of the Earth or the dynamically determined mass is too great. The present opinion of authorities in planetary structure is that the mean density is probably no higher than that of the Earth or Mercury; accordingly the mass most probably is less than 0.1 and could be as little as 0.03 of the Earth's mass.

Possible atmosphere. Whether Pluto has an atmosphere is not known with any degree of assurance, but certain conditions relating to a possible atmosphere can be stated in general terms. It can be estimated that the surface temperature on the sunlit portion of Pluto's surface is about 60° K when the planet is at perihelion and 47° K at aphelion. The dark side of the planet probably has a temperature of about 20° K. At such temperatures, virtually all materials are frozen, or at least liquefied, except a few gases such as hydrogen, helium, and neon, so that any atmosphere would be composed of these gases. While hydrogen would be expected to be the most abundant of these due to its high cosmic abundance, it is also the most likely to escape. Until more exact knowledge is available regarding Pluto's mass, size, and surface temperature, it is not possible to deduce whether a hydrogen atmosphere exists. On the other hand, any traces of helium or neon are probably retained in atmospheric form, the neon probably freezing out on the dark side and evaporating on the sunlit face. None of these atmospheric gases would produce absorption lines in the visual portion of the spectrum and hence are undetectable by customary spectroscopic means; this has been confirmed by Tobias Owen and R.H. Hardie, who find Pluto's spectral features identical with those of the Sun. Since such an atmosphere would be essentially transparent, the slightly redder quality of the observed reflected light compared with sunlight is no doubt due to the character of the surface.

Comparison with other planets. Pluto differs greatly from the major planets in its general physical properties —the other outer planets have great mass, large size, extensive atmosphere, and very rapid axial rotation—and has much higher orbital eccentricity and inclination. Thus Pluto probably had an origin and evolution different from that of the major planets. Because Pluto's physical properties appear more akin to those of the satellites, especially Triton, and because Pluto's orbit nearly intersects Neptune's, it has been proposed by R.A. Lyttleton and Kuiper that Pluto may in fact be a runaway satellite originally bound to Neptune.

Pneumatic Devices

Pneumatic devices generate and utilize compressed air in a wide variety of applications. Examples include the inflation of automobile tires, the operation of pneumatic construction tools (rock drills, pavement breakers, rivetters), and machine tools for metal processing (forging presses and grinders), for air cushions (to absorb shocks), paint sprayers, blast cleaners, atomizers and conveying materials by pneumatic tube.

Advantages of compressed-air power

Compressed-air power is flexible, economic, and safe. An air device creates no spark hazard in an explosive atmosphere and can be used under wet conditions without electric shock hazard. For these reasons compressed-air power is the only type of power used in some mining and construction operations. A relatively small compressor suffices to fill a storage tank for intermittent use, and no return lines are needed.

Several characteristics of a compressed-air system are important in meeting special service requirements. It is relatively easy to connect one device (such as a valve or a cylinder and piston) to another by pipe, tubing, or flexible hose. Many actions can be controlled by a simple manipulation of valves. The motion of an actuating piston in a cylinder can be changed quickly and in small steps with practically no shock. An air system can provide great flexibility in speed and motion control. Relief valves are easily arranged to protect a system and avoid damage. Control of operations is simple, efficient, and centralized. In general, air systems have relatively few moving parts, contributing to high reliability and low maintenance costs.

Early devices. The ordinary hand bellows, used by early smelters and blacksmiths for working iron and other metals, was a simple type of air compressor. The air intake consisted of several holes in a piece of wood, covered with flaps that served as valves. A simple check valve in the discharge prevented air from being drawn back into the bellows during the suction stroke. In the time of Hero (probably 1st century AD) a simple jet-type compressor was used to provide air for smelting and forging.

In the 17th century Otto von Guericke, of Magdeburg, Germany, carried out notable experiments and made significant improvements in compressors. In 1829 a stage or compound compressor was patented, which involved compressing air in successive cylinders. Cooling during compression by jets of water sprayed into the cylinder was introduced about 1872; later, a better system of cooling by the use of water-jacketed cylinders was developed. In the United States the first compressor used in large-scale work was a four-cylinder unit for the Hoosac Tunnel, at North Adams, Massachusetts, in 1866.

The 20th century witnessed a large increase in the use of compressed air and compressed-air devices. The introduction of jet engines for military and passenger aircraft stimulated the use and improvement of centrifugal and axial-flow compressors. The further development of automatic machinery, labour-saving devices, and automatic-control systems led to an increase in the use of pneumatics. In the late 1960s there began a significant development of a new class of compressed-air devices: digital-logic pneumatic-control components, which can be used in various power and control systems.

AIR COMPRESSORS

An air compressor is a power-driven machine for compressing air from some initial intake pressure (usually atmospheric) to a higher pressure. The familiar hand tire pump is an example of a simple machine of this type. For air pressures below eight ounces per square inch a *fan* is the most economical device, a *blower* is most efficient for pressures up to about ten pounds per square inch, and for higher pressures a *compressor* must be used. Compressors are used on aircraft engines to compress the incoming air before fuel combustion.

An air compressor may be in a fixed position, as in a factory, or portable as in building and road construction work.

Compressors, as well as other fluid machines, can be classified in two main types, depending on the air or fluid action: (1) the positive-displacement type and (2) the velocity or dynamic type. (Further information is contained in the article PUMP.)

In the positive-displacement or static-pressure type, the characteristic action is a volumetric change or displacement action. Successive volumes of air are confined within a closed space and the pressure increased by reducing the volume of the space. In the simple hand tire pump pressure is developed by moving a piston in a cylinder. The positive-displacement type may be subdivided into reciprocating (back-and-forth straightline motion) and rotary (motion in a circular path) compressors. In a positive-displacement machine, neglecting leakage, the volume rate of flow (cubic feet per second) through the compressor is essentially constant over a wide range of discharge pressures.

The common propeller type of desk fan is an example of a dynamic machine. The dynamic type may be subdivided into centrifugal (flow through a rotating runner or rotor primarily in a radial direction), axial-flow (flow through a runner primarily in a direction parallel to the axis of rotation), and fluid jet compressors.

Reciprocating compressors. A positive-displacement reciprocating compressor consists of a cylinder with a reciprocating piston and check valves for directing the air to and from the cylinder. The check valves permit flow in one direction only. The crank can be driven by an electric motor, an internal combustion engine, or a steam turbine. If it be assumed that air at atmospheric pressure exists outside the inlet valve and that the piston is at the right end of the stroke, then as the piston moves to the left the outlet valve will be closed, the pressure inside the cylinder will drop below atmospheric and air will flow into the cylinder through the inlet valve. When the piston is at the left end of the stroke the cylinder is full of air. As the piston starts to move from left to right, both valves are closed and the air is compressed. Assume that it is desired to develop an air pressure of 100 psig (pounds per square inch gage, or above atmospheric pressure). The discharge valve is set to operate at this pressure. Then at some position of the piston (between the left and right ends of the stroke) the air pressure reaches 100 psig and, as the piston continues to move, the outlet valve opens and compressed air leaves the cylinder. In a single-acting compressor the air is compressed only on one side of the piston. In a double-acting piston arrangement, the air is compressed on both sides of the piston.

Air discharged from a compressor is frequently piped into a tank or receiver for storage, to smooth out pulsations, and to remove some of the heat generated by compression. In some compressors cooling fins are arranged on the outside of the cylinder. The compression may be done in two or more stages; that is, the air is compressed only part way to its final pressure in the first stage, some heat is extracted by an intercooler, and the air is raised to its final pressure in an additional stage or stages.

In positive-displacement reciprocating compressors the number of stages is normally one for 0 to 150 psig, two for 80 to 500 psig, and three for 500–2500 psig. The reciprocating compressor is useful for supplying small amounts of air at relatively high pressures.

Rotary compressors. Positive-displacement rotary compressors are designated according to the type of mechanical rotor element. A rotary lobe compressor or blower consists of a pair of meshed identical lobes in a housing or casing. The two lobes are usually kept in proper relative rotation by a pair of external meshed gears. The incoming air is trapped between the lobe surfaces and the casing, compressed, and pushed to the outlet. The construction is simple and no separate valves are needed. Longitudinally the lobes can have helical or straight surfaces. Compressors of this type can develop 10 psig in one stage. In a rotary sliding-vane compressor the rotating member, with its sliding vanes, is eccentric (off-centre) in the casing by an amount *e*. The entering air is trapped between the vanes (which ride on the inside of the case) and is carried to the outlet. Sliding-vane compressors are used for pressures of 50 psig in one

Rotary lobe compressor

stage and 125 psig in two stages, with motor drives of up to 700 horsepower.

Centrifugal compressors. A centrifugal compressor consists of a rotating member or "impeller" with fixed vanes and a casing surrounding it. In a low-pressure centrifugal compressor the air flows axially through the inlet pipe to the centre of the rotating impeller and then outward radially, perpendicular to the axis of rotation. In the impeller the centrifugal action serves to build up velocity and pressure. At the impeller exit the air has a high velocity and flows into the volute, where it is led through the conical diffuser to the exit. The function of the volute and conical diffuser is to slow down the fluid and build up the pressure.

Centrifugal compressors are built with many different arrangements of impellers and with many variations in other details of construction. In the single suction compressor the fluid enters the impeller from one side only. In the double-suction compressor air enters both sides. A compressor may consist of several impellers on one shaft; that is, several single-stage compressors may be arranged in series.

The impeller can be driven by an electric motor, a gas turbine, or a steam turbine. The speed of rotation may range from 3,000 to 10,000 revolutions per minute and pressure up to 100 psig, depending on the number of impellers used. Flow rates may range up to as much as 150,000 cubic feet per minute. Centrifugal compressors are employed to handle large volumes of flow at moderate pressures.

Axial-flow compressors. Figure 1 shows a diagrammatic sketch of a multistage axial-flow compressor. Such

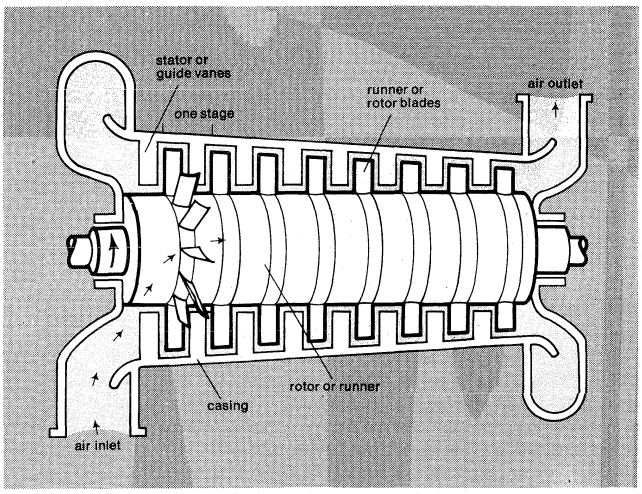

Figure 1: Multistage axial-flow compressor.

a machine may include a number of runner or rotor blades and a number of fixed, stationary guide or stator blades. The term stage designates a pair of blade rows, one row on the runner and the other on the adjacent fixed guide vanes. In an axial-flow compressor the main flow is in an annular space parallel to the axis of rotation of the runner. In a compressor stage, the curved runner blade does work on the air to increase the pressure; the fixed guide vane serves to change the velocity and increase the pressure. Like the centrifugal compressor, the axial-flow compressor is usually operated at high rotative speeds and the pressure rise is relatively low.

The centrifugal compressor is normally employed where relatively high pressures and low flow rates are desired, whereas the axial-flow compressor is more useful for relatively low pressures and high flow rates.

Jet compressors. In the jet compressor the pressure of the air is increased as it is forced through an arrangement of fixed channels by a motive fluid. These devices are sometimes called injectors, ejectors, or evacuators.

Injectors, ejectors, and evacuators

In operation, some motive fluid enters the nozzle at a high pressure. This motive fluid is accelerated in the nozzle as the pressure drops. The air to be compressed is then entrained by the high-velocity motive fluid. The entrained air is accelerated while the motive fluid is decelerated. The mixture enters the diffuser whose function is to slow the fluid down and to increase the pressure. The pressure at the exit is higher than the pressure at inlet. The motive fluid can be separated from the compressed air and reused.

In a steam-jet ejector, steam is the motive fluid. In many applications a steam-jet ejector functions as a vacuum pump; it removes air from a region initially at a pressure less than atmospheric and exhausts this air at atmospheric pressure.

PNEUMATIC TOOLS

Pneumatic tools can be divided into two groups depending on the driving method: rotor, or reciprocating piston. Both types are known as air motors. A rotating type of compressor, operating in reverse, serves as one type of motor. Compressed air enters the housing, pushes on the vanes, and rotates a central shaft or spindle. A drill, grinding wheel, or other device is fastened to the spindle. A reciprocating compressor, operating in reverse, also functions as a motor. Compressed air enters the cylinder, expands, and forces the piston to move. The return stroke may be actuated by compressed air on the other side of the piston, or by spring action. A tool, such as a rivetting hammer, may be connected to the reciprocating piston. Pneumatic tools are normally supplied with compressed air at about 90 psig.

Principal types of pneumatic tools

With compressed air as the power source, tools have been designed that are relatively light in weight, compact, portable, easy to operate, and free from electrical shock and spark hazards. In underwater operations, compressed air prevents water from entering the air motor.

Pneumatic tools can also be divided into two groups according to the type of tools: portable tools and rock drills.

Portable pneumatic tools. Portable pneumatic tools include abrasive devices (grinders, buffers, and sanders), drills, reamers, tappers, stud setters, screwdrivers, nutsetters, shears, wrenches, and impact tools. They are normally powered by a rotary-vane type of air motor. Operating speeds can be varied by throttling the air to the motor. Air motors do not become hot when overloaded; they will stand repeated stalling and rapid reversals without damage. Figure 2 illustrates a grinder; the air motor is typical for this class of device.

Portable tools also include percussion tools, chipping hammers, rivetters, scaling hammers, sand rammers, compression and yoke rivetters, air hoists, concrete vibrators, paint mixers, valve grinders, and saws.

Reprinted from the *CAGI Fundamentals of Compressed Air Power* with permission of Compressed Air and Gas Institute, 122 East 42nd Street, New York, New York 10017

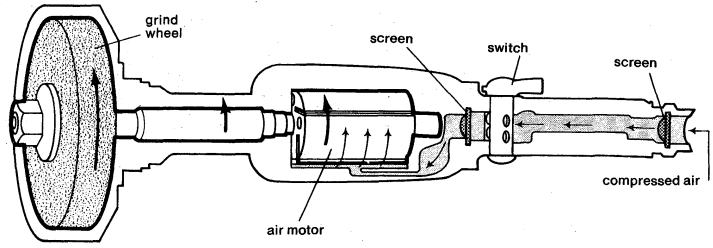

Figure 2: Pneumatic grinder.

Pneumatic chipping or scaling hammers contain an air-operated piston that delivers successive blows to a chisel or forming tool at the end of the hammer. The valve type of tool has a separate mechanism to control the air flow to the piston, thus allowing the operator to control the speed and force of the blows. This type is used for chipping and rivetting, for which control is important.

There are two designs of rivetting hammers. In a compression rivetter the compression or squeezing action on the rivet is obtained from an air piston connected to a cam, wedge, or toggle. A yoke rivetter has an air-operated clamp or vise that holds the work in place; the yoke absorbs the hammering action and thus reduces operator fatigue.

Hoists operated by compressed air are used in operations requiring accurate control of lifting or lowering speeds. Air hoists are used outdoors and under conditions in which corrosive fumes, explosive gases, or inflammable fluids are present. Safety devices prevent dropping of the load when the air pressure falls or the brakes fail.

Specialty tools

There are also various portable specialty tools, such as concrete vibrators, countersinking tools, spikedrivers, paint mixers, air cranking motors, railway roadbed tampers, valve grinders, reciprocating filing machines, and shank grinders.

Rock drills. For mining and rock excavation the usual air-operated tool is the hammer drill or percussion hammer, composed of a piston and a drill made of high-carbon steel. The drill is held loosely in a chuck at the end of the cylinder and is struck by rapid blows from the freely moving piston.

For downward-sloping holes, some means must be provided for removing drill cuttings, dust, and sludge. A hollow drill is usually used, and water or air is passed through it to remove the cuttings and cool the drill bit. Also, the bit must be rotated to produce a round uniform hole; this may be done either manually by the operator, using a wrench attached to the drill, or automatically by a ratchet-and-pawl mechanism that turns the bit slightly after each blow from the piston.

The hand-held rock drill with a self-rotating hammer is sometimes called a sinker or jackhammer. Rock drills are frequently classified on the basis of weight. A drill of less than 25 pounds may be used for drilling shallow holes in brick or concrete. A 55-pound drill may be used for road construction.

Drifter drills

The drifter drill, with an air-cylinder diameter of 3, 3½, or 4 inches, is used for horizontal holes in mining operations and tunnel driving. It is mounted on some type of rig or frame and is mechanically fed into the work. Stoper drills are used primarily on up-hole or overhead drilling because of the automatic feed characteristics. The usual stoper is a hammer drill with a self-rotating drill bit and an automatic feed by means of an air piston.

Large air-operated earth drills, mounted on motor trucks on trailers, are used for digging water wells and blast holes for quarry operations. A high capacity compressor provides air not only to power the drill tool but also to raise the tools in the hole and to remove drill cuttings from the hole. Such machines are used to advantage in areas where surface water supplies are insufficient to provide the drilling fluid needed for standard rotary and cable-tool well drilling machines.

Paving breakers. Hand-operated pneumatic paving breakers usually use solid steel drills and are not equipped for automatic rotation. Figure 3 shows a portable paving breaker. One type of tool is valve actuated, another is valveless. Heavy machines of about 80 pounds are used to break concrete pavement, foundations, and boulders. Medium breakers, weighing about 50 to 70 pounds, are used to break light concrete floors, macadam, and frozen ground. Light tools, weighing less than 50 pounds, are used for breaking floors, paving, and masonry walls. Heavy and medium-weight breakers can be adapted for driving spikes.

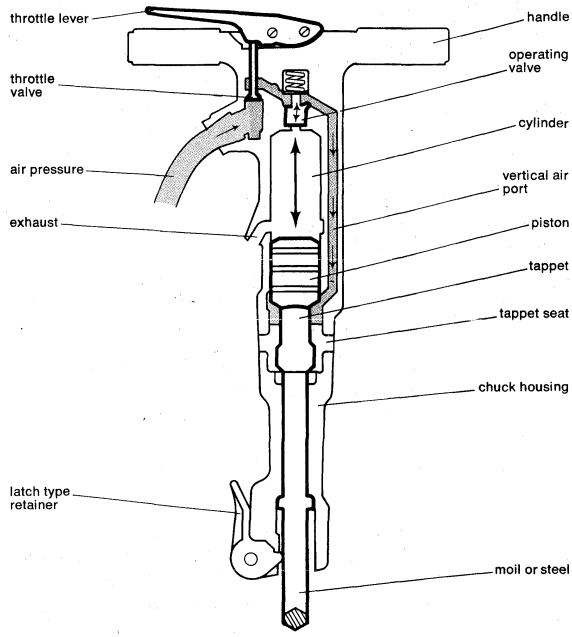

Figure 3: Pneumatic paving breaker.

OTHER PNEUMATIC DEVICES

Compressed air is a good vehicle for conveying a paint spray. In a spray gun, the paint (lacquer, enamel, or plastic coating) is atomized and mixed with compressed air. The principle of operation is similar to that of the jet compressor, with the compressed air serving as the motive fluid to draw the paint into the mixing area. Spray painting has various advantages, such as good coverage of the surface and low cost. Spray painting usually implies covering relatively large surfaces, such as a building. The term airbrush usually implies a device for developing a fine, small diameter spray of paint, protective coating, or liquid colour. The airbrush can be a pencil-shaped atomizer used for shading drawings and retouching photographs.

Pneumatic conveyers are used in many applications for handling materials. In a pressure system the outlet of the compressor leads into the inlet of the conveyer system. In a vacuum system the compressor inlet is at the end of the system. The air pressure difference across the system depends on the material to be handled.

Pneumatic mail delivery

In many places, mail is handled by pneumatic transport capsules in tubes—a technique based on an invention. All sorts of materials may be conveyed by pneumatic systems, from ashes and cement to frozen foods, minerals, nuts, and seeds. Pneumatic handling is safe, fast, clean, automatic, and flexible.

Various recently developed vehicles are supported by a cushion of air. In the planning of many city transit systems, consideration is being given to air-cushion vehicles capable of speeds up to 300 miles per hour.

Brakes on trains are operated by air pressure. A piston rod from an air cylinder exerts force on the braking device. On railroad cars the air-brake system includes a compressor, pneumatic valves, regulators, piping, reservoir, and other accessories. There are levers, cylinders, and other rigging to apply forces to the brake shoe, which bear directly on the rim of the wheel. Various automatic-control safety arrangements assure a definite braking action should some malfunction develop.

The city of Paris has a system of underground pipes, varying in diameter from 1½ inches to 20 inches, which carry compressed air to users of pneumatic devices in all sections of the city. The system was installed in the 1880s, before equipment for the generation and distribution of electric power was available.

(1966), a reference book on all phases of industrial air and gas compressors, and compressed-air-powered portable tools and rock drills used by industry; W.E. WILSON, *Positive-Displacement Pumps and Fluid Motors* (1950), an engineering text and reference book covering the design, theory of operation, and characteristics of a class of pumps and fluid motors that includes pneumatic devices; B.W. ANDERSEN, *The Analysis and Design of Pneumatic Systems* (1967), a discussion of the basic mechanics of compressible flow, the detailed design of pneumatic components and systems, and the methods for analyzing pneumatic systems; *Hydraulics and Pneumatics* (1948–), a monthly trade magazine including articles on the design and application of hydraulic and pneumatic components and systems.

(R.C.B.)

Poales

Poales is an order of flowering plants consisting of a single family, the grass family, called the Gramineae, or Poaceae. The family Gramineae probably is the most

abundant family of vascular plants, considered in terms of numbers of individuals; it dominates great areas of the earth's surface, including prairies, steppes, savannas, pampas, and paramos (all types of grassland). The family is also fairly sizable in its number of species, with an estimated 600 to 700 genera containing 6,000 to 10,000 species. It ranks about fifth among the angiosperms (flowering plants) in total number of species. The family is of prime importance to the world's agriculture because it contains all the important cereal grains. Moreover, a large number of species furnish the principal sustenance of grazing livestock and wild herbivores. The group was intimately involved in the evolution of man's domestic animals and very likely of man himself.

A great diversity of products is derived from grasses, but grain is the most important single category. Scarcely less important but more difficult to evaluate are the cultivated and wild forages obtained from grasses. The bamboos, for instance, which are highly specialized woody grasses, provide building and handcraft material, paper pulp, and edible shoots.

GENERAL FEATURES

Structural diversity and habitat range. Grasses are found in all parts of the land surface of the earth, and their ecological diversity is tremendous. The greatest number of species is found in the tropics, as is true of most plant families. The family as a whole ranges from the tropics to the high Arctic, with two species occurring on the northern extremity of the Antarctic continent.

Habitats occupied by grasses

Although the greatest abundance of grasses occurs on open lands, such as the prairies, steppes, and paramos, some species are adapted to many specialized habitats, such as saltwater and freshwater marshes, running or still water, rain forests, deserts, and Alpine or Arctic tundra. Because of their manifold adaptations to varying climates and habitats, the grasses have become an extremely successful family, and, consequently, there are probably more individual grass plants than there are of all other vascular plants combined.

Grasses range from minute forms, such as the annual bluegrass (*Poa annua*) and the high Alpine *Phippsia algida*, which are only a few centimetres tall, to the giant timber bamboos, which may reach 100 feet (30 metres) in height. The stem width is also extremely variable. Small grasses have stems only a millimetre or two in diameter, while the larger bamboos have stems as much as ten inches (25 centimetres) thick. Such large stems are produced only by very old clumps that have a large amount of stored food in their underground parts.

Grass leaf blades are commonly thought of as being ribbon shaped and with parallel veins. While the great majority of grass leaf blades are of this shape, some of the tropical forest grasses have broadly oval blades. One remarkable grass genus, *Pharus*, has broad leaf blades with the veins diverging from the midrib. The leaf blade is attached to a petiole (leafstalk, not a true one in this case), which has 180° twist, so that the leaf blade is actually upside down. Certain broad-leaved grasses of the genus *Raddia* have short sprays of crowded leaf blades that mimic the appearance of the compound leaves of certain legumes (members of the pea family, Leguminosae or Fabaceae). In this case, the leaf blades even fold up at night as legume leaves do. The leaves of desert grasses, however, are stiff, harsh, and frequently inrolled. In some species they become bristly and are probably unattractive to grazing animals. Aquatic grasses are also known, and some of these are able to float on the surface of the water because of inflated leaf sheaths or waxy, nonwettable leaves.

Economic importance. The grasses are surpassed in numbers of species by the orchids, composites (sunflowers, asters, etc.), legumes, and members of the coffee family. No other plant family, with the exception of the legumes, however, remotely approaches the grasses in agricultural importance. Their principal areas of utility include exploitation for cereal grains, sugar, timber and paper pulp, hay, pasturage, native forage, and numerous other lesser known products.

Cereal grains. The grains, which form the staple foodstuffs for much of the less affluent majority of mankind, are all derived from grasses. The more important of these are rice, wheat, maize (corn), oats, barley, rye, sorghum, and millets.

Rice (*Oryza sativa*) is an Asiatic tropical grass and is the only semi-aquatic species among the cultivated cereals. Cultivation is widespread in all warm temperate and tropical climates where sufficient moisture is available. Rice is traditionally thought of as a crop grown under flooded conditions, but certain strains will grow under moist conditions without flooding. Such strains are called upland rices, and they generally yield much less grain than does flooded rice. Although statistics are inexact, rice is probably the world's leading grain crop. Recent introduction of semidwarf strains with high productivity has greatly increased rice yields and is helping to make former rice-importing regions self-sufficient.

Wheat (*Triticum aestivum* and other species) originated in the Middle East and has spread to all temperate and cool temperate areas of the earth, being cultivated widely in southern Europe, the U.S.S.R., the United States, Canada, Argentina, and parts of India, China, and Australia. Wheat grain, containing an abundance of the elastic protein gluten, is the only cereal capable of producing a satisfactory light bread. In quantity of production, it probably ranks second to rice.

Maize

Maize or corn (*Zea mays*) is the only cereal of American origin. Discovered in the primitive wild state by the early Indians of Mesoamerica and developed extensively by them, corn became the principal foodstuff of the great Indian civilizations of Mexico, Central America, and the Andean countries. Although corn is of tropical origin, man has selected strains that are adapted to temperate climates with warm summer seasons. Its culture is now extended to all the inhabited continents. The principal use of corn is as animal feed, but great amounts are used as human food or as a source of starch, syrup, and alcohol.

Oats (*Avena sativa*), like wheat, are native to Eurasia and probably originated in the Mediterranean Basin. They are widely cultivated in the cooler temperate portions of the Northern Hemisphere and, to a limited extent, in the Southern Hemisphere. The grain is much used for animal feed, with lesser amounts going into cereals for human consumption. Cultivation of oats has decreased in recent years, however, probably because of farm mechanization and the decline in numbers of draft animals. Although the grain lacks gluten and cannot be used to make bread, the protein quality is excellent, and the quantity is susceptible to being increased by selective breeding. In Latin America, pulverized oatmeal is frequently mixed with water and used as a cold drink, called *avena*.

Barley (*Hordeum vulgare*) is another small grain of Middle Eastern origin. It is adapted to about the same areas and climatic conditions as is wheat, but barley has notable tolerance to drought and cold. Much of the grain is used in animal feed except in less developed countries. One of the principal uses of barley is the production of malt for use in brewing beer.

Rye (*Secale cereale*) is a comparative newcomer among the cereals, and its cultivation is largely confined to areas of cold climates. As a breadstuff, it scarcely competes with wheat. The grain is also used in the preparation of alcoholic liquors, and the straw is used in hats. Rye is the host plant for the fungus that produces medicinal ergot. In the United States, rye is much used to stabilize the shoulders of new roads, because of its ability to grow on poor subsoil.

The sorghums (*Sorghum bicolor*, *S. sudanense*, and others) are the most diverse of the grains, in both aspect and usages. They are of African and Middle Eastern origin and thrive best in warm, often subhumid climates. The various types furnish feed grains, silage, temporary and perennial pasture, syrups, and broomcorn.

Lesser grains

The term millet generally applies to various minor and usually inferior grains, mostly grown in less advanced agricultural areas or as emergency crops. The most common types are foxtail millet (*Setaria italica*), proso millet

(*Panicum miliaceum*), pearl millet (*Pennisetum glaucum*), and ragi, or coracan millet (*Eleusine coracana*). Millet grain is used in animal feeds, birdseed, and for human food.

Sugar. Sugar derived from grasses is mostly the product of sugarcane (*Saccharum officinarum*). Smaller amounts, nearly all in the form of syrup or molasses, are produced from certain types of sorghum.

Timber and paper pulp. These are the principal products of the bamboos (subfamily Bambusoideae). Certain types of soft construction board, such as Celotex, are often produced from sugarcane refuse (bagasse).

Hay, pasturage, and native range. The total production of these vegetational types is difficult to estimate, but land devoted to them aggregates more total area than all cultivated cropland. Many of these areas can be economically productive only through harvest of forage by grazing animals. The species prevalent in a given area differ greatly in various climatic regions. In the temperate zones some of the principal hay and pasture grasses include timothy (*Phleum pratense*), smooth brome (*Bromus inermis*), orchard grass (*Dactylis glomerata*), redtop (*Agrostis alba*), alta fescue (*Festuca arundinacea*), and Bermuda grass (*Cynodon dactylon*). The widespread Kentucky bluegrass (*Poa pratensis*), a Eurasian species, has assumed the aspect of a native in North America, furnishing large amounts of pasture, as well as being the principal lawn grass in the cooler regions.

Principal hay and pasture grasses

In the western Great Plains and the Southwest of the United States, great areas are still populated by native forage grasses, including buffalo grass (*Buchloë dactyloides*) and species of *Bouteloua* (grama grasses) and *Hilaria* (tobosa and galleta grasses). Species of *Panicum, Andropogon, Spartina,* and *Sorghastrum* are important in tallgrass areas.

In subtropical and tropical areas of the world, most of the wild and cultivated grasses belong to the subfamilies Eragrostoideae and Panicoideae. Species of *Eragrostis* (love grasses), *Cynodon* (Bermuda grass), *Chloris* (finger grass), *Panicum, Paspalum, Digitaria* (crabgrass), *Axonopus, Andropogon* (bluestem grasses), and their allies are important in cultivation.

Unusual products. A number of tropical Asiatic grasses produce sufficient quantities of aromatic compounds to merit use in perfumes. The roots of the vetiver (*Vetiveria zizanioides*) of India yield an excellent perfume after drying. The lemon-oil grass, *Cymbopogon citratus,* has a strong lemon scent, and its foliage is widely used in the tropics for tea or medicine. The grass is grown on a commercial scale for production of lemon oil, which is distilled from the leaves. Citronella oil is similarly distilled from the foliage of *Cymbopogon nardus* and is used as an insect repellent, as a perfume in soaps, and in the synthesis of menthol. The stems of sugarcane are covered with quantities of finely powdered wax that gives them a bluish hue. This wax may be recovered in the processing of cane sugar and is used in the manufacture of coatings for carbon paper.

Paper is made from a variety of grasses, including many bamboos and the North African esparto (*Stipa tenacissima*) and alfa (*Lygeum spartum*). The straw of wheat and rye is used in the manufacture of straw hats. In many parts of the world, hay or straw is used for the thatching of roofs, which last for many years when properly laid.

Special uses of bamboo

The tropical peoples of the world use the bamboos in a great variety of ways, in addition to their common usage as a timber substitute. Fishing poles and props for banana plants are commonly made from bamboo stems. Larger canes are reamed to remove the partitions at the joints and then serve as water pipes. Thin peelings from the exterior of the stems are used in basketry and mat weaving. Elegant screens of fine bamboo fibres are used to filter the suspended pulp used in the making of paper, and the pulp itself is frequently made from bamboos. Young shoots of certain bamboos are used for food and are commonly found in Oriental cookery. Tabashir, a fine, white powder (colloidal silica) found in the hollow stems of some bamboos, has been used in Oriental folk medicine. Other bamboos are grown as ornamentals for their graceful, wandlike manner of growth or as clipped hedges.

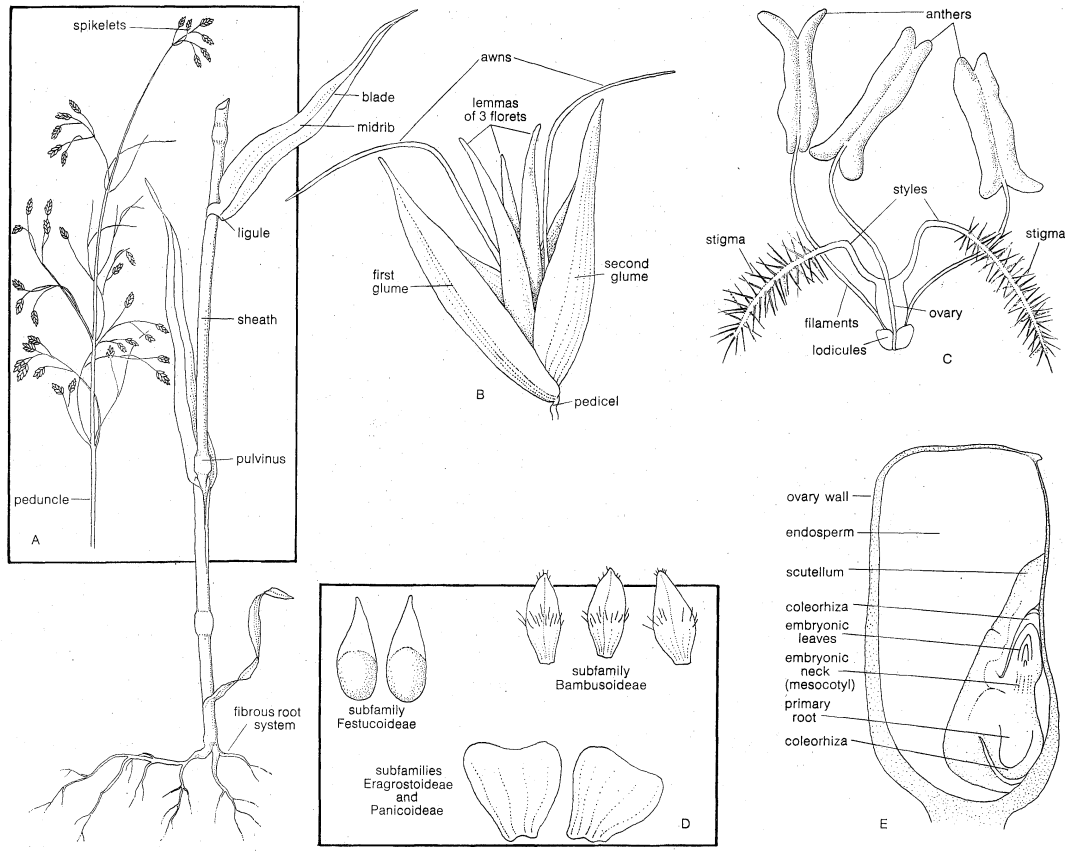
One of the most widespread tropical grasses is Job's tears (*Coix lacryma-jobi*). The hard, bony sheaths that surround the female flowers are excellent natural beads and are extensively used for necklaces and rosary beads.

Brooms are fabricated of many materials, but one of the most common materials is the stiff straw from the seed heads of the broomcorn, a variety of sorghum. The immature seed heads are dried and threshed to provide the common broomstraw of commerce.

Deleterious grasses. A considerable number of grasses are regarded as pests by man. Most of these are weeds that invade clean-tilled croplands, although there are various species that invade ranges and pastures; they are disliked because they are mechanically injurious or of lower feed value than the species they displace. Some species are invaders of lawns, where they are objectionable because of colour, texture, or growth habits.

The majority of grass weeds are annuals of rapid growth, not easily suppressed by the usual tillage methods or by the herbicide 2,4-D. Chemicals, however, are increasingly being used to control such grasses. The following list includes some of the more important annual and short-lived perennial grass weeds of temperate North America, listed with the crops or habitats in which they are important: species of *Aristida* (needlegrasses, in deteriorated ranges and wasteland); species of *Avena* (wild oats, in spring wheat or on dry rangelands of the Southwest); species of *Bromus* (ripgut grasses, cheatgrasses, and bromegrasses, in grain crops or on deteriorated Southwestern ranges); species of *Cenchrus* (sandburs, in disturbed light soils); species of *Digitaria* (crabgrasses, in lawns, gardens, and crops); species of *Echinochloa* (barnyard grasses, in crops, especially in moist areas); species of *Hordeum* (wild barley, along roadsides, in pastures and native ranges); and species of *Setaria* (foxtail grasses, in crops).

Important weedy grasses



Long-lived perennial grass weeds (those that live through more than one growing season) of importance are far fewer. In the northern United States and Canada, quackgrass (*Agropyron repens*), a persistent European weed that spreads extensively by rhizomes (underground leafless creeping stems) is the most important species. In the south of the United States, Johnson grass (*Sorghum halepense*), a tall perennial with thick, widely spreading rhizomes, is a major competitor with cotton agriculture. Bermuda grass (*Cynodon dactylon*), while extensively planted for lawns and pasturage, is also a severe pest when it invades fields and gardens. Several species of *Andropogon,* notably *A. virginicus* (broomsedge), are invaders of abandoned fields and have low apparent forage value.

NATURAL HISTORY

Life cycle. The fruit of the grasses is a single-seeded dry grain—the caryopsis, as it is known botanically; it is characteristic of the family. Grains of many grasses are capable of immediate germination, but other species have dormant seeds that require afterripening or chilling to permit germination. Such dormancy has adaptive value in preventing germination in the fall or during dry periods, when the seedling would have little chance of establishment. Cultivated types of oats (*Avena sativa*), for example, are capable of germination immediately after the grain is harvested. Probably because of this trait, the plants are virtually unable to maintain themselves in nature. The wild oat (*A. fatua*), which is a probable parent of many cultivated types, has seed that is dormant when mature. Thus the grain is able to survive the winter without injury and then germinate in the spring. As a consequence, *A. fatua* is a widespread weed. Similar examples of dormancy are widespread among grasses.

Value of seed dormancy

In germination, the embryo ruptures the thin ovary wall and any enclosing structures. The first visible signs of germination are the emergence of the tubular sheath (coleoptile) surrounding the young shoot and a similar sheath (coleorhiza) surrounding the primary root. The primary root breaks through the coleorhiza, and, shortly

Grass structures.

(D) Grass lodicules (rudimentary perianth parts) from the four largest grass subfamilies. (E) A mature caryopsis, or grain (longitudinal section).
Drawing by M. Moran

thereafter, one or more roots (seminal roots) may arise near the attachment of the embryo to a shield-shaped mass of tissue, the scutellum. The coleoptile and the structures it conceals are pushed through the soil by the elongation of the embryonic neck (mesocotyl) until the tip of the coleoptile is exposed to air and light. It is then burst by the emergence of the young leaves. The shape of the first leaf differs in the various subfamilies. In the common grass subfamily Festucoideae of the temperate zone, for example, it is very slender and elongated and tends to be vertical. In the subfamily Panicoideae, whose members are common in warmer climates, the first leaf is short, broad, and horizontal. The young seedling may continue to produce basal leaves for a time, without signs of a visible stem, or it may rapidly produce a flowering stem (culm). Except in rare instances, some form of vegetative multiplication soon becomes evident. Some species, especially perennials, may produce stolons (creeping leafy stems) or rhizomes. Grasses lacking these usually produce new stems by basal branching (tillering), to form larger and larger clumps. Old clumps may decay in the centre, and the segments of the growing periphery become isolated, forming new, small clumps.

Initiation of flowering

The sexual reproductive cycle in grasses is initiated with the development of the embryonic rudiments of a flower cluster hidden within the sheathing leaves at the tip of a culm or one of its branches. The first evidence of incipient flowering may be the swelling of the upper sheath, or "boot." The young inflorescence (flower cluster), with tightly appressed erect branches, begins to emerge, and the branches spread by means of swellings, the pulvini, at their bases (axils). Flowering usually begins at the tip of the inflorescence and proceeds downward and from the branch tips toward their bases. Reversals or alterations of this flowering sequence also occur. The spikelets of the inflorescence mature and begin to flower after emergence from the boot. Some species bloom early in the morning, others at various times of the day.

Pollination. Practically all grasses that have open flowers are exclusively wind pollinated, although a few instances of insect visits to grass flowers are known. The great prevalence of grasses in the world is a strong indication of their evolutionary success in adaptation to wind pollination. Structural specializations contributing to this success include the clustering of the tiny, naked flowers into scaly spikelets and the aggregation of the spikelets into large compound inflorescences, the presence of large anthers (pollen containers) and abundant light, fluffy pollen, and the relatively enormous and extremely feathery stigmas, which are the female structures that receive the pollen. All these factors and the colonial habit increase the chances of pollination.

After pollination has occurred, the open florets (a floret is a flower plus the two modified leaves that enclose it) close once again, and rather rapid development of the caryopsis (grain) occurs. When the caryopsis is mature, the spikelets dry and the grains are dispersed from the parent plant. In many instances, the spikelets break up into individual florets, each enclosing a grain, but, in many other grasses, entire spikelets or spikelet groups fall from the parent plant and serve as means of distribution.

Many grasses have florets that do not open because the lodicules (swollen motor structures at the base of the flower) do not function or because the spikelets are hidden within the sheaths or even, in rare instances, are underground. Such flowers that fail to open are said to be cleistogamous. They are of necessity self-pollinated. There are both evolutionary advantages and hazards in this type of reproduction. If a grass is predominantly or nearly entirely self-pollinated, the population becomes increasingly inbred. At times, this inbreeding may bring out undesirable traits and cause the death or low fertility of the individuals exhibiting them. In other cases, the inbreeding may cause the expression of traits highly desirable in fitting the species into a specific limited type of habitat, and the species may become extremely success-

Cleistogamy

ful. The homozygous, or inbred, condition of such a species or the individual populations of which it is composed, however, may make it so inflexible that it cannot change rapidly enough to cope with alterations in the environment. Most cleistogamous species, however, have a small percentage of open-pollinated flowers, allowing some crossing. Cleistogamy is especially prevalent in annual grasses, which have to produce a seed crop every year to survive well. A number of species of the genera *Sporobolus* (dropseed grass), *Panicum, Amphicarpum,* and *Danthonia* (poverty oats), among others, have well-developed cleistogamous reproduction. In some species, highly specialized hidden spikelets (cleistogenes) occur. Usually, these are quite different in appearance from the normal spikelets of the same species and may be hidden within the sheaths. In the genera *Triplasis* and *Danthonia,* the cleistogenes are concealed in the lower sheaths. At maturity the culms disarticulate at the nodes (joints), and the segments of stems, carrying the cleistogenes concealed within the sheaths, serve as disseminules (means of dispersal). In a few extreme cases, grasses produce underground spikelets on the tips of slender rhizomes. This process occurs in the genera *Chloris* and *Amphicarpum.* Despite the apparently considerable advantage of having "preplanted" seeds, such grasses are rare and restricted in range.

Cleistogamy is the dominant mode of reproduction in wheat, oats, and barley. Since there is little open pollination and, hence, little opportunity for crossing, strains of these crops tend to remain pure, even though they are grown in close proximity to one another. Rye (*Secale cereale),* on the other hand, is open-pollinated and crosses so freely that few selected strains exist.

Asexual production of seed. In certain grasses, no sexual fusion of egg and sperm occurs in the production of the seed. The embryo arises from a vegetative cell of the ovule, and the offspring are genetically identical with the maternal parent. Pollination may be necessary in some species to initiate the development of endosperm (the starchy food stored outside of the embryo), even though no fertilization of the egg occurs, and in many cases no egg, as such, is produced. Such asexually produced seed is said to be apomictic, and this process of seed production is called apomixis. The process is of great importance in the grass family and occurs in many only distantly related grasses. There is a general tendency for apomixis to be more frequent in grasses with high chromosome numbers. It is particularly prevalent in the large temperate-zone genus *Poa* (the bluegrasses) but occurs as well in many tropical grasses, including species of *Panicum, Paspalum,* and the numerous relatives of the bluestems (*Andropogon* and related genera).

Like cleistogamy, apomixis has both evolutionary advantages and drawbacks. Since an apomictic plant produces offspring exactly like the maternal parent in genetic composition, it may generate a highly uniform stand, with all individuals adapted to the same conditions and all susceptible to the same diseases. If conditions of climate or growth change radically, the population may be unable to adapt rapidly enough to accommodate to the environmental changes and may be destroyed. It is rare, however, that a species is completely apomictic, and generally a small percentage of sexually produced seed is generated as well. Thus the apomictic mechanism may serve as a stabilizing procedure, serving well to adapt a species to a relatively constant environment, while the occasional sexually produced seed allows the introduction of new variation into the population. Along with cleistogamy and vegetative reproduction, apomixis tends to preserve particularly advantageous genetic combinations but to slow down the rate of evolutionary change.

Relationship between grass evolution and grazing animals

Grasses are predominantly plants that tend to form large, treeless communities, usually composed of only a few species. Such open areas were undoubtedly responsible for the evolutionary development of the grazing herbivores, and the grasses themselves bear the evidences of evolutionary specialization to accommodate themselves to being grazed. Among these specializations are the great predominance of vegetative reproduction, by stolons, rhizomes, or tillering. Frequently, heavily grazed grasses may survive for years by vegetative spread, where other types of plants that reproduce only by seed are practically eliminated. Certain savanna grasses, growing in areas where fires occur frequently, have survived because they have evolved deep-seated corms (hard, bulblike stem bases) that are immune to fire damage. Many grassland communities occur in areas that are dry at some period of the year. Perennial grasses of such areas are well adapted to surviving seasonal drought by mechanisms that cause folding or rolling of the leaves or by the dormancy of the plants during drought periods.

The slender, erect culms of grasses are often subject to being knocked down or "lodged" by the wind. Stems that have been lodged are often able to erect themselves by the operation of a swollen region of the stem or sheath at the nodes. This swollen area, the pulvinus, is sensitive to position changes, and, when a normally erect stem is laid in a horizontal position, the pulvini begin to grow more rapidly on the lowermost side and cause the stems to erect themselves.

The grass leaf blade has a growing zone (meristem) near its base, which permits regrowth when the leaf tip is cropped or mowed. This feature of the blades, plus the abundance of basal buds possessed by grasses, serves to permit their survival under intensive grazing or mowing.

Dispersal mechanisms. A great variety of mechanisms has been exploited by the grasses in providing for the dispersal of the plants. Vegetative reproduction is often extremely efficacious in promoting dispersal by means of rhizomes, stolons, or the gradual spread of old clumps. Circumstantial evidence suggests that many colonies of rhizomatous perennial grasses may be hundreds of years old. Grasses of severe habitats, such as the sand binders of coastal dunes (*Ammophila, Elymus, Uniola, Jouvea,* and others) and of continental sand dunes (*Calamovilfa, Redfieldia, Swallenia*) may reproduce almost entirely by rhizomes or stolons in an environment hostile to the establishment of seedlings. Of all the grasses, the bamboos have most fully exploited vegetative reproduction. Many large colonies of bamboos appear to have originated as single individual plants from one seed (such colonies are called clones), as is evidenced by the fact that they remain vegetative for many years, and, when flowering finally occurs, the entire colony blooms simultaneously over great areas. The bamboos may produce short, thick rhizomes and hence produce dense clumps, or they may produce very long, slender rhizomes that spread the plants over considerable distances.

Vegetative reproduction

Another dispersal mechanism that is essentially vegetative is the production and release of vegetative bulbils in the inflorescence. These are modified spikelets that function in place of seed. Bulbous bluegrass (*Poa bulbosa*), a European species occasionally found in the United States, possesses such bulbils. Most grasses, however, produce normal seed on a regular basis, and the dispersal of the grain, either naked or with accessory structures, is the common method of spread.

Some grasses, such as the cereals wheat and rye, release naked caryopses (grains) from the spikelets. Grains as large as these have great appeal to birds and rodents and apparently are not very efficient disseminules. Many fine-seeded grasses, such as the love grasses (*Eragrostis*), however, produce an abundance of fine grains that have no special means of dispersal. The success of these plants indicates that specialized means of transportation are not always necessary to accomplish dissemination.

In a few cases, especially in the genus *Sporobolus* (dropseed grass), the ovary wall of the mature grain becomes gelatinous and swollen when wet, and such grains often adhere to passing animals. *Sporobolus indicus,* a highly successful pantropical weed, uses this dispersal method.

In most grasses, dispersal is effected by the movement of florets, entire spikelets, or groups of spikelets. In many species, individual florets are released from the plant and may be light or hairy enough to be dispersed easily by the wind. The tremendous range of the common aquatic reed (*Phragmites australis*) is testimony to the effectiveness of this type of wind dispersal of the hairy florets. In the

Wind and water dispersal

manna grasses (species of *Glyceria*), which usually grow in or around water, the light florets float upon the water surface. Wild rice (*Zizania aquatica*), which grows in water, is similarly dispersed.

A small number of grasses have spikelets enclosed in hard, bony structures that may be disseminated in various ways, including ingestion by animals that cannot digest them. The hard beads of Job's tears (*Coix lacryma-jobi*) and the hardened fruit cases of *Manisuris* and *Tripsacum* are examples of these structures. Similarly, the female spikelets of buffalo grass (*Buchloë dactyloides*) are enclosed in a bony husk that not only retards germination but also protects the grain. Ants may harvest these structures and carry them away. Certain grasses have spikelets that either form or are enclosed in spiny burs that adhere to animals and clothing. The sandburs (*Cenchrus*) are the most common examples of this. In the genus *Tragus*, the glumes (outer bracts of the spikelet) are covered with hooks that adhere to the wool of sheep, so that this genus is a commensal of the animals. In the bristly foxtail (*Setaria verticillata*), the sterile branches of the spikelike flower clusters (panicles) have minute backwardly directed barbs, so that the whole inflorescence may be carried away by passersby.

In open areas, some grasses have become tumbleweeds —their entire panicles break loose from the mature plant and roll with the wind, dispersing seed as they go. Witchgrass (*Panicum capillare*) is a common example.

Self-planting adaptations

Elaborate self-planting devices have been evolved in certain grasses. Sometimes these work all too well, causing puncture wounds in grazing animals. In the wild barleys (species of *Hordeum*) the mature spike breaks up into individual joints, or internodes, each bearing a triad of spikelets at its apex. The internode has a sharp chisel edge, and the awns, or beards (needlelike projections), of the spikelets have minute, upwardly directed barbs. This combination ensures that spikelet groups placed upon a rough surface tend to move only in one direction, forcing the chisel edge into crevices of the soil or sometimes into animal tissues. Even more elaborate is the ratchet drill device of the genus *Stipa* (porcupine grass, needle and thread). Its lower end, or callus, is extremely sharp pointed and is provided with upwardly directed bristles. When this pointed callus has penetrated any object, be it soil, clothing, or animal fur, it is extremely difficult to remove. The upper end of the floret bears a long awn with a highly hygroscopic (water-absorbing), twisted lower segment. As moisture changes occur, this twisted segment winds up (when drying) and unwinds (when moistened). These changes cause the bent awn to flail about until it lodges against an obstacle and then cause the floret to screw itself into the soil or into the unfortunate animal. Similar devices, although fabricated of different anatomical structures, occur in distantly related genera, such as *Heteropogon* and *Trachypogon*.

Finally, some grasses have adapted themselves as parasites of man's agriculture. Two of these are especially notable—chess (*Bromus secalinus*) and goat grass (*Aegilops*). These annual grasses tend to grow with wheat. They mature at the same time as wheat does, are harvested along with the grain and, unless great care is taken with cleaning the crop, will be replanted along with the next year's seed.

Ecology. Great grasslands exist on all the continents with the exception of Antarctica. In such widely separated areas, climatic, physiographic, and soil differences are great, but in general it may be said that grasses occupy areas where there is at least one period of the year with deficient moisture (usually the winter). With higher and more evenly distributed rainfall, forests hold dominance over grasslands, although man, fire, and grazing animals have apparently caused the replacement of forest by savanna or grassland in many areas, especially in the tropics. Grassland verges into desert as rainfall becomes increasingly inadequate, while forests penetrate the grasslands in especially favourable situations, as along major streams. Within grassland regions, areas of high rainfall tend to be occupied by sod-forming, often rhizomatous grasses, while scattered bunch grasses live in drier parts.

Climatic regulation of grassland occurrence

Even in deserts, scattered grasses occur. The so-called six-weeks grasses, including various short-lived annual species of *Festuca* (*Vulpia*), *Bouteloua*, and *Aristida*, may appear in profusion after heavy rains in semidesert areas.

Other grassland types occur above timberline on mountains. The Alpine tundra of high mountains in temperate North America contains many dwarf species of *Poa, Festuca, Trisetum, Calamagrostis, Agrostis,* and *Phleum.* There is a gradual transition between these Alpine grasslands and the Arctic tundra of low elevations, which includes many of the same genera. The high-elevation grasslands of the American tropics are often designated as paramo. Such areas contain many grass genera that are typically temperate-zone inhabitants and frequently dwarf bamboos as well.

In addition to the grassland species, there are many grasses that live as secondary or primary components of other vegetational types. In the temperate zone, grasses form a characteristic component of the herbaceous understory of deciduous forests. In temperate North America, various species of the following genera may be found in such forests; *Agrostis, Brachyelytrum, Bromus, Cinna, Elymus, Festuca, Hystrix, Melica, Muhlenbergia, Oryzopsis, Poa, Panicum,* and *Schizachne*. In tropical climates, a number of primitive grasses are found in the rain forests. Some of these have broad leaves, very unlike those of typical grasses. Included in this group are such genera as *Streptochaeta, Pharus, Leptaspis, Olyra, Raddia,* and others. In open areas of tropical-forest margins or where forests have been destroyed, the bamboos, which are merely giant woody grasses, may form dense, nearly impenetrable stands. In coastal areas, salt marshes are often populated by dense stands of various species of *Spartina* or *Distichlis.* Coastal or inland dunes are stabilized by species of *Uniola, Ammophila, Jouvea, Sporobolus, Elymus, Redfieldia, Calamovilfa,* and others.

The grasses are primarily a group of plants adapted to land habitats, and they are replaced in wet areas by sedges (family Cyperaceae) or rushes (family Juncaceae). A few specialized grass species, however, occur in or around water. The most widespread is the common reed, *Phragmites australis.* The genera *Leersia* and *Glyceria* are also usually confined to wet habitats. Rice (*Oryza sativa*) and wild rice (*Zizania aquatica*) have previously been noted as aquatic grasses. In many of the major groups of grasses, a few species adapted to moist or wet habitats are to be found. The most truly aquatic of all grasses are *Hydrochloa caroliniensis* and *Luziola fragilis.* Both of these species have bases rooted in the mud of ponds or streams. The weak, slender culms allow the foliage leaves and inflorescences to float on the water surface.

Aquatic and moist-habitat grasses

At the other ecological extreme, there are a wide variety of grasses adapted to extremely dry habitats. The genera *Aristida, Bouteloua, Muhlenbergia, Hilaria, Schismus,* and others occur commonly in desert areas of the American Southwest. The desert grasses are predominantly of two contrasting types. Some, such as the six-weeks grasses, are small, shallow-rooted, short-lived annuals, surviving unfavourable periods in the seed stage. The remainder are harsh perennials with narrow, fibrous, often rolled leaves, propagating largely by rhizomatous spread or by the basal growth of clumps, and are capable of remaining dormant for long periods during drought.

At least 30 percent of the land surface of the world was once grassland, although much of this area has now been put into cultivation. Soils that developed under temperate grasslands are uniquely fertile and form some of the most productive croplands. Grassland areas of great extent are found on all the continents of the world except Antarctica, and, even there, two of the three species of flowering plants that occur are grasses of the genus *Deschampsia.* (For descriptions, maps, and other material relating to these areas see GRASSLANDS.)

FORM AND FUNCTION

Vegetative characteristics. The adult grass plant consists of a jointed axis or stem, usually with solid nodes

(joints) and hollow internodes (stem regions between nodes). At each node a single leaf, with a sheathing base, is borne. The leaves are arranged distichously (in two vertical rows, 180° apart). Fibrous roots (called adventitious roots) may be borne at the basal nodes of the stems, forming the majority of the root system. Leafy, rooting portions of the stem (stolons) may creep along the surface of the earth. Beneath the soil surface, scaly, leafless stems (rhizomes) occur. Both stem types (stolons and rhizomes) serve for vegetative reproduction and food storage. Aerial stems, or culms, bear foliage leaves, each of which consists of a sheath (tubular sheathing portion), usually with overlapping edges, that surrounds the stem, and an elongated blade with parallel veins. A hairy or membranous collar, the ligule, arises at the juncture of the sheath and blade. At the base of the internode, inside of the midrib of the sheath, a bud is borne that may give rise to a branch. Between the branch and the main stem, a peculiar two-keeled modified leaf, the prophyllum, occurs. All other vegetative or floral structures of the grass plant may be homologized with one or another of the foregoing structures.

Horizontal creeping stems

Roots of grasses are usually of small diameter and are much branched, forming the so-called fibrous root system. Except in small, short-lived annual grasses, the primary root and other roots arising directly from the embryo are soon lost, and the remainder of the root system is entirely adventitious (growing from other than the usual place, such as on stems) from the lower stem nodes. In perennials, much of the root system is replaced each growing season.

Rhizomes are extremely important in the economy of many grasses, providing the principal means of reproduction, in addition to storing much food. Creeping leafy stems lying above the soil surface, the stolons, function similarly. Short, leafy basal shoots, without visible stems, are called innovations. Their leaf area may be important in furnishing forage or adding to the quality of lawns. Kentucky bluegrass (*Poa pratensis*), for example, has many such innovations, which are responsible for the density of the grass sward. Erect stems of grasses, which ultimately bear inflorescences (flower clusters), are called culms. The culm terminates in an inflorescence borne on a more or less exserted (extended beyond the rest of the plant) stalk or peduncle.

Inflorescences. Inflorescences are of many types, but panicles (much-branched flower clusters) are by far the most common. Grass flowers are extremely reduced in size and structure and are always borne in small, scaly-bracted spikes called spikelets. The spikelet, not the individual flower, is the unit of the grass inflorescence. The spikelet, which is basically homologous with a leafy stem bearing branches (the flowers), may be specialized in many diverse ways. Practical identification depends largely on characteristics of the spikelets and other parts of the inflorescence, although these characteristics have proved inadequate for the production of an evolutionary system of classification for the family Gramineae.

Importance of spikelet to grass identification

A simple type of spikelet is depicted in the accompanying Figure. The spikelet is usually supported on a stalk conventionally called a pedicel. The central axis, or rachilla, of the spikelet bears at its base two empty bracts (scalelike leaves), the glumes. These, like all the subsequent bracts of the spikelet, are distichous (arranged in two rows), as are the foliage leaves. Above the glumes each node of the rachilla bears a bract, the lemma, hidden inside of which a flower arises. At the base of the flower and actually on the flower branch is another bract, the palea, homologous with the prophyllum at the base of a vegetative branch. The palea is a two-keeled structure, somewhat H-shaped in cross section, having one vascular bundle near each keel but no midrib. The flower is enclosed between the lemma and the palea.

Flowers. Grass flowers are extremely small and simple, usually only a few millimetres long at the time of flowering. The perianth (surrounding flower parts, calyx and corolla) consists of a single cycle of small flattened or fleshy bodies, the lodicules. The number and structure of these vary in the different subfamilies of the grasses. In the bamboos and the subfamily Olyroideae, for example, three lodicules are present, two being placed between the ovary and the lemma and one between ovary and palea. The lodicules of bamboos are thin and flat, narrow and pointed, and they have several vascular bundles. In other grasses, two lodicules ordinarily are present, and these are located at the base of the lemma. In grasses of the subfamily Festucoideae they are pointed, nonvascular, and capable of swelling near the base. In the subfamilies Eragrostoideae and Panicoideae, the lodicules are square-tipped and fleshy and contain several vascular bundles. The sole surviving function of lodicules in grass flowers is to become engorged with water at the time of maturity of the flower, thereby forcing the lemma outward and allowing the anthers (pollen sacs) and stigmas (pollen receptors) to emerge.

In the great majority of grasses, three stamens (male reproductive structures) are present. Bamboos, however, characteristically have six stamens, and one genus (*Ochlandra*) has up to 120. The stamens show high evolutionary specialization toward wind pollination. The filaments (stalks of the anthers) are long and lax, permitting the anthers to dangle well out, exposed to air currents. The centrally attached anthers are proportionally very large and liberate enormous amounts of pollen. A field of rye (*Secale cereale*) during flowering, for example, can be seen to liberate clouds of yellow pollen. Plants of maize (*Zea mays*) often become noticeably dusted with pollen. Because of its abundance, grass pollen is a frequent cause of allergies, often but wrongly called rose fever. This vast excess of pollen is characteristic of wind-pollinated plants in general. The pollen, which is light and fluffy, consists of individual grains that are simple spheres with a single pore and no surface sculpturing. Each pollen mother cell produces four independent pollen grains.

Stamens and pollen specialized to wind pollination

The pistil (female reproductive organ) of grasses is composed of three united segments, or carpels, but produces only a single ovule and one seed. In bamboos and related grasses, three stigmas are usually present but in other grasses only two. In maize the two stigmas have become united, forming the silk. The stigmas are extremely feathery, serving to "comb" pollen out of the air. Despite the great waste of pollen, the combination of large anthers and extremely large stigmas has proved efficient enough to make the grasses one of the most successful and numerous families of plants.

The flower, the enveloping lemma and palea, and the usually adhering rachilla segment form a unit called a floret. Frequently the floret becomes the disseminule of the plant when the grain (caryopsis) matures.

Grass spikelets have multitudinous forms and structures, and no single description can encompass all of the variations known. Authorities generally agree that the spikelets of the ancestral grasses, typified by those of such present-day types as the bamboos, had bisexual (perfect) flowers that were borne in spikelets of several to many flowers. One common evolutionary tendency is for the loss of some or all of the upper flowers from an ancestrally many-flowered spikelet type, resulting in few-flowered or more commonly single-flowered spikelets. In the subfamily Panicoideae and in a few other forms, the lower flowers are reduced or absent, and only one perfect flower remains at the apex of the spikelet. In certain grasses, notably in the rice subfamily (Oryzoideae), the glumes have become reduced to mere ridges or a minute cup at the tip of the pedicel. In the crabgrasses (species of *Digitaria*) and related forms, the first glume has been lost or reduced to a minute rudiment.

Relatively few grasses have flowers that are unisexual. Frequently, the rudiments of the organs of the other sex may be detected in flowers of this type. Grasses with unisexual flowers may be monoecious (having both sexes on the same plant) or very rarely dioecious (the two sexes on different plants). Maize (*Zea mays*) is a prime example of monoecious grass. In maize, the male inflorescence (tassel) is situated at the tip of the stem, so that pollen may easily drift down upon the silks (stigmas) of the female spikelets, which are borne on the ear shoot below. The opposite situation occurs in wild rice (*Zizania*

Variations in sexuality

aquatica), in which the female spikelets are borne in a bunch at the tip of the stem, and the male spikelets are on lower branches of the same inflorescence. This situation encourages cross-pollination, since most of the pollen tends to drop downward. Grass species that are completely unisexual (dioecious) are much rarer.

Since the grasses are wind pollinated, there is a great wastage of pollen at any great distance from the parent plant. The difficulty in obtaining good seed set in unisexual grasses has apparently restricted the evolution of such types. The genus *Distichlis*, which occurs in maritime or saline habitats, and the common buffalo grass (*Buchloë dactyloides*) of the American Great Plains are examples of dioecious grasses. In both of these genera and other similar ones, the plants rely largely on vegetative reproduction by stolons or rhizomes, and highly effective sexual reproduction is not essential for the survival of the populations.

Shedding of spikelet parts

Spikelets vary as to the manner in which they or their parts are shed from the parent plant. In the more primitive grasses, the glumes remain on the plant, while the florets (or the grains) are shed individually or, more rarely, in a group. The shedding (disarticulation) of individual grains or florets has the obvious advantage of securing more even dispersal of the seed. In grasses with only one flower per spikelet, the entire spikelet may be shed as a unit, as in the rice subfamily (Oryzoideae) or the subfamily Panicoideae. Certain grasses that have evolved special means of seed dispersal may have clustered spikelets that disarticulate as a group from the plant, often surrounded by hooks or spines, as in the sandburs (species of *Cenchrus*).

In more primitive grasses, spikelets are laterally compressed—that is, they are flattened from the sides—so that the individual bracts are more or less boat shaped. Many common grasses, such as bluegrass (*Poa pratensis*), orchard grass (*Dactylis*), and the species of brome grass (*Bromus*), illustrate this type of structure. In the subfamily Panicoideae, however, the spikelets are flattened from the backs of the bracts (dorsally compressed), as in the genus *Panicum* or crabgrasses (species of *Digitaria*).

Fruit and seed. The fruit of the grasses is ordinarily a grain, or caryopsis. Technically, this differs from other small indehiscent (nonopening) fruits, such as the achene, by having the pericarp, or ovary wall, completely adherent to the seed. The seed coats themselves are usually crushed by the growth of the seed. In a few cases, the ovary wall may be shed, as in *Sporobolus* (dropseed grass) and *Eleusine* (goose grass), and in rare instances, especially in the bamboos, other types of fruits may occur.

The seed itself consists of a flattened, more or less boat-shaped embryo lying along one side of a large mass of starchy endosperm (stored food outside of the embryo). The bulk of the embryo consists of a fleshy body, the scutellum, which lies in contact with the endosperm and serves as a digestive and absorptive structure during germination. The true nature of the scutellum is debatable, but it has conventionally been called a cotyledon (seed leaf). The remainder of the embryo is attached on the external surface of the scutellum by its medial portion. The portion above the point of attachment is enclosed by a cylindrical sheath, the coleoptile, which protects the young shoot during germination. Within the coleoptile several embryonic leaves and the apical meristem (growing tip) of the stem are borne. The coleoptile and its contents may be attached directly to the face of the scutellum, or a short internode (embryonic neck or mesocotyl) may intervene. The lower portion of the embryo, which in some grasses is fused to the lower part of the scutellum, is a tubular sheath containing the primordium (the initial tissues) of the primary root. In certain subfamilies of the grasses a small flap of tissue, the epiblast, occurs on the external face of the embryo opposite the point of attachment. Certain features of the embryo have great value in determining the relationship of the grasses.

Leaves. The anatomy of grass leaves has been shown to be indicative of relationships within the order. The leaf epidermis, or outer "skin," in grasses is composed fundamentally of longitudinally elongated cells, usually with rippled walls. Interspersed with these are various specialized short cells, which are either suberized (corky) or impregnated with silica. The simplest of these are found in the subfamily Festucoideae, in which most of the isolated circular silicified cells are accompanied by crescent-shaped suberized cells. The other subfamilies have silicified cells in the form of double-bitted axheads, X's, collapsed quadrilaterals, or other complicated shapes. Frequently, such silicified cells occur in long rows over the vascular bundles. Many grass leaves bear elongated hairs, but these have little importance in determining relationships. Short, stiff, clawlike hairs also are common on leaf margins and may cause cuts when the leaves are handled. Plants of most of the grass subfamilies also bear specialized two-celled microhairs on the leaves. These may be linear and composed of two equal cells, the upper pointed, or they may be blunt or obtuse, with the upper cell smaller than the basal one. The type of microhair is specific to particular subfamilies. Such bicellular hairs are entirely lacking in the subfamily Festucoideae but are present in most of the other subfamilies. The shape of the complex of cells surrounding the stomates (air pores) in the epidermis is of importance in determining the subfamily to which a grass belongs. This group of cells consists, in grasses, of the two guard cells that surround the opening and two additional cells, the subsidiary cells, alongside each guard cell. In the subfamily Festucoideae, the general outline of this group of cells is rectangular, but in the other subfamilies, it varies from broadly oval to rhombic (diamond-shaped).

Internal leaf structure

The leaf cross section also reveals many features of importance in the classification of the family. Transverse sections of the leaf blade reveal a series of parallel vascular bundles, at intervals joined by small, transverse connecting bundles. Ordinarily each two large bundles are interspersed with one to several smaller and simpler ones. A typical bundle is surrounded by a thick-walled, woody sheath and often by an external layer of thin-walled, living cells (parenchyma). Internally the bundle contains a patch of phloem (food-conducting vascular tissue), oriented toward the bottom of the leaf, and several xylem vessels (water-conducting tubes). The number and nature of the bundle sheaths often indicate the subfamily to which the grass belongs. In the subfamily Eragrostoideae, for example, the outer sheath consists of large parenchyma cells that store starch, while in the subfamily Arundinoideae it consists of apparently empty cells. The green parenchyma cells filling the leaf are variously arranged. In grasses of the subfamily Festucoideae, the cells are loosely packed and without apparent order. In those of the subfamily Eragrostoideae, however, the cells are tightly packed and radially oriented in a ring around each vascular bundle. In several subfamilies, especially the Bambusoideae, Olyroideae, and Arundinoideae, the mesophyll cells (middle layers of green parenchyma cells of the leaf) often have folded-in walls or armlike processes (rachymorphous cells). Both the subfamilies Bambusoideae and Olyroideae and a few species of the subfamily Oryzoideae have large empty cells running crosswise in the leaf, between each two vascular bundles. These spindle-shaped, or fusoid, cells appear in the longitudinal sections of the leaf as I-shaped structures with large openings between them. Bulliform cells are enlarged epidermal cells, usually present between the vascular bundles on the upper leaf surface. Their function has been debated, but many authorities have claimed that they aid in folding or rolling the leaf blades at times of water stress, thereby reducing water loss.

Some grass leaf blades, especially those of the subfamilies Bambusoideae and Olyroideae, possess a constriction at the base of the blade that has been called a petiole (leafstalk) or pseudopetiole. Anatomically, it is merely a narrow portion of the leaf blade. Bamboo leaf blades are deciduous (*i.e.*, they fall) from the sheath at this point. Ordinarily, the petioles are only a few millimetres long but may reach several centimetres in *Zeugites* and as much as 13 centimetres (about five inches) in *Rattraya petiolata*.

Chromosome numbers. Since the first major compilation of grass cytology in 1931, interest in the correlation of grass chromosomes to the possible phylogenetic relationships within the family has been high, and probably the cytology of the family is better known than that of any other large family. Members of the subfamily Festucoideae, which includes the common grasses of temperate and cold climates, possess relatively large chromosomes, with the basic number of $x = 7$. All other subfamilies of the grasses possess much smaller chromosomes with basic number of $x = 5$, 6, 8, 9, 10, and 12. The bamboos, which are regarded as primitive from the standpoint of floral and spikelet structure, have $x = 10$ or 12. The evolutionary significance of the differences in chromosome number and size can only be guessed, and trying to assign one subfamily as parental to the others on the basis of cytology or morphology of living forms seems an exercise in futility.

Polyploidy among grasses

A high percentage of grasses are polyploid; that is, their somatic (body) cells possess more than the two sets of chromosomes typical of ancestral forms. Numerous species with 4, 6, 8, 10, 12, or more basic sets of chromosomes are known. This increase of chromosome number has occurred by natural means, probably after the accidental formation of nearly sterile interspecific hybrids (crosses between species). When the chromosome number of such a hybrid becomes doubled, the offspring (known as an allopolyploid) may be fertile and sometimes highly successful in nature. This spontaneous increase of chromosome numbers has been a major evolutionary method in the grasses and has undoubtedly aided greatly in fitting the members of the family to the exceedingly diverse climatic and soil conditions under which they live. Many of the most valuable agronomic grasses have had this type of origin. Examples of grass allopolyploids include timothy (*Phleum pratense*), orchard grass (*Dactylis glomerata*), wheat (*Triticum aestivum*), oats (*Avena sativa*), and many bluegrasses (*Poa* species).

Biochemical and physiological features. The grasses are notably free of alkaloids and similar compounds that abound in other monocot families, such as the Liliaceae and Amaryllidaceae. In a few instances, notably in the genus *Sorghum,* young or injured plants may contain amounts of cyanogenetic glycosides, which are organic compounds containing sugar and capable of liberating lethal amounts of hydrocyanic acid when the plants are grazed by livestock. Many grasses also may become infected with various species of ergot fungus (species of *Claviceps*), which renders the seed heads toxic.

A limited number of attempts have been made to determine relationships within the grass family by means of immune reactions similar to those used in blood typing. The results indicate that various genera formerly placed in the subfamily Festucoideae are more properly attached to the subfamily Eragrostoideae, as has been indicated also by numerous anatomical and cytological data.

EVOLUTION

Since the grasses are primarily herbaceous plants, they have not left an impressive fossil record. While claims have been made for the presence of grasses from the Cretaceous Period of some 65,000,000 to 136,000,000 years ago, all reasonably well identifiable fossil grass remains are from the Tertiary Period (beginning 65,000,000 years ago) or later. Vegetative remains of rhizomes and stem bases ascribed to the genera *Arundo* or *Phragmites* have been described from Europe. An excellent series of fossil grasses from the Great Plains of central North America was described in 1942. These fossils consist mostly of hardened fertile florets of species of grasses related to the living genera *Stipa, Oryzopsis, Piptochaetium, Nassella,* and *Setaria* or *Panicum*. They span the period from the early Miocene Epoch through the Pliocene (beginning about 26,000,000 years ago to about 2,500,000 years ago). Their nature, relationships, and associated plant and animal fossils indicate that they were inhabitants of open, dry plains. It is significant that the first appearance of these fossils of steppe-type grasses coincides closely with the evolution of ancestral horses having high-crowned teeth and strong jaws, suited to eating siliceous dry-land grasses. Their elongated legbones and sharp hooves enabled rapid running. These adaptations indicate that the animals evolved and lived in extensive grasslands. The presence of the grass fossils over a wide area indicates that rather modern type grasses and grasslands were well developed by the Miocene time and that the origin of the family must have occurred much earlier. It is likely that the ancestral grasses were delicate forest inhabitants and were incapable of fossilization.

Fossil record

Primitive grasses

Tropical-rain-forest areas of the world presently contain various peculiar, frequently broad-leaved grasses that are thought to be primitive in certain respects. The genus *Streptochaeta* of the American tropics is frequently mentioned as the most primitive living grass, yet its spikelets are highly atypical of those of other grasses and may themselves represent reduction from still earlier forms.

The relationships of the grasses to other monocotyledons has been the subject of much speculation. Earlier and undoubtedly erroneous systems of classification developed in the late 19th century were based upon the premise that the grasses are primitively simple; that is, that their small, simple, wind-pollinated flowers represent an early stage in floral evolution. A radically different system, based upon later anatomical studies of flowering plants, was presented early in the 20th century by the famous American botanist C.E. Bessey. His system, which is basic to most later arrangements, is based upon the idea that the primitive flowering plants are dicotyledons, such as the buttercups and their relatives (order Ranales in older systems, Ranunculales here) and the magnolias and their kin (order Magnoliales). The monocotyledons are regarded as having originated from the older dicotyledon orders. The lily relatives (order Liliales) represent a basic group of monocotyledons from which several lines of specialization arose. The grasses were regarded by Bessey as the apex of the wind-pollinated line of the monocotyledons, derived from the lily order by the loss of sepals and petals and various adaptations to wind pollination. Most recent authorities on plant phylogeny have followed somewhat similar arrangements of the monocotyledon families.

Recent concepts concerning relationships

A recent French writer states that the grasses arose in the Cretaceous Period from a lilylike ancestry. The rushes (family Juncaceae), which are wiry, grasslike plants with minute, six-parted green flowers, and the sedges (family Cyperaceae) are thought by this writer to have diverged from the same ancestry at about the same time. As treated here, a similar derivation of the order Poales from the order Liliales is suggested, but the sedges and rushes are separated on a different line of development. A recent system developed in the United States places both the family Cyperaceae (sedges) and the grass family (Poaceae or Gramineae) in one order, called the Cyperales. Both of these systems propose that the grasses are derived from a line based on the order Commelinales. This order contains insect-pollinated plants whose flowers have both calyx and corolla but lack nectar production. The absence of nectar is regarded as a first step in the derivation of wind-pollinated flowering plants from insect-pollinated ones, since the flowers have lost one of the structures (nectar glands) making flowers attractive to insects. Certain members of the order Commelinales are grasslike in aspect (*e.g.,* the family Xyridaceae), and all have sheathing leaf bases, somewhat similar to those of the grasses. The fruit in these groups, however, is a capsule, and the overall resemblances of these plants to the grasses are rather remote. More directly on the line of descent of the order Poales is the order Restionales. This order includes plants with wind-pollinated, reduced flowers and ovaries that have single ovules in their cavities. They are similar to the grasses in their pollen and in having sheathing leaf bases.

In the absence of a meaningful fossil record for the monocots, all of these varying systems are based upon interpretations of structure of living plants. While the details of the newer systems differ, all are alike in regarding the grasses and their kin as reduced, highly specialized plants rather than primitively simple ones.

CLASSIFICATION

Distinguishing taxonomic features. There is no single distinguishing trait of the order Poales. The presence of reduced flowers in scaly spikelets, two-ranked leaves with sheathing bases that have overlapping margins, hollow internodes, two bracts per flower, and a caryopsis as the fruit are the usual features used, but all of these are subject to variation. While the stems are ordinarily annual and herbaceous, they are long-lived and woody in the bamboos.

Plants similar to grass in appearance

Plants of three common families, the grasses (Gramineae), the sedges (Cyperaceae), and the rushes (Juncaceae), have a similar aspect and are frequently confused by casual observers. Species of the family Juncaceae are at once separable from the other two families by having flowers with a well-developed, six-parted perianth and a capsular, dehiscent fruit containing three to many seeds. Differences between the Gramineae and the Cyperaceae are summarized in the Table.

Comparison of Two Easily Confused Families, the Grasses and Sedges

character	grass family (Gramineae)	sedge family (Cyperaceae)
Leaf orientation	two rows	three rows
Leaf sheath	usually with overlapping edges	always with united edges
Stem structure	usually hollow, cylindrical	usually solid, triangular
Bracts per flower	two: lemma and palea	one: glume
Type of fruit	caryopsis	achene
Habitats	mostly dry land	mostly moist or wet areas

The features most used in modern classifications to subdivide the order Poales include the basic chromosome number and relative chromosome size, nature of specialized epidermal cells, internal leaf anatomy, root hair position on the epidermal cells, embryo structure, structure of the flower (including the number and nature of the lodicules), biochemistry and immunology, ecology, and distribution. The systems of classification produced by use of these and other characteristics must be supplemented with keys based upon easily observed superficial characteristics. Such aids to identification are now beginning to appear in recent works on grasses that use the modern evolutionary classifications as a basis for subdividing the family.

The classification used below represents a consensus of modern opinions regarding grass classification that has grown up in recent years. Since there is no modern worldwide treatment of the family, some segments of the classification stated here are adapted from different authors.

Annotated classification.

ORDER POALES

Anemophilous (wind-pollinated) herbs, rarely woody or of giant structure, with jointed, cylindrical, usually hollow stems; leaves 2-ranked (distichous), alternate, each composed of a sheathing base, a ligule, and a usually linear blade; root system fibrous, mostly adventitious; rhizomes or stolons frequent; inflorescences various (panicles, spikes, rames, or racemes) but always bearing distinctive subunits, the spikelets. Spikelets diverse but typically consisting of a central axis, the rachilla, bearing at its base a pair of empty bracts, the glumes, and above these 1 or more florets. The floret consists of an outer bract, the lemma, an inner, or secondary, bract, the palea, and the reduced flower included between them. Flowers small, typically consisting of 2 reduced perianth segments (the lodicules), 3 stamens with anthers attached at the centre, and a pistil fundamentally made up of 3 united carpels or segments but usually with 2 styles bearing feathery stigmas; ovule 1; fruit a caryopsis. Number of genera estimated at 600 to 700; species 6,000 to 10,000.

Family Poaceae or Gramineae

The only family of the order; it has the characteristics of the order.

Subfamily Bambusoideae (the bamboos)

Tropical and warm temperate woody perennial grasses; culms from diminutive to as much as 45 m, or 150 ft (rarely 90 m, or 300 ft), long, usually with hollow internodes and solid nodes, from less than 1 cm (0.5 in.) to more than 25 cm (10 in.) in diameter; propagation mostly by rhizomes; main culms ordinarily lacking foliage leaves but bearing deciduous sheaths; foliage leaves produced, after the cessation of culm growth, on small lateral branches; leaves with a short pseudopetiole between the sheath and blade; blades often deciduous at this point; leaf anatomy and epidermis "bambusoid" (*i.e.*, the long cells of the epidermis bear rows of warts; silica-bearing cells of various complex forms abundant; stomates, including the subsidiary cells, of rhombic form; bicellular microhairs pointed, the 2 cells about equal; cross-sectional anatomy of blades characterized by presence of large oval fusoid cells in the mesophyll, these appearing as large empty spaces in cross section); flowering usually rare, although some species (*e.g.*, *Chusquea subtessellata*) seem always to be in bloom. Flowering is often gregarious and periodic at long intervals of up to 60 years. Plants frequently monocarpic (flowering only once and then dying). Inflorescences terminal or axillary, paniculate, spicate, or racemose, sometimes of dense heads. The units of the inflorescence may be typical grass spikelets, or they may be "pseudospikelets," which are bracted structures concealing further lateral spikelets; spikelets with 1 to many florets; disarticulation usually between florets; lemmas usually awnless; flowers usually perfect, but sterile flowers frequent; lodicules 3, flat and with vascular bundles; stamens 3 or 6, rarely numerous; ovary of 3 carpels and with 3 stigmas; fruit a caryopsis, rarely berrylike or nutlike. Basic chromosome number $x = 10$ or 12. An expert on the subfamily states that there are 76 effectively published generic names and 1,000 species names but that many of the latter are to be regarded as synonyms. Taxonomically, the bamboos are the least known of all the grasses. Tropics and warm temperate regions of both hemispheres; a few species extending about as far north as the 40th parallel in North America.

Subfamily Olyroideae

Tropical herbaceous or semiwoody grasses having annual blooming; lacking the specialized woody perennial culms of the bamboos and their long-continued vegetative phase; leaves borne on the main culms, not on small lateral branches as in the bamboos; leaf blades often petiolate, often very broad and with conspicuous crossveins joining the longitudinal ones; leaf cross section "bambusoid," with large internal fusoid cells; spikelets 1-flowered, usually unisexual and the 2 kinds different, the pistillate (female) spikelets larger, often with a bony floret; disarticulation above or below the glumes; lodicules 3, like those of the bamboos; stamens rarely 2, usually 3 or 6; stigmas 3. Chromosomes small, with base numbers of $x = 11$ or 12. The members of this subfamily are a small group of tropical-forest grasses, apparently evolutionary relicts. About 12 genera, including 75 species, mostly in tropical America, a few in the Old World tropics.

Subfamily Festucoideae

Herbaceous grasses; spikelets from many- to single-flowered, the lemmas usually with 5 to many nerves (lines or ridges); flowers with 2 pointed, nonvascular lodicules with fleshy bases, 3 stamens, and ovary with 2 stigmas. Leaf anatomy simple, the vascular bundles with a single sclerenchyma sheath (made up of cells with thick walls), the mesophyll without special cellular arrangement; leaf epidermis simple, with few, simple specialized cells that are either solitary or paired, with 1 circular silicified cell and 1 lunate suberized (corky) cell together; stomatal complex (guard cells and subsidiary cells of stomates) rectangular in outline; bicellular hairs lacking; scutellum of the embryo lacking a separate basal limb; embryo neck (mesocotyl) lacking; epiblast present; 1st foliage leaf linear; chromosomes relatively very large, basic number $x = 7$. About 100 genera and 2,000 species. The group is widespread in both Eastern and Western hemispheres. The species are common in the temperate zones and constitute the entire grass flora of Arctic and high Alpine areas. In the tropics they are restricted to high mountains at upper elevations.

Subfamily Oryzoideae (the rice subfamily)

Spikelets 1-flowered, sometimes unisexual and then the 2 sexes borne in the same or separate inflorescences; spikelets reduced basally, with a single apical floret, the glumes reduced to mere ridges at the apex of the pedicel; basal sterile florets present in the genus *Oryza* and resembling glumes; spikelets laterally compressed or terete (cylindrical or slightly tapering); stamens 3, 6, or rarely 1; leaf epidermis complex with acuminate (sharp-pointed) bicellular hairs, rhombic or rounded stomates, complex silica bodies, often in rows; long cells often with rows of papillae (small nipple-shaped projections), as in the bamboos; leaf cross section with complex midrib, often with superposed vascular bundles; vas-

cular bundles with thin inner sclerenchyma sheath and a large-celled outer parenchyma sheath; mesophyll cells close-packed, with invaginated (inward-folded) walls; a few fusoid cells sometimes present near the major veins; embryos lacking basal limb of the scutellum and mesocotyl; epiblast present; plants mostly adapted to marshy or aquatic habitats. Chromosomes small, the base number $x = 12$ (15 in the genus *Zizania*). Genera 10, including about 35 species, found in warm temperate and tropical regions of both hemispheres.

Subfamily Arundinoideae (the reed subfamily)

Plants annual or perennial, often very tall; leaf epidermis sometimes with bicellular microhairs; silica cells of complicated forms; vascular bundles with a weak sclerenchyma sheath and outer parenchyma sheath lacking chloroplasts, mesophyll densely packed, the cell walls with invaginations; spikelets usually with several to many florets, disarticulating above the glumes; flowers usually bisexual, but some functionally dioecious types are known; lodicules 2; stamens 3; stigmas 2. Basic chromosome number $x = 11$ or 12, the chromosomes small. Genera 30, species about 450, distributed throughout the temperate and tropical regions of both hemispheres.

Subfamily Eragrostoideae

Mostly warm-climate grasses of small to moderate stature; leaf epidermis with rhombic stomates, bicellular microhairs short and obtuse, with a short upper cell; silica cells numerous, of complicated forms; leaf cross section complex, of nearly isolated units surrounding the veins and separated from the adjacent units by enlarged bulliform cells; bundle sheaths 2, the inner of small sclerenchyma cells, the outer of enlarged parenchyma cells, which store much starch and react to the iodine test; cells of the mesophyll small, mostly arranged compactly radially around the vascular bundles; spikelets usually disarticulating above the glumes, laterally compressed; florets 1 to many, sometimes the upper ones sterile; embryo with an embryonic neck and epiblast; chromosomes small, the base number $x = 6$, 9, or 10; inflorescences various, but often of 1-sided spikes or racemes. Genera about 80, including about 900 species. Distribution mostly in warm temperate and tropical regions of both hemispheres; plants especially prevalent on steppes and savannas.

Subfamily Panicoideae

Grasses of extremely diverse habits, primarily of warm climates and none Arctic or high Alpine. Culms herbaceous or rarely semiwoody, sometimes solid, as in *Zea* and *Sorghum*; leaf epidermis with acicular (needle-shaped) bicellular microhairs, rhombic stomates, and silica cells of complicated forms; leaf cross section with outer bundle sheath better developed than the inner and storing starch; mesophyll parenchyma cells somewhat radially arranged around the bundles; inflorescences are panicles or various aggregations of racemes, rames, or spikes; disarticulation below the glumes; spikelets dorsally compressed with a single perfect terminal floret and a sterile or staminate floret below it. Flower with 2 fleshy, truncate vasculated lodicules; embryo with free lower limb of scutellum and embryonic neck but no epiblast. Basal reduction of the spikelet is universal, and frequently the 1st glume is reduced or absent. Seedlings with broad, short, horizontally oriented 1st foliage leaf. Basic chromosome numbers $x = 9$ or 10, but numbers of 3, 4, 5, 7, 8 and 13 have been reported rarely; chromosomes small. The 2 tribes of the subfamily Panicoideae (Paniceae and Andropogoneae) contain 130 genera and about 2,500 species. The grasses of this subfamily are abundant and dominant in the steppe and savanna vegetation of the tropics and subtropics of both hemispheres. Numerous species extend well up into the temperate zones.

Critical appraisal. Ideas as to the classification of the grasses have undergone a veritable revolution in recent years, unparalleled in any other group of angiosperms.

Basis of early classification systems

The earlier arrangements were based primarily upon the nature of the spikelet, with secondary emphasis given to the form and structure of the inflorescence. Doubts arose as to the validity of this system when the first major compilation of chromosome numbers of the grasses was published in 1931, and the family was divided on the basis of chromosome number and size. The groupings thus defined ran counter to the system of classification current at that time, however, and were not taken up. Shortly thereafter, extensive studies were made on the grass epidermis. The wide variety of specialized cells of the epidermis was used as a basis for dividing the family into new groupings. By 1936 three subfamilies, the Bambusoideae, the Festucoideae, and the Panicoideae, were recognized. The grasses currently grouped in the subfamily Eragrostoideae were uncomfortably wedged into the subfamily Panicoideae. This system of classification, while no longer entirely accepted as to its taxonomic conclusions, was the first to incorporate such features as leaf epidermis, cross-sectional leaf anatomy, chromosome number and size, nature of the embryos and seedlings, starch grains, physiology, and ecology. Publications based upon such data led to a greatly increased interest in the construction of a more truly phylogenetic classification of the grasses. The status of grass classification was the subject of a symposium at the International Botanical Congress in Montreal in 1959. Numerous papers concerning the overall and partial classification of the group have been published since that time. More or less inclusive classifications have been published by grass evolutionists for temperate North America, for tropical Africa, and for the entire world. While these systems are not completely in accord with one another, they all show general similarities.

All of the new systems recognize the bamboos as a separate subfamily. This appears to be entirely justified, since all of this group have woody, perennial stems. In many respects, they are a highly specialized group, although their flower structure is primitive in the order. There is less general accord as to the subfamily Olyroideae, whose members are similar to the bamboos in many anatomical and cytological aspects but lack the woody stems.

The subfamily Festucoideae of the older standard system of classification has suffered the greatest remodelling. As it was originally construed, this group was united only by spikelet characteristics. It was shown by later investigators that the members differed greatly in numerous anatomical characteristics, in their basic chromosome numbers and size, and in their ecological and geographical relationships. The removal of certain genera to the subfamilies Bambusoideae, Eragrostoideae, Arundinoideae, and Oryzoideae has left the subfamily Festucoideae much more homogeneous.

The subfamily Panicoideae, which had long been recognized on the basis of spikelet structure, continues to be accepted in the original circumscription, although with some internal rearrangements.

The subfamily Arundinoideae is the least well characterized of the recently accepted divisions and will probably undergo further revision. A few isolated genera of grasses are so unusual that placement of them in any system of classification is problematical, and they can be only arbitrarily assigned to a subfamily.

Basis of recent classification systems

In general, the new systems of classification recognize about six or seven major groups (subfamilies or series), based upon numerous criteria, including microscopic anatomy and cytology. One major work on grass classification published in 1954 is at considerable odds with those previously discussed. This system uses nine subfamilies, but their constitution is very different from that proposed by later authors. The large subfamily Festucoideae of this system is even more inclusive than that of the previous standard system containing such aberrant genera as *Phyllorachis, Pariana, Thysanolaena, Arundinella, Pappophorum, Phragmites,* and others, which are placed in other subfamilies by more recent authors. The subfamily Arundinoideae, containing the giant reed grasses and other grasses, is not recognized, but, on the other hand, the bluestem grasses (*Andropogon* and its relatives) and the maize relatives are separated into a new subfamily, the Andropogonoideae. This radically different classification has not been favourably received by agrostologists, but the comprehensive nature of the work and its keys to genera make it useful.

The work of the last 40 years on grass cytology, anatomy, physiology, biochemistry, and ecology has succeeded in establishing the general outlines of a new and more informative system of classification. It seems reasonably clear that paleobotany, on the other hand, will do little or nothing to either confirm or contradict the newer classifications.

Future cytological and anatomical research is still need-

ed to fix the positions of many anomalous genera. Since the 1954 proposal of a complete general system, no attempt has been made to provide a worldwide treatment of the grasses at the generic level, using a modern system of classification. Such a treatment would be an excellent skeleton on which to place the accumulating body of data on grasses. There are no world monographs of the great majority of grass genera, even on the level of gross morphology. The availability of such monographs would be a great stimulus to the study of the family in the various parts of the world.

The wet forests of the tropics contain many rare or isolated primitive grasses, especially members of the subfamily Olyroideae. Study of these, which may reveal further clues as to grass relationships, is urgently needed before the surging population pressures of the tropical lands completely wipe out their habitats.

CRAMPTON, "A Suggested Revision of the Grass Genera of Temperate North America," *Recent Advances in Botany*, 1:133–145 (1961), the first formulation of an entirely modern system of grass classification; UNITED STATES DEPARTMENT OF AGRICULTURE, *Grass: Yearbook of Agriculture for 1948* (1948), a sourcebook of much general information on grasses, legumes, and grassland agriculture.

(R.W.P.)

Pobedonostsev, Konstantin Petrovich

Russian civil servant, tutor and adviser to tsars Alexander III and his son Nicholas II, lay leader of the Russian Orthodox Church, and political philosopher, Konstantin P. Pobedonostsev was the dominant figure in the turn to reaction that followed the assassination of Alexander II in 1881. Nicknamed the "Grand Inquisitor," he came to be the symbol of Russian monarchal absolutism.

The youngest son of a Russian Orthodox priest who was also professor of Russian literature at Moscow University, Pobedonostsev was born in Moscow on May 21, 1827. He was educated at home and at the Oldenburg School of Law in St. Petersburg (now Leningrad), from 1841 to 1846. His adult life was devoted to service at the centre of the Russian state bureaucracy, beginning in the Moscow office of the senate. The publications he produced in his spare time there on the history of Russian civil law and institutions led to his being invited in 1859 also to lecture on civil law in Moscow University. His courses were so distinguished in organization, learning, and clarity that in 1861 Alexander II asked him to serve also as a tutor to his sons during the time they spent in Moscow each year. At the same time, he was an important contributor to the 1864 reform of the Russian judicial system. In 1865 he accepted the Tsar's invitation to leave Moscow University, the senate, and his beloved Moscow to serve as a tutor to the Tsar's sons and their families in St. Petersburg. He was appointed to the senate in 1868, to the council of state (a high advisory body) in 1872, and in 1880 to the director generalship, or chief administrative position, of the Most Holy Synod of the Russian Orthodox Church, a position he held until the fall of 1905 and that was the foundation of his political influence and reputation.

Pobedonostsev.
H. Roger-Viollet

Political philosophy

Pobedonostsev was valued as an adviser by the two tsars whom he had tutored, Alexander III and Nicholas II. He considered man by nature "weak, vicious, worthless, and rebellious," denounced the 18th-century Enlightenment view of the perfectibility of man and of society, and therefore strongly supported paternalistic and authoritarian government. He looked upon each national society as an independent organic growth, based on the land, the family, and the national church, and regarded the maintenance of stability as the principal purpose of government. He sought, therefore, to defend Russia and the Russian Orthodox Church against all rival religious groups, such as the Old Believers, who had separated from the main Russian Orthodox Church, Baptists, Catholics, and Jews, against the national minorities, and against political and intellectual challenges. As a Russian nationalist, he defended Russian rule over the various minority groups and supported their Russianization, especially that of the minorities living in the western border areas. As lay head of the church, he promoted rapid expansion of primary education in parish schools because he saw it, with its emphasis upon religion, the Russian language, and song, as a strong bulwark of the autocracy. He sought to keep each person in that station in life into which he had been born and to restrict higher education to the upper classes and exceptionally talented. He tried also to prohibit and to banish all foreign influences, especially ideas concerning constitutional and democratic government, except for the "aristocracy of intellect," who needed such information in order to govern well.

Influence

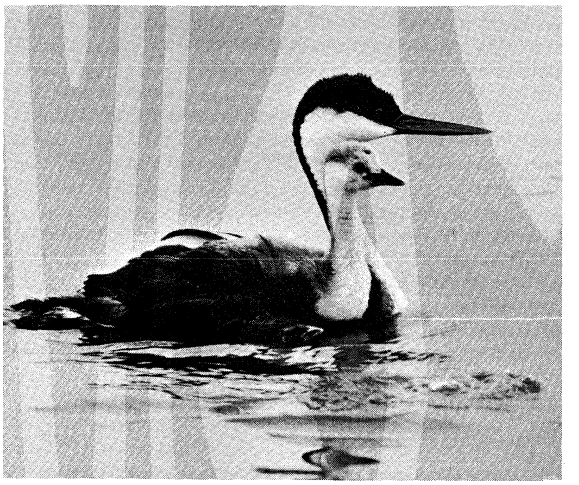
Pobedonostsev had great influence in 1881, immediately after the assassination of Alexander II, when he persuaded Alexander III to reject the so-called Loris-Melikov constitution that was designed to bridge the gap between the government and the leading elements of society. He also influenced the government's reactionary domestic policies during the 1880s but exercised little authority during the last 15 years of his life. He exerted almost no

influence on Russian foreign policy, largely because he believed Russia should isolate itself from world affairs, a belief greatly strengthened by the disappointment that followed his brief passionate advocacy of Pan-Slavist expansionism and the unsuccessful war against the Turks in 1877–78. His role, however, was exaggerated during his lifetime by critics of the regime and since then by historians, largely because his personality, appearance, and known views superbly qualified him as the symbol of a system of government deeply unpopular among many educated Russians and among all liberals and radicals.

Pobedonostsev was a childless, dry, reserved, and deeply pessimistic ascetic with almost no close friends, except for the novelist Dostoyevsky, who died in 1881. At the same time, he was a man of immense learning and scholarship, widely respected among foreign diplomats. He read and spoke most European languages, was deeply familiar with the great body of European and American literature and philosophy, and spent many of his vacations in western Europe—although he strongly supported censorship and tight controls for other Russians. Especially after 1890 he was convinced the regime would be overthrown by revolution. While he read Marx and other socialists, he saw constitutionalism and democracy as the enemies and ignored the various Russian Socialist groups. He also sought to introduce American techniques into Russian agriculture and supported rapid industrialization, which began in the early 1890s. He died in St. Petersburg on March 23 (March 10, old style), 1907.

(1925–26), a valuable collection of his letters to Alexander III and to Nicholas II as well; *L'Autocratie russe, Constantine Pobédonostsev: Mémoires politiques, correspondance officielle et documents inédits* (1927), an incomplete but still valuable translation of *К. П. Победоносцев и его корреспонденты* (1923), collection of Pobedonostsev's memoranda and of letters to him, especially from Alexander III and Nicholas II.

(R.F.B.)



Podicipediformes

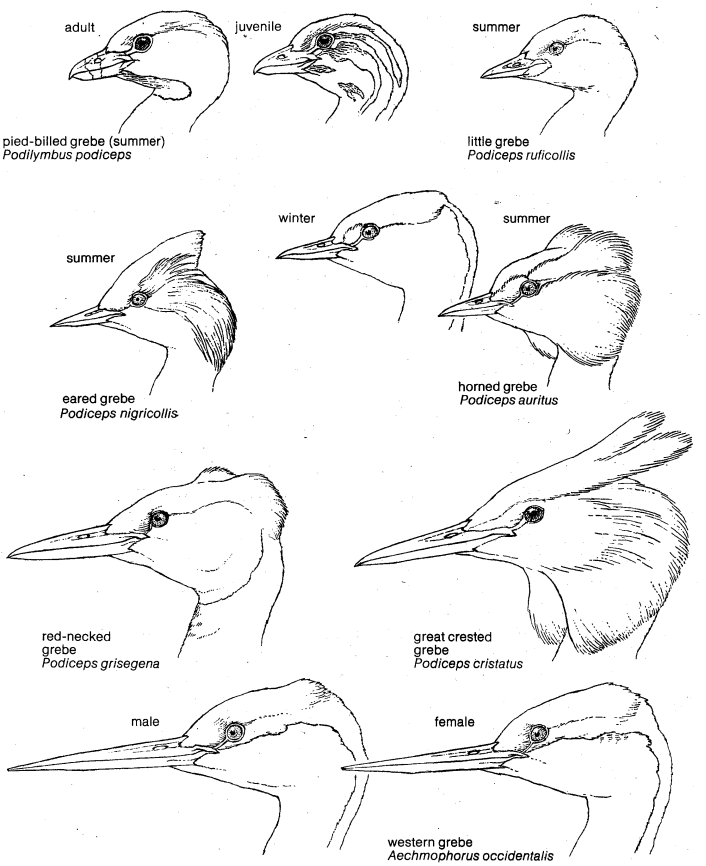
The order Podicipediformes includes only the grebes, foot-propelled diving birds best known for the striking courtship displays of some species and for the silky plumage of the underparts, which formerly was much used in millinery. The speed with which grebes can submerge has earned them such names as water-witch and helldiver, while the position of the feet near the tail is responsible for the early English name arsefoot, from which the family name, Podicipedidae, was derived.

Adult grebes range in weight from less than 150 grams (five ounces) to more than 1.4 kilograms (about three pounds) and in total length from 21 to 73 centimetres (eight to 29 inches). They vary largely in bill shape and ornamentation of the head. The group is found on all continents and many island groups, but it is best represented in temperate regions. Seven species each are found in North and South America, five in Eurasia, and three each in Africa and Australia. The species range from conspicuous and gregarious to solitary and skulking.

Natural history. Both parents share in nest building, incubation, and care of the young. The long pair bond that makes this possible is formed and strengthened by elaborate courtship displays, including ritualized preening, head shaking, diving, weed carrying, and rapid water treading with the body in a nearly vertical position. These displays may be combined into complex ceremonies such as the discovery ceremony of the great crested, rednecked, horned, eared, and related species or the rushing display of the western grebe. In nearly all courtship ceremonies the roles of the sexes are interchangeable. The same is true of the precopulatory displays, and reverse mounting has been reported for all species that have been thoroughly studied. Courtship feeding is known only in the western grebe (*Aechmophorus occidentalis*), the male of which feeds the female. Grebe vocalizations include advertising calls, copulation trills, "conversational" notes, and duetting trills. In the courtship of more secretive species, such as the pied-billed grebe (*Podilymbus podiceps*) and the dabchicks (a name given to several of the smaller grebes), vocalizations are relatively more important than visual displays.

Courtship displays

Western grebe (*Aechmophorus occidentalis*). The young are carried upon the parents' backs for protection and warmth.
Willis Peterson



Following pair formation, grebes build one or more floating platforms of aquatic vegetation. On these mating takes place and the three to seven unmarked chalky, white eggs are laid. On leaving the nest, adults often cover the eggs with the soggy nest material, and, by the end of the incubation period (three to four weeks), the eggs are strongly stained. The nest is usually deserted after the young hatch, and the small young spend most of their time on the swimming parents' backs, which they reach by clambering up the adult's foot. On hatching, the downy young are marked with bold longitudinal stripes, though these are rarely visible on the gray young of the western grebe. Remnants of the head stripes are carried over into the juvenile plumage. In addition to the stripes, the young have either one or more patches of rufous down or a bare spot on the crown. The skin of the latter changes from pink to red when the young become excited.

In winter plumage most grebes are brown, black, or gray above and white or light brown below. In summer plumage, rufous, buff, black, or white markings or elongated plumes are found, chiefly on the head and neck. In this plumage, the males tend to be more brightly coloured and to have somewhat longer plumes than the females. The males also tend to be larger and larger billed than the females.

Grebes' wings are short and the wing bones small in diameter. Some species nesting in cold regions are migratory. Major flights are usually made at night. One species, the short-winged grebe (*Rollandia micropterum*) of Lake Titicaca, between Peru and Bolivia, is flightless; two others, Taczanowski's grebe (*Podiceps taczanowskii*) of Lake Junín, Peru, and the giant pied-billed grebe *Podylimbus gigas*) of Lake Atitlán, Guatemala, have somewhat reduced wings and fly little, if at all.

While on the surface, grebes usually swim with alternate strokes of the feet, whereas under water, the feet move simultaneously. Between recovery and power strokes, the feet are turned 90° so that the broad side can be used for propulsion; just before the recovery stroke, the feet are rotated in the opposite direction. While resting, grebes keep one or both feet shipped under the wings, and the head is kept forward with the bill under the neck (the "pork-pie" posture).

Grebes breed on still or slow-moving bodies of fresh water. The dabchicks and the pied-billed grebe are most numerous on small waters with much emergent vegetation, the western grebe on large bodies of open water. Some species winter on sheltered coastal waters. Grebes'

Heads of typical grebes.
Drawing by R. Keane

diets consist almost entirely of animal matter. The western grebe feeds largely on fish, the eared grebe (*Podiceps nigricollis*) on small invertebrates, and the pied-billed grebe takes many heavy-bodied crustaceans. Other species, such as the horned and red-necked grebes (*Podiceps auritus* and *P. grisegena*), have more varied diets. Grebes are noted for swallowing feathers, which form a plug in the pyloric pocket of the stomach and effectively filter material passing to the intestine. Adults feed feathers to the young, establishing this plug shortly after hatching. Grebes feeding on invertebrates containing much chitin regurgitate pellets rather frequently; fish eaters tend to maintain masses of feathers in the main portion of the stomach, presumably to hold fish bones until they are digested.

Feather-eating

Grebes can be distinguished by their lobed toes with flat nails, greatly reduced tail feathers, and satiny breast feathers. The last is due to the loose structure of the feathers and to spirally coiled barbules (the secondary branches of the feathers), which lie parallel to the barbs (the primary branches). As with most diving birds, the conspicuous features that distinguish species are found on the head and figure prominently in courtship.

Classification and paleontology. Grebes comprise a single family, Podicipedidae, of the order Podicipediformes. There are approximately 18 species, usually placed in five genera: *Aechmophorus* (the western grebe), *Podiceps* (most species), *Podilymbus* (the pied-billed grebes), *Rollandia* (Rolland's and short-winged grebes), and *Tachybaptus* (dabchicks). The order and family are defined on the basis of structural features, especially the form of the nostrils, the absence of certain processes in the skull, and the absence of the ambiens muscle in the leg. The knee process consists of a large pyramidal patella (kneecap) and a large projection on the tibia (the main bone of the lower leg). The wing is diastataxic (*i.e.*, there is a space where the fifth secondary feather is located in many birds), with 12 primaries, seven of which are attached to the metacarpus (midhand). The oil gland is tufted and has two openings. Only the left carotid artery is present. The intestinal caeca (blind pouches) are small.

Grebes are highly specialized diving birds with no obvious relatives, living or fossil. Statements to the effect that they are "primitive" or "reptilian" are erroneously based on a superficial resemblance to the toothed Cretaceous Hesperornithiformes, themselves very specialized forms. The earliest known fossil grebe, *Podiceps oligoceanus* from lower Miocene deposits (about 25,000,000 years old) in Oregon, is essentially like modern species.

The names *Colymbus*, Colymbidae, and Colymbiformes were formerly applied to the grebes in North America and to the loons (*Gavia*) in Europe.

BIBLIOGRAPHY. R.S. PALMER (ed.), *Handbook of North American Birds*, vol. 1 (1962), provides an up-to-date summary of information on North American species; K.E.L. SIMMONS, "Studies on Great Crested Grebes," *Avicult. Mag.*, 61:3–13, 93–102, 131–146, 181–201, 235–253, 294–316 (1955), is a classic study of grebe behaviour; R.W. STORER, "The Behavior of the Horned Grebe in Spring," *Condor*, 71:180–205 (1969), contains comparative material on several species, and "The Patterns of Downy Grebes," *Condor*, 69:469–478 (1967), is concerned with the colour patterns of grebe chicks. The same author's "Courtship and Mating Behavior and the Phylogeny of the Grebes," *Proc. 13th Int. Orn. Congr.*, pp. 562–569 (1963), and "Evolution in the Diving Birds," *Proc. 12th Int. Orn. Congr.*, pp. 694–707 (1960), provide insight into the evolution and classification of grebes.

Poe, Edgar Allan

The creator of the American Gothic tale and of the whole detective fiction genre, Edgar Allan Poe cultivated the literature of mystery and the macabre to an extent unknown before. His tales of mystery and detection initiated the modern detective story, and the other-world atmosphere in his tales of horror is unrivalled in American literature.

Poe, oil portrait by S.S. Osgood, 1845.

Life. Edgar Allan Poe was born January 19, 1809, in Boston, the son of the English-born actress Elizabeth Arnold Poe and David Poe, Jr., an actor from Baltimore, Maryland. After his mother died in Richmond, Virginia, in 1811, he was taken into the home of John Allan, a Richmond merchant (presumably his godfather), and of his childless wife. He was taken to Scotland and England (1815–20), where he was given a classical education that was continued in Richmond. For 11 months in 1826 he attended the University of Virginia, where he studied Greek, Latin, French, Spanish, and Italian; but his gambling losses at the university so incensed his guardian that he refused to let him continue, and Poe returned to Richmond to find his sweetheart, (Sarah) Elmira Royster, engaged. He went to Boston where in 1827 he published a pamphlet of youthful Byronic poems, *Tamerlane and Other Poems*, some of which allude to Elmira. Poverty

forced him to join the Army under the name of Edgar A. Perry, but on the death of Poe's foster mother, John Allan purchased his release from the Army and helped in getting him an appointment to the U.S. Military Academy at West Point. Before going, Poe published a new volume at Baltimore, *Al Aaraaf, Tamerlane and Minor Poems* (1829), showing the influence of Milton and Thomas Moore, as well as of a local poet, E.C. Pinkney. He successfully sought expulsion from the academy, where he was absent from all drills and classes for a week. He proceeded to New York City and brought out a volume of *Poems*, containing several masterpieces, some showing the influence of Keats, Shelley, and Coleridge. He then returned to Baltimore, where he began to write stories. In 1833 his "MS. Found in a Bottle" won $50 from a Baltimore weekly, and by 1835 he was in Richmond as editor of the *Southern Literary Messenger*. There he made a name as a critical reviewer and married his young cousin Virginia Clemm, who was only 13. Poe seems to have been an affectionate husband and son-in-law. He wrote a tribute "To My Mother" to his aunt, Mrs. Clemm, in 1849.

Editor and critical reviewer

Poe was dismissed from his job in Richmond, apparently for drinking, and went to New York. Drinking was in fact to be the bane of his life. To talk well in a large company he needed a slight stimulant, but a glass of sherry might start him on a spree; and although he rarely succumbed to intoxication, he was often seen in public when he did. This gave rise to the conjecture that Poe was a drug addict, but according to medical testimony he had a brain lesion. While in New York in 1838 he published a long prose narrative, *The Narrative of Arthur Gordon Pym*, combining (as so often in his tales) much factual material with the wildest fancies. It is considered one inspiration of Melville's *Moby Dick*. In 1839 he became co-editor of *Burton's Gentleman's Magazine* in Philadelphia. There a contract for a monthly feature stimulated him to write "William Wilson" and "The Fall of the House of Usher"—stories of supernatural horror. The latter contains a study of a neurotic now known to have been an acquaintance of Poe, not Poe himself.

Later in 1839 his *Tales of the Grotesque and Arabesque* appeared (dated 1840). He resigned from *Burton's* about June 1840 but returned in 1841 to edit its successor, *Graham's Lady's and Gentleman's Magazine*, in which he printed the first detective story, "The Murders in the Rue Morgue." In 1843 his "The Gold Bug" won a prize of $100 from the Philadelphia *Dollar Newspaper*, which gave him great publicity. In 1844 he returned to New York, wrote the "Balloon Hoax" for the *Sun*, and became subeditor of the *New York Mirror* under N.P. Willis, thereafter another lifelong friend. In the *New York Mirror* of January 29, 1845, appeared, from advance sheets of the *American Review*, his most famous poem, "The Raven," which gave him national fame at once. Poe then became editor of the *Broadway Journal*, a short-lived weekly, in which he republished most of his short stories, in 1845. During this last year the now forgotten poet Frances Sargent Locke Osgood pursued Poe. Virginia did not object, but "Fanny's" indiscreet writings about her literary love caused great scandal. His *The Raven and Other Poems* and a selection of his *Tales* came out in 1845, and in 1846 Poe moved to a cottage at Fordham (now part of New York City), where he wrote for *Godey's Lady's Book* (May–October 1846) on the "Literati of New York"—gossipy sketches on personalities of the day, which led to a libel suit.

National fame

His wife, Virginia, died in January 1847. The following year Poe went to Providence, Rhode Island, to woo Sarah Helen Whitman, a poet. There was a brief engagement. Poe had close but platonic entanglements with Annie Richmond and with Sarah Anna Lewis, who helped him financially. He composed poetic tributes to all of them. In 1848 he also published the lecture "Eureka," a transcendental "explanation" of the universe, which has been hailed as a masterpiece by some critics and as nonsense by others. In 1849 he went south, had a wild spree in Philadelphia, but got safely to Richmond, where he finally became engaged to Elmira Royster, by then the widowed Mrs. Shelton, and spent a happy summer with only one or two relapses. He enjoyed the companionship of childhood friends and an unromantic friendship with a young poet, Susan Archer Talley.

Poe had some forebodings of death when he left Richmond for Baltimore late in September. There, after toasting a lady at her birthday party, he began to drink heavily. The indulgence proved fatal, for Poe had a weak heart. He died on October 7, 1849, and was buried in Westminister Presbyterian churchyard in Baltimore.

Early death

Appraisal. Poe's work owes much to the concern of romanticism with the occult and satanic. It owes much also to his own feverish dreams, to which he applied a rare faculty of shaping plausible fabrics out of impalpable materials. With an air of objectivity and spontaneity, his productions are closely dependent on his own powers of imagination and an elaborate technique. His keen and sound judgment as appraiser of contemporary literature, his idealism and musical gift as a poet, his dramatic art as a storyteller, considerably appreciated in his lifetime, secured him a prominent place among universally known men of letters.

The outstanding fact in Poe's character is a strange duality. The wide divergence of contemporary judgments on the man seems almost to point to the coexistence of two persons in him. With those he loved he was gentle and devoted. Others, who were the butt of his sharp criticism, found him irritable and self-centred and went so far as to accuse him of lack of principle. Was it, it has been asked, a double of the man rising from harrowing nightmares or from the haggard inner vision of dark crimes or from appalling graveyard fantasies that loomed in Poe's unstable being?

Much of Poe's best work is concerned with terror and sadness, but in ordinary circumstances the poet was a pleasant companion. He talked brilliantly, chiefly of literature, and read his own poetry and that of others in a voice of surpassing beauty. He admired Shakespeare and Alexander Pope. He had a sense of humour, apologizing to a visitor for not keeping a pet raven. If the mind of Poe is considered, the duality is still more striking. On one side, he was an idealist and a visionary. His yearning for the ideal was both of the heart and of the imagination. His sensitiveness to the beauty and sweetness of women inspired his most touching lyrics ("To Helen," "Annabel Lee," "Eulalie," "To One in Paradise") and the full-toned prose hymns to beauty and love in "Ligeia" and "Eleonora." In "Israfel" his imagination carried him away from the material world into a dreamland. This Pythian mood was especially characteristic of the later years of his life.

More generally, in such verses as "The Valley of Unrest," "Lenore," "The Raven," "For Annie," and "Ulalume" and in his prose tales his familiar mode of evasion from the universe of common experience was through eerie thoughts, impulses, or fears. From these materials he drew the startling effects of his tales of death ("The Fall of the House of Usher," "The Masque of the Red Death," "The Facts in the Case of M. Valdemar," "The Premature Burial," "The Oval Portrait," "Shadow"), his tales of wickedness and crime ("Berenice," "The Black Cat," "William Wilson," "Imp of the Perverse," "The Cask of Amontillado," "The Tell-Tale Heart"), his tales of survival after dissolution ("Ligeia," "Morella," "Metzengerstein"), and his tales of fatality ("The Assignation," "The Man of the Crowd"). Even when he does not hurl his characters into the clutch of mysterious forces or onto the untrodden paths of the beyond, he uses the anguish of imminent death as the means of causing the nerves to quiver ("The Pit and the Pendulum"), and his grotesque invention deals with corpses and decay in an uncanny play with the aftermath of death.

Prose tales

On the other side, Poe is conspicuous for a close observation of minute details, as in the long narratives and in many of the descriptions that introduce the tales or constitute their settings. Closely connected with this is his power of ratiocination. He prided himself on his logic and carefully handled this real accomplishment so as to impress the public with his possessing still more of it than he had; hence the would-be feats of thought reading, problem un-

ravelling, and cryptography that he attributed to his Legrand and Dupin. This suggested to him the analytical tales, which created the detective story, and his science fiction tales.

Duality in his art

The same duality is evinced in his art. He was capable of writing angelic or weird poetry, with a supreme sense of rhythm and word appeal, or prose of sumptuous beauty and suggestiveness, with the apparent abandon of compelling inspiration; yet he would write down a problem of morbid psychology or the outlines of an unrelenting plot in a hard and dry style. In Poe's masterpieces the double contents of his temper, of his mind, and of his art are fused into a oneness of tone, structure, and movement, the more effective, perhaps, as it is compounded of various elements.

As a critic, Poe laid great stress upon correctness of language, metre, and structure. He formulated rules for the short story, in which he sought for the ancient unities: *i.e.*, the short story should relate a complete action and take place within one day in one place. To these unities he added that of mood or effect. He was not extreme in these views, however. He praised longer works and sometimes thought allegories and morals admirable if not crudely presented. Poe admired originality, often in work very different from his own, and was sometimes an unexpectedly generous critic of decidedly minor writers.

Poe's genius was early recognized abroad. No one did more to persuade the world and, in the long run, the United States, of Poe's greatness than the French poets Charles Baudelaire and Stéphane Mallarmé. Indeed his role in French literature was that of a poetic master-model and guide to criticism. French Symbolism relied on his "Philosophy of Composition," borrowed from his imagery, and used his examples to generate the modern theory of "pure poetry."

MAJOR WORKS

POEMS: *Tamerlane and Other Poems* (1827); *Al Aaraaf, Tamerlane, and Minor Poems* (1829); *Poems by Edgar Allan Poe* (1831); *The Raven and Other Poems* (1845); "Ulalume" (1847); "Annabel Lee" (1849); "The Bells" (1849).

SHORT STORIES: *Tales of the Grotesque and Arabesque* (1840); *The Prose Romances of Edgar A. Poe* (1843), includes "The Murders in the Rue Morgue" and "The Man That Was Used Up"; *Tales* (1845), includes "The Fall of the House of Usher," "The Mystery of Marie Roget," "The Gold Bug," "The Black Cat," and "The Purloined Letter"; "The Masque of the Red Death" (1842); "The Pit and the Pendulum" (1843); "The Tell-Tale Heart" (1843); "The Premature Burial" (1844); "The Cask of Amontillado" (1846).

(C.Ce./T.O.M./J.Ba.)

Poetry

Poetry is a vast subject, as old as history and older, present wherever religion is present, possibly—under some definitions—the primal and primary form of languages themselves. The present article means only to describe in as general a way as possible certain properties of poetry and of poetic thought regarded as in some sense independent modes of the mind. Naturally, not every tradition nor every local or individual variation can be—or need be—included, but the article illustrates by examples of poetry ranging between nursery rhyme and epic. (For particular information about various types of poetry, see PROSODY and FOLK LITERATURE and articles on poetic genres, such as BALLAD and EPIC; for specific national poetic forms, see AFRICAN PEOPLES, ARTS OF; AMERICAN INDIAN PEOPLES, ARTS OF; CENTRAL ASIAN PEOPLES, ARTS OF; ISLAMIC PEOPLES, ARTS OF; JEWISH PEOPLES, ARTS OF; LITERATURE, EAST ASIAN; LITERATURE, WESTERN; OCEANIC PEOPLES, ARTS OF; SOUTH ASIAN PEOPLES, ARTS OF; and SOUTHEAST ASIAN PEOPLES, ARTS OF.) This article will consider the difficulty or impossibility of defining poetry; man's nevertheless familiar acquaintance with it; the differences between poetry and prose; the idea of form in poetry; poetry as a mode of thought; and what little may be said in prose of the spirit of poetry.

Attempts to define poetry. Poetry is the other way of using language. Perhaps in some hypothetical beginning of things it was the only way of using language or simply was language *tout court*, prose being the derivative and younger rival. Both poetry and language are fashionably thought to have belonged to ritual in early agricultural societies; and poetry in particular, it has been claimed, arose at first in the form of magical spells recited to ensure a good harvest. Whatever the truth of this hy-

pothesis, it blurs a useful distinction: by the time there begins to be a separate class of objects called poems, recognizable as such, these objects are no longer much regarded for their possible yam-growing properties, and such magic as they may be thought capable of has retired to do its business upon the human spirit and not directly upon the natural world outside.

Formally, poetry is recognizable by its greater dependence on at least one more parameter, the *line*, than appears in prose composition. This changes its appearance on the page; and it seems clear that people take their cue from this changed appearance, reading poetry aloud in a very different voice from their habitual voice, possibly because, as Ben Jonson said, poetry "speaketh somewhat above a mortal mouth." If, as a test of this description, people are shown poems printed as prose, it most often turns out that they will read the result as prose simply because it looks that way; which is to say that they are no longer guided in their reading by the balance and shift of the line in relation to the breath as well as the syntax.

That is a minimal definition but perhaps not altogether uninformative. It may be all that ought to be attempted in the way of a definition: Poetry is the way it is because it looks that way, and it looks that way because it sounds that way and vice versa.

Poetry and prose. People's reason for wanting a definition is to take care of the borderline case, and this is what a definition, as if by definition, will not do. That is, if a man asks for a definition of poetry, it will most certainly not be the case that he has never seen one of the objects called poems that are said to embody poetry; on the contrary, he is already tolerably certain what poetry in the main is, and his reason for wanting a definition is either that his certainty has been challenged by someone else or that he wants to take care of a possible or seeming exception to it: hence the perennial squabble about distinguishing poetry from prose, which is rather like distinguishing rain from snow—everyone is reasonably capable of doing so, and yet there are some weathers that are either-neither.

Distinguishing prose from poetry

Sensible things have been said on the question. The poet T.S. Eliot suggested that part of the difficulty lies in the fact that there is the technical term "verse" to go with the term "poetry," while there is no equivalent technical term to distinguish the mechanical part of prose and make the relation symmetrical. The French poet Paul Valéry said that prose was walking, poetry dancing. Indeed, the original two terms, *prosus* and *versus*, meant, respectively, "going straight forth" and "returning"; and that distinction does point up the tendency of poetry to incremental repetition, variation, and the treatment of many matters and different themes in a single recurrent form such as couplet or stanza.

Robert Frost said shrewdly that poetry was what got left behind in translation, which suggests a criterion of almost scientific refinement: when in doubt, translate; whatever comes through is prose, the remainder is poetry. And yet to even so acute a definition the obvious exception is a startling and a formidable one: some of the greatest poetry in the world is in the Authorized Version of the Bible, which is not only a translation but also, as to its appearance in print, identifiable neither with verse nor with prose in English but rather with a cadence owing something to both.

There may be a better way of putting the question by the simple test alluded to above. When people are presented with a series of passages drawn indifferently from poems and stories but all printed as prose, they will show a dominant inclination to identify everything they possibly can as prose. This will be true, surprisingly enough, even if the poem rhymes and will often be true even if the poem in its original typographical arrangement would have been familiar to them. The reason seems to be absurdly plain: the reader recognizes poems by their appearance on the page, and he responds to the convention whereby he recognizes them by reading them aloud in a quite different tone of voice from that which he applies to prose (which, indeed, he scarcely reads aloud at all). It should be added that he makes this distinction also without reading aloud; even in silence he confers upon a piece of poetry an attention that differs from what he gives to prose in two ways especially: in tone and in pace.

In place of further worrying over definitions, it may be both a relief and an illumination to exhibit certain plain and mighty differences between prose and poetry by a comparison. In the following passages a prose writer and a poet are talking about the same subject, growing older.

> Between the ages of 30 and 90, the weight of our muscles falls by 30 percent and the power we can exert likewise . . . . The number of nerve fibres in a nerve trunk falls by a quarter. The weight of our brains falls from an average of 3.03 lb. to 2.27 lb. as cells die and are not replaced. . . . (Gordon Rattray Taylor, *The Biological Time Bomb*, 1968.)

> Let me disclose the gifts reserved for age
> To set a crown upon your lifetime's effort.
> First, the cold friction of expiring sense
> Without enchantment, offering no promise
> But bitter tastelessness of shadow fruit
> As body and soul begin to fall asunder.
> Second, the conscious impotence of rage
> At human folly, and the laceration
> Of laughter at what ceases to amuse.
> And last, the rending pain of re-enactment
> Of all that you have done, and been. . . .
> (T.S. Eliot, *Four Quartets.*)

Before objecting that a simple comparison cannot possibly cover all the possible ranges of poetry and prose compared, the reader should consider for a moment what differences are exhibited. The passages are oddly parallel, hence comparable, even in a formal sense; for both consist of the several items of a catalog under the general title of growing old. The significant differences are of tone, pace, and object of attention. If the prose passage interests itself in the neutral, material, measurable properties of the process, while the poetry interests itself in what the process will signify to someone going through it, that is not accidental but of the essence; if one reads the prose passage with an interest in being informed, noting the parallel constructions without being affected by them either in tone or in pace, while reading the poetry with a sense of considerable gravity and solemnity, that too is of the essence. One might say as tersely as possible that the difference between prose and poetry is most strikingly shown in the two uses of the verb "to fall":

Differences of tone, pace, and object of attention

> The number of nerve fibres in a nerve trunk falls by a quarter
> As body and soul begin to fall asunder

It should be specified here that the important differences exhibited by the comparison belong to the present age. In each period, speaking for poetry in English at any rate, the dividing line will be seen to come at a different place. In Elizabethan times the diction of prose was much closer to that of poetry than it later became, and in the 18th century authors saw nothing strange about writing in couplets about subjects that later would automatically and compulsorily belong to prose—for example, horticulture, botany, even dentistry. This brief article is not the place for entering into a discussion of so rich a chapter in the history of ideas; but it should be remarked that the changes involved in the relation between poetry and prose are powerfully influenced by the immense growth of science, commerce, and number in man's ways of describing, even of viewing, the world.

Returning to the comparison, it is observable that though the diction of the poem is well within what could be commanded by a moderately well-educated speaker, it is at the same time well outside the range of terms in fact employed by such a speaker in his daily occasions; it is a diction very conscious, as it were, of its power of choosing terms with an effect of peculiar precision and of combining the terms into phrases with the same effect of peculiar precision and also of combining sounds with the same effect of peculiar precision. Doubtless the precision of the prose passage is greater in the more obvious property of dealing in the measurable; but the poet attempts a precision with respect to what is not in the same sense measurable nor even in the same sense accessible to observation; the distinction is perhaps just that made by the French scientist and philosopher Blaise Pascal in discrim-

Precision of poetic diction

inating the spirits of geometry and finesse; and if one speaks of "effects of precision" rather than of precision itself, that serves to distinguish one's sense that the art work is always somewhat removed from what people are pleased to call the real world, operating instead, in Immanuel Kant's shrewd formula, by exhibiting "purposefulness without purpose." To much the same point is what Samuel Taylor Coleridge remembers having learned from his schoolmaster:

> I learnt from him, that Poetry, even that of the loftiest and, seemingly, that of the wildest odes, had a logic of its own, as severe as that of science; and more difficult, because more subtle, more complex, and dependent on more, and more fugitive causes. In the truly great poets, he would say, there is a reason assignable, not only for every word, but for the position of every word. (*Biographia Literaria*, ch. I.)

Perhaps this is a somewhat exaggerated, as it is almost always an unprovable, claim, illustrating also a propensity for competing with the prestige of science on something like its own terms—but the last remark in particular illuminates the same author's terser formulation: "prose = words in the best order, poetry = the best words in the best order." This attempt at definition, impeccable because uninformative, was derived from Jonathan Swift, who had said, also impeccably and uninformatively, that style in writing was "the best words in the best order." Which may be much to the same effect as Louis Armstrong's saying, on being asked to define jazz, "Baby, if you got to ask the question, you're never going to know the answer." Or the painter Marcel Duchamp's elegant remark on what psychologists call "the problem of perception": "If no solution, then maybe no problem?" This species of gnomic, riddling remark may be determinate for the artistic attitude toward definition of every sort; and its skepticism is not confined to definitions of poetry but extends to definitions of anything whatever, directing one not to dictionaries but to experience and, above all, to use: "Anyone with a watch can tell you what time it is," said Valéry, "but who can tell you what is time?"

Experiencing poetry

Happily, if poetry is almost impossible to define, it is extremely easy to recognize in experience; even untutored children are rarely in doubt about it when it appears:

> Little Jack Jingle,
> He used to live single,
> But when he got tired of this kind of life,
> He left off being single, and liv'd with his wife.

It might be objected that this little verse is not of sufficient import and weight to serve as an exemplar for poetry. It ought to be remembered, though, that it has given people pleasure so that they continued to say it until and after it was written down, nearly two centuries ago. The verse has survived, and its survival has something to do with pleasure, with delight; and while it still lives, how many more imposing works of language—epic poems, books of science, philosophy, theology—have gone down, deservedly or not, into dust and silence. It has, obviously, a form, an arrangement of sounds in relation to thoughts that somehow makes its agreeable nonsense closed, complete, and decisive. But this somewhat muddled matter of form deserves a heading and an instance all to itself.

Form in poetry. People nowadays who speak of form in poetry almost always mean such externals as regular measure and rhyme, and most often they mean to get rid of these in favour of the freedom they suppose must follow upon the absence of form in this limited sense. But in fact a poem having only one form would be of doubtful interest even if it could exist. In this connection, the poet J.V. Cunningham speaks of "a convergence of forms, and forms of disparate orders," adding: "It is the coincidence of forms that locks in the poem." For a poem is composed of internal and intellectual forms as well as forms externally imposed and pre-existing any particular instance, and these may be sufficient without regular measure and rhyme; if the intellectual forms are absent, as in greeting-card verse and advertising jingles, no amount of thumping and banging will supply the want.

Form, in effect, is like the doughnut that may be made either by putting some nothing into a circle of something or by closing some something around some nothing; it is either the outside of an inside, as when people speak of "good form" or "bourgeois formalism," or the inside of an outside, as in the scholastic saying that "the soul is the form of the body." Taking this principle, together with what Cunningham says of the matter, one may now look at a very short and very powerful poem with a view to distinguishing the forms, or schemes, of which it is made. It was written by Rudyard Kipling—a great poet at present somewhat sunken in reputation, probably on account of misinterpretations having to do more with his imputed politics than with his poetry—and its subject, one of a series of epitaphs for the dead of World War I, is a soldier shot by his comrades for cowardice in battle.

> I could not look on Death, which being known,
> Men led me to him, blindfold and alone.

The aim of the following observations and reflections is to distinguish as clearly as possible—distinguish without dividing—the feelings evoked by the subject, so grim, horrifying, tending to helpless sorrow and despair, from the feelings, which might better be thought of as meanings, evoked by careful contemplation of the poem in its manifold and somewhat subtle ways of handling the subject, leading the reader on to a view of the strange delight intrinsic to art, whose mirroring and shielding power allows him to contemplate the world's horrible realities without being turned to stone.

Kinds of poetic form

There is, first, the obvious external form of a rhymed, closed couplet in iambic pentameter (that is, five poetic "feet," each consisting of one stressed and one unstressed syllable, per line). There is, second, the obvious external form of a single sentence balanced in four grammatical units with and in counterpoint with the metrical form. There is, third, the conventional form belonging to the epitaph and reflecting back to antiquity; it is terse enough to be cut in stone and tight-lipped also, perhaps for other reasons, such as the speaker's shame. There is, fourth, the fictional form belonging to the epitaph, according to which the dead man is supposed to be saying the words himself. There is, fifth, especially poignant in this instance, the real form behind or within the fictional one, for the reader is aware that in reality it is not the dead man speaking, nor are his feelings the only ones the reader is receiving, but that the comrades who were forced to execute him may themselves have made up these two lines with their incalculably complex and exquisite balance of scorn, awe, guilt, and consideration even to tenderness for the dead soldier. There is, sixth, the metaphorical form, with its many resonances ranging from the tragic through the pathetic to irony and apology: dying in battle is spoken of in language relating it to a social occasion in drawing room or court; the coward's fear is implicitly represented as merely the timorousness and embarassment one might feel about being introduced to a somewhat superior and majestic person, so that the soldiers responsible for killing him are seen as sympathetically helping him through a difficult moment in the realm of manners. In addition, there is, seventh, a linguistic or syntactical form, with at least a couple of tricks to it: the second clause, with its reminiscence of Latin construction, participates in the meaning by conferring a Roman stoicism and archaic gravity on the saying; remembering that the soldiers in the poem had been British schoolboys not long before, the reader might hear the remote resonance of a whole lost world built upon Greek and Roman models; and the last epithets, "blindfold and alone," while in the literal acceptation they clearly refer to the coward, show a distinct tendency to waver over and apply mysteriously to Death as well, sitting there waiting "blindfold and alone." One might add another form, the eighth, composed of the balance of sounds, from the obvious likeness in the rhyme down to subtleties and refinements beneath the ability of coarse analysis to discriminate. And even there one would not be quite at an end; an overall principle remains, the compression of what might have been epic or five-act tragedy into two lines, or the poet's precise election of a single instant to carry what the novelist, if he did his business properly, would have been hundreds of pages arriving at.

The coincidence of poetic forms

It is not at all to be inferred that the poet composed his poem in the manner of the above laborious analysis of its strands; the whole insistence, rather, is that he did not catalog eight or 10 forms and assemble them into a poem; more likely it "just came to him." But the example may serve to indicate how many modes of the mind go together in this articulation of an implied drama and the tension among many possible sentiments that might arise in response to it.

In this way, by the coincidence of forms that locks in the poem, one may see how to answer a question that often arises about poems: though their thoughts are commonplace, they themselves mysteriously are not. One may answer on the basis of the example and the inferences produced from it that a poem is not so much a thought as it is a mind: talk with it, and it will talk back, telling you many things that you might have thought for yourself but somehow didn't until it brought them together. Doubtless a poem is a much simplified model for the mind. But it might still be one of the best man has available. On this great theme, however, it will be best to proceed not by definition but by parable and interpretation.

Poetry as a mode of thought: the Protean encounter. In the fourth book of the *Odyssey* Homer tells the following strange tale. After the war at Troy, Menelaus wanted very much to get home but was held up in Egypt for want of a wind because, as he later told Telemachus, he had not sacrificed enough to the gods. "Ever jealous the Gods are," he said, "that we men mind their dues." But because the gods work both ways, it was on the advice of a goddess, Eidothea, that Menelaus went to consult Proteus, the old one of the sea, as one might consult a travel agency.

Proteus was not at all easy to consult. He was herding seals, and the seals stank even through the ambrosia Eidothea had thoughtfully provided. And when Menelaus crept up close, disguised as a seal, and grabbed him, Proteus turned into a lion, a dragon, a leopard, a boar, a film of water, and a high-branched tree. But Menelaus managed to hang on through all this until at last Proteus gave up and was himself again; whereupon Menelaus asked him the one great question: How do I get home? And Proteus told him: You had better go back to Egypt and sacrifice to the gods some more.

This story may be taken as a parable about poetry. A man has an urgent question about his way in the world. He already knows the answer, but it fails to satisfy him. So at great inconvenience, hardship, and even peril, he consults a powerful and refractory spirit who tries to evade his question by turning into anything in the world. Then, when the spirit sees he cannot get free of the man, and only then, he answers the man's question, not simply with a commonplace but with the same commonplace the man had been dissatisfied with before. Satisfied or not, however, the man now obeys the advice given him.

A foolish story? All the same, it is to be observed that Menelaus did get home. And it was a heroic thing to have hung onto Proteus through those terrifying changes and compelled him to be himself and answer up. Nor does it matter in the least to the story that Menelaus personally may have been a disagreeable old fool as well as a cuckold.

A poet also has one great and simple question, simple though it may take many forms indeed. Geoffrey Chaucer put it as well as anyone could, and in three lines at that:

> What is this world? what asketh men to have?
> Now with his love, now in his colde grave,
> Allone, with-outen any companye.
> ("The Knights Tale," 1919–1921)

And a poet gets the simple answer he might expect, the one the world grudgingly gives to anyone who asks such a question: The world is this way, not that way, and you ask for more than you will be given, which the poet, being scarcely more fool than his fellowmen, knew already. But on the path from question to answer, hanging onto the slippery disguiser and shape-shifter Proteus, he will see many marvels; he will follow the metamorphoses of things in the metamorphoses of their phrases, and he will be so elated and ecstatic in this realm of wonders that the voice in which he speaks these things, down even to the stupid, obvious, and commonplace answer, will be to his hearers a solace and a happiness in the midst of sorrows:

> When I do count the clock that tells the time,
> And see the brave day sunk in hideous night;
> When I behold the violet past prime,
> And sable curls, all silver'd o'er with white;
> When lofty trees I see barren of leaves,
> Which erst from heat did canopy the herd,
> And summer's green all girded up in sheaves,
> Borne on the bier with white and bristly beard,
> Then of thy beauty do I question make,
> That thou among the wastes of time must go,
> Since sweets and beauties must themselves forsake
> And die as fast as they see others grow;
> And nothing 'gainst Time's scythe can make defence
> Save breed, to brave him when he takes thee hence.
> (Shakespeare, Sonnet 12.)

The poetic question and answer

Like Menelaus, the poet asks a simple question, to which, moreover, he already knows the unsatisfying answer. Question and answer, one might say, have to be present, although of themselves they seem to do nothing much; but they assert the limits of a journey to be taken. They are the necessary but not sufficient conditions of what really seems to matter here, the Protean encounter itself, the grasping and hanging on to the powerful and refractory spirit in its slippery transformations of a single force flowing through clock, day, violet, graying hair, trees dropping their leaves, the harvest in which, by a peculiarly ceremonial transmutation, the grain man lives by is seen without contradiction as the corpse he comes to. As for the answer to the question, it is not surprising nor meant to be surprising; it is only just.

On this point—that the answer comes as no surprise—poets show an agreement that quite transcends the differences of periods and schools. Alexander Pope's formula, "What oft was thought, but ne'er so well expresst," sometimes considered as the epitome of a shallow and parochial decorum, is not in essence other than this of John Keats:

> I think Poetry should surprise by a fine excess, and not by Singularity—it should strike the Reader as a wording of his own highest thoughts, and appear almost a Remembrance. (Letter to John Taylor, 1818.)

In the present century, Robert Frost is strikingly in agreement:

> A word about recognition: In literature it is our business to give people the thing that will make them say, "Oh yes I know what you mean." It is never to tell them something they dont know, but something they know and hadnt thought of saying. It must be something they recognize. (Letter to John Bartlett, in *Modern Poetics*, ed. James Scully, 1965.)

And the poet and critic John Crowe Ransom gives the thought a cryptically and characteristically elegant variation: "Poetry is the kind of knowledge by which we must know that we have arranged that we shall not know otherwise." Perhaps this point about recognition might be carried further, to the extreme at which it would be seen to pose the problem of how poetry, which at its highest has always carried, at least implicitly, a kind of Platonism and claimed to give, if not knowledge itself, what was more important, a "form" to knowledge, can survive the triumph of scientific materialism and a positivism minded to skepticism about everything in the world except its own self (where it turns credulous, extremely). The poets' adjustment, over two or three centuries, to a Newtonian cosmos, Kantian criticism, the spectral universe portrayed by physics has conspicuously not been a happy one and has led alternately or simultaneously to the extremes of rejection of reason and speaking in tongues on the one hand and the hysterical claim that poetry will save the world on the other. But of this let the Protean parable speak as it will.

There is another part to the story of Menelaus and Proteus, for Menelaus asked another question: What happened to my friends who were with me at Troy? Proteus replies, "Son of Atreus, why enquire too closely of me on

this? To know or learn what I know about it is not your need: I warn you that when you hear all the truth your tears will not be far behind. . . ." But he tells him all the same: "Of those others many went under; many came through. . . ." And Menelaus does indeed respond with tears of despair, until Proteus advises him to stop crying and get started on the journey home. So it sometimes happens in poetry, too: the sorrowful contemplation of what is, consoles, in the end, and heals, but only after the contemplative process has been gone through and articulated in the detail of its change:

> When to the sessions of sweet silent thought
> I summon up remembrance of things past,
> I sigh the lack of many a thing I sought,
> And with old woes new wail my dear time's waste;
> Then can I drown an eye, unused to flow,
> For precious friends hid in death's dateless night,
> And weep afresh love's long since cancell'd woe,
> And moan the expense of many a vanish'd sight.
> Then can I grieve at grievances foregone,
> And heavily from woe to woe tell o'er
> The sad account of fore-bemoaned moan,
> Which I new pay as if not paid before.
> But if the while I think on thee, dear friend,
> All losses are restor'd and sorrows end.
>
> (Shakespeare, Sonnet 30)

This poem, acknowledged to be a masterpiece by so many generations of readers, may stand as an epitome and emblem for the art altogether, about which it raises a question that must be put, although it cannot be satisfactorily and unequivocally answered: the question of whether poetry is a sacrament or a confidence game or both or neither. To reply firmly that poetry is not religion and must not promise what religion does is to preserve a useful distinction; nevertheless, the religions of the world, if they have nothing else in common, seem to be based on collections of sacred poems. Nor, at the other extreme, can any guarantee that poetry is not a confidence game be found in the often-heard appeal to the poet's "sincerity." One will never know whether Shakespeare wept all over the page while writing the 30th sonnet, though one inclines to doubt it, nor would it be to his credit if he did, nor to the reader's that he should know it or care to know it.

The nature of poetry

For one thing, the sonnet is obviously artful—that is, full of artifice—and even the artifice degenerates here and there into being artsy. "Then can I drown an eye, unused to flow." Surely that is poesy itself, at or near its worst, where the literal and the conventional, whatever their relations may have been for Shakespeare and the first reader of these sugar'd sonnets among his friends, now live very uncomfortably together (Ben Jonson's "Drink to me only with thine eyes" is a like example of this bathetic crossing of levels), though perhaps it has merely become unattractive as a result of changing fashions in diction.

Moreover, while the whole poem is uniquely Shakespearean, the bits and pieces are many of them common property of the age, what one writer called "joint stock company poetry." And the tricks are terribly visible, too; art is not being used to conceal art in such goings-on as "grieve at grievances" and "fore-bemoaned moan." "He who thus grieves will excite no sympathy," as Samuel Johnson sternly wrote of John Milton's style in the elegy "Lycidas," "he who thus praises will confer no honour."

Nor is that the worst of it. This man who so powerfully works on the reader's sympathies by lamenting what is past contrives to do so by thinking obsessively about litigation and, of all things, money; his hand is ever at his wallet, bidding adieu. He cannot merely "think" sweet silent thoughts about the past; no, he has to turn them into a court in "session," whereto he "summons" the probably culprit "remembrance"; when he "grieves," it is at a "grievance"—in the hands of the law again; finally, as with the sinners in Dante's *Divine Comedy*, his avarice and prodigality occupy two halves of the one circle: he bemoans his expenses while paying double the asking price.

And still, for all that, the poem remains beautiful; it continues to move both the young who come to it still innocent of their dear time's waste and the old who have sorrows to match its sorrows. As between confidence game and sacrament there may be no need to decide, as well as no possibility of deciding: elements of play and artifice, elements of true feeling, elements of convention both in the writing and in one's response to it, all combine to veil the answer. But the poem remains.

Effect of the poem as a whole

If it could be plainly demonstrated by the partisans either of unaided reason or revealed religion that poetry was metaphorical, mythological, and a delusion, while science, say, or religion or politics were real and true, then one might throw poetry away and live honestly though poorly on what was left. But, for better or worse, that is not the condition of man's life in the world; and perhaps men care for poetry so much—if they care at all—because, at last, it is the only one of man's many mythologies to be aware, and to make him aware, that it, and the others, are indeed mythological. The literary critic I.A. Richards, in a deep and searching consideration of this matter, concludes: "It is the privilege of poetry to preserve us from mistaking our notions either for things or for ourselves. Poetry is the completest mode of utterance."

The last thing Proteus says to Menelaus is strange indeed:

> You are not to die in Argos of the fair horse-pastures, not there to encounter death: rather will the Deathless Ones carry you to the Elysian plain, the place beyond the world. . . . There you will have Helen to yourself and will be deemed of the household of Zeus.

So the greatest of our poets have said, or not so much said, perhaps, as indicated by their fables, though nowadays people mostly sing a different tune. To be as the gods, to be rejoined with the beloved, the world forgotten. . . . Sacrament or con game? Homer, of course, is only telling an old story and promises mankind nothing; that is left to the priests to do; and in that respect poetry, as one critic puts it, must always be "a ship that is wrecked on entering the harbor." And yet the greatest poetry sings always, at the end, of transcendence; while seeing clearly and saying plainly the wickedness and terror and beauty of the world, it is at the same time humming to itself, so that one overhears rather than hears: All will be well.

BIBLIOGRAPHY. The most convenient way to get to know poetry is to read poetry. It would be invidious for the writer of a general article on the subject to prejudice the reader by making a selection of poems or poets; in experience, anyhow, one's acquaintance with poetry comes about chiefly by love and accident, supported, when not undermined, by schools, colleges, and libraries. Beyond that, the bibliographical temptation is to put before the reader numerous learned works that are not poetry but about poetry; whatever their usefulness at various stages of study, and it may be great, they must not substitute for poetry itself. Therefore no such list is attempted.

The beginning reader, however, may well be able to use some help in interpreting, such as a critical or explanatory anthology. CLEANTH BROOKS and ROBERT PENN WARREN, *Understanding Poetry*, 3rd ed. (1960), is still probably the best of its kind, as numerous imitations amply attest. Useful instruction in method may be found in I.A. RICHARDS, *Practical Criticism: A Study of Literary Judgment* (1929, reprinted 1964).

(H.Ne.)

Pogonophora

Members of the phylum Pogonophora are invertebrate animals that live a sedentary life in long protective tubes on sea floors throughout the world. Pogonophora, which have neither mouth, anus, nor gut, bear one to many pinnate (featherlike) tentacles at their anterior end; hence their common name beardworms. An intestine, which forms in embryos, disappears as development progresses. Males of the phylum are generally similar in appearance to females.

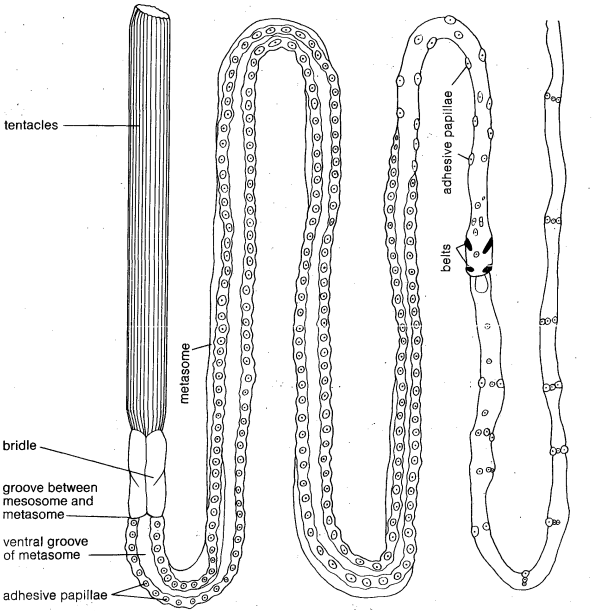
Pogonophora were first classified as a distinct phylum in the middle of the 20th century. The first species, *Siboglinum weberi*, described in 1914, came from the seas of the Malayan Archipelago; the second species, *Lamellisabella zachsi*, which came from the Okhotsk Sea, was described

in 1933. In 1937 a new class called Pogonophora was established for *Lamellisabella*. In 1955 a close affinity between *Siboglinum* and *Lamellisabella* was proved, and the members were placed in the newly established phylum Pogonophora.

Pogonophora usually inhabit marine waters to depths that exceed 1,000 metres; some species have been found at depths ranging from 7,000 to 10,000 metres. A native population of Pogonophora inhabits the trenches of the Pacific and the Indian oceans. Many genera have a discontinuous distribution.

Feeding

Natural history. The tentacles, probably used during feeding, vary in number from 1 to 2,000; the number is correlated with body size. The primitive Pogonophora have a few tentacles. Among members of the families Lamellisabellidae, Spirobrachiidae, and Lamellibrachiidae, the neighbouring tentacles are fused through most of their length. The tentacles, long processes containing blood vessels, are continuous with the body cavity, or coelom. Rows of very thin single-celled units called pinnules are found on the tentacles. The pinnules, which extend into the intertentacular cavity formed by the free or fused tentacles, intermesh to form a filter. Beside each pinnule base is a ciliary tract. In each intertentacular region, ciliary tracts produce a current of water that carries in micro-organisms and other nutrients; these are filtered through the pinnule filter. Digestive enzymes probably are secreted by gland cells located at the pinnule bases. Water leaves by an opening at the base of certain tentacles. The digested food may be absorbed by the pinnules. The pinching off of small food particles in the outer layers of the pinnules during a process known as pinocytosis also has been observed. Direct penetration of amino acids from sea water into the tentacles also has been reported to take place.



Reproduction in Pogonophora is sexual. Eggs, which have a high yolk content, are laid by the female in the anterior part of the tube, in which fertilization and early development to formation of a swimming larva also occur. Cleavage leads to the formation of a bilaterally symmetrical embryo. A cell layer called the endoderm first is represented by a few yolk-rich cells, which form a primary intestine; the intestine disappears as the yolk is utilized. Both mouth and anus fail to develop. A secondary body cavity is formed by separation of coelomic pockets from the primary intestine. The embryo eventually develops into a larva having two ciliary belts and three body segments.

Body plan

Form and function. The wormlike body varies in length from several centimetres to 0.5 metre, the body diameter, from 0.06 millimetre to 4 millimetres. *Lamellibrachia barhami* is one of the largest species. The body consists of three segments; two small anterior regions are called protosome and mesosome; the long trunk section is called the metasome. Each segment has its own coelom. The small protosome bears tentacles. The mesosome contains a structure known as a bridle, also called a frenulum, a pair of oblique cuticular ridges that extend backward to meet in the midventral line (see drawing). The bridle supports the protruding worm on the edge of its tube. The metasome is divided into two sections by a pair of parallel ridges called belts; these have rows of small platelets containing minute teeth. One part of the metasome, in front of the belts, has a groove bordered by low folds, each bearing a row of papillae. In *Siboglinum* the papillae contain glands or in other pogonophores may be topped with chitin-like platelets; in this case, papillae probably help the animal to cling to the inner surface of the tube. Behind the groove, the papillae decrease in number and are arranged irregularly.

The protective tube is submerged in mud at the lower end; the very thin tubes of *Sclerolinum*, however, pierce pieces of sunken wood. The tube, secreted by special glands, contains a hard substance called chitin. Although the animals never leave their tubes, they are able to move inside them.

The body wall consists of an outer layer of epidermal cells covered by a cuticle. Beneath the epidermal cells is a layer of longitudinal muscle cells. The nervous system, found within the epidermis, forms an almost continuous network. There are no sense organs. The circulatory system consists of two long vessels; in one, blood flows forward; in the other, backward. At the base of the tentacles, the vessel through which blood flows forward is differentiated into a muscular heart, which serves to push blood into the tentacle vessels. The blood, red in colour, contains the pigment hemoglobin. The excretory system consists of a pair of nephridia, or coelomoducts, which connect the body cavity of the protosome with the exterior. The reproductive system consists of a pair of sexual glands that lie in the trunk. In females, ovaries are found in the anterior part of the metasome, while the sexual openings, or oviducts, are found in the middle of the body. In males, the testes are located in the posterior part of the body, and the sexual openings, called sperm ducts, in the anterior part. Numerous capsules containing sperm (spermatophores) form in the sperm ducts of the males.

Female *Spirobrachia beklemischevi*, ventral view with posterior one-sixth of trunk not shown.
From A.V. Ivanov, *Zoologische Jahrbucher Abt. 1 Systematik*, 85 (1957); Gustav Fischer Verlag

Evolution and classification. The Pogonophora may be separated into two classes, Afrenulata and Frenulata. The Afrenulata contains one species—*Lamellibrachia barhami*, which has been found in the Pacific Ocean near the coast of California. The class Frenulata contains 16 genera in six families. A total of 110 species of Pogonophora thus far have been identified; it is probable that many more species remain to be identified.

According to general body plan and embryological development, Pogonophora should be included with the large group of animals that have a secondary body cavity; this group also includes Chaetognatha, Tentaculata, Hemichordata, and Echinodermata. A rich fossil Pogonophora fauna has been found in Cambrian (about 500,000,000 to 570,000,000 years ago) and Ordovician (about 430,000,000 to 500,000,000 years ago) deposits near Leningrad, in Poland, and in Siberia.

Poincaré, Henri

The French mathematician, theoretical astronomer, and philosopher of science Jules-Henri Poincaré was generally acknowledged as the greatest living mathemati-

cian at the turn of the 20th century. He substantially influenced modern ideas concerning cosmogony, relativity, and topology. Read by thousands in all walks of life, he was a master of French prose in his writings on philosophical topics.

H. Roger-Viollet

Poincaré, 1909.

Education

Poincaré was born at Nancy on April 29, 1854, into a family distinguished by its contributions to government and administration. His first cousin was Raymond Poincaré, president of the French Republic during World War I. Poincaré was ambidextrous and was nearsighted; during his childhood he had poor muscular coordination and was seriously ill for a time with diphtheria. He received special instruction from his gifted mother, learned German during the Franco-Prussian War—at which time he also witnessed the suffering of the soldiers and populace with his father, who was a physician—and excelled in written composition in elementary school. Becoming deeply interested in mathematics during adolescence, he attended in 1872–75 the École Polytéchnique in Paris, where he easily won top honours in mathematics—but was undistinguished in physical exercise and in art. He had an unusually retentive memory for everything he read; moreover, he could visualize what he heard, a useful faculty because he could not clearly see at a distance the mathematical symbols that were on the blackboard. Throughout his life he was able to perform complex mathematical calculations in his head and could quickly write a paper without extensive revisions. He received, in 1879, a doctorate from the École Nationale Supérieure des Mines with a thesis on differential equations.

Following a brief appointment in mathematical analysis at the Université de Caen, in 1881 Poincaré joined the Université de Paris, where, during the rest of his life, he lectured and wrote prolifically—almost 500 papers—on mechanics and experimental physics, in all branches of pure and applied mathematics, and in theoretical astronomy. Changing his lectures every year, he would review optics, electricity, the equilibrium of fluid masses, the mathematics of electricity, astronomy, thermodynamics, light, and probability. Many of these lectures appeared in print shortly after they were delivered at the university. In his extensive writings on probability, Poincaré anticipated the concept of ergodicity that is basic to statistical mechanics.

Applying his mastery of analysis to the question of the solvability of algebraic equations, Poincaré developed before age 30 the idea of the automorphic function—one that is invariant under a group of transformations that are characterized algebraically by ratios of linear terms. He showed how these functions can be used to integrate linear differential equations with rational algebraic coefficients and how to express the coordinates of any point on an algebraic curve as uniform functions of a single algebraic variable (or parameter). Some of these automorphic functions he called Fuchsian, after the German mathematician Immanuel Lazarus Fuchs, who was one of the founders of the theory of differential equations; he found that they were associated with transformations arising in non-Euclidean geometry. In recognition of his fundamental contributions to mathematics, he was elected, in 1887, to membership in the Académie des Sciences in Paris.

Work in celestial mechanics

In celestial mechanics, Poincaré made substantial contributions to the theory of orbits, particularly the classical three-body problem (for example, the system involving the Sun, Moon, and Earth). This was part of the "problem of n bodies" (planets, stars, etc.), set for a prize by King Oscar II of Sweden: given the present masses, velocities, motions, and mutual distances of "n bodies," how long will they remain stable in their present spatial relationships, or will their orbits change at some future date? In his solution, Poincaré developed powerful new mathematical techniques, including the theories of asymptotic expansions and integral invariants, and made fundamental discoveries on the behaviour of the integral curves of differential equations near singularities. He was awarded the prize in 1889, even though his solution to the problem was only partially correct; in the same year he was also made a knight of the French Legion of Honour.

Poincaré summarized his new mathematical methods in astronomy in *Les Méthodes nouvelles de la mécanique céleste* (3 vol., 1892, 1893, 1899). Another result of this work, his *Analysis situs* in 1895, was an early systematic treatment of topology, which deals with properties of a system that endure when metric distortion occurs—that is, topology deals with the qualitative characteristics of spatial configurations that do not vary during cumulative transformations. He also contributed to the theory of numbers by demonstrating how the conception of binary quadratic forms, which was developed by the German mathematician Carl Friedrich Gauss, could be cast in geometric form. In 1904 he lectured at the St. Louis Exposition.

In mathematical analysis, Poincaré made important contributions to the theory of equilibrium of rotating fluid masses. In particular, he described the conditions of stability of the pear-shaped figures that played so prominent a part in the researches of later cosmogony, with reference to the evolution of celestial bodies. He attempted an application of these ideas to the stability of Saturn's rings and to the origin of binary stars. In 1906, in a paper on the dynamics of the electron, he obtained, independently of Einstein, many of the results of the special theory of relativity. The principal difference was that Einstein developed the theory from elementary considerations concerning light signalling, whereas Poincaré's treatment was based on the full theory of electromagnetism and was restricted to phenomena associated with the concept of a universal ether that functioned as the means of transmitting light, a concept that Einstein shared.

Books on the philosophy of science

After Poincaré achieved prominence as a mathematician, he turned his superb literary gifts to the challenge of describing for the general public the meaning and importance of science and mathematics. Always deeply interested in the philosophy of science, he wrote *La Science et l'hypothèse* (1903; *Science and Hypothesis*, 1905), *La Valeur de la science* (1905; *The Value of Science*, 1907), and *Science et méthode* (1908; *Science and Method*, 1914), all of which reached a wide public of nonprofessionals. His works were translated into English, German, Hungarian, Japanese, Spanish, and Swedish. He emphasized the subconscious, while probing the psychology of mathematical discovery and invention. He was a forerunner of the modern intuitionist school in that he believed that some mathematical induction is a priori and independent of logic. In his view, sudden illumination, following long subconscious work, is a prélude to mathematical creation. But his greatest contribution to philosophy was to emphasize the role played in scientific method by convention—*i.e.*, by the arbitrary choice of concepts.

Poincaré's prestige and influence increased in French science, and in 1906 he was elected president of the

Académie des Sciences and in 1908 to membership in the Académie Française, the highest honour accorded a French writer.

He died in Paris on July 17, 1912, from an embolism following prostate surgery.

BIBLIOGRAPHY. There is no definitive biography of Henri Poincaré, but ERIC T. BELL, *Men of Mathematics*, ch. 28 (1937, reprinted 1961), contains a biographical study of his work. A useful obituary notice is in the *Proc. R. Soc.*, series A, 91:5–16 (1915). The bibliography of ERNST LEBON, *Henri Poincaré: biographie, bibliographie analytique des écrits* (1909), was supplemented by R.C. ARCHIBALD, "Jules Henri Poincaré," *Bull. Am. Math. Soc.*, 22:125–136 (1915). A biographical article by VITO VOLTERRA, "Henri Poincaré," appeared as a Rice Institute pamphlet, vol. 1, no. 2, pp. 113–162 (1915). The collected works, *Oeuvres de Henri Poincaré*, were published by the *Académie des Sciences de Paris*, 10 vol. (1916–54). His writings on the philosophy of science and of mathematics can be found in *The Foundations of Science*, containing *Science and Hypothesis, The Value of Science*, and *Science and Method*, trans. by GEORGE BRUCE HALSTED (1913); and in *Dernières pensées* (1913; Eng. trans., *Mathematics and Science: Last Essays*, 1963).

(G.J.W.)

Poisonous Animals and Plants

The study of poisonous animals and plants, in the broadest sense, deals with the poisons produced by all living organisms. The science concerned with poisons produced by biological organisms is known as biotoxicology. The term poison refers to any substance that, when ingested, injected, absorbed, or applied to the body of an animal in relatively small quantities, may cause, by its chemical action, damage to a structure, a disturbance of function, or, if the quantity is sufficient, death.

GENERAL FEATURES

Properties and occurrence of biotoxins. The poisons produced by biological organisms are referred to as biotoxins, or biological poisons. Numerous micro-organisms, plants, and animals produce a vast array of toxic chemical substances, most of which have not yet been adequately characterized as to their chemical nature or biological effects. The classical definition of the term toxin referred only to poisons of microbial origin with high molecular weights (based on the weight of a hydrogen atom as 1) and antigenic properties (*i.e.*, substances to which the body reacts by producing antibodies, proteins that attack and neutralize the antigens). In recent years, however, the definition has been expanded to include poisons derived from higher plants and animals.

Definition of toxic substances

It is virtually impossible to assign a precise meaning to the term toxic. Obviously, almost any substance may be toxic if used in sufficient quantity. One property of a toxin that permits it to be so categorized, however, is that it is harmful to sensitive hosts when administered in relatively small amounts. The quantitative relationship between the amount of toxin administered and its effect on a host, or experimental subject, can be depicted by a graph called the dose–response curve. A potent toxin produces a steep slope in the linear portion of the curve (*i.e.*, a small amount of toxin has a great effect), whereas a less toxic substance results in a shallow-sloped linear portion of the curve.

Results of the various methods used to measure the dose response of a given host to a toxin depend upon a statistical treatment of one type or another. In most instances the effect measured is the death of the host. The response is greatest in the region of 50 percent mortality; the 50 percent lethal dose (LD_{50}), or the dosage that will result in the death of 50 percent of the tested animals, thus has been established as the most useful way to estimate toxicity. Unfortunately, animal hosts do not act as completely homogeneous populations, and considerable variation between groups usually occurs. Even when homogeneous groups of animals are used, individual variation in response to toxins is encountered from such factors as the health of the individual host.

Biotoxins can be conveniently grouped into three major categories: (1) microbial toxins, poisons produced by bacteria, blue-green algae, dinoflagellates, golden-brown algae, etc.; (2) phytotoxins, poisons produced by higher plants; and (3) zootoxins, poisons produced by animals. The term phytotoxin is also commonly used by plant pathologists to refer to substances that are toxic to plants. The term as used in this article, however, is restricted to poisons derived from plants that are toxic to animals and particularly to man. The geographical distribution of poisonous organisms varies greatly; poison-producing micro-organisms tend to be ubiquitous in their distribution. Poisonous plants and animals are found in greatest abundance and varieties in warm-temperate and tropical regions. Relatively few toxic organisms of any kind are found in polar latitudes.

Evolutionary aspects of biotoxins

Knowledge of the evolutionary significance and development of most biotoxins is largely speculative and poorly understood. In some instances they may have developed during the evolution of certain animal species as part of the food procurement mechanism (*e.g.*, in snakes; cnidarians, jellyfishes, and their relatives; mollusks, octopuses, and others; and spiders). Biotoxins may also function as defensive mechanisms, as in some snakes, fishes, arthropods (*e.g.*, insects, millipedes), and others. The defense may be quite complex—as in the protection of territorial rights for reproductive purposes—and inhibitory or antibiotic substances may be produced that result in the exclusion of competitive animal or plant species. Certain marine organisms and terrestrial plants may release into the water, air, or soil inhibitory substances that discourage the growth of other organisms; well-known examples include the production of antibiotic substances by micro-organisms. Similar chemical-warfare mechanisms are used in battles for territorial rights among the inhabitants of a coral reef, a field, or a forest. Thus biotoxins play important roles in the regulation of natural populations. Of increasing interest has been the discovery that certain substances, which may be toxic to one group of organisms, may serve a vital function in the life processes of the source organism.

The complex ecological relationships between some of the more toxic marine invertebrates and fishes are as yet poorly understood. Interactions between species may, in the presence of certain chemical substances, contribute directly to the production of highly toxic biochemical products, an interaction that is sometimes referred to as ecological biogenesis.

Importance of biotoxins to man. Toxic plants and animals are of importance to man in a variety of ways. Many biotoxins are potent agents capable of adversely affecting man directly by causing disease, pain, or death or indirectly by damaging his plants or animals. Toxic organisms thus constitute a potential public-health problem with economic and sociological implications.

Venom-producing animals and stinging and dermatogenic (*i.e.*, skin-poisoning) plants capable of inflicting pain and sometimes death by means of parenteral contact (*i.e.*, by bringing poisons into the body other than through the digestive tract) constitute environmental hazards. Biotoxic agents may produce their injurious effects by becoming involved in man's food supply; ingestion of a poisonous microbial organism, plant, or marine animal or one of their toxic by-products may cause intoxication. An example is that of the shore fishes of many tropical islands; otherwise valuable food fishes are frequently contaminated by a poison called ciguatoxin. The poison, a potent neurotoxin (nerve poison), is accidentally ingested by the fishes in their food; such fish can no longer be used for either human or animal consumption.

Entry methods for biological poisons

Some of the effects produced by biotoxins on man are of an acute nature, and the injuries they cause are readily discernible. The effects of some of the mycotoxins (poisons produced by fungi) and poisons produced by higher plants, however, are long-term and chronic; they result in the development of cancerous growths and other chronic degenerative changes that are sometimes difficult to detect.

The scientific importance of biotoxicology is frequently misunderstood. One popular attitude is that, because poisons are potentially lethal substances capable of causing

intoxication and death, they are therefore to be avoided and that research is justified to determine their pharmacological and chemical properties with the hope of ultimately developing useful antitoxins. Another aspect equally deserving of consideration, however, is the exploration of biologically active substances and chemical structures in order to determine their physical nature and biological properties. Many of the biotoxins studied even in a cursory manner have been found to have diverse biological properties, some of which have application to medicine: fungicidal, growth inhibitory, antiviral, antibiotic, antitumour, hemolytic (red-blood-cell destroying), anti-inflammatory, analgesic (pain controlling), cardioinhibitory (heart arresting), psychopharmacological (affecting mental processes), and others. Toxicity thus provides important information regarding valuable pharmacological properties of biotoxins.

In the area of natural-products research, of which biotoxicology is an important segment, ethnic data provides insight into biological activity. Ethnobotanical and ethnozoological studies reveal the way in which plants and animals have been utilized by primitive peoples; crude data of this type serve as useful indicators of the general pharmacological properties of biotoxins. Biotoxins also offer a spectrum of new or little-known chemical substances, which the chemist may ultimately be able to synthesize and manipulate into useful products. Highly active biotoxins may eventually be useful in neurophysiological research, especially in elucidating the nature of both nervous activity and muscular function.

Medical uses of biotoxins

The study of biotoxicology ultimately will yield a vast amount of valuable data in such diverse areas as nutrition, medicine, chemistry, pharmacology, biology, ecology, military science, and drug development.

HISTORICAL BACKGROUND

The story of poisonous plants and animals and their relationship to mankind dates to the dawn of man's written language; poisons and poisonous organisms played a dominant role in the affairs of early man, especially in those of ancient magician-physicians and priests. Not only was it of value for them to know the means of treating a poisonous sting but it was equally useful that they be familiar with the biological poisons capable of causing death of an enemy. Because of the profound and little-understood physiological effects resulting from contact with plant and animal poisons, ancient man often surrounded biotoxins with an aura of mystery, superstition, and religion. The pre-Grecian era of Mesopotamian medicine was also dominated by magicians and priests. Little is known about their knowledge of specific poisonous animals, but they were keen observers of natural history and were undoubtedly aware of many noxious pests. Medical records of ancient Egypt include a practicing physician's formulary containing about 260 prescriptions, some of which are for various kinds of animal stings, including the poisonous puffer fish. The Bible and Talmudic records document the toxic effects of dinoflagellates (a group of algae). Other records list some 760 medicinal plants and mention venomous animals and antidotes for bites and stings.

Out of ancient Chinese science, which was based on plant and animal lore, demoniac beliefs, and faith healing, arose a legendary emperor revered as god of medicine and father of agriculture and herbal therapy; he is credited with the authorship of the predecessor of Chinese pharmacopeias. Ancient Chinese phytotoxicology was a comparatively well-developed science, and poisonous plants and their antidotes were described in elaborate detail.

In the Western world the ancient Greeks were probably the first to dissociate medicine from magic and religion. Aristotle was familiar with the venom of jellyfishes and scorpion fishes. Mithradates VI, king of Pontus in the 2nd century BC, experimented with the giving and taking of poisons and is said to have been one of the first to study intensively the art of poisoning and the preparation of antidotes. He aspired to develop a universal antidote, which became known as mithridates and theriacs. In the 1st century AD, Pedanius Dioscorides, a Greek army surgeon, wrote on many terrestrial plants used as drugs and also recorded the toxic nature of sea hares, polychaete worms, stingrays, and sea vipers. Pliny the Elder, the Latin naturalist, dealt with poisonous plants and animals in his *Natural History* (*Historia naturalis*) and wrote about the dangerous wounds inflicted by the venomous spines of the weever fishes and stingrays and about the toxicity of the sea hare. He also recommended that a powder of the sting of the stringray be used as a potion to treat toothache.

From the 5th to the 8th century the centre of medical culture was Constantinople; Paulus of Aegina wrote an *Epitome* on medical subjects comprised of seven books, one of which was concerned with venomous stings, bites, and toxicology. During the early years of the 7th century, the Arabs wrote extensively about poisons, the effect of venoms, and antidotal remedies.

From the 9th through the 15th century, when there was neither induction nor experiment, biotoxicology languished along with most other sciences. One of the few important works was that of the Persian physician Avicenna. His *Qānūn fī aṭ-ṭibb* (*Canon of Medicine*) was a compilation of his experiences in the practice of medicine and a compendium of all that was known about medicine at the time. The *Canon* is concerned with, among other things, the composition and preparation of drugs. He recognized both oral and parenteral poisons, discussed venomous stings and their treatment, and dealt with animal, plant, and mineral poisons. For more than 500 years his work was considered the outstanding authority on poisons and their antidotes.

Avicenna's *Canon of Medicine*

Many printed herbals, which began to appear around 1470, including discussions about poisonous plants. The great work in biotoxicology of the Renaissance was that of the father of modern biotoxicology, the French physician Jacques Grevin, who published his book *Deux livres des venins* in 1568. Another important work that appeared in the latter half of the 17th century dealt with various types of poisonous plants.

In 1756 the British physician Richard Mead described snake poisoning in his *Mechanical Account of Poisons* in several essays and how he had swallowed the venom, thereby proving that parenteral administration was in this case essential to produce intoxication. Other important works of this period were influential because they paid particular attention to poisonings resulting from the injudicious use of medicinal plants and to some of the effects of poisons on animals.

The important toxicological contributions of the French physician M.J.B. Orfila, who has been designated the father of experimental toxicology, marked the opening of the 19th century. His *Traité de toxicologie*, first published in 1814, went through many editions and translations. Most of his investigations were concerned with inorganic agents and plant poisons and, to a lesser extent, with the venoms of snakes, spiders, bees, wasps, and poisonous fishes. In 1888 occurred the first demonstration that the disease-producing mechanism of a micro-organism in man could be explained in terms of a toxic substance released by bacteria. Tetanus toxin was discovered in 1890.

Experimental research based on sophisticated analytical procedures accelerated in the early part of the 20th century. This period also saw the discovery of hypersensitivity reactions and a better understanding of anaphylaxis and allergies. With the advent of World War II, environmental biological poisons became medically important in many military operations. A rapidly expanding world population in the postwar years further pointed up the need for the utilization of food resources in heavily populated tropical regions in which oral biotoxins are most likely to be encountered. There have also been increased demands for new therapeutic agents, and biotoxins have served as a rich and varied resource.

MAJOR CATEGORIES OF BIOTOXINS

Microbial toxins. Microbial poisons are produced by the so-called Monera (bacteria and blue-green algae) and

Protista (fungi, dinoflagellates, golden-brown algae, and others). Various classifications have been proposed for the microbial poisons, but none is entirely satisfactory. The problems encountered when dealing with these organisms result from a lack of precise knowledge concerning their biological nature and their phylogenetic relationships; in addition, their poisons show great diversity and chemical complexity. The following outline, however, is useful in dealing with this subject.

Bacterial toxins. The prefixes "exo-" and "endo-" are retained in classifying the bacterial toxins mainly for historical reasons rather than because they are found either outside or inside the bacterial cell. The main differences in these toxins lie in their chemical structure. A list of representative species of toxic bacteria and their toxins is given in Table 1.

Table 1: Representative Toxic Bacteria and Their Toxins

	toxin	chemical nature	comments
Gram-positive bacteria			
Corynebacterium diphtheriae	diphtheria toxin	protein	involved in diphtheria in man
Staphylococcus aureus	α-toxin, β-hemolysin, enterotoxins, leukocidin	protein	causes pyogenic (pus-forming) infections in animals and in man
Clostridium botulinum	botulinus toxin	protein	involved in botulism in man
Clostridium perfringens	α-toxin, θ-toxin	protein	causes gas gangrene in man
Clostridium tetani	tetanospasmin	protein	causes tetanus in man
Streptococcus pyogenes	streptolysin O, erythrogenic toxin	protein	causes scarlet fever and other streptococcal infections in animals and man
Gram-negative bacteria			
Shigella dysenteriae	neurotoxin	protein	causes bacillary dysentery in man
Vibrio cholerae	cholera toxin	protein	causes cholera in man
Escherichia coli, *Salmonella* species, *Shigella* species, *Brucella* species, and others	"conventional endotoxins"	complex of protein, lipid, and polysaccharide	most gram-negative bacteria produce toxic complex chemical mixtures that are categorically referred to as "endotoxins"

Bacterial exotoxins

Poisonous proteins from bacteria are sometimes referred to as bacterial exotoxins. The exotoxins are generally produced by gram-positive organisms (*i.e.*, bacteria that react in certain ways to the staining procedure known as gram staining); at least two bacteria, *Shigella dysenteriae* and *Vibrio cholerae*, that produce exotoxins are gram-negative, however. The exotoxins usually do not contain any nonprotein substances, and most are antigenic; *i.e.*, they stimulate the formation of antibodies. The exotoxins may appear in the culture medium in which the bacteria are growing during the declining phases of growth; in some cases they are released at the time of normal destruction of the cells after death (autolysis). The exotoxins, less stable to heat than the endotoxins, may be detoxified by agents that do not affect endotoxins. They are more toxic than endotoxins, and each exotoxin exerts specific effects, collectively known as pharmacological properties. Exotoxins are neutralized by homologous antibodies—*i.e.*, the active agents in blood serum produced by a process involving the bacteria against which the serum is to be used.

Endotoxins are antigens composed of complexes of proteins, polysaccharides (large molecules built up of numerous sugars), and lipids (fats). The protein part determines the antigenicity, or quality of being reacted against as a foreign substance in a living organism. The polysaccharide part determines the immunological specificity, or limitations on the types of antibodies that can react with the endotoxin molecule and neutralize it (the immunological reaction). Some of the lipids possibly determine the toxicity. Endotoxins are derived from the bacterial cell wall and, when cells are grown in culture, are released only on autolysis. Endotoxins are not neutralized by homologous antibodies and are relatively stable to heat; all of them have the same pharmacological properties.

Mycotoxins. Fungi are plantlike members of the phylum Mycota that do not contain any chlorophyll. It has been estimated that there are about 85,000 species of fungi, about 55,000 of which are microscopically small in size. A significant number are known to produce poisons of various types. Toxic fungi can be roughly divided into two main categories on the basis of their size: the smaller microfungi and the larger mushrooms. The toxic microfungi are members of one of two classes: Ascomycetes, or the sac fungi, and the Deuteromycetes, or the imperfect fungi (*i.e.*, fungi in which no sexual reproductive stages are known). The large toxic mushrooms, or toadstools, are mostly members of the class Basidiomycetes, although some Ascomycetes, such as the poisonous false morel (*Gyromitra esculenta*), may attain a size as large as some of the mushrooms.

The ability of fungi, such as ergot (*Claviceps purpurea*) and some mushrooms, to produce intoxication has long been known. During the 19th century it was recognized that molds are responsible for such diseases as yellow-rice toxicoses in Japan and alimentary toxic aleukia in Russia. The eruption of so-called turkey X disease in England in 1960 and the resulting discovery of the substance known as aflatoxin (see Table 2) stimulated study of the subject of mycotoxicology. Despite the vast amount of research on mycotoxins, much remains to be done. Mycotoxins are continuously being discovered, and their chemical and biological properties, which vary greatly from one poison to the next, are being studied with great interest. Because mycotoxins have now been recognized as potential cancer-producing agents (carcinogens) that become in-

Table 2: Representative Toxic Microfungi

	toxin	comments
Claviceps purpurea (ergot)	"ergotoxine," a complex of toxic alkaloids, ergocryptine, ergocornine, ergocristine, and others	causes ergot poisoning in animals and humans; produces vomiting, abdominal pain, numbness, nervous disorders, convulsions, gangrene, and abortion
Stachybotrys alternans	stachybotryotoxin	causes a toxicosis in animals and humans; produces stomatitis (inflammatory diseases of the mouth), rhinitis (inflammation of the mucous membranes of the nose), conjunctivitis (inflammation of the inner surface of the eyelid); failure of blood to clot, blood abnormalities, neurological disturbances, and death
Aspergillus flavus and other species *Penicillium* species	aflatoxin complex (16 or more known toxins)	causes toxicosis in animals and possibly man; toxins damage liver and kidneys; aflatoxin is one of the most potent liver-cancer producing agents known
Fusarium sporotrichioides and other *Fusarium* species	fusariogenin, epicladosporic acid, fagicladosporic acid	causes alimentary toxic aleukia in animals and man; produces burning sensation of the mouth, tongue, throat, and stomach, nausea, vomiting, headache, cold extremities, hemorrhagic spots, convulsions, anemia, gangrene, death
Cladosporium epiphyllum and other species of *Cladosporium*	same as *Fusarium* species	
Pithomyces chartarum (*Sporidesmium bakeri*)	sporidesmin	causes facial eczema (an eruptive severe rash) in cattle; produces sensitization of the skin to sunlight resulting in scab formation and sores; there may also be severe liver damage
Fusarium species, *Rhizopus* species, *Aspergillus* species, *Penicillium islandicum*, and others	luteoskyrin, "islanditoxin," citrinin, citreoviridin, and others; a large complex of poisons involved	causes moldy or yellowed rice, which is toxic to animals and man; the effects in man have not been well defined; may cause nausea, vomiting, diarrhea, prostration, liver damage, and death; the effects vary greatly because of the various poisons involved

Table 3: Representative Poisonous Mushrooms

	toxin	type of poisoning
Lorchel, or false morel (*Helvella esculenta*)	gyromitrin	toxicity to people is variable; causes severe liver damage accompanied by nausea, vomiting, abdominal pain, jaundice, enlarged and tender liver, coma, convulsions; fatality rate about 15 percent
Fly mushroom, or fly agaric (*Amanita muscaria*)	muscarine	symptoms develop rapidly, are severe, consisting of severe gastrointestinal disturbances, delirium, hallucinations, convulsions; rarely causes death
Panther mushroom (*Amanita pantherina*)	muscarine	symptoms are similar to *A. muscaria* poisoning
Destroying angel, or death cup (*Amanita phalloides*)	amanitine, phalloidine	symptoms develop slowly, about 6–15 hours after eating: extreme abdominal pain, nausea, vomiting, excessive thirst, anuria (absence or defective excretion of urine), prostration, weakness, jaundice, cyanosis, convulsion, death; fatality rate up to 90 percent; no known antidote
Boletus miniato-olivaceus	muscarine (?)	causes gastrointestinal and visual disturbances
Jack-o'-Lantern fungus (*Clitocybe illudens*)	muscarine	causes gastrointestinal upset, not fatal
Inky cap (*Coprinus atramentarius*)	unknown	some people experience a peculiar type of intoxication after eating this mushroom then drinking an alcoholic beverage: giddiness, gastrointestinal upset, prostration, and tachycardia (rapid heart action); the alcohol is believed to increase the solubility and absorption of the poison
Entoloma lividum	unknown	causes gastrointestinal upset, usually not fatal
Inocybe patouillardi	muscarine	symptoms are similar to *A. muscaria* poisoning
Lepiota morgani	unknown	causes gastrointestinal upset; fatalities have been reported
Mexican hallucinogenic mushroom (*Psilocybe mexicana*)	psilocybin, psilocin	causes euphoria, loss of sense of distance and size, and hallucinations

volved in man's food supply, they are important in the study of environmental carcinogenesis.

Poisonous mushrooms

Poisonous mushrooms, or toadstools as they are commonly called, are the widely distributed members of the class Basidiomycetes. Although there are more than 30,000 species of large mushrooms, only a few are known to be poisonous when eaten (see Table 3); some of the poisons, however, are deadly. About 90 percent of the deaths attributed to mushroom poisoning result from eating members of the genus *Amanita*. When eating wild mushrooms, they should be accurately identified by an experienced person; the safest procedure is to eat only cultivated species. The problem of toxicity in mushrooms is complex; no single rule or test method exists by which the toxicity of a mushroom can be determined. The most poisonous species closely resemble some of the most prized edible species; in addition, toxicity within a given wild species may vary from one set of ecological conditions or from one geographical locality to the next. Moreover, although some mushrooms that are poisonous when fresh are edible when cooked, dried, salted, or preserved in some other way, others remain poisonous in spite of all preparation procedures. It has also been observed that some people may become poisoned by eating mushrooms that apparently do not affect others. As with microfungi, the mushroom poisons vary in their chemical and biological properties from species to species.

Algal poisons. The study of poisonous algae is known as phycotoxicology. Two major groups of algae produce toxic substances: the Cyanophyta, or blue-green algae, and the Pyrrophyta, or dinoflagellates.

Environmental extremes for blue-green algae

Algae comprise some of the smallest forms of chlorophyll-bearing organisms. The approximately 1,500 species of blue-green algae are among the most primitive organisms; they resemble the bacteria in their mode of reproduction and in certain physiological functions. The blue-green algae, among the most widely distributed of all organisms, live in all parts of the aquatic environment that receive light, including the exceedingly saline waters of the Dead Sea. They have extreme temperature tolerances and inhabit waters whose temperatures vary from near the freezing point to those of thermal springs as hot as 82° C (180° F). Blue-green algae have a remarkable ability to survive drying for years under desert conditions. About twice as many species are found inhabiting marine waters as freshwaters. Some strains of a species are toxic; other strains of the same species are not. Water blooms of blue-green algae have been responsible for the death of fishes, waterfowl, cattle, horses, swine, and other animals. Blue-green algae have also been implicated as causes of human intoxications. A list of representative poisonous blue-green algae and their poisons appears in Table 4.

The approximately 1,100 species of dinoflagellates, important producers of the primary food supply of the sea, are microscopic one-celled organisms that are dependent upon various inorganic nutrients in the water and upon radiant energy for photosynthesis, the process by which they produce their own food supplies. Although dinoflagellates inhabit both marine waters and freshwaters, most species are marine. Dinoflagellates are most often found in cool or temperate waters. During periods of planktonic blooms (times of high concentrations of microscopic organisms in the water) dinoflagellates multiply in large numbers. These planktonic blooms, sometimes referred to as red tide because they discolour the water, are often associated with weather disturbances that may bring about changes in water masses or upwellings. During periods of bloom large numbers of toxic dinoflagellates may be ingested by shellfish; the poisons accumulate in their digestive glands. Man and animals may in turn be poisoned by eating poisoned shellfish. Certain species of dinoflagellates are capable of producing some of the most toxic substances known. The two species of dinoflagellates most commonly involved in human intoxications have been *Gonyaulax catenella* along the Pacific coast of North America and *G. tamarensis* along the eastern coast of North America. Intoxications from these organisms are known as paralytic shellfish poisoning. The symptoms, which begin with a tingling or burning sensation, then numbness of the lips, gums, tongue, and face, gradually spread. Gastrointestinal upset may be present. Other symptoms include weakness, joint aches, and muscular paralysis; death may result. There is no specific treatment nor antidote. The poison, variously called paralytic shellfish poison, mussel poison, and saxitoxin, is a complex nonprotein nitrogen-containing compound. Paralytic shellfish poisoning is best avoided by following local public-health quarantine regulations. Despite the numerous folk tales as to methods for differentiating poisonous from edible mussels, there is no reliable substitute for laboratory toxicity tests.

Table 4: Representative Blue-green Algae and Their Poisons

	toxin	toxic effects
Anacystis cyanea (also called *Microcystis aeruginosa*), a freshwater alga	neurotoxin (a polypeptide)	ingestion causes mass mortality of fish; strychnine-like convulsions in cattle and death; respiratory distress, convulsions and death in laboratory animals; gastroenteritis (inflammation of intestinal tissues) in humans; poison is rapid acting
Anabaena flos-aquae, a freshwater alga	neurotoxin (a polypeptide)	toxic effects are similar to those above; poison is rapid acting
Aphanizomenon flos-aquae, a freshwater alga	neurotoxin (a polypeptide ?)	toxic effects are similar to above, but the poison is usually slower acting
Lyngbya majuscula, a marine and freshwater blue-green alga	dermatogenic toxin, chemistry unknown	causes an acute inflammatory reaction when brought in contact with human skin; toxin has antiviral, antibacterial, and antifungal activity

Symptoms of paralytic shellfish poisoning

Table 5: Representative Poisonous Plants

name and distribution	toxic principle	toxic effects and comments
Plants poisonous to eat		
Rosary pea, or jequirity bean (*Abrus precatorius*); tropical regions	abrin (*N*-methyltryptophan) and abric acid	onset of symptoms may be delayed several hours to two days, vomiting, diarrhea, acute gastroenteritis, chills, convulsions, death from heart failure; one seed chewed may be fatal to a child
Aconite, or monkshood (*Aconitum napellus*); North America, Europe	aconite and a complex of other alkaloids	tingling, burning sensation in tongue, throat, skin, restlessness, respiratory distress, muscular uncoordination, vomiting, diarrhea, convulsions, possible death; an extremely poisonous plant
Corn cockle (*Agrostemma githago*); North America, Europe	githagin, agrostemmic acid (saponins)	dizziness, diarrhea, respiratory distress, vomiting, headache, sharp pains in spine, coma, death; frequent ingestion of small amounts results in chronic githagism (a disease similar to lathyrism, that results in pain, burning and prickling sensations in lower extremities, and increasing paralysis); milled seeds may be found in wheat flour
Purple loco weed (*Astragulus mollissimus*); Northern Hemisphere	locoine	dullness, weakness, irregular behaviour, impaired vision, edema of eyelids, loss of muscular control, loss of appetite, emaciation, starvation, death in sheep, horses, and cattle
Belladonna (*Atropa belladonna*); United States, Europe, Asia	hyoscyamine, atropine, hyoscine, and a complex of other alkaloids	dryness of the skin, mouth, throat, difficulty in swallowing, flushing of the face, cyanosis (a bluish discoloration of skin due to insufficient oxygen), nausea, vomiting, slurred speech, coma, death; children and animals frequently poisoned by eating fruit
Akee (*Blighia sapida*)	hypoglycin A, B	sudden vomiting, drowsiness, muscular and nervous exhaustion, prostration, coma, death
Rape (*Brassica napus*)	glycosides (isothiocyanates)	pulmonary emphysema, respiratory distress, anemia, constipation, irritability, blindness in cattle
Marihuana (*Cannabis sativa*); United States, Mexico, tropical America	cannabinol, canabidiol, and related compounds	exaltation, inebriety, confusion, followed by central nervous system depression; prolonged addiction may produce dullness or mania; excessive quantities may cause death as a result of cardiac depression
Water hemlock (*Cicuta maculata*); northern temperate regions	cicutoxin	abdominal pain, nausea, vomiting, diarrhea, respiratory distress, hypersalivation, convulsions, death; among the most poisonous plants
Poison hemlock (*Conium maculatum*); temperate United States, South America, northern Africa, Asia	coniine, conhydrine, *N*-methyleoniine, coniceine, and other alkaloids	muscular weakness, paralysis of extremities, blindness, respiratory paralysis, death; responsible for many human fatalities; leaves most toxic when plant is flowering
Purging croton (*Croton tiglium*); Asia, Pacific Islands, Africa	croton, croton resin, ricinine	vomiting, violent purging, collapse, death; croton oil is also a skin irritant, causing reddening, swelling, and pustules
Daphne (*Daphne mezereum*); temperate regions	glycoside involving aglycone dihydroxycoumarin	vomiting, burning sensation of the mouth, ulceration of the oral mucosa, diarrhea, stupor, weakness, convulsions, and death
Jimson weed or thornapple (*Datura stramonium*); temperate and tropical regions	hyoscine, hyoscyamine, atropine	headache, nausea, vomiting, dizziness, thirst, dry and burning sensation in skin, mental confusion, mania, loss of memory, convulsions, death; children are often poisoned by eating seeds or sucking flowers
Larkspur (*Delphinium* species); northern temperate regions	delphinine, delphinoidine, delphisine, and other alkaloids	burning and inflammation of mouth, nausea, vomiting, respiratory distress, itching, cyanosis; one of the greatest causes of death in grazing livestock
Dumbcane (*Dieffenbachia seguine*); widely cultivated in temperate regions, tropical regions	protoanemonine, calcium oxalate	irritation and burning of the mouth, tongue, and lips, hypersalivation, swelling of the tongue, difficulty in swallowing and breathing
Foxglove (*Digitalis purpurea*); Europe, North America	glycosides, digitoxigenin, and others	loss of appetite, nausea, vomiting, slow pulse and irregular heartbeat, diarrhea, abdominal pain, headache, fatigue, drowsiness, convulsions, death
Wild yam (*Dioscorea hispida*); southern Asia, Pacific Islands	dioscorine	discomfort, then burning of the throat, giddiness, vomiting of blood, respiratory distress, drowsiness, exhaustion, paralysis of the nervous system, death; raw tubers are a frequent cause of death in the Philippines
Huanuco cocaine (*Erythroxylon coca*); tropics of both hemispheres	cocaine and other alkaloids	central nervous system stimulation followed by depression, numbness of tongue, paralysis of respiratory centres, cyanosis, respiratory distress, death; leaves are commonly chewed by Indians of Peru and Bolivia as a stimulant
Manchineel (*Hippomane mancinella*); Florida, Central America, South America, West Indies	physostigmine or a similar alkaloid plus a sapogenin	fruit causes gastroenteritis, which may be fatal, and causes ulceration of intestinal tract; sap causes burning of skin, swelling and hemorrhage of the eyes; sap is used as an arrow poison
Black henbane (*Hyoscyamus niger*); North America, Europe, Asia, Oceania	hyoscyamine, hyoscine, atropine, and other alkaloids	similar to belladonna poisoning caused by *Atropa belladonna;* children are poisoned by eating seeds and pods
Barbados nut (*Jatropha curcas*); tropics	curcin	burning of the throat, bloating, dizziness, vomiting, diarrhea, drowsiness, dysuria, leg cramps, violent purgative action; may be fatal to children
Mountain laurel (*Kalmia latifolia*); North America	andromedotoxin	hypersalivation, tears, impaired vision, tingling of skin, dizziness, vomiting, muscular paralysis, convulsions, coma, death; children are poisoned by eating leaves
Grass peavine (*Lathyrus sativus*); North America, Europe, northern Africa, Asia	β-aminopropionitrile	back pain, weakness in legs, paralysis; has caused death in children

Respiratory irritation may result from the inhalation of toxic products in the windblown spray from red-tide areas containing the toxic dinoflagellate *Gymnodinium brevis*, which is found in the Gulf of Mexico and Florida; the nature of the poison is unknown. Deaths of large numbers of brackish-water pond fishes because of *Prymnesium parvum* have been reported in Israel; the poison is known as prymnesin.

Plant poisons (phytotoxins). The study of plant poisons is known as phytotoxicology. Most of the poisonous higher plants are angiosperms, or flowering plants. Of the 300 families of angiosperms representing about 200,000 species, only a small percentage are recognized as poisonous. Several systems have been devised for the classification of poisonous plants, none of which is completely satisfactory. Poisonous plants may be classified according to the chemical nature of their toxic constituents, their phylogenetic relationship, or their botanical characteristics. The following classification, which is based on their toxic effects, has been found to be useful: (1) plants that are poisonous to eat; (2) plants that are poisonous upon contact; (3) plants that produce photosensitization; and (4) plants that produce airborne allergies (see Table 5).

Plant poisons, or phytotoxins, comprise a vast range of biologically active chemical substances, such as alkaloids, polypeptides, amines, glycosides, oxalates, resins, toxal-

Table 5: Representative Poisonous Plants (continued)

name and distribution	toxic principle	toxic effects and comments
Cassava (*Manihot esculenta*); tropics	cyanophoric glycosides	nausea, respiratory distress, twitching, staggering, convulsions, coma, death
Chinaberry (*Melia azedarach*); North America, southern Africa, Asia	azadarin	stomatitis with violent and bloody vomiting, paralysis
Opium poppy (*Papaver somniferum*); Europe, Asia, tropics	morphine, codeine, thebaine, papavarine, narcotine	central nervous system depression, pinpoint pupils, depressed respiration, cyanosis, coma, death
Pokeberry (*Phytolacca americana*); North America, Europe, southern Africa	phytolaccine	burning, bitterness in mouth, vomiting, purging, spasms, convulsions, death
Castor bean (*Ricinus communis*); United States, tropics	ricin, a toxalbumin	burning of mouth, throat, and stomach, vomiting, diarrhea, abdominal cramps, dulled vision, convulsions, respiratory distress, paralysis, death; one to three seeds may be fatal in children
Deadly nightshade (*Solanum nigrum*); North America, Europe	solanine, a glycoalkaloid	nausea, vomiting, abdominal pain, diarrhea, trembling, paralysis, coma, death
Nuxvomica tree (*Strychnos nux-vomica*); India, Hawaii	strychnine, brucine, and other alkaloids	extreme irritability, tonic convulsions, exhaustion, sweating, muscular rigidity, respiratory distress, death
Thevetia (*Thevetia peruviana*); tropics	thevetin, thevetoxin, neriifolin	vomiting, diarrhea, high blood pressure, erratic heartbeat, respiratory distress, heart paralysis, death
False hellebore (*Veratrum viride*)	protoveritrine, germerine, jervine, and other alkaloids	vomiting, abdominal pain, muscular weakness, convulsions, respiratory distress, coma, death
Death camas (*Zigadenus* species)	zygadenine	vomiting, hypersalivation, staggering, paralysis, convulsions, coma, death
Plants poisonous by contact		
Euphorbia, spurge (*Euphorbia* species); worldwide	a complex of substances including alkaloids, glycosides, and others	eye irritation, blindness, blistering of the skin, swelling around the mouth, burning of the mouth, unconsciousness, death; milky sap is used as an arrow poison
Spurge nettle (*Jatropha stimulosus*); North America, Europe, Asia	toxin unknown	contact produces instant, intense stinging and itching due to an irritating substance injected into the skin by the stinging hairs; results in a skin eruption of minute red papular (small conical elevations of the skin) rash, which wears off in about 30 minutes; a dull purplish discoloration of the skin may remain for several weeks
Shiney-leaf stinging tree, tree nettle (*Laportea photiniphylla*); Australia	5-hydroxytryptamine (and other toxic substances?)	contact with the stinging hairs of this plant produces intense rapidly spreading pain, reddened rash, and later a severe skin eruption; severe stings may result in the victim dashing about, rolling on the ground, and crying out with pain; fatalities have been reported; dried leaves may cause intense sneezing
Poisonwood (*Metopium toxiferum*); West Indies, Florida	similar to poison ivy	contact with any part of the tree, especially sap, turns the skin black, causes a rash, blisters, etc; smoke from a burning tree is very irritating causing illness and temporary blindness
Strophanthus (*Strophanthus* species); Florida, tropical America, Africa	an alkaloid, trigonelline, and a large number of cardiac glycosides and aglycones	vomiting, slow and irregular pulse, blurred vision, delirium, circulatory failure, death; used as an arrow poison
Curare (*Strychnos toxifera*); Central America and northern South America	toxiferines, caracurines, and other alkaloids	haziness of vision, relaxation of facial muscles, inability to raise head, loss of muscle control of arms, legs, and respiratory muscles, death; used as a poison for arrows and for blow-gun darts
Poison ivy (*Toxicodendron radicans*, also called *Rhus toxicodendron*); North America	urushiol	skin irritation, swelling, blistering, itching; may be fatal to young children; smoke from burning plant is toxic
Plants that produce photosensitization		
Buckwheat (*Fagopyrum sagittatum*); North America, Europe	fagopyrin, a naphthodianthrone derivative	ingestion of the leaves by animals causes liver dysfunction, thereby resulting in deposition of a photosensitizing pigment in the skin; sunlight then causes redness of the skin, nervousness, swelling of the eyelids, convulsions, and prostration in farm animals
St. Johnswort (*Hypericum perforatum*); North America, Europe	hypericin, a naphthodianthrone derivative	similar to buckwheat
Plants that produce airborne allergies		
Box elder (*Acer negundo*); Northern Hemisphere	oleoresin and a water soluble antigen	hay fever (respiratory allergy) may also cause an eczematous dermatitis of the exposed parts of the body
Poplar, cottonwood (*Populus* species); almost worldwide	same as box elder	
Ash (*Fraxinus* species); temperate regions	same as box elder	
Elm (*Ulmus* species); Northern Hemisphere, tropics	same as box elder	

Chemical variability of plant poisons

bumins, and a large group of miscellaneous compounds whose chemical structure has not yet been determined. Alkaloids, most of which are found in plants, are characterized by the presence of nitrogen and their ability to combine with acids to form salts. They are usually bitter in taste. It has been estimated that about 10 percent of the plant species contain some type of alkaloid. Only a few of the 5,000 alkaloids characterized thus far do not produce any biological activity; most cause a strong physiological reaction when administered to an animal. Amines are organic compounds containing nitrogen. A polypeptide is a string of three or more amino acids. A few polypeptides and amines are toxic to animals. Some glycosides, which are compounds that yield one or more sugars and one or more other compounds—aglycones (nonsugars)—when hydrolyzed (chemically degraded by the introduction of water molecules between adjacent subunits), are extremely toxic to animals. Toxicity resides in the aglycone component or a part of it. Oxalates are salts of oxalic acid, which under natural conditions is not toxic but becomes so because of the oxalate ion. Resins, a heterogeneous assemblage of complex compounds, differ widely in chemical properties but have certain similar physical properties. Some resins are physiologically very active, causing irritation to nervous and muscle tissue. Toxalbumins are highly toxic protein molecules that are

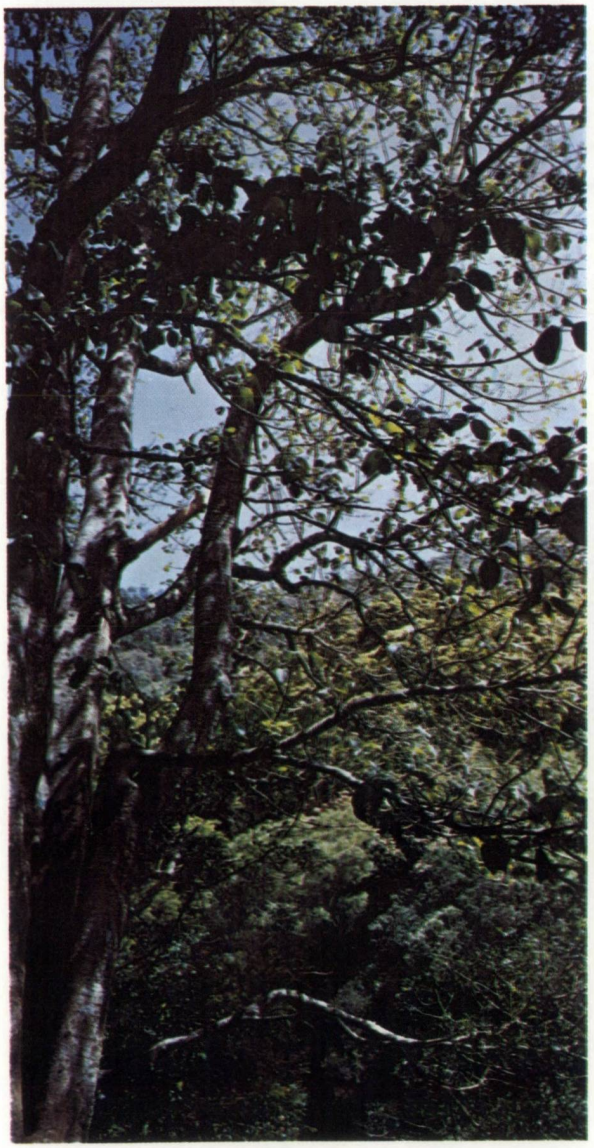
Table 6: Representative Animals Poisonous When Eaten

name and distribution	toxic principle	toxic effects and comments
Protozoans—one-celled animals		
Dinoflagellate (*Gymnodinium brevis*); Gulf of Mexico, Florida	unknown	irritation of mucous membranes of nose and throat; causes sneezing, coughing, respiratory distress due to inhalation of windblown spray from red tide areas
Dinoflagellate (*Gonyaulax catenella*); Pacific coast of North America	paralytic shellfish poison, saxitoxin ($C_{10}H_{15}N_7O_8 \cdot 2\ HCl$)	tingling, burning sensation and numbness of lips, tongue, face, spreading elsewhere to the body; weakness, dizziness, joint aches, hypersalivation, intense thirst, difficulty in swallowing, muscular paralysis, and death; extremely toxic; usually involved with the eating of shellfish
Dinoflagellate (*Gonyaulax tamarensis*); east coast of North America	same as *Gonyaulax catenella*	that have been feeding on toxic dinoflagellates
Cnidarians—jellyfish, sea anemones, and relatives		
Matamalu samasama, a sea anemone (*Radianthus paumotensis*); southern Polynesia to Micronesia	poison unknown	nausea, vomiting, abdominal pain, cyanosis, prostration, coma, death; this species of sea anemone eaten raw or cooked is poisonous
Echinoderms—starfishes, sea cucumbers, and relatives		
Sea cucumber (*Holothuria* species); tropical Pacific	holothurin	little is known concerning the symptoms produced by poisonous sea cucumbers; ingestion of toxic sea cucumbers may be fatal; sea cucumbers under most circumstances are safe to eat, but some species are toxic; species are difficult to identify
Mollusks—octopus, squid, shellfish, and others		
California mussel (*Mytilus californianus*); Pacific coast of North America	paralytic shellfish poison, saxitoxin	these mollusks become poisonous to eat because of feeding on toxic dinoflagellates; symptoms same as for dinoflagellates (*Gonyaulax* species)
Butter clam (*Saxidomus giganteus*); Alaska to California	same as California mussel	
Surf clam (*Spisula solidissima*); Labrador to North Carolina	same as California mussel	
Whelk (*Neptunea* species); Europe, Pacific region	tetramine	nausea, vomiting, diarrhea, weakness, fatigue, dizziness, photophobia (intolerance to light), impaired vision, and dryness of the mouth; poison is believed to be restricted to the salivary glands of the whelk
Turban shell (*Turbo argyrostoma*); tropical Pacific Ocean	poison believed to be related to ciguatoxin	diarrhea, weakness of the legs, fatigue, cold water produces a painful stinging sensation, itching; the illness closely resembles ciguatera fish poisoning
Callista shellfish (*Callista brevisiphonata*); Japan	a histamine-like substance, choline	flushing of the face, itching, urticaria (stinging sensation of skin), sensation of constriction of the chest, abdominal pain, nausea, respiratory distress, asthmatic attacks, paralysis, hypersalivation, numbness of the tongue, throat; recovery usually within 10 days
Japanese dosinea (*Dosinia japonica*); Japan	venerupin	nausea, vomiting, nervousness, bleeding from the mucous membranes of the nose, mouth, and gums, halitosis, hemorrhages into the skin, enlarged liver, delirium, coma, death
Japanese littleneck cockle (*Tapes semidecussata*); Japan	same as Japanese dosinea	
Arthropods—joint-legged animals: crabs, spiders, and others		
Shore crab (*Demania toxica*); Philippines	unknown	nausea, vomiting, diarrhea, muscular weakness, respiratory distress, difficulty in speaking, hypersalivation, muscular paralysis, convulsions, death
Crab (*Zozymus aeneus*); Indo-Pacific	similar to tetrodotoxin; toxicity of these crabs variable	tingling about the mouth, nausea, vomiting, muscular paralysis, coma, convulsions, death
Crab (*Eriphia sebana*); tropical Pacific Ocean	same as *Z. aeneus*	
Asiatic horseshoe crab (*Tachypleus tridentatus*); Southeast Asia	unknown	dizziness, headache, nausea, vomiting, abdominal pain, cardiac palpitation, numbness of the lips, weakness, muscular paralysis, hypersalivation, loss of consciousness, death
Sharks, eels, and other fish		
Greenland shark (*Somniosus microcephalus*); Arctic	unknown; flesh toxic; liver of tropical sharks very toxic and may also cause death	nausea, vomiting, diarrhea, abdominal pain, tingling and burning sensation of the tongue, throat, and esophagus, muscular cramps, respiratory distress, coma, death
Moray eel (*Gymnothorax javanicus*); Indo-Pacific†	ciguatoxin*	symptoms may develop rapidly or slowly; tingling about the lips, tongue, and throat, followed by numbness, nausea, vomiting, abdominal cramps, muscular weakness, paralysis, convulsions, teeth feel loose, visual impairment, skin rash, hot objects feel cold and vice versa ("Dry Ice" or "electric shock" sensation); loss of muscular coordination, coma, death in about 12 percent of the cases; known as ciguatera fish poisoning, this is one of the most common forms of fish poisoning
Blue crevally (*Caranx melampygus*); Indo-Pacific†	same as Moray eel	
Red snapper (*Lutjanus bohar*); Indo-Pacific†	same as Moray eel	
Spotted grouper (*Cephalopholis argus*); Indo-Pacific†	same as Moray eel	

*Fish poisoning is categorically referred to as "ichthyosarcotoxism," but there are several different forms of fish poisoning such as ciguatera fish poisoning, clupeotoxism, scombrotoxism, and others. †More than 400 species of tropical reef fishes have been involved in ciguatera fish poisoning. These fish are normally edible, but under certain conditions may become toxic.

produced by only a small number of plants. Ricin, a toxalbumin from the castor bean (*Ricinus communis*), is one of the most toxic substances known.

Under certain ecological conditions plants may become poisonous as a result of the accumulation of toxic inorganic minerals such as copper, lead, cadmium, fluorine, manganese, nitrates, or selenium. Photosensitization, an unusual toxic reaction resulting from the ingestion of certain plants, may be of two types. The toxic substance may be obtained directly from the plant, which thereupon acts on the skin (primary photosensitivity), or the toxicity may result from liver damage caused by the metabolism of a toxic plant and failure of the breakdown products to be eliminated by the liver (hepatic photosensitivity). In either case the animal reacts by becoming restless; in addition, the skin reddens, and a severe sloughing of the skin develops. Death seldom occurs.



A large number of poisonous plants occur throughout the world; a few representative species and their poisons are listed in Table 5.

Queen hornet *(Vespa crabro)*.

Black widow *(Latrodectus mactans)*.

Poison hemlock (*Conium maculatum*).

Amanita pantherina.

Laportea gigas, (left) entire tree, (below) underside of a leaf showing stinging hairs.

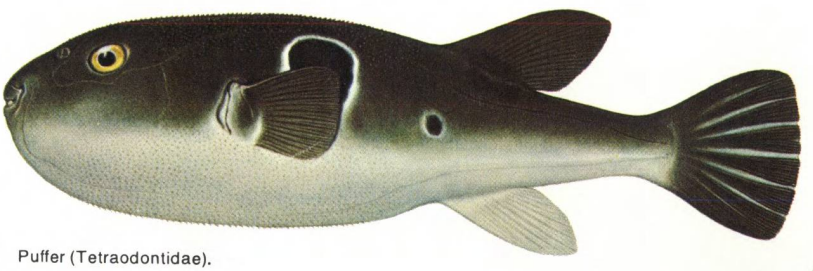
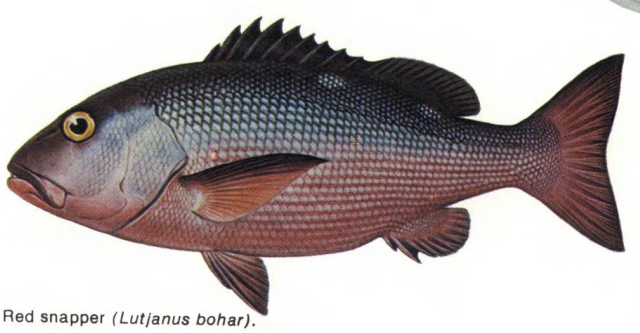
Plate 3: B.W. Halstead, World Life Research Institute; artwork, (top right) H. Matsuura, (others) J. Fujishima



Crab *(Zozymus aeneus).*

Lionfish *(Pterois volitans).*



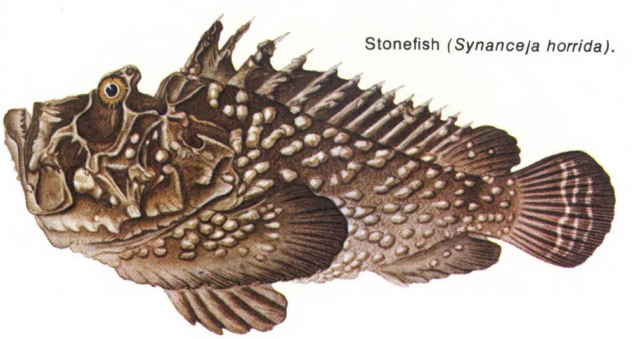
Moray eel *(Gymnothorax javanicus).*

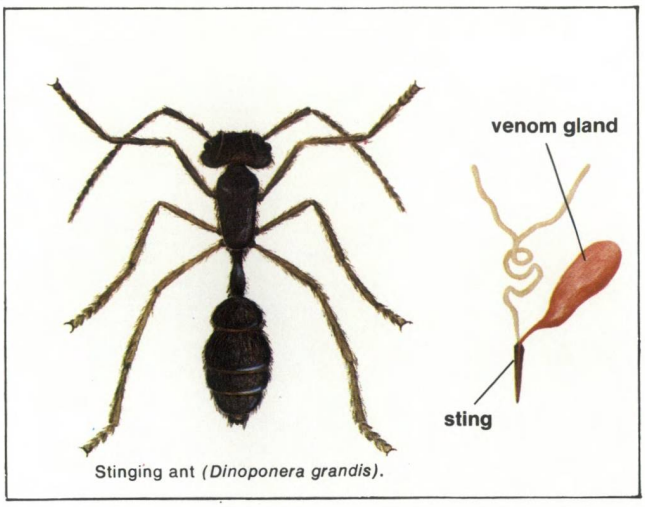
Puffer (Tetraodontidae).

Blue crevally *(Caranx melampygus).*

Red snapper *(Lutjanus bohar).*

Stonefish *(Synanceja horrida).*





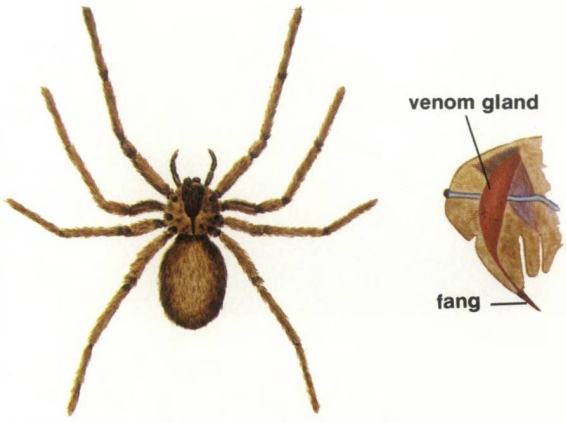


Plate 4: B.W. Halstead—World Life Research Institute; artwork, (centre right above) T. Kumada, (centre right below) K. Tomita, (bottom right) S. Arita, (others) M. Shirao

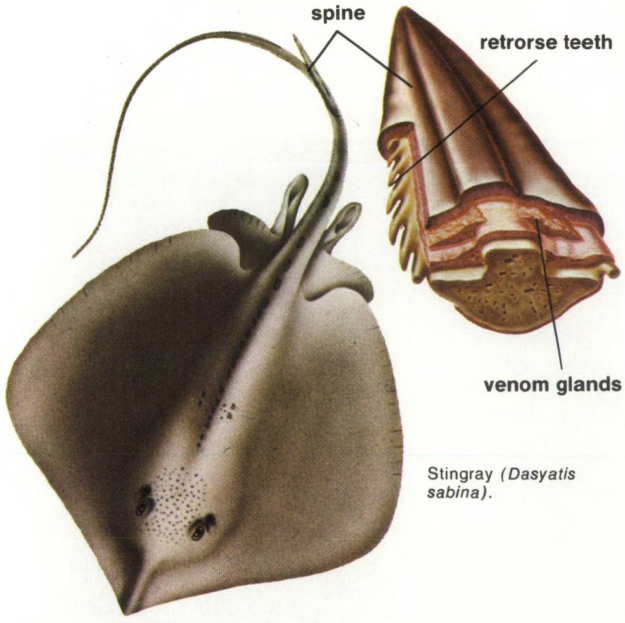

Plate 5: B.W. Halstead—World Life Research Institute; artwork, (centre left) L. Barlow, (bottom right) L. Barlow and M. Shirao, (others) K. Fogassy

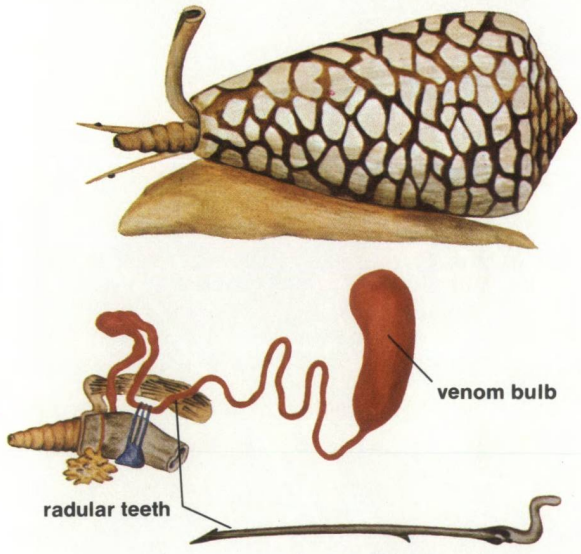
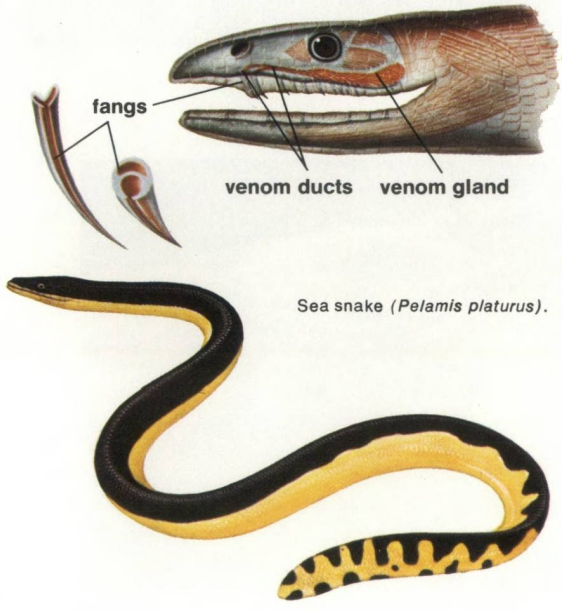
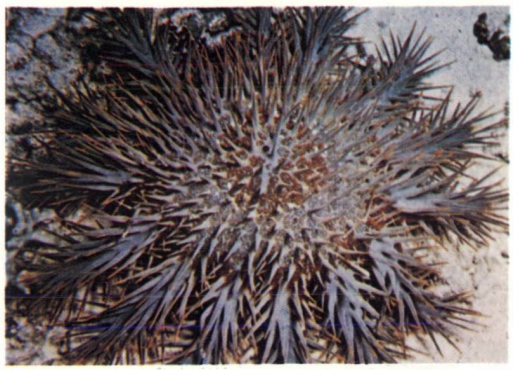


Stinging ant *(Dinoponera grandis)*.

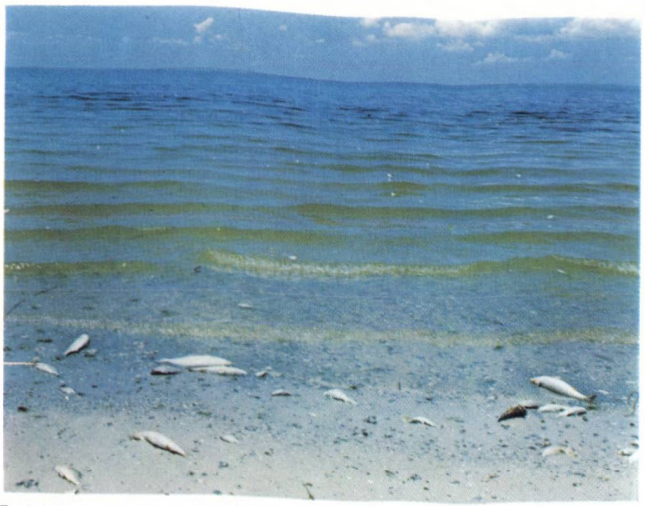
Brown recluse spider *(Loxosceles reclusa)*.



Stingray *(Dasyatis sabina)*.

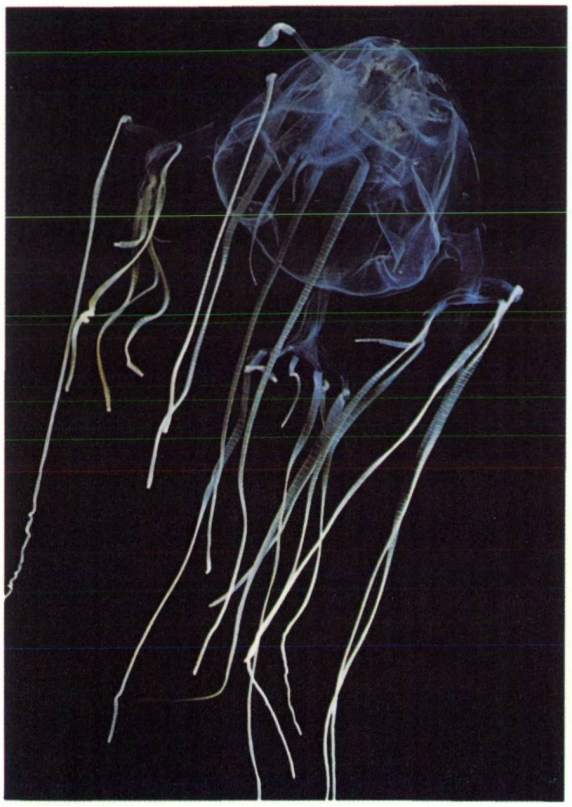


Marbled cone snail *(Conus marmoreus)*.

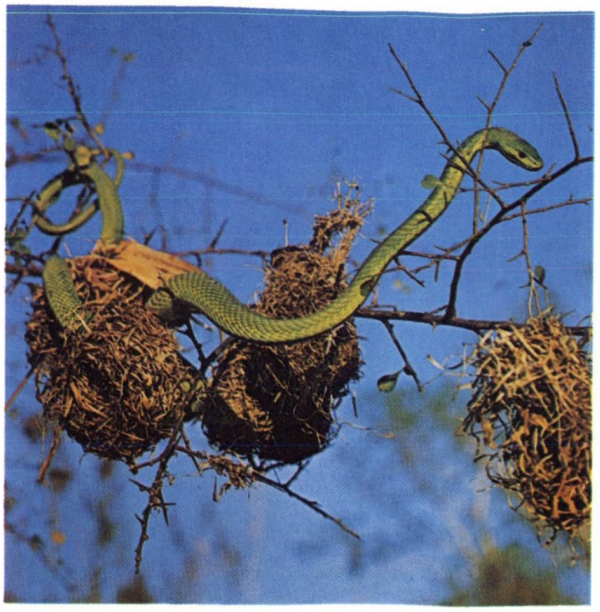


Blue-spotted octopus *(Octopus maculosus)*.

Sea snake *(Pelamis platurus)*.



Crown of thorns starfish *(Acanthaster planci)*.



Red tide, Tampa Bay, Florida, showing fish kill and red coloration caused by dinoflagellates.

Sea wasp *(Chironex fleckeri)*.

Green mamba *(Dendroaspis viridis)*.

Kokoa frog or South American arrow poison frog (*Dendrobates* species).

Gila monster *(Heloderma suspectum)*.

Table 6: Representative Animals Poisonous When Eaten (continued)

name and distribution	toxic principle	toxic effects and comments
Yellowfin grouper (*Mycteroperca venenosa*); west tropical Atlantic†	same as Moray eel*	
Emperor sea bass (*Variola louti*); Indo-Pacific†	same as Moray eel	
Great barracuda (*Sphyraena barracuda*); tropical seas†	same as Moray eel	
Triggerfish (*Balistes vetula*); tropical Atlantic†	same as Moray eel	
Trunkfish (*Lactoria cornutus*); Indo-Pacific†	same as Moray eel	
Thread herring (*Clupanodon thrissa*); Indo-Pacific	clupeotoxin, chemical nature unknown	metallic taste, nausea, vomiting, abdominal pain, vascular collapse, hypersalivation, numbness, muscular paralysis, convulsions, coma, death; this form of poisoning develops rapidly and violently; mortality rate is about 50 percent and death may come within a few minutes; this form of fish poisoning is known as clupeotoxism; no known antidote
Atlantic thread herring, or yellow-billed sprat (*Opisthonema oglinum*); West Indies	same as thread herring	
Red-ear sardine, also called yellow-billed sprat (*Harengula humeralis*); West Indies	same as thread herring	
Castor-oil fish (*Ruvettus pretiosus*); tropical Atlantic, Indo-Pacific	oleic acid	produces a painless diarrhea; poisoning known as gempylotoxism; no treatment needed
Skipjack tuna (*Euthynnus pelamis*); tropical seas Bluefin tuna (*Thunnus thynnus*); subtropical and temperate seas	saurine, a histamine-like substance; scombroid fishes (mackerals, tunas, swordfishes, and allies), contain a chemical constituent in their flesh called histidine; when histidine is acted upon, it forms a histamine-like substance called saurine; this occurs when the fishes are permitted to stand at room temperature for several hours; scombroid fishes are more susceptible to the development of saurine poison than most other kinds of fishes	the symptoms of acute scombroid poisoning resemble those of a severe allergy: sharp, peppery taste, headache, throbbing of the large blood vessels of the neck, nausea, vomiting, massive red welts, and intense itching; recovery after 8–12 hours; this is probably the most common and cosmopolitan form of fish poisoning; antihistamines are used for treatment
Deadly death puffer (*Arothron hispidus*); tropical Pacific, Indian Ocean, Red Sea	tetrodotoxin ($C_{11}H_{17}O_8N_3 \pm y\ H_2O$)	tingling of lips and tongue, loss of motor coordination, floating sensation, hypersalivation, numbness of the entire body, muscular paralysis, difficulty in swallowing, weakness, nausea, vomiting, convulsions, about 60 percent fatality in humans; no known antidote
White-spotted puffer (*Arothron meleagris*); tropical Pacific	same as deadly death puffer	
Amphibians		
California newt (*Taricha torosa*); California	tarichatoxin; poison said to be identical to tetrodotoxin; the eggs of this newt are extremely toxic	effects in man are unknown; no known antidote
Reptiles		
Hawksbill turtle (*Eretmochelys imbricata*); tropical seas Leatherback turtle (*Dermochelys coriacea*); temperate and tropical seas	chelonitoxin, chemistry unknown; the flesh of some species of marine turtles is extremely poisonous	nausea, vomiting, diarrhea, burning sensation of lips, tongue, mouth, tightness of the chest, difficulty in swallowing, hypersalivation, foul breath, skin rash, sloughing of the skin, enlargement of the liver, coma, death; fatality rate is high; no known antidote
Mammals		
Sei whale (*Balaenoptera borealis*); North Pacific and North Atlantic oceans	unknown; livers of many marine mammals are toxic	intense headache, neck pain, photophobia, desquamation (peeling in scales) around the mouth and face, flushing of the face; antihistamines are used in treatment
White whale (*Delphinapterus*); Arctic seas	unknown	flesh is poisonous and has caused fatalities in humans; no known antidote
Polar bear (*Thalarctos maritimus*); Arctic	vitamin A, and possibly other toxic substances	intense throbbing headaches, nausea, vomiting, diarrhea, abdominal pain, dizziness, drowsiness, irritability, muscle cramps, visual disturbances, collapse, coma, rarely death

*See footnote for *ciquatoxin*. †See footnote for *Moray eel*.

Animal poisons (zootoxins). Poisonous animals are widely distributed throughout the approximately 1,000,000 species of animals, ranging from protozoans to polar bears; the only major group that seems to be exempt is the birds. The percentage of organisms that produces toxic substances is not known, but a significant number are poisonous. There are probably many more poisonous animals inhabiting the marine environment than are found on land.

Zootoxins can be divided into several categories: (1) oral poisons—those that are poisonous when eaten; (2) parenteral poisons, or venoms—those that are produced by a specialized poison gland and administered by means of a venom apparatus; and (3) crinotoxins—those that are produced by a specialized poison gland but are merely released into the environment, usually by means of a pore. Categories of zootoxins

Oral zootoxins (see Table 6) are generally thought to be small molecules; most venoms (Table 7) are believed to be large molecules, usually a protein or a substance in

Table 7: Representative Venomous Animals That Inflict a Sting

name and distribution	toxic principle	toxic effects and comments
Cnidarians*		
Fire coral (*Millepora* species); tropical seas	unknown	skin irritation, mild prickly or stinging sensation similar to a nettle (plant) sting
Portuguese man-of-war (*Physalia* species); tropical seas	tetramine, 5-hydroxytryptamine	immediate, intense stinging, throbbing, or burning sensation, shooting sensation, inflammatory rash, blistering of the skin, shock, collapse, in very rare cases death
Sea wasp (*Chironex fleckeri*); northern and northeast Australia	cardiotoxin	immediate extreme painful stinging sensation, seared reddened lines wherever the tentacles touch the skin, large indurated wheallike lesions, prostration, dizziness, circulatory failure, respiratory distress, rapid death in a high percentage of cases; no specific antidote available
Sea anemone (*Actinia equina*); Mediterranean, Black Sea, etc.	nature of venom unknown	burning, stinging sensation, itching, swelling, redness, ulceration, nausea, vomiting, prostration; no specific antidote available
Mollusks		
Cone shell (*Conus* species); tropical Indo-Pacific region	quarternary ammonium compounds and others	blanching at the site of injection, cyanosis of the surrounding area, numbness, stinging or burning sensation, blurring of vision, loss of speech, difficulty in swallowing, nausea, extreme weakness, coma, and death in some cases; no specific antidote
Spotted octopus (*Octopus maculosus*); Indo-Pacific, Indian Ocean	cephalotoxin, a neuromuscular poison	sharp burning pain, similar to a bee sting, numbness of the mouth and tongue, blurring of vision, loss of tactile sensation, difficulty in speech and swallowing, paralysis of legs, nausea, prostration, coma, and death in a high percentage of cases
Insects		
Kissing bug (*Triatoma* species); Latin America, United States	unknown	bite usually painless; later itching, edema about the bite, nausea, palpitation, redness; the bite is of relatively minor importance but spreads Chagas disease caused by a trypanosome (protozoan)
Hawkmoth (*Acanthosphinx guessfelotii*)	unknown	tibial spurs are capable of inflicting a painful scratch; a poison may be present
Moth (*Anaphe* species); Europe	unknown	female moth possesses hollow barbed setae or hairs in the anal tuft which are released at time of egg laying; during the breeding season they become so numerous they are released in the atmosphere and produce a severe dermatitis; the hairs contain a poison
Puss caterpillar (*Megalopyge* species); United States, Latin America	unknown	stinging hairs of the caterpillar associated with poison-secreting glands; contact with the hairs produces an intense burning pain, itching, pustules, redness, nausea, fever, numbness, swelling, and paralysis; recovery usually within about six days
Honeybee (*Apis* species); worldwide	neurotoxin, hemolytic, melittin, hyaluronidase, phospholipase A, histamine, and others	sting produces acute local pain or burning sensation, blanching at the site of the sting surrounded by zone of redness, and itching; local symptoms usually disappear after 24 hours; severe cases may develop massive swelling, redness, shock, prostration, vomiting, rapid heart beat, respiratory distress, trembling, coma, and death; it is estimated that 500 stings delivered in a short period of time can provide a lethal dose to a human; bees kill more people in the United States than do venomous reptiles
Bumblebee (*Bombus* species); temperate regions	similar to honeybee (*Apis*) venom	stings are similar to honeybee (*Apis*) stings; bumblebees are not as vicious as honeybees
Carpenter bee (*Xylocopa* species); temperate regions	similar to honeybee venom	similar to honeybee stings
Wasp (*Seliphron* species); temperate regions	similar to honeybee venom	similar to honeybee stings; stings may be fatal
Yellow jacket, hornet (*Vespula* species); temperate regions	similar to bee venom; also acetylcholine	they can both bite and sting; the sting is similar to that of the honeybee but more painful; yellow jackets are quite aggressive; stings may be fatal
Wasp (*Polistes* species and *Vespa* species); worldwide	similar to bee venom; also acetylcholine	wasps are less aggressive than hornets and their sting is similar to the honeybee but generally less painful than hornets; stings may be fatal
Velvet ant (*Dasymutilla* species); United States	similar to wasp venom	velvet ants are actually female wingless wasps; stings are similar to other wasp stings
Harvester ant (*Pogonomyrmex* species); United States	bradykinin, formic acid, hyaluronidase, hemolytic, phospholipase A, and others.	ant stings cause immediate intense burning, pain, blanched area at site of sting surrounded by redness, ulceration, fever, blistering, itching, hemorrhaging into the skin, eczematoid dermatitis, pustules, respiratory distress, prostration, coma, and death in some instances
Fire ant (*Solenopsis* species); United States, Latin America	similar to harvester-ant venom	similar to above; stings are very painful, burning sensation, etc.
Ponerine ant (*Paraponera clavata*); Latin America	same as fire ant	
Spiders		
Brown spider (*Loxosceles* species); United States, South America, Europe, Asia	cytotoxic, hyaluronidase, hemolytic, and others	bite causes stinging sensation or burning pain, blanching at site of bite surrounded by redness, blistering, hemorrhages into the skin and internal organs, ulceration, vomiting, fever, cardiovascular collapse, convulsions, sometimes death
Black widow (*Latrodectus* species); tropical and temperate regions	neurotoxic	bite may or may not be painful, two tiny red dots at site of bite, localized swelling after a few minutes; intense cramping pain of abdomen, legs, chest, back; pain may become agonizing causing patient to scream; rigidity of muscles, lasting 12–48 hours, nausea, sweating, respiratory distress, priapism (abnormal, painful erection of the penis) in males, chills, skin rash, restlessness, fever, numbness, tingling, about 4 percent are fatal; antiserum is available
Tarantula (*Dugesiella* and *Lycosa* species); temperate and tropical regions	venom varies, usually mild	most of the large tarantulas found in the United States, Mexico, and Central America are harmless to man; their bites are similar to a pin prick and relatively mild; their danger to man has been grossly exaggerated; some of the large tropical species may be more poisonous, but their effects are largely localized
Scorpions†		
Scorpion (species of *Centruroides*, *Tityus*, and *Leiurus*); warm temperate and tropical regions	neurotoxin, cardiotoxin, hemolytic, lecithinase, hyaluronidase, and others	symptoms vary depending upon the species of scorpion; sting from the tail stinger causes a sharp burning sensation, swelling, sweating, restlessness, salivation, confusion, vomiting, abdominal pain, chest pain, numbness, muscular twitching, respiratory distress, convulsions, death; the mortality rate from stings from certain species of scorpions is very high; antiserum is available

*About 9,000 species of jellyfish, sea anemones, etc.; stings are produced by means of nematocysts, specialized stinging cells. †About 650 species.

Table 7: Representative Venomous Animals That Inflict a Sting (continued)

name and distribution	toxic principle	toxic effects and comments
Echinoderms‡		
Crown-of-thorns starfish (*Acanthaster planci*); Indo-Pacific	nature of poison unknown	penetration of the spines produces a painful wound, redness, swelling, vomiting, numbness, and paralysis
Long-spined sea urchin (*Diadema setosum*); Indo-Pacific	nature of poison unknown	penetration of the spines produces an immediate and intense burning sensation, redness, swelling, numbness, muscular paralysis
Sea urchin (*Toxopneustes pileolus*); Indo-Pacific	nature of poison unknown	bites from the stinging jaws or pedicellariae (small pincer-like organs) produce an immediate intense radiating pain, faintness, numbness, muscular paralysis, respiratory distress, and occasionally death
Sharks and rays		
Stingray (*Dasyatis* species); warm temperate and tropical seas	stingray venom, cardiotoxin, chemistry unknown	penetration of the tail spines inflicts jagged painful wounds that produce sharp, shooting, throbbing pain, fall in blood pressure, nausea, vomiting, cardiac failure, muscular paralysis, rarely death; no known antidote; stingrays are among the most common causes of envenomations in the marine environment
Bony fishes		
Weever fish (*Trachinus draco*); Mediterranean Sea	weeverfish venom, chemistry unknown	opercular and dorsal fin spines can produce instant pain, burning, stabbing or crushing sensation; pain spreads and becomes progressively more intense causing the victim to scream with anguish, suffer loss of consciousness, numbness about the wound, swelling, redness, nausea, delirium, difficulty in breathing, convulsions, and death; no known antidote
Scorpion fish (*Scorpaena* species); temperate and tropical seas	scorpionfish venom, chemistry unknown	fin spines can inflict painful stings and intense immediate pain that may cause victim to scream followed by redness, swelling, loss of consciousness, ulceration of the wound, paralysis, cardiac failure, delirium, convulsions, nausea, prostration, and respiratory distress, but rarely death; no known antidote
Stonefish (*Synanceja* species); Indo-Pacific region	stonefish venom, chemistry unknown	produces an extremely painful sting by means of the dorsal fin spines; symptoms similar to other scorpionfish stings but more serious
Reptiles		
Gila monster (*Heloderma suspectum*); southwestern United States	heloderma venom, primarily a neurotoxin	all of the teeth are venomous; bite causes local pain, swelling, weakness, ringing of the ears, nausea, respiratory distress, cardiac failure, may cause death; no antiserum available
Rear-fanged snakes		
Boomslang (*Dispholidus typus*); Africa	coagulates the blood; proteolytic and other enzymes are present	local pain, swelling, hemorrhages, bleeding from nose, mouth, and skin, headache, vomiting, collapse, death; antiserum is available
Front-fixed-fanged snakes		
Death adder (*Acanthophis antarcticus*); Australia, New Guinea	coagulates blood; proteolytic and other enzymes present	effects of envenomation develop slowly (15–60 minutes); nausea, vomiting, faintness, drowsiness, staggering, slurred speech, respiratory distress, hemorrhages, death; antiserum available
Indian krait (*Bungarus candidus caeruleus*); India, Burma, Malaya, Indonesia	cholinesterase, protease, and other enzymes present	little pain or local reaction, latent period up to 12 hours; abdominal pain, staggering gait, difficulty in swallowing, stiffness of jaws, coma, respiratory distress, cardiac failure, death; antiserum available
Brown snake (*Demansia textilis*); Australia	cholinesterase, ophio-adenosinetriphosphatase, phospholipase, and other enzymes	latent period up to 12 hours; abdominal pain, vomiting, headache, dizziness, blood in the urine, weakness, respiratory and circulatory collapse, death; antiserum available; this snake is responsible for most of the deaths due to snake bite in Australia; very dangerous
Black mamba (*Dendroaspis polylepis*); Ethiopia, Somalia, Natal, southwest Africa	cholinesterase, L-amino-acid oxidase, ophio-adenosine, triphosphatase, and other substances	local pain, swelling, salivation, paralysis of vocal cords, sweating, vomiting, restlessness, drowsiness, collapse, coma, respiratory distress, death; one of the most dangerous of all living snakes; antiserum available; a large black mamba secretes enough venom to kill ten men
Ringhals (*Hemachatus hemachatus*); South Africa	coagulates blood; cholinesterase, L-amino-acid oxidase, 5-nucleotidase, lecithinase, protease, and other enzymes	pain, weakness, respiratory distress, may cause blindness, cyanosis, collapse, death; venom sprayed at eyes; this is one of the spitting cobras; antiserum available
Coral snake (*Micrurus corallinus*); subtropical South America	cholinesterase, hyaluronidase, L-amino-acid oxidase, and other enzymes	numbness without pain at bite, headache, swelling of face and lips, hyperesthesia (unusual sensitivity of skin), sore throat, drooping of eyelids, photophobia, vomiting, rapid heart rate, backache, irritability, salivation, death; there are about 40 species in the genus *Micrurus;* all are dangerous; antiserum available for some species but not others
Indian cobra (*Naja naja*); southern Asia, Indonesia, Taiwan, Philippines	carboxypolypeptidase, cholinesterase, diastase, dipeptidase, polypeptidase, protease, and other enzymes; one of the most complex snake venoms	pain radiating from site of bite, edema, numbness, drooping of the eyelids, head, salivation, difficulty in speech, muscular incoordination, weakness, respiratory distress, blindness, incontinence, convulsions, death; antiserum available
Black-necked cobra (*Naja nigricollis*); Africa	cholinesterase, L-amino-acid oxidase, phospholipase, protease, and other enzymes	similar to poisonings by the Indian cobra; venom sometimes sprayed at eyes; produces an intense irritation but permanent damage to eyes is rare; antiserum available
Tiger snake (*Notechis scutatus*); Australia	coagulates blood; cholinesterase, hyaluronidase, ophio-adenosine-triphosphatase, phosphatase, and other enzymes	latent period of 15–60 minutes; nausea, vomiting, faintness, sweating, drowsiness, staggering, slurred speech, difficulty in swallowing, drooping of eyelids, respiratory distress, death; antiserum available
King cobra (*Ophiophagus hannah*); India, Burma, Philippines, Thailand	cholinesterase, L-amino-acid oxidase, ophio-adenosinetriphosphotase	symptoms similar to those produced by other cobras; symptoms develop rapidly, death often occurs in 30–60 minutes; one of the largest of venomous snakes—obtains a length of 16 feet; antiserum available
Taipan (*Oxyuranus scutellatus*); Australia, New Guinea	lecithinase, phospholipase	symptoms similar to those produced by the tiger snake; its long fangs and potent venom make this one of the world's most dangerous snakes; produces flaccid paralysis, respiratory paralysis, often rapidly fatal; antiserum available
Australian black snake (*Pseudechis porphyriacus*); Australia	L-amino-acid oxidase, lecithinase, phospholipase	local pain and swelling, vomiting, hemorrhages from nose and mouth, prostration, hematuria (presence of blood in the urine), and sometimes death; usually the bites are nonfatal; antiserum available
Sea snakes		
Beaked sea snake (*Enhydrina schistosa*); Indo-Pacific; all sea snakes are venomous, but only a few species have caused death in man	lecithinase	no local reaction; latent period minutes to hours; giddiness, muscle ache, muscular weakness, drooping of the eyelids, lockjaw, respiratory failure, acute renal (kidney) failure, death

‡Sea urchins, starfish, etc., about 4,000 species.

Table 7: Representative Venomous Animals That Inflict a Sting (continued)

name and distribution	toxic principle	toxic effects and comments
Erectile-fanged snakes		
Copperhead (*Ancistrodon contortrix*); eastern and southern United States	cholinesterase, L-amino-acid oxidase, phosphodiesterase, and other enzymes	local pain, swelling, necrosis, nausea, vomiting, shock, petechiae (minute bleeding spots), bloody stools, death; antiserum available
Eastern cottonmouth (*Ancistrodon piscivorus*); southeastern United States to central Texas	cephalinase, cholinesterase, hyaluronidase, lacithinase, and other enzymes	similar to poisoning by the copperhead but more severe; local necrosis more marked; death; antiserum available
Fer-de-lance (*Bothrops atrox*); central Mexico, south into South America	cholinesterase, deoxyribonuclease, L-amino-acid oxidase, protease, and other enzymes	local pain, bleeding from bite, gums, nose, mouth, rectum, blood fails to clot, shock, respiratory distress, hemorrhages into muscles and nervous system, death; antiserum available
Eastern diamondhead rattlesnake (*Crotalus adamanteus*); southeastern United States	cephalinase, cholinesterase, hyaluronidase, and other enzymes	local pain, edema, hemorrhaging into the tissues, dryness of the mouth, vomiting, shock, anemia, tingling sensation, blood in feces, difficulty in speech, yellow vision, loss of consciousness, death; antiserum available
Western diamondback rattlesnake (*Crotalus atrox*); southwestern United States	bradykininogen, cholinesterase, hyaluroindase, L-amino-acid oxidase, and other substances	symptoms similar to poisoning by *C. adamanteus*, but neurological symptoms less marked; antiserum available
Cascabel (*Crotalus durissus terrificus*); southern Mexico south to Argentina	cholinesterase, deoxyribonuclease, hyaluronidase, lecithinase, and other enzymes	symptoms similar to cobra bites, except that no edema occurs; antiserum available
Bushmaster (*Lachesis muta*); Costa Rica to northern South America	protease	very few bites recorded and little is known concerning the effects of its venom; severe prostration, rapid death; antiserum available
Taiwan habu (*Trimeresurus mucrosquamatus*); southeastern China, Taiwan	neurotoxin, amino-acid oxidase, hemorrhagin, and other substances	local pain, blistering, bleeding into the tissues, shock, death; antiserum available
True vipers		
Puff adder (*Bitis arietans*); Africa, Saudia Arabia	fibrinolytic, bradykininogen, cholinesterase, L-amino-acid oxidase, protease, and other substances	severe local edema, necrosis and sloughing of the tissues, restlessness, respiratory distress, gastrointestinal hemorrhages, death; antiserum available
Saw-scaled viper (*Echis carinatus*); India, Iraq, Saudia Arabia, Africa	carboxypolypeptidase, cholinesterase, dipeptidase, endopeptidase, and other enzymes	local pain and edema, hemorrhages into the skin, mucous membranes, and gastrointestinal tract, liver damage, shock, death; antiserum available
European viper (*Vipera berus*); Europe, Asia, Japan	bradykininogen, L-amino-acid oxidase	local pain and edema, hemorrhages along lymphatics, very little general reaction, vomiting, abdominal pain, shock, death; antiserum available
Russell's viper (*Vipera russelli*); Asia, Indonesia	carboxypolypeptidase, cholinesterase, dipeptidase, lipase, lecithinase, protease, and other enzymes	rapidly spreading edema with hemorrhages into the tissues, abdominal pain, vomiting, blood does not clot, loss of consciousness, circulatory failure, shock, death; antiserum available
Mammals		
Duck-billed platypus (*Ornithorhynchus anatinus*); Australia	protease and other enzymes	may inflict envenomation by means of the spurs on the hindlegs of the male platypus; immediate intense pain, swelling, redness in the area of the sting, faintness, numbness about the wound, restlessness, prostration; no death recorded; recovery is uneventful after a few days
Short-tailed shrew (*Blarina brevicauda*); North America	neurotoxic, proteolytic	the lower incisor teeth are associated with submaxillary poison glands; bites produce localized pain, redness in the area of the bite, shooting pains, and general discomfort of the affected part; gradual recovery after several days; no fatalities recorded
Solenodon (*Solenodon paradoxus*); Haiti	same as short-tailed shrew	
European water shrew (*Neomys fodiens*); Europe, Asia	same as short-tailed shrew	

close association with one. Venoms, which are produced by specialized poison glands, are injected by means of a mechanical device that is able to penetrate the flesh of the victim. Little is known about the biological or chemical properties of most crinotoxins (Table 8). The term poisonous may be used in the generic sense to refer to all three categories of zootoxins.

It is difficult to generalize when dealing with poisonous animals because they involve such a complex assemblage of unrelated organisms. Although there are poisonous animals in polar regions, by far the greatest number and variety inhabit warm temperate or tropical areas. One of the most dangerous of all toxic organisms probably is the sea wasp (*Chironex fleckeri*), which inhabits the northeast coastal waters of Australia. In less than one minute this jellyfish is able to inflict death in an adult human by means of its nematocyst, or stinging apparatus.

Some of the most complex relationships in biotoxicology are found in the marine environment. Certain marine biotoxins, such as ciguatera fish poison, apparently originate in marine plants, are ingested by herbivores and then passed on to carnivores and eventually to man. The extremely complex mechanism by which this is accomplished has eluded scientists for many years. With the build-up of toxic industrial chemical pollutants in the marine environment, the problems of toxicity in marine organisms are becoming increasingly more serious. There is evidence that under certain conditions chemical pollutants may trigger biotoxicity cycles in marine organisms. The outbreaks in Japan of Minamata disease were the result of such a cycle: micro-organisms, algae, shellfishes, and fishes ingested or absorbed industrial wastes with highly toxic organic compounds containing mercury and were in turn consumed by humans, causing a number of deaths among the population.

The relationships of representative poisonous animals and their position in the total framework of the animal kingdom can best be appreciated by categorizing them according to the group in which they belong. They are further grouped as to whether they are poisonous to eat, venomous, or crinotoxic in Tables 6, 7, and 8.

BIBLIOGRAPHY. S.J. AJL *et al.*, *Microbial Toxins*, 8 vol. (1970–72), the most comprehensive series of review articles ever assembled on the subject of bacterial protein toxins, bacterial endotoxins, and algal and fungal toxins; G. BRESADOLA, *Funghi mangerecci e velenosi*, 2 vol. (1932–33), one of the great classical works on poisonous mushrooms—although primarily European, most of the species discussed have a somewhat cosmopolitan distribution (magnificently illustrated); W. BUCHERL, E. BUCKLEY, and V. DEULOFEU, *Venomous Animals and Their Venoms*, vol. 1 (1968), and W. BUCHERL and E. BUCKLEY, vol. 2–3 (1971), a comprehensive series of review articles on venomous animals, their biology, effects of the venom, and treatment; UNITED STATES NAVY, BUREAU OF MEDICINE AND SURGERY, *Poisonous Snakes of the World: A Manual for Use by U.S. Amphibious Forces* (1968), a valuable, well-illustrated compendium on the poisonous snakes of the world, including their identification,

Table 8: Representative Crinotoxic Animals*

name and distribution	toxic principle	toxic effects and comments
Sponges		
Red moss (*Microciona prolifera*); eastern United States coastal waters	unknown	contact with the sponge produces a chemical irritation of the skin, redness, stiffness of the finger joints, swelling, blisters, and pustules
Flatworms		
Flatworm (*Leptoplana tremellaris*); European coastal waters	unknown	poison is produced by epidermal skin glands; no human intoxications recorded; extracts from the skin of these worms injected into laboratory animals produces cardiac arrest
Arthropods—joint-legged animals		
Blister beetles (*Cantharis vesicatorea*); United States	cantharidin	toxic substance does not seem to be produced by special glands but is found throughout the body of the beetle; no discomfort at time of initial contact; after about 8–10 hours large blisters develop on the skin accompanied by slight burning or tingling sensation; swallowing of the beetles may cause kidney damage; cantharidin is used as an aphrodisiac known as Spanish fly—a very dangerous substance to use; ingestion can cause severe gastroenteritis, kidney damage, blood in the urine, priapism, profound collapse, and death
Millipedes (species of *Orthoporus*, *Rhinocrichus*, *Julus*, and *Spirobolus*); temperate and tropical regions	unknown	repugnatorial (distasteful to enemies) fluid may be exuded or forcefully squirted from body pores a distance up to 30 inches or more; contact with the skin causes mild to moderately intense burning pain, redness, and pigmentation of the skin; toxic fluid squirted in the eyes may cause temporary blindness, an inflammatory reaction, and pain
Venomous ticks (species of *Ixodes* and *Ornithodoros*); temperate and tropical regions	unknown	tick bites result in swelling, redness, intense pain, headache, muscle cramps, loss of memory, etc.
Fishes		
Sea lamprey (*Petromyzon marinus*); Atlantic Ocean	unknown	slime of the lamprey is toxic, ingestion may cause diarrhea
Pacific sea bass (*Grammistes sexlineatus*); Indo-Pacific	antibiotic, neurotoxic	slime of fish is toxic; effects on man not known
Soapfish (*Rypticus saponaceus*); tropical and subtropical Atlantic	neurotoxic	slime of fish is toxic; produces an irritation of the mucous membrane
Amphibians†		
European earth salamander (*Salamandra maculosa*); Europe	skin glands of the salamander are poisonous; contains the alkaloids samandarine, samandenone, samandine, samanine, samandarone, samandaridine, and others	effects on humans not known; affects the heart and nervous system; causes in animals convulsions, cardiac irregularity, paralysis, and death
Toads (*Bufo* species); temperate and tropical regions	bufotoxin, bufogenins, and 5-hydroxytryplanime; poison includes a complex of many substances	produces a poisonous secretion in the parotid glands and skin; handling of some toads may cause a skin irritation; ingestion causes nausea, vomiting, numbness of the mouth and tongue, and tightness of the chest; the poison has a digitalis-like action
Frogs (some species of *Dendrobates*, *Physalaemus*, and *Rana*); northern South America and Central America	skin secretions are poisonous; histamine, bufotenine, physalaemin, serotonin, and other substances; composition varies with the species	skin secretions produce a burning sensation when handled; used by Indians as an arrow poison
Tree frogs (some species of *Hyla* and *Phyllobates*); northern South America, Central America	skin secretions are poisonous; batrachotoxin, steroidal alkaloids, serotonin, histamine, and other substances; bufotenine varies with the species	some frog species produce a burning sensation and a skin rash when handled; skin secretions in the eye may produce a severe inflammatory reaction; if ingested poison causes vomiting and abdominal pain; batrachotoxin is extremely toxic if injected; used by Indians as an arrow poison

*Animals in which poison glands are present and poison is released into environment through a pore. †Poisonous amphibians are sometimes referred to as "venomous," but they do not possess a true venom apparatus. They possess only poison glands.

distribution, habits, and first aid measures and treatment for their bites; C.A. FRAZIER, *Insect Allergy* (1969), one of the most complete works available concerning allergies and the poisonous effects of terrestrial arthropods; B.W. HALSTEAD, *Poisonous and Venomous Marine Animals of the World*, 3 vol. (1965–70), an exhaustive and profusely illustrated compendium on the toxic marine animals of the world from protozoans to polar bears, including their historical background, names, geographical distribution, biology, mechanism of intoxication, and medical, toxicological, pharmacological, and chemical aspects; R. HEIM, *Les Champignons toxiques et hallucinogènes* (1963), a valuable handbook on poisonous and hallucinogenic mushrooms, their biology, and poisonous effects; H.L. KEEGAN and W.V. PHISALIX-PICOT, *Animaux venimeux et venins*, 2 vol. (1922), one of the great classical works on poisonous animals and their toxins.

(B.W.H.)

Poisons and Poisoning

Poisons are substances that in small amounts are capable of producing serious injury or death. In truth, however, the poison is in the dose. It is a commonplace that drugs of unchallenged benefit in appropriate doses may become seriously poisonous when such doses are exceeded. It must not be forgotten, also, that variation in response of different individuals may be so great that an average dose can induce serious adverse reactions in the susceptible. Toxins are poisons of natural origin, whether bacterial, plant, or animal, and comprise some of the most lethal materials known; *e.g.*, aconite, botulinus toxin, and fish poisons.

The sciences of pharmacology and toxicology, the latter of which has poisons and poisoning in its province, share common principles, common procedures, and a common vocabulary; they have so much in common that university departments of pharmacology and toxicology grant advanced degrees in either or both disciplines, and pharmacology–toxicology research centres have been created under government sponsorship. The differences, practical and important, are based on points of view. Toxicology may be defined as the science of the injurious effects of chemicals on living systems or simply as the science of poisons; pharmacology, as the science of the useful, advantageous effects of drugs and chemicals on living sys-

tems, especially the effects related to disease, whether preventive, curative, or diagnostic.

Scope of the article. This review of poisons and poisoning will (1) define the field of toxicology and the mission of the toxicologist; (2) describe some of the problems attendant on the recognition, treatment, and prevention of poisonings; and (3) consider in general terms the fate of poisons introduced into the body and the sites and mechanisms of toxic actions. Material relevant to this subject may also be found in two related articles, POISONOUS ANIMALS AND PLANTS; DRUG AND DRUG ACTION.

Background. In the adaptive struggle for survival, members of every kingdom—unicelluiar forms, fungi, plants, and animals alike—evolved chemical agents to discourage competition, to defend themselves, and to secure prey. Primitive chemical-warfare agents are well known to man; for example, the antibiotics produced by bacteria and fungi, the growth inhibitors that suppress competitors of higher plants, and the venoms of bacteria, parasites, insects, and predatory animals. Some of these chemicals are synthesized by the organism—*e.g.*, the nicotine formed in the tobacco root—and some are obtained from the food—*e.g.*, the toxic cardiac glycosides (carbohydrates that affect the heart) in the monarch butterfly that come from the milkweed diet of its caterpillar; these are apparently the reason that birds shun the monarch. Presumably, curiosity led prehistoric man to touch, to taste, and to rub on his skin everything that came to hand and to discover the irritating, emetic, and purging properties of certain earths, molds, plants, and animal tissues. Witch doctors learned to practice these effects on their fellows. Through hallucinations, they established rituals and ordeals; through illness or death, they punished enemies or tribal wrongdoers; they tipped arrows with malignant extracts. A survival of this practice is our word "toxic," from the Greek words *toxon* ("bow") and *toxikon* (*pharmikon*), "arrow (poison)." Poisons, like infectious diseases, may inflict their injuries subtly. It is easy to imagine that, long ago, witch doctors also employed toxins against disease, an image repeated by Shakespeare, "In poison there is physic." Into medieval times, medical remedies included many of these physiologically potent substances, and some remain today as irreplaceable. The extent of the fear and hatred of poisons can be judged from the pronouncement in 1450 by James II forbidding all persons to bring home poisons "Under pain of treason." The persistence into modern times of the king's taster attests to the grim success of poison as a political weapon.

Natural poisons

Organisms also developed defenses against the poisons of everyday life. Painful experience (man and poison ivy) teaches individuals, and instinct (birds and monarch butterflies, horses and rattlesnakes) guides species to avoid exposures. Rejection mechanisms (regurgitation, purgation) expel noxious matter. Inside the cells, gene-controlled, special metabolic processes detoxify life-endangering molecules.

Modern man has borrowed practices and, in some instances, chemical substances from other species. In addition, man has developed a broad array of specialized chemicals to protect himself, to enhance his health, and to reduce competition for food or for living space. The remedies made use of by today's physician include many substances with astonishing healing powers in therapeutic doses but also capable of devastating injury. Highly-irritant substances disperse mobs. Agriculture uses millions of pounds annually of compounds selectively toxic for pests of many sorts, from bacteria, molds, and weeds to insects and coyotes.

THE FIELD OF TOXICOLOGY

The field of toxicology comprises many areas of service and research; selected examples are listed in the accompanying chart. Even casual inspection of the list invites the conclusion that toxicology is destined to play an increasingly prominent role in man's future development. The toxicological activities under "medical," "environmental," and "industrial" in Table 1 lie mainly in the field of preventive medicine, in which the mission of the toxicologist is to prevent injury and to insure safety. The sum total of toxicological problems is staggering. The advent in the past score of years of waves of new, frequently highly specific, and highly potent drugs has produced a flood of physician-caused illness. From other sources, the number of poisonings annually, including ingestions however slight, is estimated at 1,600,000 in the United States; of these perhaps one-fifth to one-half are associated with obvious acute illnesses; about 3,000 are fatal. The death toll from alcohol-associated motor accidents adds 25,000 or more deaths annually. Threats to the quality of the environment have led to serious exploration of the enormous field of ecologic toxicology. Among industrial employees, certain groups, such as farm workers, thousands of whom are repeatedly poisoned, are not yet covered by the widely enforced and increasingly effective occupational health measures. During the past 75 years, for example, illnesses among those handling toxic metals in Great Britain have decreased from over 1,000 annually, with nearly 40 deaths, to less than 60 illnesses, with no deaths. The toxicological activities listed under "pesticidal" and "military," in contrast, seek more effective poisons. Ideally, pesticides selectively control pests without injury to man or to other nontarget organisms, and military agents incapacitate without causing death or lasting injury. In either field, adequate defenses must protect the users.

The importance of toxicology

Table 1: Service Areas of the Toxicologist

medical	environmental	industrial	pesticidal	military
Toxicologic evaluation	air and water pollution	occupational health	insecticides	agents
Adverse drug reactions	radiation toxicology	industrial hygiene	rodenticides	lacrimators
Treatment of acute poisonings	space toxicology	metals	herbicides	nerve gases
Forensic toxicology	ecologic toxicology	solvents	fungicides	vesicants
Public health toxicology	food additives	gases	defoliants	incapacitating agents
Chemotherapy	household toxicology	dusts	fumigants	defense

To many people, the coroner's chemist of 30 years ago, the forensic toxicologist of today, represents the field of toxicology. These specialists, armed with the penetrating methods of modern analytical chemistry as applied to body tissues and fluids, with a knowledge of poisons, their doses and effects, and trained in the rules of evidence, provide expert testimony when a death, injury, or disease is due to poisoning. Although, formerly, toxicology was concerned largely with the recognition and treatment of poisonings, today, this important work consumes a small fraction of the professional talent and money expended. The emphasis now is safety, the prevention of injury by such means as: (1) providing working conditions such that earning a livelihood does not cost the worker his health or his life, whether the work is in the factory, the field, or the house; (2) providing foods that nourish and medicines that heal without causing illnesses that destroy; and (3) helping to provide food, clothing, comfort, and recreation for a burgeoning population while maintaining an environment of optimal quality for the human race. The knowledge of toxic effects furnishes the basis for this work.

CLASSIFICATIONS OF TOXICITY

Several levels of effect may be defined: (1) doses that produce no detectable effects—*i.e.*, cause no symptoms; (2) doses that produce useful or therapeutic effects; (3) doses that produce toxic or injurious effects; and (4) lethal doses. As a rule of thumb, toxicologists assume that doses increase about tenfold between each of the four levels. Such a prediction holds fairly well for morphine and for salicylates, for example, but is by no means universally applicable. Many substances are less lethal than predicted—*e.g.*, the sulfonamide drugs, atropine, and especially penicillin—and others are more lethal; *e.g.*, digi-

Table 2: Selected Household Products and Drugs of Significant Toxicity

	supertoxic (class 6)	extremely toxic (class 5)	very toxic (class 4)	moderately toxic (class 3)	slightly toxic (class 2)	practically nontoxic (class 1)
Probable lethal dose (human)						
Amount per kg	less than 5 mg	5–50 mg	50–500 mg	0.5–5 g	5–15 g	more than 15 g
For a 70 kg (154 lb) man	a taste (less than 7 drops)	7 drops–1 tsp	1 tsp–1 oz	1 oz–1 pt	1 pt–1 qt	more than 1 qt
Household products and farm chemicals	a few insecticides, fungicides, rodenticides	drain and sewer cleaners (caustics), fireplace flame colours, some pesticides	disinfectants, degreasers, rust removers, some depilatories, fire extinguishing liquids, many agricultural chemicals	polishes, hair dyes, permanent waves, motor fuels, antifreeze, bleaches, turpentine	most cosmetics, lubricating oils, soap products, waxes, incense, some insecticides	foods, candles, mucilage, pure soap, lead pencils, modelling clay
Drugs	digitoxin atropine cyanide heroin nicotine strychnine	amphetamines antihistamines morphine mercury bichloride ephedrine amobarbital (Amytal) ergot	aspirin phenobarbital boric acid fluoride quinidine chlorpromazine	ether kerosene isopropyl alcohol meprobamate methanol Enovid Dilatin	ethyl alcohol milk of magnesia saccharin	kaolin liquid petrolatum talc aluminum silicate

talis. Quantitative toxicity must be measured for each substance, however; toxicity is unpredictable even for substances with nearly identical chemical structures.

Degrees of toxicity

To permit rapid estimates of the chances for recovery of poisoned patients when the ingested material has been identified, systems of toxicity ratings have been proposed. One such system defines toxicity classes based on six commonly-used measures, such as a taste, a mouthful, and an ounce. Substances so poisonous that a taste (less than seven drops) probably would kill a man are rated 6, "supertoxic." At the other end of the scale are found substances in class 1, "practically nontoxic," with probably lethal doses of a quart or more. Examples of selected household products and of drugs are offered in Table 2. A few household products warrant ratings of 5 to 6; *e.g.*, concentrated caustic cleaners, some insecticides, and other pesticides. About 70 percent of the consumer products considered in one survey were rated 3 or lower. Most cosmetics and toiletries are found in class 2 (slightly toxic); others—*e.g.*, those with high concentrations of alcohol—were given toxicity ratings of 3. Among drugs, many well-known natural products are rated 5 and 6, including digitoxin, nicotine, morphine, and strychnine. The toxicity of aspirin (rating, 4) and its ready availability in many homes confers on aspirin a special hazard for children. The distinction between toxicity and hazard should be noted. Toxicity is the ability of a substance to injure; hazard is the probability that the circumstances of exposure are such as to produce injury.

The search for increasingly effective pesticides, antipersonnel agents, and drugs that has included efforts to isolate and identify naturally occurring toxins, has also revealed substances (Table 3) more toxic than any cited in Table 2. These toxicities can be contrasted with those of the insecticide parathion, the oral lethal dose of which is three or more milligrams per kilogram in rats, and the fungicide, methyl mercury dicyandiamide, the intraperitoneal lethal dose of which is 0.4 milligram per kilogram in mice.

Table 3: Some Extremely Toxic Substances

	estimated average lethal dose (mg/kg)	species	route
Botulinus toxin	0.00015	man	oral
Palytoxin*	0.00015	mouse	intravenous
Tetrodotoxin	0.01	mouse	intravenous
Aflatoxin	0.03–3	duckling	oral
Sarin	0.05	mouse	intravenous

*From a plant growing on coral.

Five types of classification

Poisons are sometimes classified on the basis of origins, of form, of chemical nature, of activity, and of use: (1) With respect to origins: (*a*) toxins of plant and animal origin are of special interest to veterinary toxicologists, medicinal herbalists, chemists, metabolic biochemists, and nutritionists; (*b*) industrial chemicals and minerals are of concern to occupational physicians and industrial hygienists; (*c*) drugs are the focus of pharmacologists and clinical toxicologists. (2) With respect to form: (*a*) radiation: radioactive nuclides (*e.g.*, radioactive iodine); (*b*) gases: carbon monoxide, hydrogen sulfide, war gases; (*c*) liquids: solvents; (*d*) solids: asbestos, metals. (3) With respect to chemical nature: (*a*) acids: oxalic; (*b*) alkalies: lye, ammonia; (*c*) alcohols: ethyl, methyl; (*d*) amines: aniline; (*e*) heavy metals: mercury, lead, cadmium; (*f*) hydrocarbons: kerosene, benzene; (*g*) chlorinated hydrocarbons: dichlorodiphenyltrichloroethane (DDT), dieldrin, carbon tetrachloride, polychlorinated biphenyls; (*h*) organic phosphates: parathion, malathion, and others. (4) With respect to activity: (*a*) corrosives: acids, alkalis, phenols; (*b*) irritants: (this class formerly comprised toxic elements but is now obsolete); (*c*) systemic poisons: convulsants, central-nervous-system stimulants and depressants, peripheral-nerve poisons, muscle poisons, metabolic poisons, blood poisons. (5) With respect to use: (*a*) pesticides or economic poisons: herbicides, rodenticides, insecticides, acaricides, fungicides, fumigants, germicides; (*b*) chemotherapeutic agents: antibiotics, anthelminthics, and parasiticides in general; (*c*) homicidal agents: chemicals used in executions (cyanide), in homicide (arsenic, strychnine), in suicide (barbiturates, etc.), in war gases (organic phosphates, mustards); (*d*) riot-control agents: chlorobenzylidine malononitrile, chloracetophenone—"tear gas."

ACUTE AND CHRONIC POISONING

Acute poisoning is characterized by a sudden onset and a rapid rise to intense effect; the symptoms run a short course that does not necessarily terminate in death. Acute poisonings frequently follow a single, relatively large dose. Chronic poisoning, in contrast, is characterized by a gradual and unnoticed development, a gradual onset of symptoms, and a slowly increasing weakness. The illness may appear in any one or more of a number of ways; for example, it may involve the nervous system, the blood and blood-forming tissues, or the gastrointestinal (digestive) tract. Chronic poisonings, often with frequent remissions and recurrences, as a rule develop from protracted or repeated exposures to small doses. The danger of chronic poisoning is high with some compounds, low with others; a few compounds never cause it. Identification of the causes of chronic poisonings may be exceedingly difficult.

Factors affecting toxicity

In both acute and chronic poisoning, the size of the dose required to elicit a toxic response depends on many factors: (1) the physical form; whether the substance is a gas, a liquid, or a solid; (2) certain chemical properties; especially solubility in water or in oil; (3) the chemical nature of the substance; *e.g.*, whether it is a hydrocarbon, an alcohol, or an amine; (4) the route of exposure; *e.g.*, the skin, eye, lung, gastrointestinal tract, or by way of the

veins or the muscles; (5) the species exposed; (6) the characteristics of the individual; *e.g.*, age, sex, state of health, susceptibility, heredity; (7) the kind of biological response; *e.g.*, local or systemic, characteristic or not, whether tolerance develops, whether there is interaction with other agents.

The susceptibility of some individuals and the toxic potentialities of many drugs combine to make drug-induced illness so common that 1 out of 20 acute medical hospital admissions for acute disease is for a poisoning. In addition, in some hospitals there are as many admissions for acute alcoholic intoxication. One in ten hospitalized persons is treated for drug-induced disease during hospitalization. Although most of the 1,600,000 incidents of ingesting possible poisons that occur annually in the United States are of little moment, more than 80,000 are serious enough to appear in the records of the National Clearinghouse for Poison Control Centers. Drugs are the substances most frequently involved, with cleaning and polishing agents, pesticides, cosmetics, solvents, various botanicals, and miscellaneous agents listed in order of frequency of ingestion. The Poisoning Treatment Centre of the Royal Infirmary of Edinburgh found that most (80 percent) of the acutely poisoned persons treated there suffered from "self-poisoning," defined as "a conscious, often impulsive manipulative act, undertaken to secure redress of an intolerable situation." The remaining 20 percent were distributed evenly between accidental poisonings and determined suicidal attempts; only a few cases were instances of homicidal poisonings. Fifty percent or more of the Edinburgh patients had psychiatric problems that were severe enough to require subsequent treatment.

Poisonings, now considered a common emergency, are most frequent in the young adult, 18–25 years of age; there is an equal distribution between males and females. Fatal poisonings often follow overdoses of the nonbarbiturate sedatives, the hypnotics, the tranquillizers and antidepressants (sedatives allay excitement; hypnotics induce sleep; tranquillizers have a quieting and calming effect), the widely prescribed barbiturates, aspirin and other salicylates, and the drugs taken for cultural or social reasons —ethyl alcohol and, recently, morphine and other opium derivatives. Carbon monoxide and other gases account for at least half of all fatal poisonings.

Recognition that an acute illness is a poisoning may come by testimony or by circumstantial evidence; for example, a suicide note or a partially empty container; in general, specific diagnostic features are rare. In the absence of head injury, poisoning is the commonest cause of unconsciousness from adolescence to middle age. An acute poisoning is always an emergency.

When the poisoned person is brought to the medical centre, the physician immediately assesses the status of the patient, the degree of impairment of consciousness, of respiratory failure, of circulatory failure, or of other injuries. Respiration and circulation of the blood must be maintained so that other emergency measures can be effective. Measures to prevent further absorption of swallowed poisons traditionally include gastric lavage (washing out the stomach), inducing vomiting, or administration of an adsorbing substance, such as activated charcoal.

Lavage is dangerous after the ingestion of nonirritating, deceptively bland hydrocarbons (*e.g.*, kerosene) or of corrosive agents (*e.g.*, concentrated acids or lye). Certain recent studies have questioned the practice of stomach lavage (1) as potentially dangerous in unconscious persons, and (2) as a strenuous and traumatic experience of variable but usually limited efficacy. Instead, inducing of vomiting by administration of syrup of ipecac is recommended.

Life-saving treatment depends primarily on intensive supportive therapy; *i.e.*, on expert nursing and on vigilance in maintaining vital functions. From the mid-1940s to the present, deaths from ingesting potentially lethal quantities of barbiturates have decreased from 25 percent to less than 1 percent as a result of combatting shock, maintaining respiration, and placing patients under the expert and conservative care of nurses and physicians in teams and special facilities analogous to the intensive care units for heart patients. The role of antidotes is often exaggerated, there being specific antidotes available in less than 2 percent of all poisonings.

The most effective measures for reducing incidence of poisoning are those of prevention: the keeping of medicines under lock and key, the physician's giving thought to limiting the prescribing and stocking of sedatives and to watching for side effects of drugs and drug combinations; and the segregation and guarding of dangerous pesticides and household chemicals.

Poison-control centres

Beginning in 1953, under the leadership of the American Academy of Pediatrics, certain hospitals in the United States began collecting and furnishing information on poisonings through units called poison-control centres. Over 500 such centres are now registered with the National Clearinghouse for Poison Control Centers established in 1957 by the Public Health Service. In many cities, the telephone directory lists a poison-control centre. Government-sponsored poison information services are maintained in several cities in Great Britain and elsewhere in Europe. These services and the National Clearinghouse serve as central repositories for information on new and old products and for case reports of poisonings from local centres and from other government agencies. Statements of product composition and toxicity and of treatment are distributed in the United States to poison-control centres.

Sophisticated drug-information services are being developed in certain teaching hospitals under the supervision of drug specialists; *e.g.*, clinical pharmacists. These services furnish information and advice to physicians not only on poisonings and on adverse drug reactions but also on any aspect of drug use in patient care.

Chronic poisoning. Chronic poisoning frequently develops gradually after long-continued exposures to relatively small, repeated doses; there is characteristically a symptom-free latent period. This type of poisoning represents cumulative effects, usually from repeated undetectable injuries that are not completely repaired in the intervals between exposures. In exceptional circumstances these injuries may follow a single dose; *e.g.*, of a radioactive element, of a cancer-causing substance, or of a toxic metal. Even rarer are chronic effects that suddenly appear when an effective acute dose is given in divided portions; an example is the paralytic response to tri-*o*-cresyl phosphate in chicks when one-thirtieth of the acute paralytic dose is given daily for a month. Cumulative effects are often but not necessarily associated with a buildup of the poisonous substances in the body. The body burden of lead is increased in chronic lead poisoning; chronic carbon monoxide poisoning, on the other hand, does not bring accumulation of carbon monoxide; and there may be scarcely any concentration of beryllium in the tissues in chronic beryllium disease with widespread pulmonary granulomatosis—formation in the lungs of the type of connective tissue that develops in the process of wound healing and scar formation. Furthermore, accumulation is not synonymous with illness; witness the slow but demonstrable increase in skeletal fluoride during the first five or six decades of life in persons with low fluoride intakes who show no functional evidence of any fluoride effect. Certain delayed, long-lasting effects of exposures to substances foreign to the body, such as sensitizations or immune responses, are not usually classed as chronic poisoning.

The group of symptoms in a chronic poisoning may be entirely different from that in an acute poisoning by the same agent. Acute and chronic mercury poisoning furnish classic examples. Fatal, acute inorganic mercury poisoning, such as follows the ingestion of mercury bichloride (corrosive sublimate) runs a catastrophic course of nausea, vomiting, and diarrhea, leading to a shocklike, circulatory collapse, either with death in a few hours or, for survivors of this phase, to death in a few days from kidney failure. Chronic mercurialism sometimes takes the form of progressive kidney disease, but the affected person may instead show profound personality changes, sometimes other mental effects (drowsiness, confusion)

or predominantly nervous-system signs (tremour, pain, or fever) or may develop muscle weakness and tenderness or may show abnormalities of the heart and circulatory system.

Types of treatment

Treatment cannot be generalized. For some important poisonings, specific antidotes of variable efficacy are available. Chronic lead poisoning in adults yields, on occasion, to treatment with ethylenediaminetetraacetic acid (EDTA); in children afflicted with the preventable effects of lead on the brain (one-half of all chronic cases) EDTA and dimercaprol (BAL) may be life-saving. Unfortunately, of the 75 percent who survive, a third suffer permanent brain damage with mental retardation and sometimes blindness.

In most chronic poisonings, treatment is supportive rather than specific. Removal from further exposure, good nursing care, and the remarkable restorative potential of the body favour recovery. Irreversible alterations in structures or in functions of susceptible parts of the body may cause crippling, even when the poison no longer is present and undamaged tissues function normally.

FATE OF POISON

A poisonous effect, acute or chronic, whether discerned as an impairment of function or as a derangement of structure, usually can be traced to the presence of the toxic agent in the affected area. The degree and kind of injury is often dependent (1) on the amount as well as (2) on the form in which the agent reaches the tissue, (3) on what happens to the agent there, and (4) on how long it remains. One of the keys to understanding how poisons injure lies in discovering what the body does to the poison (variously described as its fate, its metabolism, or its biotransformation).

Introduced into the stomach or gut, toxic substances may be absorbed or they may be destroyed by digestive action (as is rattlesnake toxin, a mixture of proteins). Insoluble substances, when swallowed, may pass through the body virtually unchanged and be lost in the feces.

The speed with which a poison swallowed, inhaled, spread on the skin, or injected enters the body tissues depends on (1) its solubility in fat or water, (2) its degree of irritancy, (3) its chemical reactivity, (4) the toxicologic reactivity, and other factors. In the bloodstream, portions are carried in greater or lesser amounts to all parts of the body. Gaseous substances stable in the body are usually exhaled. Some substances are tightly bound by (enter into stable combination with) blood constituents, especially proteins, and are slowly released. Particulates are apt to be engulfed by scavenger cells, the macrophages, and carried to the special trapping cells of the spleen, liver, bone marrow, or lymph nodes. Insoluble particulates may thereby create special hazards if their properties are dangerous (*e.g.*, if they are radioactive) and if mobilization (release from the tissues) is slow. Toxic substances with high fat solubility pose special problems. Membranes contain fatty layers across which fat-soluble substances are readily transported during initial absorption as well as during reabsorption from newly formed urine in the kidney tubule. Reabsorption tends to retard excretion and to build up the body load, obviously increasing the hazard of poisoning. Water-soluble substances generally pass out in the urine; some, like penicillin, are swiftly excreted (half is gone in 30 minutes). In contrast, substances of high fat solubility, such as alcohol, tend to remain longer; in the case of alcohol, until it is oxidized.

The body has some chemical defenses. Metabolic machinery in the cytoplasm (cell substance outside the nucleus) alters foreign molecules by various methods, including oxidizing, reducing, or hydrolyzing them (breaking them down by adding of water). All of these chemical changes tend to form products that are less fat-soluble, more water-soluble, frequently more acidic or basic than the original molecule, and therefore less resorbable and much more readily excreted in the urine. In these ways, such processes detoxify the foreign molecule and have long been known as detoxication mechanisms. Natural foodstuffs may contain traces of biologically active substances that, if retained unchanged, may be poisonous. The various detoxifying processes therefore have survival value.

The products of the chemical reactions within the body are occasionally more poisonous than the original molecules. A famous example is the transformation of fluoroacetate (inherently not toxic) into the extremely toxic fluorocitrate, which blocks a key enzyme, aconitase, of an important energy-producing mechanism (the citric-acid cycle) of the mitochondria (the energy-producing structural elements of cytoplasm).

Toxic substances may be stored in the body, sometimes briefly (carbon monoxide as carboxyhemoglobin for hours), sometimes for years (uranium dioxide particles in lymph nodes of the lung, strontium-90 in the skeleton, DDT in fatty tissue, silver in the skin).

Manner of excretion

Excretion occurs mainly by way of the urine or the feces, or both. Some solvents (certain chlorinated hydrocarbons, for example) are exhaled in detectable traces over periods of weeks. Traces of lead, mercury, and arsenic are deposited in hair. Sweat contains detectable quantities of certain poisons. Excretion in milk, though uncommon, is known; epidemics of sometimes fatal milk sickness have afflicted those drinking milk from cows feeding on white snakeroot (*Eupatorium rugosum*).

MECHANISM OF ACTION

Although most poisons act at several sites in the body, simultaneously or in sequence, not infrequently, the injury to one organ or system is predominantly responsible for serious illness or death. Cyanide blocks a basic energy-providing mechanism (cytochrome oxidase) in most cells. Many substances in overdose injure the liver; the list includes such diverse materials as carbon tetrachloride, *Amanita phalloides* (death cap mushroom) toxins, and elemental phosphorus. Carbon tetrachloride also destroys kidney tissue, as do mercury and arsenic.

Substances that break down red blood cells (hemolysis), such as primaquine and a number of other drugs, are more likely to cause trouble to individuals anemic because of hereditary deficiency in the enzyme glucose-6-phosphate dehydrogenase. Hemolysis can secondarily produce acute kidney failure by blockage of the tubules. Carbon monoxide acts primarily in the blood, combining with hemoglobin to form carboxyhemoglobin in a combination 200 times tighter than with oxygen, thereby effectively preventing the transport of vitally essential oxygen to the brain, heart, muscles and other tissues. Squill can fatally affect the heart by overexciting it. Recently, sudden deaths from inhaling a variety of substances (gasoline and fluorocarbon propellants, for example) have been traced to another kind of heart injury, a loss of coordination of muscle contraction so that individual muscle fibres beat at random; the heart fails to propel blood, and death swiftly ensues. Intoxications prominently involving the central nervous system are commonplace: drunkenness with alcohol, the "high" of marihuana, the ecstasy or the terror of lysergic acid diethylamide (LSD), convulsions from cocaine, poisoning with strychnine, organic phosphate, or dieldrin, destruction of brain tissue by methyl mercury or by severe exposure to carbon monoxide. Injuries to bone tissues are rare but not unknown; the bone cancers of the radium-dial painters of World War I are a frequently cited example.

The dislocations and distortions induced by poisons into the normal workings of organs and tissues can be useful in revealing secrets of the life processes. The inhibitory role of recurrent nerve branches in the spinal cord, for example, was made clear by the effect of strychnine in blocking their normal function. The neurohormone (acetylcholine) was discovered when the enzyme that normally inactivates acetylcholine in seconds was inhibited by a primitive ordeal poison (eserine).

Despite a multitude of experiments and the availability of immensely powerful new tools, only a few mechanisms of toxic action have been described in detail. The limit is often ignorance of the normal action that is disturbed by the poison. From the volumes of experimental work, a

few examples of the varied natures of toxic actions have been selected and are listed (Table 4), more to illustrate the diversity than to claim detailed knowledge, and certainly not to suggest that the mechanisms of all or even of many are fully understood.

Table 4: Various Toxic Reactions

site	nature of toxic effect	example of poison
Cell membrane	destruction	lye; phenol; heat
	altered permeability	mercury; squill, carbon tetrachloride, hydrocarbons
	formation prevented	penicillin in susceptible bacteria
Blood	interference with circulation by clotting	some snake venoms
	interference with oxygen access in lung	chlorine, nitrous oxides, ozone
	interference with oxygen transport	carbon monoxide, nitrites
	clotting prevented	warfarin
Nerve	transmission blocked along fibre	cocaine
	release of neurohormone blocked	botulinus toxin
	access to receptor blocked	strychnine, atropine, curare
	enzyme inactivating neurohormone inhibited	organic phosphates
Cell function	growth interference	colchicine, nitrogen mustard
	DNA structure or function altered	nitrosamine, radiation, actinomycin D
	energy-supplying cycle blocked	fluoroacetate
	antimetabolite	methotrexate

Synergism

Interactions between similar or dissimilar compounds can be important. Two organic phosphates, for example, may be synergistic (each may enhance the effect of the other) in their insecticidal action. For this reason, when several chemically-related pesticides are used as mixtures, the amounts permitted as food residues are set for the class and not for individual pesticides.

Another kind of interaction has been identified. Some pesticides (DDT, for example) and some drugs are able to stimulate the production by the liver cells of enzymes that account for much of the detoxication of foreign molecules (including drugs). While the traces of pesticides in foods as consumed are insufficient to stimulate these enzymes, occupational exposures either in manufacture or use may possibly do so. By this type of interaction, certain drugs (*e.g.*, barbiturates) are known to increase the rate of destruction of other drugs, thereby necessitating increase in dosage to maintain therapeutic efficacy.

ATTAINMENT OF SAFETY AGAINST POISONING

The mission of the toxicologist is most importantly safety —ensuring that injury will not result from chemical exposures whether of consumer or housewife, factory worker or chemist, farmer, astronaut, or submariner. The toxicologist's intent on safety is joined by the conservationist, who seeks to re-establish and maintain a pristine quality of the human environment. In these efforts, as in all phases of the practical mission of the toxicologist, judgments repeatedly and inevitably balance the benefit against cost or risk. At some sites, trace pollution of the environment must be accepted or an industry closed. Higher yields and better quality must more than repay the farmer the cost of pesticides. The use of chemicals in food production and processing increases the amount and variety of foodstuff in the supermarket; some items unavoidably contain additives, in traces judged to be innocuous. Modern drugs add to the general health but frequently induce side effects, toxic effects that may endanger life.

Testing new drugs and other chemicals

The role of the toxicologist includes the search for antidotes and for means of treating toxic injuries, but a prime task in the development of new drugs, food additives, pesticides, and household or other chemicals is to identify and eliminate unacceptably toxic substances. Toxicity evaluation begins by experiments, generally in the mouse or rat, to classify the substance with respect to its lethality. Effects of repeated doses—*e.g.*, daily for a week or a month or more—are next observed, usually in at least two species, to learn (1) the sites and kinds of any characteristic injuries from exaggerated doses, (2) the pattern of toxic responses, and (3) the size of a tolerated or asymptomatic dose. For food additives or drugs to be administered over protracted periods, further studies are stipulated: customarily (1) lifetime (*i.e.*, two-year) studies of rats, or mice, and (2) one- or two-year studies of dogs or monkeys or both. Additional research may include (1) investigation of the metabolic fate of the substance in at least one species and preferably several; (2) tissue analyses to discover any sites of accumulation; (3) dosing pregnant animals to detect fetal injuries or abnormalities; (4) studies on actively dividing cells to detect chromosome damage or mutations; and (5) detailed and frequently protracted observations designed to detect cancer-producing potential. All such data are brought to focus in the selection of a tolerance value for a pesticide in a raw agricultural product, or an acceptable daily intake (ADI) for an intentional food additive, to provide margins of safety in human use. Candidate new drugs that have shown, through such animal tests, evidence of reasonable safety, are then evaluated in progressively larger groups of human subjects. In phase 1 of such studies in human beings, observations often include the fate as well as the effects of minimal doses on a limited number of normal subjects. Phase 2 explores the efficacy of the new drug as a curative, prophylactic, or diagnostic agent in small groups of selected ill patients. In phase 3, the usefulness and drawbacks (*i.e.*, the medicinal value and the side effects) are recorded on larger groups of patients, when specialists employ the investigational new drug under conditions of practice. In the United States, satisfactory performance throughout normally leads to a new drug application (NDA) and permission from the Food and Drug Administration to market the product. Costs of toxicity testing, including chronic tests on a single compound, are high.

Industrial exposures typically occur when workmen inhale dusty or contaminated air. To provide standards for safe working conditions, the toxicologist compares the concentrations of toxicants in factory air and the consequent illness or health with the effects in experimental animals breathing controlled concentrations of the same toxicants in laboratory studies. All available evidence enters into the choice of a Threshold Limit Value (TLV), a concentration to which "it is believed that nearly all workers may be repeatedly exposed, day after day, without adverse effect."

Poker

Poker is a card game or, more properly, a family of card games. Although played throughout the world, it has its greatest popularity in North America and at one time was known as the national card game of the United States.

A Poker hand consists of five cards. Players try to build combinations of two or more cards of a kind, five-card sequences, or five cards of the same suit. The more unusual hands rank higher than the more common.

Poker is essentially a game of money management and is practically never played except for purposes of gambling. Each deal is a separate game in which there is a pot, which is the aggregate of all bets and antes made on that deal. Players try either to win the pot or to get out as cheaply as possible if they cannot win it. There are one or more rounds of betting. At the conclusion of the last round, the players who have remained show their hands. All money in the pot, including the bets made by players who dropped out after an earlier round, is taken by the player with the best hand or, in some forms of the game, divided among several hands. A player may bluff by betting that he has the best hand when in fact he knows he does not. He can win by bluffing if players with superior hands do not match, or call, his bet.

History. The earliest known game of the Poker family evolved in Europe and was mentioned in literature in 1526. While Poker is essentially a five-card game, this was a three-card game known as *primero* in Spain, *primiera* in Italy, and *la prime* in France. The game involved betting, and the valued combinations were three of a kind, pairs, and three of the same suit, called a flux (flush).

European beginnings

By 1700 the betting and bluffing aspects of these games had been incorporated in five-card games such as Brag in England, Pochen in Germany, and Poque in France. In these early games the importance of bluffing, or betting with a poor hand, to get other hands to drop out of the pot may be seen from the fact that *pochen* is a German verb meaning "to bluff." It further appears that the French name Poque is a corruption of the German and that the name Poker is a corruption of the French.

The game was carried to America by the French colonists of the Louisiana territory and spread up the Mississippi to the rest of the country. Poker itself was first mentioned in 1829 in the memoirs of Joe Cowell, a touring English actor. By 1834 it was adapted to the 52-card deck and made its first appearance in books on card games in 1858, but it was treated as an old game in those references. Poker undoubtedly received its first great impetus during the Civil War, when the game was much played among soldiers on both sides.

In Brag, Pochen, and Poque there was just one round of betting. The showdown—exposing the hands to determine the winner—took place after this one round. The rank of hands was four of a kind (high); full house (three of one kind and two of another); three of one kind; two pairs; one pair; and no pair (high card). Cards ranked ace (high), king, queen, jack, ten, and so on down to deuce. There was, and is, no distinction among suits.

Straights (five cards in sequence, regardless of suit), flushes (five cards of the same suit, regardless of sequence), and additional rounds of betting were added later. Two principal forms of the game developed: (1) Closed (Straight or Draw Poker), in which each player's hand is dealt face down and (2) Open, or Stud, Poker, in which each player is dealt one or two cards face down and the rest of his hand one card at a time face up.

The spread of Poker from the United States back to Europe started when Col. Jacob Schenck, U.S. ambassador to Great Britain, introduced it to members of the court of Queen Victoria around 1870. Schenck actually prepared a set of rules for the Queen, who had expressed interest in the game. This was the first known work devoted exclusively to Poker. The game did not reach the rest of Europe until brought there during World War I by the American Expeditionary Force.

The first book on Poker

For many years Poker was considered to be a game for men only, but by the mid-20th century it was often played by women as well. Draw and Stud Poker remain classic men's games, however.

GENERAL PRINCIPLES OF POKER

Poker can be played by any number from 2 to 14, but 6 or 7 make the best game. It is almost always played with the standard 52-card pack. All suits are of equal value, and cards rank A (high)–K–Q–J–10–9–8–7–6–5–4–3–2, although the ace may also be considered low in forming a straight with the 5–4–3–2.

Rank of hands. The traditional ranking is as follows: (1) straight flush (five cards of the same suit and in sequence; the highest, A–K–Q–J–10, is called a royal flush); (2) four of a kind (as 6–6–6–6 and any fifth card); (3) full house (three of one kind and a pair, such as K–K–K–8–8); (4) flush (five cards of the same suit, regardless of sequence); (5) straight (five cards in succession, regardless of suit; the highest is A–K–Q–J–10, and the lowest is 5–4–3–2–A); (6) three of a kind (as 10–10–10, and any two other cards not a pair); (7) two pairs (as J–J–9–9 and any fifth card); (8) one pair (as 8–8 and any three unmatched cards); and (9) high card, or no pair (hand having no pair, ranked by its highest card or cards).

Determining the winner among hands of the same rank is a problem often encountered. Among straight flushes, flushes, straights, or hands containing no pair, the one containing the highest card wins. If the high cards are identical, the second highest card decides, and so on. Among hands of four or three of a kind, the higher matched set wins, as 9–9–9–9 beats 7–7–7–7. With full houses, the higher three of a kind wins. With two pairs, the highest pair decides, or if these are identical, the other pair; if these two are identical, the odd card is the deciding factor. Among hands of one pair, the higher pair wins, or if identical, the highest odd card. Identical hands have identical value.

Wild cards. A wild card is one that may be used to represent any card its holder desires. There are any number of wild card games, including Joker, in which the joker is wild and is added to the deck as a 53rd card; Bug, in which the joker is called the bug, and though not completely wild, may be used as a fifth ace or to form a straight or a flush; Deuces Wild, in which all deuces are wild cards; or any other wild cards the players care to designate. When there are any wild cards in a game, the highest hand becomes five of a kind, although in some games a royal flush is allowed to beat any five of a kind.

Canadian Poker. In Canadian Five-Card Stud, a hand of four cards in sequence and open at both ends (a four-straight, such as 6–5–4–3 or 9–8–7–6 but not A–K–Q–J) beats a pair, and four cards of the same suit (a four-flush) beats a four-straight. In some forms only the four-flush is counted.

European Poker. In the European form of Draw Poker, some of the low cards (usually the 2s, 3s, and 4s) are taken out of the pack. Flushes rank above full houses, and the ace may be used as low card at the bottom of a straight, as in 8–7–6–5–A.

Betting. In each deal there are one or more betting intervals. In each interval one player, as designated by the rules of the variant being played, has the privilege or obligation of opening, or making the first bet. This player and each player in turn after him must place in the pot a number of chips (representing money, for which Poker is almost invariably played). After the opening, each bettor must make his total contribution to the pot at least equal the total contribution of any player before him. When a player does this, he is said to have "called," or "seen," the bet. A player who bets more than the previous bettor is said to raise. If a player declines to bet or raise, he discards his hand (drops or passes) and may no longer compete for the pot.

Before the deal, each player may be required to make a contribution to the pot, called an ante. In some variants a player is permitted to check, or stay in without betting, provided no other player has made a bet in that betting interval.

"Showdown"

At the end of the last betting interval there is a "showdown," in which each active player shows his full hand and the highest-ranking hand wins the pot. In practice, especially in informal games, players simply announce

the values of their hands and only show their hands as confirmation. On demand of any player, however, the full hand must be shown, and any false or mistaken announcement is not valid: "the cards speak for themselves."

In Poker legends there were "no-limit" or "sky's-the-limit" games, but in practice some limit is placed on what one may bet in any game. There are three popular methods: fixed limit, pot limit, and table stakes. In the first, no one may bet or raise by more than a limit previously and arbitrarily established by mutual agreement or the house. A limit is also usually placed on the number of raises that may be made in any betting interval. In pot-limit games a player may bet or raise by no more than the amount in the pot at the time the bet or raise is made. In the table stakes method, which most closely approximates the legendary no-limit game, each player's limit is the number of chips he has on the table at the beginning of the deal.

PRINCIPAL FORMS OF POKER

Poker has two main branches: Closed (Straight or Draw) Poker, in which each player's full hand remains concealed until the showdown, and Open (Stud) Poker, in which some but not all of a player's cards are dealt or turned face up.

Straight Poker. In Straight Poker each player is dealt five cards, face down. There is one betting interval, followed by a showdown. This was the original form of Poker, but it has practically passed out of existence.

Draw Poker. In Draw Poker, there is usually an ante, after which each player is dealt five cards face down. There is a betting interval. Then each active player, in turn, beginning at dealer's left, may discard one or more of his original cards (usually no more than three) and receive replacements for them, dealt from the undealt portion of the pack. A player who declines to draw cards is said to stand pat. After the draw there is a final betting interval, followed by the showdown.

Jackpots and Blind Opening

Draw Poker has two main varieties: Jackpots, the variant most played in the United States and Canada, and Blind Opening, played almost to the exclusion of other variants in England, Europe, and the British Commonwealth except Canada and favoured in men's clubs in the U.S. and Latin America. The basic difference between the two is in their betting procedures. In Jackpots there is an ante before each deal. There is usually a requirement that a player must hold a pair of jacks or a better hand to open the betting. If no one opens, players ante again and there is a new deal. In Blind Opening there may or may not be an ante, but before any cards are dealt, the player to dealer's left must make an opening bet, called the blind, usually only one chip or unit. In some games the player to the blind opener's left must then "straddle," or bet double the amount of the first bet.

Stud Poker. In the basic five-card form of Stud Poker, each player receives one card face down, called his hole card, then one card face up. The deal is then interrupted for a betting interval (in some games a betting interval also follows the dealing of the hole cards). There follow three more rounds of dealing, each consisting of giving one face-up card to each active player, with a betting interval after each round. In each betting interval the first bettor is the player with the highest ranking Poker combination among his face-up cards; if two or more players have the same combination, the one nearest the dealer's left bets first. The showdown, in which the hole cards are shown, follows the fourth and last betting interval.

Stud Poker usually is played with pot limit. The Canadians have enlivened it by playing with a fairly large ante, a moderate limit increasing each round, and with special hands (see above *Canadian Poker*). This encourages a player who is dealt something like the 7–6 of a suit to stay for a third card. Then if his next card fits the first two he has a strong hand.

Seven-Card Stud. In Seven-Card Stud, a popular variant of Stud Poker, each player is dealt two hole cards and a face-up card, followed by a betting interval; then three more face-up cards and one final face-down card, each followed by a betting interval. For the showdown each player selects the best five of his seven cards to be his Poker hand. There are also six-card and eight-card variants of this game, in each of which a player ultimately selects five of his cards.

A game with two winners

High-Low Poker. In High-Low the highest-ranking hand and the lowest-ranking hand divide the pot. If two or more hands tie for high or low, they divide their half of the pot equally. Nearly any form of Poker may be played High-Low.

In High-Low Seven-Card Stud, each player may select any five of his cards as his candidate for high hand and any five as his candidate for low hand in attempting to win the entire pot. In some games each player must declare for high, low, or both before the showdown and cannot win unless he fulfills his declaration.

Low Poker or Lowball. This is Draw Poker and is played similarly to Jackpots, except that the lowest-ranking hand wins the pot. In California, where the game is most popular, straights and flushes never count and the ace is always the lowest ranking card. The lowest possible hand is 5–4–3–2–A and is called a bicycle or wheel.

Dealer's Choice. In informal Poker games, each successive dealer may dictate the variant of Poker that will be played. He may also designate certain cards to be wild. Sometimes it is agreed that the dealer may select or invent any variant he wishes, subject to only two restrictions: the dealer may not require any player to ante more than any other player; and, if the game requires a minimum to open (as Jackpots) and is passed out, the same dealer deals again.

RULES OF POKER

No code of Poker rules has been universally adopted. Nearly every club or serious game has certain house rules that may differ in some respects from those of other clubs and groups. The usual practice is to adopt a published code and add the house rules to it. A code prepared by Oswald Jacoby in 1940, and another appearing in *The Official Rules of Card Games* published by the United States Playing Card Company since 1945, are the ones most often adopted in the United States. Poker rules, unlike those of other card games, provide only rectification; there are no penalties for irregularities. Certain departures, such as having the wrong number of cards in hand or cards exposed in dealing, are necessarily treated differently in Draw Poker and Stud Poker.

PLAYING THE HAND

No game rewards skillful play or penalizes bad play more than Poker. Although it is not so complicated as some other games, the player has better control over the result, since he may drop bad hands. Consequently, a good player is less likely to lose to inferior players.

Knowledge of probabilities is important. Chances are about 1 in 2 of receiving a hand of one pair or better, 1 in 5 for a pair of jacks or better, rising to 1 in 590 for a full house or better, and much higher for four of a kind or a straight flush. Odds against improving the original hand in Draw Poker range from 2½ to 1 to improve a pair by drawing three to 1,080 to 1 to make a pair and an ace into four of a kind by drawing two. In Five-Card Stud, after 12 cards have been seen, odds against pairing an ace are 6 to 1 if none of the 12 were aces and 10 to 1 if one was. Chances of receiving a strong hand are better in games where cards are wild or where more than five cards are dealt to each player. Many published works on Poker contain detailed tables of odds and statistics applicable to a variety of situations.

Betting decisions are based on the ratio of expected profit to the amount bet and on chances of winning. If a one chip bet can win ten chips (10 to 1 odds) and chances of winning appear to be 1 in 6, this is a good bet.

Psychology in Poker

It is important to know the mathematics of the game, but it is even more important to know the character of the other players. For example, in playing Draw Poker, A opens. B calls, as do two other players. A draws three cards. B draws one card to a four-flush and makes his flush. A checks without looking at his draw. B bets the

limit. The next two players drop out. A raises the limit. The mathematical odds against his making a full house or four of a kind are over 70 to 1, and these are the only hands in this situation that can beat a flush (A had to have a pair to open, has obviously drawn to this pair, and therefore could not get a flush or a straight flush). Is he silly enough to be raising with just a pair or three of a kind? B decides that he is not. Then A either has made a winning hand or he is bluffing. B must decide, based on his knowledge of A as a player.

The fine points of psychological play, adjustment of strategy to the various forms of the game, and knowledge of when and how to bluff are acquired best through experience.

BIBLIOGRAPHY. See *Oswald Jacoby on Poker* (1947) for the game as played in the U.S.; M. ELLINGER, *Poker* (1950), for the game as played in England. Other works include: A. DOWLING, *Great American Pastime: Notes on Poker, the Game and the Players* (1970); T. REESE and A. WATKINS, *Poker: Game of Skill* (1962); and J.L. CASTLE, *How Not to Lose at Poker* (1970).

(O.J.)

Poland

The location of Poland has been a major force in the molding of the character of its contemporary peoples, their culture, and their society. The country lies between approximately 49° and 55° north latitude and 14° and 24° east longitude. It is in the zone of transition between the continental lowland block of eastern Europe and the mountainous peninsula of western Europe. It also lies midway between the northern and southern extremities of the continent, in the belt of cool, temperate climates, and is at the same distance from the Equator as England and southern Canada. The area of Poland, 120,725 square miles (312,677 square kilometres), is greater than that of Italy, while its population, which exceeded 34,000,000 by the mid-1970s, is comparable to that of Spain. In area and population, Poland (officially, the Polish People's Republic) ranks second among the Communist states of eastern Europe, after the Soviet Union itself.

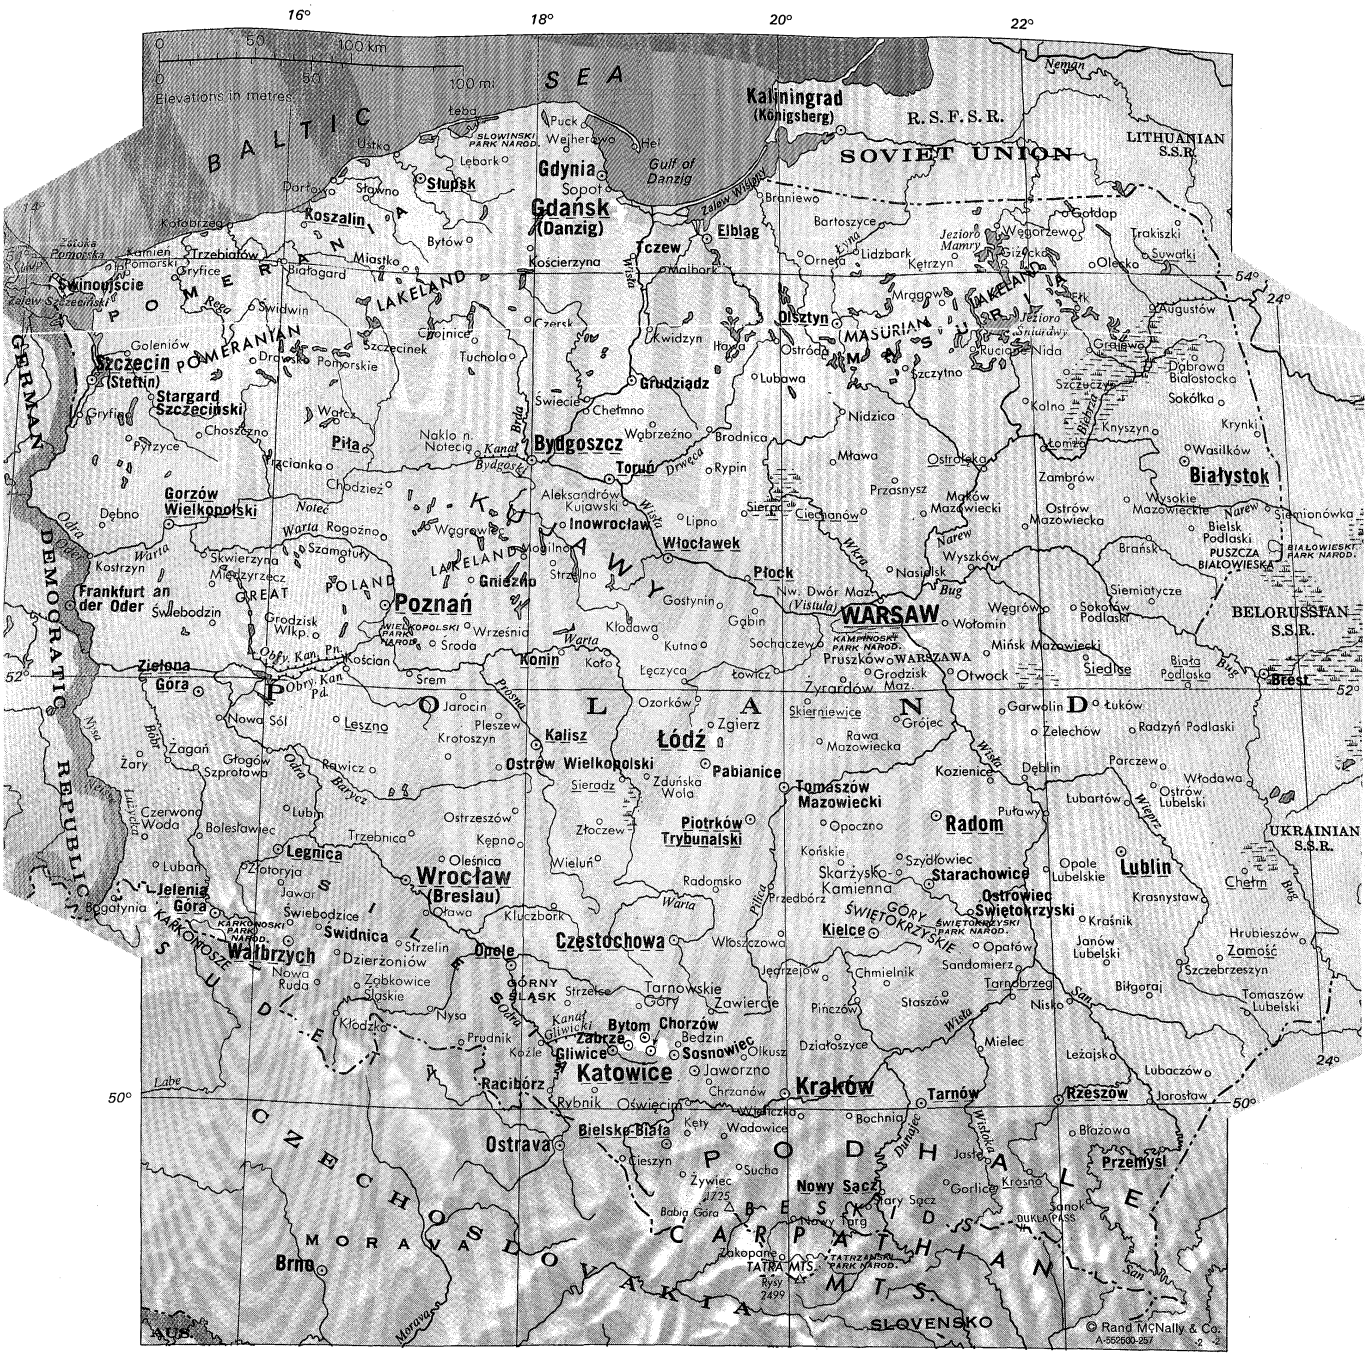
On the north the country borders the Baltic Sea; the southern boundary runs along the peaks of the Carpathian and Sudety mountain ranges; and the eastern and western boundaries follow, respectively, parts of the courses of the Bug and Odra–Nysa (Oder–Neisse) river systems. Historically, the nation has proved vulnerable to movements and incursions of peoples across its exposed eastern and western flanks, for its northern plains are part of one of the great corridors of the Eurasian landmass. Poland has but three contemporary neighbours. The mainly mountainous frontier with Czechoslovakia runs for 814 miles (1,310 kilometres) in the south; to the east and northeast, the frontier with the Soviet Union is 773 miles (1,244 kilometres) long; and to the west is a 286-mile (460-kilometre) border with the German Democratic Republic. The Baltic Sea border is 326 miles (524 kilometres) long, from the mouth of the Odra (Oder) River in the west to the Gulf of Gdańsk (Zatoka Gdańska) in the east.

A thousand-year heritage

Poland is a country with a thousand years of culture and historical tradition behind it. Although afflicted by hostile incursions, wars, economic difficulty, and the total loss of national independence for well over a century, Poland has nevertheless contributed much of lasting value to world culture. The astronomer Nicolaus Copernicus was one of the creators of modern scientific thought, and Marie Curie (*née* Skłodowska), the discoverer of radioactive elements, provides a more contemporary parallel. The music of Frédéric Chopin has stirred the world. So have the exploits of Poland's military and political leaders: King John III Sobieski defended the whole of Europe against the threat of Turkish invasion, and Tadeusz Kościuszko and Kazimierz Pułaski became heroes in the youthful United States as well as in their native land.

Not until the end of World War I in 1918 did a republic of the west European type emerge in Poland, and this proved to be economically weak and burdened with several large national minorities. During World War II, a fifth of the population, some 6,000,000 people (including almost the entire Jewish population of more than 3,000,000), perished under the Nazi occupation, and the nation suffered great physical devastation. A new Polish state was formed in 1945; the country's boundaries reverted to the original territories of ethnic Poland in the Middle Ages, and, as a result of a substantial migration of Poles and Germans, the ethnic composition of the nation since then has been almost entirely homogeneous. The need for reconstruction faced the nation at all levels; the ensuing 25 years were to witness the transformation of the Polish economy to one in which industry played a much larger role than it had in the past. Economic development was irregular, however, and the Poland of the 1970s continued to be plagued—as many Polish experts pointed out—by the unsatisfactory performance of agriculture, the weak development of transportation, the relatively poor quality of many services, and the damage that rapid industrial growth had caused to the environment. Progress was nevertheless being made in the difficult task of catching up with richer societies.

This article is concerned with the contemporary nation. For history, see POLAND, HISTORY OF. For information on related topics, see CARPATHIAN MOUNTAINS; ODER RIVER; VISTULA RIVER; and WARSAW.



THE LAND

Relief. Poland has an almost entirely lowland character. The average elevation of the whole country is only 568 feet (173 metres); a mere 3 percent of the land lies above 1,650 feet (500 metres), and more than 70 percent lies below 650 feet (200 metres). Over three-quarters of the national territory owes its contemporary surface appearance to the actions of Ice Age glaciers, which advanced and receded over the northern part of the country a number of times during the Pleistocene Epoch. The great and often monotonous expanses of the Polish lowlands, part of the Central European Plain, are composed of geologically recent deposits that lie over a vast structural basin. In the southern portion of the country, by contrast, older and more diverse geological formations are exposed, and the topography is dominated by the mountainous arc of the Carpathians, dating from the Tertiary mountain-building period of about 25,000,000 years ago. Around the northern rim of the Carpathians lies a series of structural basins, separating the mountain belt proper from a much older structural mass, or foreland, that appears in the relief patterns of the region as the Bohemian Massif (Czeszka Masyw Górski), the Sudety, and the Little Poland Uplands (Wyżyna Małopolska). The upthrust of these mountains was a part of the much greater mountain-building movements that gave rise to the Carpathians and, farther west, the Alps.

Carpathian Mountains

This structure helps to explain the division of the country into a series of east–west zones. To the north lie the swamps and dunes of the Baltic coast; south of these is a belt of chaotic terrain with thousands of lakes, the southern boundary of which marks the limit of the last ice sheet. The third zone can be characterized as the Middle Polish Lowlands, whose minimal relief was created by streams issuing from the retreating glaciers. This zone is the Polish heartland, the site of agriculture in places where loess has been deposited over the relatively infertile fluvioglacial deposits. It is here also that Warsaw (Warszawa), the capital, and the cities of Wrocław and Poznań are found. The fourth zone is made up of the older mountains and highlands to the south; though limited in extent, it offers spectacular scenery. The Little Poland Uplands protect the Little Poland Lowlands, in which Kraków lies, from the colder air of the north. In the extreme south are the Carpathians and their foothills.

Climate. Varying types of air masses collide over Poland, a process that strongly influences the character of both weather and climate. The major elements involved are oceanic air masses from the west, cold polar air from the North Atlantic or from Russia, and warmer, subtropical air from the region of the Azores. All the year round, a series of barometric depressions moves eastward along the polar front, dividing the subtropical from the

colder air, bringing to Poland, as to other parts of northern Europe, cloudy, wet days. In winter, polar-continental air from eastern Europe often becomes dominant, bringing crisp, frosty weather, with still colder Arctic air following in its wake. The warm, dry, subtropical-continental air from the southeast often brings pleasant days in late summer and autumn.

These elements combine to give the overall climate of Poland a transitional—and highly variable—character, between oceanic and continental types. Six seasons may

be clearly distinguished: a snowy winter of one to three months; an early spring of one or two months, characterized by alternating wintry and springlike conditions; a predominantly sunny spring; a warm summer with plenty of both rain and sunshine; a sunny, warm autumn; and a foggy, humid period signifying the approach of winter. Sunshine reaches its maximum over the Baltic in summer and the Carpathians in winter, and mean annual temperatures range from 46° F (8° C) in the southwestern lowlands to 43° F (6° C) in the colder northeast. The climate of the mountains is determined by altitude. The highest peaks have mean annual temperatures below 32° F (0° C), but the absolute minima (as low as —44° F [—42° C]) are found in the basins. In the distribution of mean monthly temperatures may be seen a decrease from west to east (in January, from 30° F to 23° F [—1° C to —5° C] except in summer, when the trend is from south to north (e.g., from 66° F [19° C] at the foot of the Carpathians to 63° F [17° C] on the Baltic coast). There are, however, local variations caused by topography, which is also influential in the case of annual precipitation totals.

The annual average precipitation is about 24 inches (600 millimetres), but in the mountains the figure approaches 31 to 47 inches (800 to 1,200 millimetres), dropping to about 18 inches (450 millimetres) in the Middle Polish Lowlands. In winter, snow makes up about half the total in the plains and almost all of it in the mountains.

Rivers, lakes, and soils. No less than 99.7 percent of Poland drains to the Baltic, more than half via the Wisła (Vistula) River and a third via the Odra. Polish rivers experience two periods of high water each year: in spring, the lowland rivers are swollen by melted snow, the effect intensified both by ice dams (which block the rivers for one to three months) and by the fact that the thaw first strikes the upper reaches of the northward-flowing rivers; the summer rains bring a second maximum around the beginning of July.

There are about 9,300 Polish lakes with areas of more than 2½ acres (one hectare), and their total area is about 1,200 square miles (3,200 square kilometres), or 1 percent of the national territory. The majority, however, are found in the northern glaciated belt, where they occupy more than a tenth of the surface area.

Polish soils are varied and without clearly marked regional types. The greatest area is covered by podzol and pseudopodzol types, followed by the less widely distributed brown-earth soils, which are richer in nutrients. In the south are patches of the fertile loess-based soils, especially in the Little Poland Lowlands. The rendzinas, formed on limestone rocks, are a unique type. Alluvial soils filling the river valleys and peaty swamp soils found in the lake area and in poorly drained valleys are also of importance.

Plant and animal life. The vegetation of Poland has developed only over the 10,000 years that have elapsed since the last Ice Age, and, as a result, it is not rich, consisting of some 2,250 species of seed plants, 630 mosses, 200 liverworts, 1,200 lichens, and 1,500 fungi. Holarctic elements (*i.e.*, those appertaining to the temperate belt of the Northern Hemisphere) are dominant among the seed plants.

Trees

The northeastern limits of certain trees—notably beech, fir, and the variety of oak known as pedunculate—run through Polish territory. There are few endemic species: the Polish larch (*Larix polonica*) and the Ojców birch (*Betula oycoviensis*) are two examples. Some relics of tundra vegetation have been preserved in the peat bogs and mountains. About 27 percent of the country is wooded; fundamentally, Poland lies in the zone of mixed forests, but in the southeast a fragment of the forest–steppe vegetation zone intrudes, while in the northeast there are portions of the east European subtaiga, with spruce as a characteristic component. In the mountains, the vegetation, like the climate, is distinctly altitudinal. Fir and beech woods give way to the spruce of the upper woods, which in turn fade into subalpine, alpine, and snowline vegetation. The areas with the best preserved vegetation cover are now under protection in Poland's 11 national parks and more than 500 nature reserves.

Poland's animal life belongs to the zoogeographic province known as the European–West Siberian, itself part of the Palaearctic subregion, and is closely linked with the vegetation cover. The vertebrate fauna includes nearly 400 species, of which 83 are mammals and 212 native birds. Deer and wild pig roam the woods; the elk is found in the coniferous forests of the northeast; and such steppe rodents as the brindled gopher are found in the south. Brown bear and wildcat live in the mountain woods, and the chamois and marmot are found at the highest levels. The great Puszcza Białowieska (Białowieża Forest, a national park contiguous with the Belovezhskaya Pushcha in Belorussian S.S.R.) provides shelter for about 300 wisent, or European bison, which once roamed the continent in vast numbers.

Geographic regions. The natural landscape of Poland can be divided broadly into three groups: the lowlands, the highlands, and the mountains. Further subdivision is possible by allowing for the effect of specific locations; the eastern extremes of Poland display characteristics common to eastern Europe, but the rest of the country is linked by structure, climate, and the character of its vegetation to western Europe.

The coastal plain. The Baltic Coastal Plain stretches across northern Poland from East Germany to the Soviet border, forming a low-lying region built of various sediments. The scarcely indented Baltic coastline was formed by wave action after the retreat of the ice sheet and the raising of sea levels. The Pomeranian Bay (Zatoka Pomorska) in the west and the Gulf of Gdańsk in the east are the two major inlets. In the southern portion of the former, two islands block off the Szczecin Lagoon (Zalew Szczeciński), into which the Odra discharges its waters. In the Gulf of Gdańsk, the Wisła forms a large delta. Sandbars, on which the winds have created large dunes, line much of the coast, separating the coastal lakes and lagoons from the sea. The main urban centres are the ports of Szczecin (German Stettin) on the lower Odra, and Gdańsk (Danzig) and Gdynia in the east. The central portion of the Baltic Coastal Plain is scantily peopled—there are only small fishing ports, of which Kołobrzeg is the most important—and the landscape has a desolate beauty. The regional capital is the administrative centre of Koszalin.

Coastal settlements

The lake region. The belt immediately to the south of the coastal plain presents, with its many lakes, a varied, hilly landscape of glacial origin. Wide north–south river valleys divide the region into three parts: the Pomeranian Lakeland between the lower Odra, the ancient river valley of the Warta and Noteć, and the lower Wisła; the Masurian Lakeland, east of the lower Wisła; and the Great Poland Lakeland, lowest of the three, which lies south of the Warta–Noteć river valley, between the middle Odra and the middle Wisła. The larger settlements and the main communications routes of this zone lie in and along the river valleys; the remainder of the area is mostly wooded and thinly populated. Only the eastern portion of the Great Poland Lakeland has a developed agriculture. Poznań is the main urban centre of the region; Bydgoszcz and Toruń, twin towns in a basinlike broadening of the Wisła Valley, are also important, while Olsztyn functions as the main centre of the Masurian Lakeland.

The Middle Polish Lowlands. The extensive Middle Polish Lowlands contain isolated relief features shaped by the oldest glaciations, but their character is generally flat and monotonous. The postglacial lakes have long since been filled in, and glacial outwash masks the weakly developed meltwater valley channels. The basins of the main rivers make possible a subdivision: the Silesian Lowlands lie in the upper Odra; the southern Great Poland Lowlands lie in the middle Warta basin; and the Mazovian and Podlasian lowlands lie in the middle Wisła basin. Lower Silesia and Great Poland are important agricultural areas, but large industrial centres are found in many parts of the Middle Polish Lowlands. Warsaw, the capital, situated on the middle Wisła, is most prominent, followed by Łódź, on the Wisła–Warta watershed, and Wrocław (German Breslau), on the Odra. Białystok dominates the eastern section. Rich deposits of copper have

been discovered in the ancient rocks underlying the lowlands, and mining has started north of Legnica.

The Little Poland Uplands. These uplands, south of the Middle Polish Lowlands, extend from east to west, but they are folded transversely. In the west is the Silesian–Cracovian upthrust, with rich deposits of coal. A second upthrust is formed by the ancient rocks of the Holy Cross Mountains (Świętokrzyskie Góry), which reach a maximum height of 2,008 feet (612 metres). Between these two regions lies the Nida Basin, with an average height of 650 to 1,000 feet. East of the Holy Cross Mountains, the uplands are cut by the valley of the Wisła, beyond which lie the Lublin Uplands. Climatically, this region is somewhat cooler (by 1° or 2° C) and more humid than the surrounding lowlands and basins. In the south occur patches of loess on which fertile brown- and black-earth soils have developed. The older geological regions contain valuable minerals: in the Silesian–Cracovian uplands there are—apart from coal—iron, zinc, and lead deposits, while the Holy Cross Mountains supply more ores and raw materials for building. These mineral resources have made possible the rise of Poland's most important industrial region, and the landscape of Upper Silesia is highly urbanized. Ten closely linked cities in Katowice province have populations ranging between 100,000 and 350,000 and form the core of the Upper Silesian metropolitan conurbation with a total population of almost 3,500,000, Katowice being the largest centre. Closely linked with this region is that around Kraków, which contains the Nowa Huta steelworks, Poland's largest, based on Silesian coal and on iron ore imported from the Soviet Union. The old Polish industrial region was the area around the Holy Cross Mountains, where the not very rich local iron ore was exploited in the 19th century; Kielce is the urban centre. Lublin is the main centre of the uplands that bear its name, under which substantial deposits of coal were discovered in the early 1970s.

The industrial region

The air and water of the Upper Silesian industrial district are seriously polluted. Efforts at control on the part of the authorities have met with but limited success.

The Sudety. The Sudety (German and conventional English Sudeten) and the Sudety Foreland, part of the larger Bohemian Massif, have a long and complex geological history. They owe their present rugged form, however, to earth movements that accompanied the Carpathian uplift, and the highest portion, the Giant Mountains (Karkonosze; German Riesengebirge, Czech Krkonoše), reach a height of 5,256 feet (1,602 metres) above sea level. The region contains rich mineral deposits, notably coking coal, which has occasioned the growth of an industrial centre around Wałbrzych. The whole region is densely populated and crossed by railway lines; resorts and spas are found here and there in more secluded regions. The Sudety Foreland, similar in geological structure to the Sudety but lower in relief, is separated by a large fault from the larger mass. The region contains many granite quarries.

The Carpathians. The southernmost and also most scenic portion of Poland embraces the Carpathian Mountains and their associated basins, created in the geologically recent mountain-building Tertiary Period. Within the Polish frontiers lie the Oświęcim (German Auschwitz) and Sandomierz basins; a portion of the Outer Western Carpathians (Beskidy); and the Orawa–Podhale Basin and the Tatry (Tatra Mountains), associated with the Central Western Carpathians. The sub-Carpathian basins contain deposits of salt, sulfur, natural gas, and some petroleum. There is a large rural population and many towns of medium size. The nearby mountain regions are readily accessible and also densely peopled. The highest peak of the Outer Western Carpathians, Babia Góra, reaches 5,659 feet (1,725 metres); the small but high Tatry, the highest portion of the Polish Carpathians, with a maximum elevation of 8,199 feet (2,499 metres), has a unique character. Zakopane, the largest tourist and resort centre in Poland, lies at their feet; indeed, the entire Carpathian region attracts visitors from the industrial cities to the north and the lowlands beyond.

Rural settlement. In contemporary rural Poland, survivals of a medieval settlement pattern can be found adjacent to forms originating in the 19th and 20th centuries. The first group includes compact villages with an average of 20 to 100 dwellings, associated with a nodal road system; this type is especially typical of the west and north of the country. Compact, elongated villages also occur in the northeast, having originated in economic reforms of the 16th century. In the Carpathians, the Sandomierz Basin, and the Lublin Uplands, an elongated form of settlement along river valleys is common, with roads running at right angles to the main line of buildings and linking them to the fields.

Older villages

A newer, more dispersed type of village is found only where natural conditions are less favourable—in major river valleys, in swamps and forests, and in some parts of the mountains. A final type of settlement is of more complex structure, generally compact but with some dispersion. It results from the transformation of old villages after the concentration of landholdings in long-cultivated regions and is found in the central parts of the country and also in the Masurian and Pomeranian lakelands.

Urban settlement. The earliest forms of urban settlement in Poland were linked with the disappearance of tribal organization and the development of the feudal system. Settlements of artisans and merchants were already developed in the early Middle Ages, clustering around centres of royal authority or large feudal estates, either of which could provide a stronghold against attack. In the 13th and 14th centuries, settlements of this type received legal rights and privileges and at the same time acquired a standard urban layout, with a central square and streets at right angles. In time, a settlement might be joined by neighbouring or rival towns, and the town grew, changing its character in later centuries according to changing styles. In spite of the changes, however, medieval town centres—with Gothic churches, town halls, and fragments of walls and defensive gates—were preserved until well into the 20th century in many Polish towns and cities, including Warsaw, Kraków, and Toruń. In the Middle Ages there were many towns, of much the same size and located at fairly equal distances from one another, in the southwestern part of the country. After the development of better transportation and the growth of industrial centres, however, many of them lost their function and became villages. The growth of capitalism, and the industrialization associated with it, broke the pattern and caused much greater variation in the distribution and size of towns. By the 1970s, Poland had 30 towns with populations of more than 100,000; well over 100 towns with populations between 20,000 and 100,000; and about 750 smaller towns. The number of urban dwellers has more than doubled in the 20th century, approaching 56 percent of the national population by 1976.

Effects of industrialization on settlement

The majority of the Polish cities have complex functions: Warsaw, for example, is a large centre of diversified industrial activity, but it takes its character from its function as the capital and from its large concentration of academic and cultural institutions. Port functions are of fundamental importance for Gdańsk, Gdynia, and Szczecin, while in the towns of the Upper Silesian industrial region, and in Wałbrzych and Konin, the extractive metallurgical and heavy engineering industries are dominant. In Częstochowa and Kraków metallurgy is important (although Kraków is also second only to Warsaw as a cultural centre), Poznań concentrates on engineering, and the textile industry predominates in Łódź and Białystok. In smaller urban centres, service functions—notably tourism and recreation—and local transportation are important elements in the economy. Almost all towns, however, have at least some manufacturing or extractive industry.

THE PEOPLE

Composition. All but 2 percent of the population of Poland is of Polish nationality. By the 1970s, the most numerous minorities were Belorussians (165,000), located in the eastern part of the country, and Ukrainians (180,000), scattered in the northern provinces. There

were some tens of thousands of Jews, mostly concentrated in urban areas; they represented but a tiny remnant of the former Jewish population of more than 3,000,000, most of whom perished during the Nazi occupation (1939–44). About 10,000 Lithuanians live near the border of the Lithuanian Soviet Socialist Republic. After the great migratory movements that took place toward the end of, and immediately after, World War II, there remained only a small number of Germans in Poland. Their exact number is a matter of dispute between the Polish and West German authorities. A similar situation occurs in some villages on the Czechoslovak border. Finally, entirely non-indigenous inhabitants of Poland include about 20,000 Russians, about 10,000 Greek and Macedonian immigrants, and about 12,000 Gypsies.

Ethnic origins. The Polish people originated in several West Slavic tribes inhabiting the basins of the Odra and Wisła rivers. What used to be tribal territories have retained to this day a certain diversity in dialects spoken, and indeed in folk culture generally, although these ancient traces are disappearing as a result of internal migration, urbanization, and industrialization. Five large tribal territories may be distinguished: (1) Great Poland (Wielkopolska), lying in the basin of the middle and lower Warta as far as the middle Odra and the cradle of the Polish nation, whose origin lay in the Polanian tribe (Polanie; Latin name Poloni for the tribe, Polonia Major for their territory); (2) Silesia (Śląsk), the homeland of the Silesians (Ślęzanie) and a few smaller groups inhabiting the basin of the upper and middle Odra; (3) Little Poland (Małopolska, Latin Polonia Minor), in the basin of the upper Wisła, covering the tribal territories of the Vistulans (Wiślanie); (4) Mazovia (Mazowsze), around the middle Wisła and its tributaries; and (5) Pomerania (Pomorze), stretching in a wide coastal belt from the mouth of the Odra to the Wisła, separated by the Warta–Noteć valley from Greater Poland.

Tribal territories

As a result of the expansion of settlement by these ethnic groups, further territories were annexed. East of the lower Wisła, in a coastal and lakeland belt, lived a non-Slav people—the Prussians—belonging to the Baltic tribes and related to the Lithuanians and Latvians. On these lands in the 13th century arose the German state of the Knights of the Teutonic Order, having as its purpose the conversion of the pagan Prussians. The Knights brought about the extermination or Germanization of the Prussians and conflict with Poland. After long and bloody wars, a part of this region was joined to Poland, and the remnant became the Duchy of Prussia, enfeoffed to the Polish kings. The frontier lands of Prussia were colonized by Polish peoples from Mazovia, but they became converted to Protestantism, the prevailing religion in Prussia, in contrast to the situation in predominantly Catholic Poland. In this way there arose a group of Prussian Mazurians, who retained their language until the 20th century but gradually became Germanized. Some of them still inhabit the Masurian Lakeland.

The Prussian Mazurians

The eastern part of contemporary Poland, centred around the basin of the Neman and the upper Narew and partially the Bug River, does not form a part of ethnic Poland; it formerly belonged to the Grand Duchy of Lithuania and was inhabited by Belorussian tribes. These lands were settled later by colonists from Mazovia but still contain a substantial Belorussian element.

The western parts of Silesia, Great Poland, and Pomerania gradually became Germanized from medieval times onward, this being carried out intensively in the Prussian kingdom from the middle of the 18th century, especially after the fall of the former Polish state. It was not until the end of World War II that a reversal of this trend took place. The Potsdam Conference (1945) approved the evacuation of the remainder of the German population to west of the Odra–Nysa (Oder–Neisse) Line, and it was replaced by Poles repatriated from the Soviet Union and other countries, as well as by a spontaneous migration from the central provinces. The western region thus developed over the ensuing years a completely new society, most of whose peoples are not directly descended from the original Polish inhabitants. The western and northern third of the country contain a fast-growing population that is more than a quarter of the national total.

Anthropologically, the Polish population is mixed, transitional between the north and south as well as the east and west of Europe. Poles are generally blonder and have lighter coloured eyes than do the peoples of southern Europe, but they are darker than the Scandinavians to the north.

Language. Linguistically Poles, together with Czechs, Slovaks, and Sorbs (Wends, or Lusatians), belong to the West Slavic group, and the literary Polish language developed on the basis of Great and Little Polish dialects. The first records of Polish place and personal names appear in 12th-century church documents; numerous Polish texts of hymns and sermons, psalters, and lawcourt records have been preserved from the 14th and 15th centuries. The literary language blossomed in the 16th century and was linked with the spread of Humanism, the invention of printing, and the conflict of the Reformation. A second period of the development of classical and scientific literature took place in the second half of the 18th century. Despite the fall of the Polish state, Polish culture continued to develop under foreign domination, and the language and the classical literature were, in fact, factors uniting the whole nation (see also below *Cultural life and institutions*). Despite the standardization of the language—by universal education, literature, and, more recently, the mass media—country dialects, reflecting former tribal patterns, remain of significance in the con-

Development of the written language

temporary population. They include Great Polish, Silesian, Little Polish (further subdivided into a mountain dialect), and Mazovian; the very distinctive Kashubian is commonly classified as a separate language.

Dominance of Catholicism

Religion. The overwhelming majority of the Polish population is, and traditionally has been, Roman Catholic. Other Christian denominations and Judaism have limited influence. Among Catholics, the greatest numbers —including Belorussians, Ukrainians, and Russians— adhere to churches with a measure of episcopal independence. An increasing percentage of the population does not practice any religion, or describes itself as areligious, but their numbers are difficult to ascertain as official statistics do not record religious affiliation. In November 1976 the Polish Catholic bishops issued a pastoral letter that challenged the claims of the government to religious toleration and charged that the church was being subjected to attack in an official conspiracy to enforce atheism.

Social characteristics. The social structure of the population underwent great changes after World War II. After 1944, the class of landowners, developed from the former nobility, disappeared with the dissolution of the landed estates, as did the urban bourgeoisie as a result of the nationalization of industry and trade. Social and political emphasis shifted to the working class. Many of the peasants, very numerous before the war, moved to the towns, so that those engaged in agriculture (together with their families) formed only 27 percent of the population by 1975. The character of the intelligentsia has also changed. Before the war it consisted mainly of property owners, whereas in contemporary Poland its membership consists largely of persons with peasant or working class backgrounds, this process being facilitated by educational opportunity. The number of white-collar workers in Poland has more than tripled since prewar days. Finally, as a result of the survival of private businesses, a lower middle class element is still significant in the population, although its size has been considerably decreased.

These trends are seen by Polish analysts as among the major components of the demographic and social effect on postwar economic development. Such effects, however, are produced not only by alteration of economic or social classes but also by the increasing participation of women in the economic life of the country. In addition to the increased supply of women available to the labour pool, produced by the postwar baby boom (between 1950 and 1970, the participation of women between the ages of 15 and 59 in the Polish labour force rose from 67 to 77 percent), the women themselves are increasingly well-educated, career-oriented, and motivated by family responsibilities.

The beneficial effects of the social trends mentioned above inevitably have side effects that can be expected to further exacerbate problems already created by these momentous changes. One of the most serious of these is the aging of the agricultural labour force. Most of the population migrating to the cities for the industrial and white-collar jobs there have been individuals and couples of procreating age; the result has been a rise in the proportion of agricultural workers over the age of 45 from 36 percent in 1950 to 54 in 1970. Before this trend can be reversed, or at least abated, the gap between the social conditions of employment in the cities and rural areas must narrow appreciably.

Aging agricultural workers

Another side effect of these social changes appears in the fertility differentials among women of childbearing age. As elsewhere in the world, fertility appears to vary according to level of education; for example, married women in Poland between the ages of 20 and 49 with higher education bear, on the average, 1.71 children, while those with a secondary education bear 2.01 children, and those with an incomplete elementary education bear 3.4 children. These patterns suggest that, in the future, the growth of Poland's population can be expected to slow as levels of education rise, women's social and economic roles alter, and information about birth control is more broadly disseminated.

Polish socio-economic planners hope to arrange the economic life of the country so as to afford maximum scope to members of Polish society throughout the whole of their economic life—for example, by providing an apartment to every household by 1990 and by raising the proportion of the labour force in the services sector and in manufacturing, particularly of consumer goods, to about 40 percent. Since these goals imply a decline in primary sectors of the economy (agriculture, mining, heavy industry) and since labour is already in short supply in certain sectors, planners are concentrating on improvements in mechanization of these primary activities, on modernization of existing plant, and on raising productivity of workers in these sectors.

Demographic trends. The population of Poland underwent great changes as a result of World War II. In 1939, 34,800,000 people lived within the then boundaries of Poland—a number reduced to 23,900,000 within the new frontiers in 1946. The decrease was caused primarily by war losses, calculated at 6,000,000 persons; only 644,000 of these persons were killed as a result of direct war activity, the remainder falling before the extermination policies of the Nazis. Postwar migrations and the associated change of boundaries were also important; from 1945 to 1949, the repatriation of Poles from the Soviet Union involved about 1,500,000 people; of Germans to the West, about 2,000,000 people (not counting the millions of people evacuated during wartime); and of Ukrainians, Belorussians, and Lithuanians to the Soviet Union, about 500,000 people. In the same period, the return of former emigrants and combatants from western Europe also helped swell the population.

Following these mass population movements, the 1950 census showed a total population of 25,000,000, the 1960 census 29,800,000, and the 1970 census 32,600,000. At the end of 1975 it was estimated to be 34,200,000. The total population thus increased by 10,300,000 over 30 years but still was less than it had been in 1939. The increase was not the same in all parts of the country and was not, in terms of time, steady; there was, for example, a rapid increase in the lands annexed to Poland as a consequence of the Potsdam Conference. This was attributable not only to the influx from outside but also to the large natural increase among the generally young people who were overwhelmingly in the majority among the newcomers. At the same time, there has been a nationwide movement of population from the country to the towns, linked with the rebuilding of the latter and the associated development of industry. Urbanization is especially marked in the west and north. The national urban population increased from 39 percent to about 56 percent between 1950 and 1975.

Population movements

The rate of annual natural increase in the first decade after the war was among the highest in Europe, approaching 20 percent, and resulted from a decrease in mortality as well as from an increase in births. After reaching a maximum in 1955, the rate of natural increase began to fall. This was caused by a decline in the birth rate occasioned by the spread of birth control and by the coming of age of the diminished age group born during the war. The rate of natural increase fell to 10 percent by 1965 and as low as 8.5 percent in the early 1970s but rose again slightly after 1971. The difference between the rates of natural growth in towns and the countryside is slowly declining, though the rate in the towns is still lower than that in the country. The large number of births in 1948–56 has created special demands on national education and on the labour market.

War losses and the abnormal course of natural population movements have caused other anomalies to occur in the sex and age structure, notably in the preponderance of women (especially widows) in certain older age groups. The age structure also shows great regional differences. The traditional heartland of Poland has witnessed a steady increase in percentage of older persons; in the west and north the percentage of older people is smaller, and that of the young greater, than elsewhere. The high natural increase of the postwar years has given the Poland of the mid-1970s a population that is relatively much younger than that of other northern and western Euro-

pean nations, with a pronounced excess of persons between 15 and 30. Demographic forecasts indicate that by 1980 the population of Poland will exceed 37,000,000 and that the age structure will undergo an important change through the decrease in the number of young people and an increase in the older population. (J.A.K./A.H.D.)

THE NATIONAL ECONOMY

The Poland of the 1970s is eastern Europe's largest producer of agricultural crops after the Soviet Union, as well as the world's second largest grower of potatoes and rye and its fifth most important source of sugar beets. In industry it ranks among the world's top 15 countries. It is Europe's second largest source of bituminous coal and zinc. Although Polish industry is not so well developed as that of Czechoslovakia or East Germany, the country is eastern Europe's largest producer of several industrial products (after the Soviet Union), notably steel, cement, tractors, railway freight cars, and trucks. It is not, however, a very important foreign trader; although its population was the sixth largest in Europe at the start of the 1970s, its exports were only in 10th place. After 1951 Poland's national income grew at a rate that was some 30 percent faster than the average for the world as a whole. Available statistical data do not permit detailed comparisons, but it is estimated that, in spite of this growth, national income per person is still well below that of the most developed east European and most advanced non-Communist countries.

Growth of national income

Resources. *Mineral resources.* Poland is relatively well endowed with natural resources. Its principal mineral asset is bituminous coal, and by 1975 it was the world's fourth largest producer. Almost all the output—which increased by one-third over the 1960s—is derived from the rich Upper Silesian coalfield; the remainder comes from Nowa Ruda and Wałbrzych, in Lower Silesia. In the 1970s new seams were discovered and a pilot mine was opened near Zamość. Brown coal and lignite are derived from the Konin–Turek area and from Turoszów in the southwest; development of huge deposits in the Bełchatów region also began in the 1970s. Other fuel resources include small amounts of oil—found between Bochnia and Sanok and at Krosno in the south—and large deposits of natural gas in the vicinity of Lubaczów, Nowa Sól, Trzebnica, Ostrów Wielkopolski, and Zamość. Output of crude oil more than doubled over the 1960s, but it accounts for only a fraction of total requirements. Natural gas production is substantial.

Sulfur is Poland's second most important mineral. Reserves, thought to be among the largest in the world, are located on both sides of the Vistula near Tarnobrzeg. Other important nonmetallic minerals include salt, kaolin, limestone, chalk, gypsum, and marble. Scattered rock salt reserves are estimated to total some 43,000,000,000 tons. Potassium and magnesium salts are found in some areas bordering the Baltic, around Kłodawa, and in the Sudety. Reserves are thought to total some 500,000,000,000 tons, but commercial exploitation has not yet begun. Kaolin is present in the Bolesławiec district of Lower Silesia, at Czerwona Woda, and in the Świdnica region.

Metals

Among metallic minerals, zinc is the most important. Reserves of zinc and lead ores, believed to be among the largest in the world, are located around Bytom and in the Zawiercie–Olkusz region, and by the mid-1970s Poland was Europe's second largest producer of zinc ore. There are also large quantities of copper, the two main producing areas being near Legnica and Głogów and near Bolesławiec and Złotoryja. Iron ore is mined in small quantities around Częstochowa and Kraków and near Kielce and Łęczyca, and there are also deposits at Suwałki, near the Soviet border. Nickel is found near Ząbkowice, and such other metals as vanadium, cobalt, and silver are also produced.

Other resources. The quality of the soil varies, but there are large fertile areas, including Lower Silesia and the Little Poland Lowlands, the Kujawy, the Wisła delta, and the Lublin area. The soil is somewhat poorer in large parts of central and northern Poland. About 27 percent of the country's total land area is wooded, and some 80 percent of this is occupied by coniferous timbers, with pine, larch, and spruce the most important for resource purposes. The bulk of the country's hydroelectricity comes from the Carpathians, the Sudety region, and the Brda and Wisła rivers; potential was limited in the 1970s, but more hydroelectric power stations were planned.

Sources of national income. *Agriculture.* By the mid-1970s, agriculture produced less than 10 percent of the national income and employed less than 30 percent of the economically active population. Polish agriculture is unique in eastern Europe in that private farms still account for the greater part—80 percent, in fact—of its total output. The 6,700 state farms hold only 22 percent of the land and are responsible for only about 19 percent of agricultural production; cooperatives (*i.e.*, collective farms) cultivate less than 2 percent of the land.

In the early 1950s Polish agriculture was adversely affected by inadequate investment, but the 1960s saw a gradual growth in the share of total investment spending devoted to this sector. Farm production went up by a quarter over the 1960s; this growth—which would have been faster but for the unusually adverse weather conditions of 1969—was mainly in the form of an increase in yields, made possible by the greater use of fertilizers, other agricultural chemicals, and machinery. In spite of this, yields tended to be well below the figures reached in East Germany and in Czechoslovakia, where farming is the most advanced in the Communist bloc. Polish agriculture is unable to satisfy internal demand for a number of important products—especially cereals and fodder crops—and large imports are necessary. The bulk of the country's 21,000,000 acres (8,600,000 hectares) of forest is state owned; most of the substantial log production consists of coniferous timber.

Manufacturing. By the mid-1970s, industry was responsible for just over half of Poland's net material product and employed more than 5,000,000 persons, or about 30 percent of the country's economically active population. As a result of heavy capital spending in the 1960s (more than 40 percent of all investment expenditures over the decade went to industry), growth in this sector has been very rapid. Industrial production went up by more than 100 percent during the period, bringing it to a level more than seven times higher than that of 1950. Principal emphasis was on the capital goods industry, which increased its output by 130 percent; production of consumer goods, however, advanced by only 75 percent. By the mid-1970s electrical engineering, machinery building, and transport equipment accounted for more than 30 percent of gross industrial production, compared with 15 percent in 1960. The food industry held second place (about 16 percent), although it grew only about 40 percent over the 1960s. The chemical, textile, fuel, basic metals, and metal-fabricating industries are also significant.

The role of heavy industry

Though there has been a shift of agricultural labour into industry, a large part of the gain in industrial production over the 1960s was the result of higher productivity, which raised output per person by 53 percent. Poland is eastern Europe's principal producer of a number of industrial goods, including steel, mineral fertilizers, sulfuric acid, cement, tractors, railway freight cars, and motor trucks.

By the mid-1970s there were some 174,000 industrial enterprises in Poland, of which 119,000 were private handicraft establishments. Of the remainder, cooperative firms accounted for about two-thirds, though half of these employed fewer than 11 workers. Large state-owned enterprises (with more than 1,000 employees) accounted for less than 2 percent of the total number of enterprises but provided employment for almost all of the industrial labour force. Private, nonhandicraft industrial establishments employed an average of only three workers per firm.

Energy. Over the 1960s and '70s, electricity output increased rapidly to about 97,000,000,000 kilowatt-hours in 1975, most of them generated by public supply plants. All but a small portion of this total was derived from bituminous coal and lignite; the share of liquid fuels was

less than 4 percent and that of hydroelectricity only about 2 percent. There are long-term plans for building a giant nuclear-power station in northern Poland. By the early 1970s natural gas had largely replaced manufactured gas. Crude oil production contributes less than 5 percent to the annual consumption of petroleum, most of which has to be imported.

The financial sector. The banking system is state owned and is controlled by the National Bank of Poland (Narodowy Bank Polski). This body fulfills all the usual functions of a central bank, including issuing notes; it also controls credit, exercises financial control over state enterprises, regulates the money supply, and executes the government's financial policy. Other important banks include the Commercial Bank of Warsaw (Bank Handlowy w Warszawie), which carries out foreign trade transactions; the Food Management Bank (Bank Gospodarki Żywnościowej), which distributes investment funds for agriculture and food production; and the Polish General Savings Bank (Bank Polska Kasa Opieki). There are no stock exchanges. The rate of exchange for certain transactions is very much higher than the official foreign exchange value.

Foreign trade. Although Poland has about a third of eastern Europe's population, it accounts for only slightly more than a quarter of its foreign trade. Over the 1960s Polish exports grew by almost 140 percent, while imports advanced by 115 percent. Imports exceeded exports by a considerable margin over the decade, but the last few years saw some reduction in the deficit. By the mid-1970s Poland's foreign trade with the Communist bloc had declined to less than half of total trade, while trade with the developed non-Communist countries was responsible for well over a third and was growing. The country's principal trading partner (though declining in importance) is the Soviet Union, which provides almost 25 percent of all Polish imports and takes about 30 percent of the exports. East Germany, West Germany, and Czechoslovakia, in that order, are the other important trading partners, while all the Western countries account for about a fifth of the total trade.

Balance of payments

By the mid-1970s more than 40 percent of Poland's exports consisted of machinery and equipment, with complete plants, power and electrical machinery, and vessels the most important items. Many of these go to Communist and developing countries. Fuels and raw materials account for a further quarter of the total, with coal, coke, iron, and steel figuring prominently. Consumer goods and food make up the remainder. Almost half of Poland's imports are machinery, 5 percent fuels. Poland is a net exporter of consumer goods, food, and fuels.

Management of the economy. *The private sector and the role of the government.* The state plays a dominant role in the economy, although its involvement is not so extensive as it is in other countries of the Communist bloc. The bulk of industry is state owned and controlled, with nationalized and cooperative enterprises accounting for all but a tiny fraction of gross industrial production and employment of the industrial labour force. Banking, foreign trade, insurance, and much internal commerce are also controlled by the state. Private enterprise, however, plays an important role in handicrafts and accounts for about 20 percent of the net output of the building trades and 80 percent of final agricultural production. In consequence, the state sector of the economy produces 86 percent of the national income—a figure high by Western standards but below that reached in other Communist countries. Since the state lays down detailed economic policies and regulates most prices, however, private enterprises are under strict control and operate within closely defined limits.

Taxation. Tax receipts amounted to 85 percent of total state revenue by the early 1970s. More than two-thirds of this was accounted for by turnover taxes—a fixed percentage of the sales value levied on consumer goods—while a further 20 percent was derived from profits and income taxes paid by enterprises. Taxes collected from the population—mainly by way of a payroll tax—made up the remainder.

Trade unions. Polish trade unions are, on the whole, organized on industrial lines. By the 1970s there were almost two dozen unions, with a total membership exceeding 11,000,000 and including more than 90 percent of the labour force (excluding those engaged in private farming). The unions do not seem to have given any support to such actions as the Baltic workers' demands for lower prices and higher wages during serious disturbances late in 1970 and are regarded by Western experts as an extension of the state apparatus.

Contemporary economic policies. Although the government did not persist with its early attempts to collectivize agriculture, it followed, over the 1950s and '60s, the policy of detailed regulation and centralization then prevailing in the Communist bloc. This led to a spectacular growth in industry, but only at the cost of serious structural difficulties, high production costs, low productivity, and an irrational pattern of production and consumption. These problems became increasingly obvious during the 1960s and forced the government to evolve a program of economic reform.

Economic difficulties

The main features of this program, which came into effect in early 1971, were somewhat greater managerial independence and stronger emphasis on profit, a system of credit and investment finance that took into account the performance of enterprises, more material incentives, and a revision of prices. The price revision (which involved a rise in food prices and a cut in consumer goods prices) was followed by widespread disturbances and strikes in some Baltic towns. These led to changes in the national leadership, increases in wages for the lower paid, a two-year freeze on food prices, and a pledge that the 1971–75 plan would be revised. Further disturbances in June 1976, when another attempt was made to raise food prices, eventually obliged the authorities to withdraw the proposed increases.

Economic problems and prospects. Many Western experts believed that the new government would retain the essential features of the reform package. This process, however, although likely to go some way toward solving the problems described above, cannot be expected to bring about any noticeable short-term improvement in the economic situation. On the contrary, since the reform program involves the pursuit of new, untried economic policies aimed at increasing competition, channelling investment funds into more profitable areas, weeding out inefficient producers, and increasing individual effort, it may well lead to some transitional difficulties. These could include unemployment, as enterprises become more conscious of cost and profit; the decline of certain inefficient industrial sectors; and other problems that could have an unfavourable effect on short-term growth in several industrial areas. In the long run, however, a policy of reform is likely to bring the benefits of greater industrial specialization—whether within a Comecon framework or not—greater efficiency, a better appreciation of the needs of the domestic and foreign markets, and a faster growth in sales to (and purchases from) the advanced non-Communist world. The export of fuel, especially coal, and the import of factories and advanced technology from western Europe, Japan, and the U.S. increased in the early and mid-1970s. (E.I.U./A.H.D.)

TRANSPORTATION

The communications system in Poland developed in the 19th and early 20th centuries, in a period when the country was divided among Russia, Germany, and Austria. The three areas thus developed in different economic and political conditions, and the main railway lines were oriented to the main towns of those nations. This characteristic was especially marked in the section that was under German rule, where the main junction was Berlin. In Austria-Hungary there were two such centres, Vienna and Budapest. The density of the railway network in the Russian sector was much less than in the Austrian, let alone the German sector, although the main junction of the western part of Russia was at Warsaw. In 1918 independent Poland thus took over a railway system that was inadequate for its needs. Among the most important rail-

way lines built after that date were those linking Warsaw with Poznań and Kraków and a coal trunk line linking Upper Silesia with the newly built seaport of Gdynia.

Railways. After the devastation of World War II the railway system was reconstructed and rebuilt. The main junctions, in particular, were enlarged, as were the reloading stations on the Soviet border, where the track gauge changes. Electrification of the most used lines also took place, and on other routes diesel engines gradually replaced steam. The electrified routes focus primarily on the Upper Silesian industrial region and include the line to Poznań via Wrocław; the coal trunk line to the ports of Gdańsk and Gdynia; lines to Warsaw; and lines to the Soviet border via Kraków and to the Czechoslovak border in the direction of Prague. By 1975 a quarter of the system had been electrified, and work was in progress to electrify more lines. A second railway line was planned between Upper Silesia and the Baltic ports.

Electrification

The railways are administered by the Polish State Railways (Polskie Koleje Państwowe). The average track density is 13.7 miles per 100 square miles (8.5 kilometres per 100 square kilometres), but there are great regional differences; Lublin province, for example, has less than half the average. Narrow-gauge railways, about 11 percent of the total in the mid-1970s, are being replaced.

In the amount of freight transported, Polish railways occupy second place in Europe (after the Soviet Union); in passenger transport, Polish railways occupy third place, after the Soviet Union and West Germany. Because of the position of the country, Polish railway lines are important in the carriage of transit freight between Comecon countries, notably between the Soviet Union and East Germany and between Czechoslovakia and the Polish ports.

Highways. The highway system originally showed disproportions similar to those of the railways; that is, the densest network was on lands belonging to Germany and the least dense on lands belonging to Russia. An attempt to remedy this situation was made between 1918 and 1938 and again, but more intensively, after 1945. Between 1945 and 1970 about 23,000 miles (37,000 kilometres) of new roads were built and the surfaces of about 35,000 miles were modernized, making possible the establishment of bus routes to almost all village communities. Modern multi-lane highways adapted to mass traffic requirements are being built in Warsaw and between that city and Kraków and Poznań. In 1945 the Polish state inherited the *Autobahn* running from the East German border to Wrocław.

Autobahn

About half of the Polish highways have improved surfaces, and the roads are more evenly distributed than the railways are. Road transport is not centralized to the same degree as rail transport since not only the National Road Transport Service (Państwowa Komunikacja Samochodowa, or PKS) but also various smaller economic bodies and branch transport concerns—notably in building, forestry, and mining—are involved in highway transport. Although roads in the mid-1970s handled about four times as much freight as railways, PKS had just under 10 percent of the total. PKS conveyed two-thirds of all passengers, but if the measure of miles per passenger is used, then PKS and the railways contribute equally to the transport service. Poland is behind most European countries in numbers of cars, though it had more than 1,000,000 in 1976; the number has been doubling every five years since 1960.

Inland waterways and merchant shipping. The middle course of the main Polish river, the Wisła (Vistula), is still not regulated, and thus the Wisła is of less importance as a waterway than the smaller Odra, linked by the modern Kanał Gliwicki to the Upper Silesian industrial region and carrying coal to the port of Szczecin. The Odra basin is also linked to the lower Wisła by the Kanał Bydgoski. Inland navigation is of little importance in Poland, however, less than 1 percent of Polish freight being carried on rivers and canals.

Shipping is well developed, and there are three large seaports—Szczecin (the leader), Gdynia, and Gdańsk—as well as smaller fishing and coastal navigation ports. The Polish merchant fleet has nearly 700 ships, with a deadweight tonnage of more than 4,000,000. The export of coal and coke accounts for more than 40 percent of the total shipping. The passenger liner "Stefan Batory" is internationally known for service on the Gdynia–Montreal route.

Air transport. Domestic and international air transport is provided by a state enterprise, LOT (from Polskie Linie Lotnicze). There are some two dozen international routes, centred on the airport at Warsaw.

ADMINISTRATION AND SOCIAL CONDITIONS

The Polish constitution of 1952 (as amended) reflects the changes that occurred after World War II following the collapse of the prewar government, the formation of radical underground political organizations during the German occupation, the liberation of the country by the army of the Soviet Union, and the taking of power by left-wing forces following the parliamentary elections of 1947. Until 1952 the legal basis of the system was the constitution of 1921, partially modified in 1947.

The national constitutional framework. The chief bodies reflecting the forms of authority laid down in the constitution are the one-house parliament (the Sejm) and the Council of State, which is chosen by the Sejm and fulfills the traditional functions of the head of state.

The Sejm consists of 460 members elected for four-year terms. Its sessions are short, and votes tend to be unanimous. The Council of State not only passes legislation during the long intervals between sessions of the Sejm but also has the power to issue decrees with the force of law. In the judicial sphere, it has the power of binding interpretation of laws. Chosen from members of the Sejm, the council consists of a chairman, four deputies, a secretary, and 11 members. It represents the country abroad, nominates and recalls ambassadors, receives the credentials of representatives of foreign countries, and ratifies international treaties.

The role of the Sejm

The Council of Ministers, which is the supreme executive and administrative organ of the Sejm, prepares the budget and formulates the economic plan and supervises the execution of both. It exercises general management of national defense and of the armed forces. The Supreme Audit Office, independent of the Council of Ministers, oversees the economic, financial, and administrative activities of central and regional state bodies.

The supreme *de facto* power in Polish government, however, is the 14-member Political Bureau (Politburo) of the Central Committee of the Polish United Workers' (Communist) Party (or PUWP; see below), headed by the first secretary of the Central Committee. The party was not mentioned in the constitution until that document was amended in 1976 to note that the Polish People's Republic is a socialist state and that the PUWP is the leading political force in the construction of socialism.

Regional administration. The regional administrative system (since the reform of 1973–75) is on two levels. The largest units are the *województwa* (provinces), of which there are 49 (including three self-governing cities). Before the reform there had been only 22 *województwa;* Western observers believe that the breaking up of the large provinces had the effect of weakening the resistance of local PUWP bosses to directives from Warsaw.

Each province is responsible for the submission of proposals for five- and one-year plans for the local economy and land use to the Central Planning Commission in Warsaw. It is also responsible for achieving the targets that are eventually approved for these periods by the Sejm. However, in order to reduce the problems of coordinating the proposals of the larger number of provinces and to avoid the difficulties that are likely to arise as a result of the boundaries of the three city provinces lying well within the actual boundaries of their hinterlands, eight *makroregiony* (macro-regions) have also been established. These units have a consultative role only and are not able to compel changes in provincial proposals. Their influence in the planning process may also be reduced because their boundaries cut through func-

tional zones in some places, thus throwing doubt upon the extent to which they are able to foster the required coordination of the proposals of neighbouring provinces.

The former *powiaty* (singular *powiat*) were abolished in 1975 and the *gminy* (rural and urban districts; singular *gmina*) enlarged. These bodies, of which there were 2,327 in the late 1970s, are responsible for the provision of some cultural and social services and for local land-use planning. The four largest cities are also divided into districts, called *dzielnice*, which have similar responsibilities.

At province and *gmina* levels, local government is controlled by people's councils, whose functions locally and composition are similar to those of the Sejm nationally.

Political parties. Three political parties are active in Poland. The most important is the Polish United Workers' (or Communist) Party (PUWP; Polska Zjednoczona Partia Robotnicza, or PZPR), formed in 1948 by the union of the Polish Socialist Party (Polska Partia Socjalistyczna) and the Polish Workers' Party (Polska Partia Robotnicza). The PUWP had more than 2,400,000 members by the mid-1970s. A much smaller role is played by the United Peasant Party (Zjednoczone Stronnictwo Ludowe), with more than 425,000 members, and the Democratic Party (Stronnictwo Demokratyczne), with 92,000 members. The latter two are in no sense opposition parties.

All three parties cooperate within the framework of the National Unity Front, which embraces all political parties, mass organizations, etc. The front handles elections; it prepares a single electoral platform, selects the candidates, and submits a single list of candidates to the electorate. The balloting is so arranged that the PUWP is guaranteed a majority in the Sejm. The political composition of the Sejm changes little; after a general election in 1976 it was identical in composition to its two predecessors.

Justice. The administration of justice is in the hands of the Supreme Court, common courts (for *województwa*), and special courts for social insurance and the army. The judges of the Supreme Court are chosen for five years by the Council of State, and the other judges are nominated. The courts investigate and solve matters in the first instance with the cooperation of independent investigative officers. There is no right of judicial review, and the courts do not question the validity of government decrees and ordinances. The Supreme Court consists of four chambers: civil, penal, work and social security, and army.

Prosecutors

The public prosecutor's office consists of the general and *województwo* offices. These prosecuting bodies attend to law and order and the protection of public property; they start penal proceedings, supervise investigations, support prosecutions before the court, and have supervision over the execution of punishment. They are subject only to the attorney general, who is responsible for their proceedings before the Council of State.

The armed forces. The armed forces are based on general army service. Basic army service is started by men in a fit state of health from the age of 19 and by volunteers from the age of 18. Active service lasts from two to three years, after which the soldier passes into the reserve. There are, however, other ways of fulfilling active service. Students of higher schools of learning, for example, have their army training during their period of study. The armed forces are under the Ministry of National Defense (Ministerstwo Obrony Narodowej), which consists of the general staff, the political headquarters, the main quartermaster's department, and a number of lesser bodies. The ministry has command over the three army regions (Silesia, Pomerania, and Warsaw) as well as over the commanding staff of the naval forces, the Operational Air Force, the Armies of the Air Defense of the Country, the Armies of Frontier Defense, and the Armies of Internal Defense.

The armed forces consist of operational armies that are subject, in the case of war, to the command of the Warsaw Pact forces and of armies for the defense of the national territory. Officers have at least a secondary education. Officer candidates are trained in more than a dozen schools, and professional officers can acquire a higher education at one of the five army colleges or at civilian higher schools of learning.

Education. Education is based on the following principles: schools of all types and on all levels are free; the system of schooling is standard; and attendance throughout the 10-year primary school course and at supplementary study until the age of 18 is obligatory.

The first grade of schools is nursery schools, for children between the ages of three and six. They serve 45 percent of the children in this age group. The 10-year primary schools, for ages seven to 14, number about 18,000, with around 4,500,000 children in attendance. Secondary schools can be divided into four-year grammar schools, art schools, five-year professional and technical schools, two-year agricultural schools, and three-year professional schools (with the possibility of continuing studies in a three-year technical school).

Secondary schools

Basically, all schools are subject to the Ministry of Education, but medical schools and colleges are subject to the Ministry of Health, army colleges to the Ministry of National Defense, and higher schools of art to the Ministry of Art and Culture. The highest academic institution is the Polish Academy of Sciences (Polska Akademia Nauk), with numerous research institutes. The academy represents Polish learning abroad.

Health services. Health care in Poland is largely handled by the social health service. The central body is the Ministry of Health and Social Care, which has authority over the health departments of *województwa* People's Councils. The health service is divided into clinics, hospitals, and sanatoriums, ambulance services, and the national sanitary inspection. By 1975 there were 66 hospital beds and 17 doctors for every 10,000 inhabitants, a ratio comparable to that in the United States, Switzerland, both the German states, and Belgium, and higher than that in France, The Netherlands, Sweden, Norway, Canada, and Japan.

Health insurance

Social insurance for the health service covers free treatment for all workers and the members of their families, as well as for pensioners, invalids, students, and certain others. Those insured pay 30 percent of the cost for medicines, and invalids and pensioners, as well as those suffering from certain social diseases (notably tuberculosis and the venereal diseases), receive medicines free of charge. Apart from the health service there is also a social service whose purpose is to ensure a suitable means of support for old people and invalids. There are almost 500 homes for social care, catering to pensioners, the chronically sick, and the mentally retarded; these contain more than 50,000 patients.

Housing. Municipal and housing authorities faced a mammoth task following World War II, which obliterated about a third of the national housing and sent a flood of people from rural to urban areas. The simultaneous development of industry limited the funds available for housing, so that the situation in this area has been and remains unsatisfactory. There is a shortage of living space in large urban centres and some overpopulation of the facilities available. Housing in towns is in the hands of the People's Councils and cooperative building societies; in the country, private building is dominant.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. The culture of Poland is fed by a great variety of traditions. The source of the basic folk culture is Slavic. In the early Middle Ages (specifically, in 966), however, Poland received, along with Christianity, elements of the evolving Western world view, particularly from the Roman Catholic priesthood. Czech, German, French, and Italian influences were felt. In the Humanist period the nobility and, in part, the rising mercantile classes took much from the civilizations of antiquity. The Polish-Lithuanian political union, by contacts with the Mongols and with the Turks, brought east European and Oriental influences into the heart of Poland. Various branches of culture held sway in successive centuries: in the 16th century social and political thought predominated; in the 18th century learning and education

came to the fore, to be succeeded in the 19th century by a flowering of literature and music. Until the 20th century, cultural life was mainly focussed on and supported by the nobility and, latterly, by the merchant bourgeoisie.

Fundamental changes in Poland's cultural life really occurred only after 1945, when great social changes, together with a quite different revolution wrought by the introduction of mass media, made culture available to the masses. This process contributed to the rapid decline of folk culture and its regional variations.

The ethnic basis of folk culture. The traditional folk culture of Poland is disappearing rapidly. In the Little Poland region, however, there is still a marked distinction between the Lachy (extra-Carpathian peoples) and the Górale, or mountain people (from *góra*, "mountain"). The Górale of the Podhale area, in particular, have a most distinctive folk culture, with characteristic costumes, decoration, architecture, and music. The Górale living in the Silesian part of the Carpathians form a similarly distinctive group. Also in Silesia, the folk tradition of the ancestral Polish population around Opole is very distinctive. In Great Poland, the Sieradzanie from the middle Warta, the Kujawiacy from the upper Noteć, and the Krajniacy of the Pomeranian frontier all have their own folk culture. In Mazovia, the inhabitants of the Łowicz area are noted for their costumes and decorative skills, and the Kurpie from the middle Narew, together with the inhabitants of the Opoczno area, to the north of the Holy Cross Mountains, are also significant. In Pomerania the Kashubians are the most distinct folk group, followed by the Kociewacy from the lower Wisła, and the Borowiacy from the Tuchola area. Among the Polish population of former East Prussia there is a sharp cultural distinction between the Catholic Warmiacy, from the Olsztyn area, and the Protestant Mazurians, who are very close to the neighbouring Kurpie.

Literature. The oldest traces of Polish folklore are preserved in the medieval Latin works of the chroniclers, who handed down numerous lay and religious legends. From the Renaissance period, many texts of Polish folk plays survive. The systematic collection of songs and other works, which were to prove a stimulus to much of Polish culture, was not started until the end of the 18th and the beginning of the 19th century.

Early literature

The first half of the 19th century witnessed the flowering of the three greatest Polish poets (Adam Mickiewicz, Juliusz Słowacki, and Zygmunt Krasiński), while in the second half, and at the beginning of the 20th century, the great Polish prose writers—including the Nobel Prize winners Henryk Sienkiewicz and Władysław Reymont—were active.

Music. The dance rhythms of the *krakowiak*, *mazur* (*mazurek*, *kujawiak*, *oberek*), and *polonaise* are particularly characteristic of Polish folk music. The music of the Górale of the Podhale has a different character: in contrast to the monodic, or elegiac, music of other regions, it is polyphonic, blending a number of discrete melodies. The oldest remnants of church music stem from the Middle Ages, and the most outstanding works—notably the compositions of Wacław of Szamotuły and Mikołaj Gomółka—date from the 16th century. The development of modern musical forms—symphony, opera, and chamber music—may be traced from the end of the 18th century. Folk music was a major source of musical content (as in the opera *Krakowiacy i Górale* [*The Cracovians and the Highlanders*]), and, inspired by it, the most famous of Polish composers, Frédéric Chopin, composed much of his work for the piano. In the second half of the 19th century, Stanisław Moniuszko created the popular operas *Halka*, *Straszny Dwór*, and *Hrabina* and also was a leading exponent of the solo song. At the end of the 19th century and at the beginning of the 20th, famous Polish performers came onto the world stage, the pianists Ignacy Paderewski and Artur Rubinstein heading a procession of violinists, conductors, and singers. The most outstanding composer of the first half of the 20th century was Karol Szymanowski, and contemporary Polish composers are known far beyond the national boundaries, having won many prizes in international competitions. The leading contemporary symphony orchestras—the National Philharmonic of Warsaw and the Great Symphonic Orchestra of the Polish Radio and Television, from Katowice—have also achieved international successes.

Folk music continues to be propagated by Mazowsze and Śląsk, two representative song and dance groups, and other musical forms by such chamber groups as the Capella Bydgostiensis and the Musicae Antiquae Collegium Varsoviense. Many festivals and international music competitions are held in Poland, the Chopin piano competition, which takes place every five years, being probably the best known. Poland also has a rich variety of musical societies and magazines devoted to music.

International music competitions

The visual arts. The oldest examples of the visual arts in Poland are survivals from the prehistoric period, chiefly pottery. From the Middle Ages many fine examples of Romanesque and Gothic architecture, both secular and religious, have been preserved, together with outstanding sculptures, among which the wooden altar triptych of Veit Stoss, in the Church of the Virgin Mary in Kraków, is the most famous. The architecture and sculpture of the Renaissance and Baroque periods were formed under Italian influence but nevertheless developed individual Polish forms, as, for example, in the characteristic Renaissance attics. The best preserved urban architecture of the late Middle Ages and Renaissance is that of the old town in Kraków, together with Wawel Castle. The classicism of the end of the 18th century and the beginning of the 19th left its most valuable monuments in Warsaw, as can be seen in the palace in Łazienki Park.

Painting attained its greatest development in the second half of the 19th century, representing styles developing at that time in western Europe, but again with specific national characteristics. The greatest fame was achieved by the creator of monumental historic pictures Jan Matejko, by Henryk Siemiradzki, and by a number of landscape and genre painters.

Theatre and motion pictures. A Polish religious theatre existed in the Middle Ages, with initially mystery and later morality plays. In the 16th century the court theatre, with the first native dramas, appeared. In the 17th century and at the beginning of the 18th, opera and ballet troupes, mostly foreign, performed in the courts of the kings and the magnates. Only in the reign of the last king, Stanisław II August Poniatowski, did the first public Polish national theatre come into being, first in Warsaw and later in other towns. The most outstanding figure of this period of the theatre was the actor, director, and author Wojciech Bogusławski. After the downfall of the Polish state, the theatre played an enormous part in the survival of the Polish language and spirit. Among the actors and actresses of this period, Helena Modjeska achieved major international status. In the interwar period, acting and staging in Poland reached a very high level. During the 1960s, the Polish Laboratory Theatre (the official title is Teatr 13 Rzędów, "Theatre of 13 Rows") in Wrocław gained an international reputation for its experimental work in the training of actors and in methods of theatrical production. Under the direction of Jerzy Grotowski, it toured western Europe and the United States, where many critics have acclaimed its artistic theories and its performances as representative of the most important new direction in theatre since the work of Konstantin Stanislavsky at the Moscow Art Theatre in the early decades of the 20th century.

The Polish Laboratory Theatre

The beginnings of Polish cinema date from before World War I. In 1909 the first film-producing company, Sfinks (Sphinx), was formed, and this, with others, was active in the interwar period. Film production at this period was not, however, marked by a high artistic and technical level, despite many ambitious attempts. After World War II, Polish films had a series of international successes, and particularly in the 1950s and early '60s when Andrzej Wajda and Andrzej Munk came to the forefront as directors. By the early 1970s, however, the quality of films had diminished, and the number of both cinemas and audiences decreased, a trend also observable in other countries.

Mass media of communication. The regular broadcasting of a radio program for general reception was begun by the Polish radio cooperative in 1926, and by September 1939 there were 10 radio stations and around 1,000,000 subscribers. After World War II Polish radio began anew. Experiments with television were begun in 1948, and regular broadcasting started in 1956, first in Warsaw and then in Łódź. By the 1970s the National Committee of Polish Radio and Television had at its disposal almost 20 radio stations and more than half a dozen television centres. On a ratio per thousand people, however, Poland still held a low place among European countries in respect of subscribers to radio and television.

The press

The beginnings of the Polish press date from the 16th century, when irregularly printed information sheets and leaflets began to appear. In 1661 the first permanent periodical, the *Merkuriusz Polski Ordynaryjny* ("Current Polish Mercury"), was published in Kraków. The growth of the periodical press continued through the period of foreign domination, and before World War II there were more than 2,500 publications, some of them in the languages of minority groups, although average circulation was small. The most readable daily, the *Ilustrowany Kurier Codzienny*, had a circulation of only 150,000. By 1975 the leading dailies were *Trybuna Ludu* (organ of the Polish United Workers' Party), *Życie Warszawy* (independent), *Dziennik Ludowy* (organ of the Supreme Executive of the United Peasant Party), and *Kurier Polski* (organ of the Democratic Party). Most of the dailies, and political and social writings generally, are issued under the Prasa imprint, and distribution is in the hands of Ruch, a nationwide group.

PROSPECTS

Poland is a proud country with roots deep in the past. Its cultural life, in particular, has been very rich, drawing on a thousand years of tradition and sustaining the national spirit when Polish frontiers and indeed the Polish state collapsed as a result of the country's unfavourable historical and geographical position. Since the blows suffered during World War II, the government has attempted to build a new state without losing sight of tradition. By the 1970s much had been accomplished in economic growth, especially in heavy industry, and in reform of education and cultural life. But, as Polish experts acknowledged, much remained to be done in both economic and social life to raise standards to those of western Europe. (J.A.K./A.H.D.)

BIBLIOGRAPHY. The quinquennial *Poland, a Handbook* is a comprehensive outline of the country and its society issued by the government of Poland; an extensive list of Polish-language publications available in English translation, *Polish Books in English, 1945–1971* (1974), compiled by JANINA HOSKINS, was issued by the U.S. Library of Congress; the basic Polish source is KAROL J. ESTREICHER, *Bibliografia Polska* (39 vol., 1870); the most extensive reference work is the *Wielka Encyklopedia Powszechna PWN*, 13 vol. (1962–70), published by the Polish Academy of Sciences; R.H. OSBORNE, *East Central Europe*, ch. 8 (1967), a concise geographical summary of facts about the land and its people; INSTITUTE OF BRITISH GEOGRAPHERS, *Problems of Applied Geography: Proceedings of the Anglo-Polish Seminar, Keele, Sept. 9–20, 1962* (1964), contains important contributions on contemporary industrialization and urbanization in Poland and on their influence on land use and agriculture; J. BOGUCKI, *The Fine Arts in Poland Today* (Eng. trans. 1967); J.Z. LOZINSKI and A. MILOBEDSKI, *Guide to Architecture in Poland* (Eng. trans. 1967), includes an introductory outline that concisely describes the development of architecture in the territory that constitutes Poland today, with maps of selected architectural monuments and a list of all the buildings located; J.C. FISHER (ed.), *City and Regional Planning in Poland* (1966), a comprehensive record of city and regional planning in Poland from theories and methods to specific case studies; *Polish Statistical Yearbook*, up-to-date statistics published annually.

Poland, History of

Poland is a nation whose often tragic history is yet coloured by past eminence and a vital role played in European history. Emerging from a loose union of Slavic tribes in the 9th century, Poland had become by the late Middle Ages a virtual empire with the highest level of civilization in eastern Europe; it was a bulwark of the Roman Catholic faith there. Polish political theory, culture, and science had a vitalizing effect on the mainstream of European thought, and ideals such as religious toleration were pioneered in Poland at a time when most of Europe was engaged in bitter persecution. Although it virtually disappeared as a state after the three partitions of the late 18th century, Poland was re-established after World War I. Its invasion by Germany in 1939 was the event that marked the outbreak of World War II.

This article is divided into the following sections:

I. Poland during the Middle Ages, 966–1492
- The founding of the Piast Kingdom, 966–1025
- Unity and disintegration, 1025–1241
- The Mongol invasions and the re-establishment of the kingdom, 1241–1382
- The Jagiellon dynasty, 1382–1492

II. The Polish Commonwealth, 1492–1795
- The "Golden Age" of the Polish-Lithuanian Empire, 1492–1572
- The "Silver Age" of the Royal Republic, 1572–1648
- The Iron Era period of wars and disintegration, 1648–97
- The Saxonian era and the Russian protectorate, 1697–1763
- Reform and partition during the reign of Stanisław II Augustus Poniatowski, 1764–95

III. Poland under partition, 1795–1914
- Foreign rule and the Duchy of Warsaw, 1795–1815
- The Kingdom of Poland and the other Polish lands, 1815–31
- Russian reprisals and the January Insurrection, 1831–64
- The founding of modern Poland, 1864–1914

I. Poland during the Middle Ages, 966–1492

THE FOUNDING OF THE PIAST KINGDOM, 966–1025

Early origins. The Poles belong to the North Indo-European language group comprising the Slavs, the Balts, and the Germans. The primordial homeland of the Slavs can be located in the immediate vicinity of the most ancient settlements of the Germans and Balts, the area occupied by the "Poles" lying in the basins of the Oder and Vistula rivers. The Polish nation originated from a union of such West Slavic tribes as the Polanians (Polanie), Vistulans (Wiślanie), Silesians (Ślęzanie), East Pomeranians (Pomorzanie), and Mazovians (Mazowianie). These "Polish" tribes shared a basically common culture and language and were much more closely related to each other than, for example, the Germanic tribes who founded the Franconian or German kingdom about 800–1024. Chronicles and geographical descriptions of Carolingian, Saxonian, Arabian, and Byzantine origin have described in some detail these Polish tribes, their names, and the regions where they lived. The Polanie tribe (open-country dwellers) lived in the fertile Polish heartland crossed by the Warta River, and this was the group after which the later Polish nation was named. Besides the Polanie tribe, there were approximately 20 Polish tribes that formed small states between the years 800 and 960. The individual tribes owed allegiance to regional leaders, chosen from an assembly of all free Polish males as commanders in case of war. These were the beginnings from which the dynasties of hereditary kings, princes, or dukes slowly evolved. Each tribe commanded several well-fortified castles or fortresses, the larger castles developing into principalities or "castle districts." There were usually fortified city-settlements (*suburbia*) near all the larger castles even in very early times. Inhabited by artisans, workmen, and merchants, these cities also served as refuges on occasion. As early as 900–1025, along the Baltic Sea coast, there were large trading centres with between 6,000 and 10,000 inhabitants; these included Wolin (Wollin) and Szczecin (Stet-

The Polanie tribe

tin), on the mouth of the Oder River, and Truso (later Elbląg) and Gdańsk (Danzig), founded before 990 on the mouth of the Vistula River. The ancient foreign trade routes linking this area with distant regions stimulated the founding and development of small states. The most significant trade route from East to West connected Ratisbon (now Regensburg)–Vienna and Cracow with Kiev and Byzantium (now Istanbul). A well-developed monetary exchange system made it possible for the individual dukes to raise tariffs and tributes, in this manner exerting their sovereign rights on the monetary economy. In all probability, mining of precious metals and iron ores must have taken place in Upper Silesia and in the Polish Central Highlands at that time.

Because of its advantageous location with regard to foreign trade, the region grew into a larger state under the dynasty of the Wiślanie (or Vistulans). One of the dynasty's dukes was described as very powerful as early as 875, and, in all probability, his rule already extended over the Lędzianie (who lived either on the upper Vistula or the upper Warta River) and perhaps even over some of the East Slavonic tribes on the Bug and San rivers. Around 875 to 880 his state and Silesia came under the sovereign rule of the Great Moravian Empire, led by Prince Svatopluk (ruled 870–894). Under his reign, Christianity was introduced in both its Latin and Greek forms through the disciples of "the apostles of the Slavs," Cyril (died 869) and Methodius (died 885). Destroying the Great Moravian Empire, the Magyars conquered and settled the Hungarian lands from about 896 to 907. This restored the independence of southern Poland for a short time until it came under the control of the Bohemian dukes Boleslav I (died 972) and Boleslav II (ruled from about 973 to 999).

Introduction of Christianity

Both the Latin and Eastern Orthodox faiths were already well established in the area by this time, and the first bishopric of Cracow was established in 969. Even though nothing is known about a local dynasty, a territorial association was formed a few decades later, consisting of the tribes of southern Poland, commonly known as Little Poland (Małopolska). Little Poland, with the exception of a few border regions, covered the same area as the bishopric of Cracow.

The Piast dynasty. The second and politically more important founding of a state took place under the Polanie dynasty. The descendants of "Piast," the legendary founder of the dynasty—Siemowit (Ziemowit), Leszek (Lestko), and Siemomysł (Ziemomysł)—united the lands around Poznań, Kruszwica, Gniezno, and Kalisz, and this region later became known as Great Poland (Wielkopolska).

Mieszko I, c. 963–992. Siemomysł's son, Mieszko I, was the first of the Piast dukes to have his biography recorded in detail in the chronicles of that time. Through his desire to conquer Western Pomerania along the Oder River to the trading cities of Szczecin and Wolin, Mieszko I came into contact with the German kingdom, whose ruler Otto I the Great (the Holy Roman emperor) had conquered and subjugated Bohemia in 950 and all the Polabic tribes (between the Elbe and the Oder rivers) between 936 and 955. This extended the sovereignty of the German king to the Oder River, and, for the time being, Mieszko acknowledged Otto's supremacy and entered into a close trade and cultural relationship with the Duchy of Saxony, Otto's homeland. To counter the German threat, Mieszko I entered into an alliance with the Bohemian duke Boleslav II, marrying his sister, Dubravka (Dąbrówka), in 965. Baptized in 966, he promoted the general spread of Christianity in his lands, although a few small Christian communities had already been in existence. In consequence, the year 966 is considered to be the year that marks the founding of Poland. The bishopric of Poznań was established in 968 and placed under the sovereignty of the archbishopric of Magdeburg. During the Great Slav Rebellion in 983, Germany lost its territory east of the Elbe and Saale rivers. In tacit agreement with Germany, Mieszko I conquered the entire coastal region of the Baltic Sea, including Szczecin, during 967 to 990. After dissolving his treaty with Bohemia, he further added Silesia and Little Poland to his other conquests. This established Mieszko as the ruler of an empire covering about 96,500 square miles (or 250,000 square kilometres) and populated by 1,250,000 people. Poland was now larger and more powerful than the Scandinavian countries, Hungary, or Bohemia. Of decisive importance for the later development of internal unity was the fact that Mieszko submitted to the formal supremacy of the Holy See in Rome around 990. He took this step in order to avoid being subjected to the authority of the German Church.

Bolesław I the Brave, 992–1025. The eldest son of Mieszko I, Bolesław, further enlarged his empire, going beyond the ethnic boundaries of the Polish tribes. With Bolesław's help, the Holy Roman emperor Otto III set up his own Polish metropolitanate (church province), with the bishoprics of Cracow, Wrocław, and Kołobrzeg and the archbishopric of Gniezno, at the Congress of Gniezno (1000). The first bishop of Prague, Adalbert (Voytěch), became the national patron saint of Poland in that year, following his martyrdom in 977 during his missionary work with the heathen Prussians in Samland in east Prussia. When Otto III died, Bolesław I conquered Bohemia, Moravia, the German borderlands in Lusatia (Lausitz), west of the Oder River, and probably also Slovakia between 1003 and 1004. But the new king of Germany, Henry II (ruled 1002–24), reconquered Bohemia and also led three campaigns against Bolesław I, without success. In 1018 Bolesław turned east, occupying Kiev for a short period and regaining the borderland at the Bug and San rivers, which had belonged to Poland before 981. Bolesław I was crowned king (presumably with the consent of the Holy See in Rome) in 1024–25, and the new kingdom became gradually known under the name of Poland (Polonia) even during his reign. After his death the Polish monarchy came to be the secular symbol of the country's unity, in spite of all the partitions and divisions that the future held in store.

UNITY AND DISINTEGRATION, 1025–1241

Attempts to expand Polish domination. *Mieszko II Lambert, 1025–34.* One of the younger sons of Bolesław I, Mieszko II Lambert was well educated but did not possess the strategic and statesmanlike talents of his father. After victorious campaigns against the barbarian Polabs in 1030, he attacked the German king Conrad II, who, in alliance with the Russian grand prince Yaroslav of Kiev, attacked Poland (1031), further supported by rebellions within the country. Eventually, about 1033, Mieszko was forced to recognize German supremacy. His death in 1034 thus came at the height of a crisis. The boom in foreign trade that had been a factor in the establishment of the Piast empire had come to a close; the regional overlords were in a state of rebellion, and the barbarian insurrections deeply affected the barely established organization of the church. Chaos followed for the next few years (1034–39), the Bohemian duke Bretislav I occupying Silesia, totally devastating Great Poland, and resettling many of its inhabitants in Bohemia. The coastal regions from Szczecin to Gdańsk seceded from the Polish crown for about a century. The bishopric of Kołobrzeg—and with it the entire Christian movement in Western Pomerania—foundered again.

Defeat of Mieszko II

Casimir I the Restorer, 1039–58. A former monk, Casimir (Kazimierz) I slowly restored Poland with the help of the German king Henry III. Both Great Poland and Little Poland recognized Casimir I as their duke in 1039–40. Mazovia followed in 1047 and Silesia recognized him in 1050, but Casimir had to pay tribute to Bohemia for Silesia.

Bolesław II the Bold, 1058–79. Casimir's successor, Bolesław II, continued the power politics of Bolesław I, leading many successful campaigns into Hungary (1060–77) and Kiev (1068–77). He also maintained the independence of Poland from Germany by skillfully taking advantage of a controversy between the German king Henry IV and Pope Gregory VII. With the help of the Pope he also renewed the crown of Poland. But after Henry IV had regained power (1077), a party of Polish

nobles rebelled in his favour against Bolesław. For reasons unknown, Bolesław had decreed the execution of Bishop Stanisław of Cracow in 1078, and this led to open rebellion. Bolesław was forced to flee to Hungary, where he died in exile in 1081. His younger brother Władysław I Herman (1079–1102) sided with the imperial party and in 1088–89 married Judith, Henry's sister, and relinquished all claims to the Polish crown.

Exile of Bolesław II

Bolesław III the Wry-Mouthed, 1102–38. Władysław's younger son, Bolesław III, again strengthened the position of the Polish monarchy, expelling his elder brothers and his half brother Zbigniew (1107). Two years later he drove back a campaign of the German king Henry V into Silesia. In difficult campaigns, he reconquered all of the Western Pomeranian lands during 1113–22 and incorporated Eastern Pomerania and Gdańsk into Poland. Bolesław then ordered the final and complete Christianization of Western Pomerania and forced Polish rule on the land of Lubusz (Lebus), on the Oder, thus restoring the previous boundaries of the empire of Mieszko I. But the German emperor Lothair finally pushed the German frontier to the banks of the Oder and the western shores of the Neisse (Nysa) River. Bolesław was forced to swear allegiance to Lothair in return for Western Pomerania and the island of Rügen in 1135.

The period of division. Endeavouring to reconcile the separatist demands of the provinces with the needs of national unity, Bolesław III divided Poland among his sons, with the result that Poland ceased to be a united state for two centuries. The eldest son, who was already prince of Silesia and also owned Pomorze (Pomerania), was to have seniority over his brothers and rule over "the land of the senior," with its capital in Cracow; this territory stretched from western Little Poland to central Poland and on to the Baltic shore (eastern Pomerania and Gdańsk). His brothers ruled over Great Poland with Poznań and western Kujavia; Mazovia (in the basin of the middle Vistula) and eastern Kujavia (within the Vistula bend); and Sandomierz (east of Little Poland).

The seniority system. A "seniority constitution" was also introduced with this arrangement, but the plan immediately led to strife. The first "senior," Władysław II the Exile (1138–46), was forced into exile and fled to Germany. His brother Bolesław IV the Curly, hereditary duke of Mazovia, asserted himself as senior between 1146 and 1173, but this led to conflict with the German emperor Frederick I Barbarossa, who intervened twice (1163 and 1172) to secure Silesia for the sons of Władysław II. Władysław's sons divided it among themselves and founded the lineage of the Silesian Piasts; yet another son became the third senior. Of these sons, Mieszko III the Old (1173–77) was exiled from Cracow during a rebellion in 1177 but succeeded in retaining his hereditary land, Great Poland. His youngest brother, Casimir II the Just (1177–94), succeeded as senior after him and, in 1186, also acquired Mazovia, thus becoming the ancestor of the Mazovian line of the Piasts. After the Congress of Łęczyca in 1180, the land of the senior—Little Poland with its capital, the city of Cracow—became a hereditary land like the other lands. Both Pope Alexander III and the emperor Frederick I recognized this decision, but one of its great disadvantages was that the internal unity of Poland would be constantly exposed to foreign hereditary claims as a result. Leszek the White was the last duke who claimed the honour of senior with some success, but he was assassinated together with other Piast dukes in 1227.

The reigns of Mieszko III the Old and Świętopełk I

Territorial losses. The internal disintegration of Poland led to the secession of the lands along the Baltic Sea and other border regions. Bogusław I (who ruled about 1156–87), the son of Warcisław I, was forced to yield Western Pomerania to the Danish crown. Even the reigning governor of Eastern Pomerania and Gdańsk, Świętopełk I (died 1266), took advantage of the weakness of the Piasts. Instrumental in the assassination of Leszek the White, he asserted his country's independence and styled himself sovereign duke of Eastern Pomerania, though regarded as a usurper by the Piasts.

The Teutonic Order. The establishment of the Order of the Teutonic Knights, a German crusading organization that had lost a sphere for its activities in Palestine, was of dangerous consequence for Poland. His lands harried by heathen Lithuanians, Jatvingians, and Prussians, Duke Konrad I of Mazovia (died 1247) called for help from the Teutonic Order in 1225–26, leaving them the lands of Chełmno (Kulm) east of the lower Vistula River as a territorial base for combat and control of the Prussians in 1228–30. The grand master of the Teutonic Knights, Hermann von Salza, received sovereign rights over the "masterless heathen country" of the Prussians in the Golden Bull of Rimini (1226) from the emperor Frederick II and in the Privilegium of Rieti (1234) from Pope Gregory IX. His Order then tried to create an independent state, in spite of Konrad I's claim to sovereignty over the land. In the event, the Order established a system of local government in Chełmno and in Prussia. The subjugation and Christianization of Prussia was completed by 1283. The Teutonic Order soon became the principal military power in Europe, for it was in possession of about 20 provinces (bailiwicks) in Germany and Italy alone and received reinforcements from all the knightly bodies in Europe for its wars.

Supremacy of the Teutonic Order

Internal developments. In Poland the era of knighthood, from about 1025 to 1241, saw the emergence of a Latin church organization and, in architecture, the development of the Romanesque style. By now the Polish aristocracy owned large landed estates and also occupied the most important administrative positions at court and in the provinces. With the division of the country into six to nine provinces and the continuous partition of the country itself from 1138 on, similar posts were also established within each individual duchy. The division into castle districts, each under a feudal baron, remained within the individual sections of the country. Fortified by mighty ramparts, the cities were under the patronage of the chief castles. The internal unity of the Polish nation remained intact in spite of the many partitions and, in accordance with Polish law, the dukes exercised no personal power but a collective sovereignty. From about 1058 Cracow was considered the common capital for about five centuries. The most important protector of the unity of Poland was the metropolitanate of Gniezno. The church supremacy of Magdeburg was once again postulated in 1133, but it was definitely rejected and Gniezno won recognition as its own church province. The archbishopric of Gniezno held the largest estates in Poland (1136), controlling 149 cities and villages. The oldest monastery of Poland was established about 1044 in Tyniec (near Cracow) by the Benedictines. The Order of the Cistercians led the second wave of founding monasteries, mainly from Morimond (Burgundia) and Altenberg (near Cologne).

THE MONGOL INVASIONS AND THE RE-ESTABLISHMENT OF THE KINGDOM, 1241–1382

The Mongol invasion (1241–42), in Poland's period of division, turned the tide of Poland's history. The Mongol leader Batu Khan first conquered Kiev and most of the Russian principalities before defeating the Polish army at Chmielnik and the Silesian knights of the Teutonic Order at Legnica (Liegnitz; 1241). This frustrated the attempt of the two Silesian dukes Henry I (1201–38) and Henry II (1238–41) to unite all the Polish lands. The Mongols retired in 1242 in order to elect a new great khan in Mongolia but still remained masters, for another 50 years, of Red Ruthenia (Red Russia), east of Little Poland; from this base their repeated raids devastated Poland. Meanwhile, Great Poland and especially Mazovia suffered from raids by the heathen Lithuanians (1246–1307) and Jatvingians (1248–82). The Mazovian border region around Drohiczyn on the Bug River was lost to Mongol Red Ruthenia around 1241–52, and the land of Lubus with its river passage across the Oder River to the Askanians of Brandenburg, about 1249–52.

The Mongol raids

Attempts at reunification. When Bishop Stanisław was canonized in 1253, Poland acquired a new national patron saint whose cult spread rapidly in the church province of Gniezno. As part of the community of the Holy See, Polish church members contributed the special levy,

Peter's Penny, to Rome. The Synod of Łęczyca (1285) further promoted unity by demanding the advancement of the Polish language. The Bohemian king Vaclav II (1278–1305) attempted a new dynastic reunification of Poland. Establishing his sovereignty over most of the Silesian duchies around 1289–91, he also gained supremacy over the Duchy of Cracow in 1291–92.

Przemysł II. His opponent was Przemysł II (1279–96), who had reunited Great Poland (including Gniezno) in 1279 and Eastern Pomerania in 1294 and who became the first Piast duke to regain direct rule over more than just a sector region. His coronation by the archbishop in 1295 in Gniezno re-established the kingdom of Poland. Przemysł was assassinated in 1296, however, presumably at the instigation of the Margrave of Brandenburg.

Re-establishment of the kingdom

Vaclav II. Vaclav (Wacław) II (1300–05) of Bohemia, who succeeded him as king, ruled over about two-thirds of all Polish territory. Vaclav II himself considered these lands as almost an extension of Bohemia and, consequently, as part of the Holy Roman Empire. His early death in 1305 and the assassination of his son Vaclav (Wacław) III the following year left both the Polish and the Bohemian thrones vacant.

Władysław I the Short, 1314–33. The opportunity had now arrived for the minor Piast prince Władysław the Short to establish himself. Władysław cleverly availed himself of the support of Hungary and the traditional protection of the Holy See. He occupied Little Poland in 1305 and sought the help of the Teutonic Order to regain Eastern Pomerania in 1308. The Teutonic Knights, however, bought the interests to these lands from the Brandenburg rulers and established themselves as the legal authority, incorporating Eastern Pomerania into Prussia. By 1314 Władysław had secured Great Poland, and in 1320 he was crowned king of Poland as Władysław I with the consent of the Roman Curia. This act restored the Polish Crown through a national dynasty, and for the next 475 years the crown was to remain the symbol of unity for Poland. The Piast dukes welcomed immigrant Germans and Flemings into Polish territories, and resettlement took place according to the municipal law of Magdeburg, based on German law, which was applied first to the great old cities of Wrocław (1241), Poznań (1253), and Cracow (1257).

Struggle against the Teutonic Order. The new king Władysław I, faced the opposition of a coalition between Bohemia and the Teutonic Order. The new Bohemian king, John of Luxemburg, laid claim to the Polish crown, and almost all of the Piast dukes in Silesia had recognized him as their feudal lord by 1327–29. Only the little principality of Wieluń (1321–29) was loyal to Władysław I. He instituted lawsuits against the Teutonic Order for the sovereignty of Eastern Pomerania but without success. The Teutonic Knights and the Bohemians terribly devastated Great Poland, especially in the war of 1328–32.

Alliance with Hungary and Lithuania. At the Battle of Płowce (1331), however, Władysław drove them back and, in alliance with Hungary and Lithuania, secured Poland. Ties with Hungary were strengthened by the marriage of Władysław's daughter Elizabeth (Elżbieta) to the new Angevin king of Hungary, Charles I, in 1320, and the Polish crown prince Casimir (Kazimierz) was married to the Lithuanian princess Anna (Aldona) in 1325, thus creating a pact with Lithuania.

Casimir III the Great, 1333–70. Władysław's son Casimir was a highly talented statesman and administrator. During the congresses of Trenčin and Vyšehrad in Upper Hungary (Slovakia), he persuaded John I of Luxemburg to relinquish his claims to the Polish crown. In return, after an unsuccessful campaign in 1348 and in face of the Silesian Piast dukes' support of the Bohemian crown, Casimir was forced to renounce finally all demands on Silesia, the country's most densely populated and wealthiest region. In the Treaty of Kalisz in 1343, Casimir relinquished all claims to Eastern Pomerania in favour of the Teutonic Order—for the time being. Instead, he coerced the Piast dukes of Mazovia to recognize him as their overlord and seized parts of Mazovia. He also regained some of the lands in the west that had been annexed by Brandenburg. Between 1340 and 1352 Casimir won Red Ruthenia with the cities of Przemyśl, Lwów (Lvov), and Halicz; and in 1366 he extended his rule over the Ruthenian principalities of Chełm, Betz, Włodzimierz, and Podolia. Poland had now become a power, and at the Congress of Cracow, Casimir functioned as a mediator between Emperor Charles IV of Bohemia and Louis (Ludwig) I of Hungary. Casimir died in 1370 without a male heir, but in his will he appointed his grandson Casimir to be prince of Pomerania and awarded him parts of the Polish territory to tie Western Pomerania to Poland.

Treaty of Kalisz

Louis I of Hungary, 1370–82. Poland nevertheless remained a unified kingdom under Casimir's successor, his nephew Louis I of Hungary. The only losses were some border areas annexed by Brandenburg and Lithuania. Louis, however, regarded Poland as his secondary kingdom, and a specially appointed governor took over the administration of Halicz Ruthenia. The Polish aristocracy, a deciding factor in the succession to the throne of Poland in 1370 and 1382, obtained from Louis the grant of special privileges at Košice (Kaschau; 1374), which formed the basis of a Polish "Magna Carta."

Internal developments and reform. *Construction of cities and buildings.* The years from 1320 to 1382 marked the founding of new cities. During the reign of Casimir the Great, as many as 47 new cities were founded in Little Poland and 32 in Great Poland. Casimir also established local courts of justice for the cities of Little Poland (1356) and Great Poland (1365), in order to separate his country from the jurisdiction of Magdeburg and the need for its appellate court. A great builder, Casimir was said to have found a country of wood and left a country of stone: he ordered the construction of 53 castles and fortifications for 27 cities, and during his reign numerous Gothic town halls and merchant houses were erected.

Role of the nobility. Even though a new social class of burghers and merchants evolved in the cities of Poland, the aristocracy remained the most influential group in politics. The first confederation of nobles in Polish history was founded in Great Poland in 1352–56. Since the previous official positions in the separate palatinates of Poland had long before become the benefices of the aristocracy, Casimir and Louis appointed a governor (*starosta capitaneus*) for each section of the country, after the example set by Vaclav II (1291). The office of *starosta* remained the most important branch of executive power during the next 470 years. In the Statute of Wiślica (about 1346) Casimir codified the law that was in force in Little Poland. This *jus Polonicum*—the law of the nobility (as opposed to the *jus Teutonicum*, which was the law for the burgher-peasant population of Poland)—was later extended and applied throughout Poland, including Red Ruthenia and Podolia.

The church. The Catholic Church influenced the character of public life in Poland. Poland had lost Silesia in 1348, but the Silesian bishopric of Wrocław remained under the church authority of Gniezno for another 400 years. The Dominican, Franciscan, and Augustine mendicant preaching orders had already built 80 monasteries in the metropolitanate of Gniezno by 1382. Yet, in spite of the power of the Catholic Church, the ideal of religious tolerance became so entrenched in the consciousness of the Polish people that Casimir the Great found it advisable to establish it as one of his basic policies. In addition to Gniezno, the metropolitanate of Halicz-Lwów was established; and a separate Eastern Orthodox metropolitanate in Halicz (later Lwów), and an Armenian bishopric (later archbishopric) of Lwów were founded. Casimir's kingdom was the only continental European country where several Christian creeds were able to live side by side for any length of time two centuries before the Reformation.

Religious tolerance

Protection of the Jews. Casimir the Great also provided, with the Statute of Wiślica (1346), protection for the Jews from pogroms and ritual murders at the hands of the Christians. When the Black Death raged through the German lands between 1348 and 1352, over 300 Jewish communities were either destroyed or expelled from their

homelands. The survivors migrated to Poland. Ever since, the majority of Polish Jews has consisted of Ashkenazim (from Germany). Retaining their own Middle High German language—later evolved into Yiddish—most of the Jews rejected any language assimilation until their near extermination by the Nazis during World War II. The Poland of Casimir thus developed into a cosmopolitan empire: Poles, Germans, Ruthenians, Flemings, Walachians, Jews, Armenians, and even Tatars and Karaites living together. There were then about a dozen official languages of administration and worship. Religious and political tolerance was reflected in the founding in 1364 of the University of Cracow, after Prague the second oldest university in Central or Eastern Europe, whose brilliant faculty of law prepared for the later juridical thinking during the Renaissance in Europe.

Founding of the University of Cracow

THE JAGIELLON DYNASTY, 1382–1492

Jadwiga and Władysław II Jagiełło. The union between Poland and Hungary was broken with the death of Louis because the Hungarian aristocracy chose his eldest daughter, Maria, to be their queen, whereas the Polish aristocracy gave preference to his ten-year-old daughter Jadwiga (1384). This was the first step in the direction of developing an elected Polish monarch. The Polish aristocracy favoured a dynastic alliance with Lithuania, especially in order to regain Red Ruthenia and Podolia, which had become estranged from Poland under Louis's regime.

Union of Poland and Lithuania. The grand duke of Lithuania (from 1377 to 1401), Jagiełło (Iogaillas), was still a heathen; but after adoption by the widow queen Elizabeth in the Union of Krewo (1385), he was married to the crown princess Jadwiga. Jagiełło thus accepted the Catholic faith and became the recognized "Master and King of Poland" under the assumed name of Władysław II Jagiełło in 1386. This procedure created a Polish–Lithuanian union, a union that continued under the Jagiełło dynasty during the following 183 years. But the effect was that Poland was able to incorporate, during 1385–86, a state about four times as large as the original Polish realm. The bishopric of Wilno was established in 1387 to convert the Lithuanian people to the Catholic faith. Another area belonged to the Eastern Orthodox Church. The polyethnic, multireligious, and legal-constitutional structure of the Jagiełło empire was more complicated than ever before. The authority of Władysław II also included the old Russian capital Kiev, which had come under Lithuanian suzerainty in 1366 and was now reduced to the status of a residential border town, set up as a buffer against the Mongols and Tatars. To the southeast of these lands stretched more than 58,000 square miles (or about 150,000 square kilometres) of almost uninhabited steppe country, which belonged to Lithuania in name only. The annexation of Lithuania secured the eastern boundaries of Poland against the attacks of the Mongol and Tatar tribes as well as against those from the great principality of Moscow, then under Mongol and Tatar control. It meant also, however, that Poland had to defend Lithuania against the incursions of the Teutonic Order. With the help of the Lithuanians (1387), Poland was able to renew the incorporation of Red Ruthenia and Podolia and to assert its authority over the principality of Moldavia (1387–1497), until then a minor country under Hungarian rule. This meant access to the direct trading route to the Orient, and Poland now became a partner in the rich Oriental commerce that flowed via the cities of Kaffa (Feodosia, in the Crimea) and Akkerman (now Belgorod-Dnestrovsky).

Władysław II and Vytautas. Władysław II and Jadwiga reigned together until Jadwiga's death in 1399. Władysław then ruled as the sole king of Poland (1399–1434). In Lithuania, Władysław found it expedient to acknowledge his cousin Vytautas (Witold; 1392–1430), first as governor, then as duke (1401), and finally as grand duke of Lithuania (1413). But he himself kept supreme command. To free his hands to attack the Tatars and annex Moscow, Vytautas surrendered the Duchy of Samogitia (Żmudź), which linked the Teutonic Order lands of Prussia and of Courland, to the Teutonic Order in 1398 in return for the cessation of all hostilities between them. He suffered a grave defeat in 1399, however, on the Vorskla River against the Mongols of the Golden Horde, which ended Lithuania's eastward expansion. Vytautas also supported rebellions in the still pagan Samogitia (1401 and 1409), which prompted the Teutonic grand master Ulrich von Jungingen to declare war against Władysław II in 1409. The Teutonic Knights suffered a decisive defeat in the Battle of Grunwald (Tannenberg) in 1410, which broke the power of the Teutonic Order. The first Treaty of Toruń (1411) returned Samogitia to Lithuania; the return of Eastern Pomerania to Poland was discussed at the Council of Constance (1414–18) and was a factor in two later wars (1421–22 and 1431–35), but the Order remained in possession of the territory. When the Protestant Hussite rebellion broke out in 1419, Władysław II favoured the Hussites, even promoting his relative Sigismund (Zygmunt) as the Hussite candidate for the Bohemian throne in 1422. Because this brought him under suspicion of being a heretic and friend of the heathens, Władysław felt obliged to issue the strong Edict of Wieluń in 1424, against Hussite trends among the Polish nobility, and he crushed a pro-Hussite confederation of the lower Polish nobility in 1438–39. Władysław had obtained 16 mainly German mountain cities in the Spisz (south of the High Tatra Mountains) in 1412, thus giving Poland a share in the mining activities of upper Hungary, the richest in Europe at that time.

Defeat by the Mongols

Edict of Wieluń

Władysław III, 1434–44. Władysław II was succeeded on his death by his ten-year-old son, Władysław III, the chief position in the realm being held by the most eminent of the Cracow magnates, Zbigniew of Oleśnica, bishop of Cracow and one of the previous king's chief advisers. Władysław III renewed the Polish–Hungarian union with the help of the Hungarian commander in chief János Hunyadi (1443–44). Under the influence of the strongly Catholic Zbigniew of Oleśnica, he organized a crusade in order to save Byzantium, which was then threatened by the Ottoman Empire. Władysław died when only 20 in the catastrophic defeat of Varna (1444) on the coast of the Black Sea. The Ottoman troops conquered Byzantium in 1453 and marched immediately against Hungary. The threat was delayed for some decades, however when Hunyadi defeated the Ottomans in 1456. But the Hungarian imperial administration of Hunyadi terminated the Polish–Hungarian union.

Casimir IV Jagiellończyk, 1447–92. The younger brother of Władysław III, Casimir, had been ruling as the grand duke of Lithuania since 1440, but it was only after a long interregnum in Poland that he was finally recognized as the king. He signed a treaty with Moscow that established the Lithuanian boundary about 90 miles (150 kilometres) west of Moscow. This secured the eastern boundary for 37 years. The peace in the east became important when, in 1454, uprising against the rule of the Teutonic knights broke into the open, led by the cities of Gdańsk, Toruń, and Elbląg, which requested Casimir IV to integrate the Prussian–Eastern Pomeranian lands of the Teutonic Knights with Poland (1454). This marked the start of the Thirteen Years' War against the Teutonic Order. The second Treaty of Toruń (1466) recovered for Poland the former Eastern Pomerania (which received the new name of Royal Prussia), along with the bishopric of Warmia (Ermland). The rest of the territory of the Teutonic Knights acknowledged the king of Poland, and Königsberg became the new residence of the Order's grand master. Poland won back the access to the Baltic Sea that it had lost in 1308–09, and Polish rule now stretched from the Baltic Sea to the Black Sea for a period of 32 years. Poland became a trading partner with access to the most profitable trading routes crossing the European continent.

Extension of Polish rule

Extension of the empire. The King's main interest still lay with the so-often-attempted union with Bohemia and Hungary. Casimir IV succeeded in temporarily acquiring the Kingdom of Bohemia in 1471 (finally acquired 1478–79), for his oldest son Władysław (Vladislav). The smaller Bohemian lands, Moravia and Silesia, remained

under the rule of Matthias I Corvinus, the son of János Hunyadi. But after the death of Matthias, even Moravia, Silesia, and Hungary finally recognized Władysław as their king (1491–92). The result of this dynastic union was the creation of one of the largest empires in Europe. By 1491–92 Casimir IV controlled an area of at least 336,000 square miles (870,000 square kilometres), while his son Władysław ruled the Bohemian lands of the crown of Vaclav and the Hungarian lands of the crown of Stephen, an area of at least 174,000 square miles (450,000 square kilometres). This agglomeration of states was, however, as much torn by internal strife as it was exposed to external danger—the greatest external threat coming from the Ottoman Empire and its ally, the tsar of Moscow.

Growth of the power of the nobility. Political authority in Poland was gradually taken over by the aristocracy. Aided by the mechanism of the election of kings, the many wars, and the tax exemptions, they were able to slowly reorganize the kingdom into a monarchy of the estates. The main organ of aristocratic authority was the Privy Council (1385–1493), which became the Senate after 1493. The rights and privileges of the nobility were successively established between 1422 and 1433, securing for them the right to a voice in political matters, their factual exemption from taxation, and finally the political and judicial maxim of habeas corpus, or no imprisonment without trial. After the Union of Horodło (1413), the regional assemblies slowly grew into provincial diets (*sejmiki*), becoming recognized as standing establishments in all parts of the country with the Privilegium of Nieszawa (1454). In addition to the Polish diet (*sejm*), the Prussian diet held a special position with its own particular law. The lower nobility represented its own interests (which were usually directed against the special hegemony of the aristocracy) through elected delegates.

Privileges of the nobility

Development of parliamentarianism. These delegates marked the beginning of parliamentarianism in Poland when they assembled for the first time in a House of Legates at Piotrków (1493). After this, the Polish Senate became the upper house and the House of Legates became the lower house of the Polish Parliament, of Sejm. Lithuania also absorbed the culture and the system of government of Poland through the German municipal laws, introduced by the Polish burghers. According to the statutes of 1386–87, at first only the newly converted Catholic nobles were equal to the nobility of Poland, excluding the Eastern Orthodox Boyars, many of whom seceded to the Tsar of Russia. But the Lithuanian and Ruthenian nobles were gradually assimilated into the Polish sphere of interests, and in 1447–93, the first diets of the great principality were formed.

II. The Polish Commonwealth, 1492–1795

THE "GOLDEN AGE" OF THE POLISH-LITHUANIAN EMPIRE, 1492–1572

After the death of Casimir IV, his second son, John Albert (1492–1501), ascended the throne of Poland, and the two countries were temporarily separated, his third son, Alexander, becoming grand prince of Lithuania. John Albert died early, and Alexander succeeded him as king of Poland (1501–06) through the Union of Mielnik (1501). Poland and Lithuania were thus united again. A statute of 1499 called the combined kingdoms a "republic" for the first time, terming the Union of Mielnik an indivisible body. The social, economic, and constitutional union became even further consolidated under the reign of the fourth of the Jagiellon brothers (Casimir IV's sons), King Sigismund I the Old (1506–48). Ruled by the eldest of the Jagiellons, Władysław (1491–1516) and his son Louis II (1516–26), the combined Kingdom of Bohemia and Hungary remained only loosely connected with the unified Kingdom of Poland-Lithuania.

Union of Mielnik

The Ottoman incursions. The Ottoman Empire directed its attacks mainly against the unified states of the Jagiellons, conquering the commercial trading cities of Kaffa (1475), Kilia, and Akkerman (1484). This meant that Poland was now cut off entirely from the trade with the Orient. In addition, Poland found yet another enemy in the Tatars in the Crimea. These had come under Ottoman rule in 1475, and from 1492 they undertook pillaging and slave raids into Red Ruthenia and Little Poland. The Tatars of the Crimea pushed into Polish territory with the aid of the Ottomans, reaching Cracow in 1498–99. Now Moldavia had also come under the influence of the Ottomans and Tatars. John Albert, the brilliant Polish commander in chief, had always been victorious against the Tatars, but he suffered a heavy defeat at the hands of the Moldavians in the forests of Suceava in 1497.

Russian invasion. Tsar Ivan III the Great took advantage of the situation, and, allying himself with the Tatars of the Crimea, he attacked Lithuania twice (1486–94 and 1500–03), capturing all the principalities on the Oka and Desna rivers as far as the middle of the Dnieper River. Another ally of Russia, the German emperor Maximilian I, laid claim to Bohemia and Hungary and prompted the states of the Teutonic Order to rebel against Poland. The result was that the grand master Frederick of Saxony (1498–1510) refused to swear his oath of allegiance, and his successor, Albert (Albrecht) of Hohenzollern, a cousin of the elector of Brandenburg, went so far as to enter into an alliance with Russia (1517). Poland supplied armed help to Lithuania, but in spite of this Russia took the city of Smoleńsk (1514) in the course of two wars (1507–08 and 1512–22). After this, at the First Congress of Vienna (1515), Maximilian changed sides, renouncing the help of both Russia and the Teutonic Order. Instead, he entered into a mutual hereditary agreement with the Jagiellon kings with respect to the succession in Bohemia and Hungary.

Rebellion of the Teutonic Order

Alliance with the Turks. The Ottoman troops advanced all the way through Little Poland (1524), under the leadership of their Sultan Süleyman I the Magnificent, and at the first Battle of Mohács (1526) they conquered the greater part of Hungary, killing King Louis II, the last Hungarian Jagiellon. The Ottomans next posed a great threat to Vienna (1529), and Poland found it wise to conclude a perpetual peace agreement with them in 1533. This did not, however, prevent the Muslims from threatening Poland's southern boundaries from bases in Hungary—a threat that was to last for about 140 years.

Re-establishment of Polish security. Renewed Moldavian and Russian attacks were repelled by the Polish troops under the brilliant leadership of Jan Tarnowski. Sigismund I the Old was able to incorporate the Duchy of Mazovia into his empire after the death of the last of the Piasts in Mazovia (1524–29). His campaign from 1519 to 1522 also secured Polish sovereignty over Prussia. Albert of Hohenzollern became the first secular duke of Prussia to swear an oath of allegiance to Sigismund (1525), and the land came to be known as Ducal Prussia.

Ducal Prussia

Sigismund II Augustus, 1548–72. The son of Sigismund the Old, Sigismund Augustus, was the last Polish Jagiellon. Trying to insure his country against the threats from the Ottoman and Russian empires, he sought alliances with the emperor Charles V and the Roman king Ferdinand I (1549). This at least brought him Charles's final renunciation of any intervention on his part in settling the question of the constitutional position of both Royal and Ducal Prussia. For 24 years Tsar Ivan IV the Terrible had led a war of conquest in order to obtain the remains of the lands of the Teutonic Order in Livonia (1558–82), and he succeeded in occupying part of the territory. This prompted Sigismund Augustus to enter into an agreement (the Union of Wilno [1561]), with the last grand master of the Order, Wilhelm Ketteler, integrating Livonia directly with Poland while Courland (now a secular duchy) had to recognize the authority of Poland. This antagonized Russia, which invaded Poland and conquered the lands of Połock on the Dvina River in the first Nordic War (1563–70). Under pressure of the threat posed by Russia and also because there was no heir to the throne, the Sejm combined the former crown lands, Lithuanian, Royal Prussia, and Livonia in the Union of Lublin, creating a unified and indivisible republic (1569).

Unification of the kingdom. The Polish population now began to integrate the nobility, the burghers, and a large part of the peasantry in the Lithuanian–Ruthenian

regions in the east. From about 1420, but in particular between 1540 and 1580, the people of densely populated Mazovia began to migrate. Resettling, they colonized the enormous virgin forests in the west of Lithuania— particularly Podlasie. Moving south, they also settled in the Duchy of Prussia. As early as 1582, there were more than 150,000 Jews among the many nationalities of the Polish Commonwealth, more than in all the rest of Europe. The two main parts of the country that comprised the Polish Republic—the crown lands and Lithuania—each retained its own ministers, treasury, and army. Unification was finally accomplished by the consolidation of a common elective kingdom with a functioning Sejm, or Diet, consisting of two houses. The upper house seated about 100 senators, and the lower house approximately 150 delegates. This arrangement created a Royal Republic in 1569, with a constitution that was in many ways similar to the constitutions of England and Hungary, and it remained basically unchanged for the next 226 years.

Establishment of the Sejm

Constitutional change. Between 1493 and 1569 the Polish Estate Kingdom slowly evolved into a parliamentary monarchy, which was governed almost entirely by the nobility. The Sejm of Piotrków, in 1493, was the first of about 200 diets that would be convened in the course of the next 300 years. From the assembly of the Sejm of Mielnik in 1501, the king was regarded as the president of the Senate, and in 1505 the constitutional act Nihil Novi ("No innovations") decreed the making of laws to be the sole right of Parliament. The supreme authority of the aristocracy led to a constantly growing opposition from the ranks of the lower nobility, who were incensed at the aristocracy's virtual escape from the burdens of taxation. The lower nobility at last secured their own appointment to the supervision of the highest courts of appeal and secured the formal recognition of their equality with the aristocracy, together with the prohibition of titles (*e.g.*, duke, prince, margrave, count). The superiority of the aristocracy over the lower nobility continued, however, since the aristocracy still remained in possession of the wealthiest estates of the country, while the lower nobility were very often poor and propertyless.

Trade and wealth. The "Golden Age" of Poland expressed itself in the wealth of the country and a favourable boom in its foreign trade. Raw materials such as grain, lumber, cattle livestock, hemp, flax, and potash showed a lively export trade, especially to the Netherlands and to England, by way of the autonomous free republic of Gdańsk (Danzig), which controlled about 80 percent of Poland's foreign trade on the basis of its monopoly (*jus stapulae*). Second only to Amsterdam, Gdańsk became the most important trading city of central and eastern Europe by 1576. The production of raw materials was in the hands of the propertied Polish nobles, now turned into farming entrepreneurs.

Importance of Gdańsk

The exploitation of the peasantry. The nobles extended their previous manorial domination over the peasant class with statutes passed in 1496, 1518–20, 1532, and 1543 that reduced the peasants to virtually the same status as property; they came under the jurisdiction of the nobles and, as a result, lived under conditions of virtual slavery as cheap labour for the nobles' farmstead economy. The discovery of the Americas paved the way to the second feudal system in Poland, made possible by the imports of gold and silver from the American continent. In contrast, the same era led to the establishment of modern manufacturing plants and industrial enterprises in western Europe, ushering in the period of early capitalism.

Just as in other countries, the wealth of the Golden Age led to a gradual currency inflation in Poland. Rather than being invested in industrial developments, the money was spent on luxury items for the nobles and, above all, on grandiose building constructions.

Cultural developments. The Renaissance and the Age of Humanism set their stamp for ever after on the spiritual and intellectual life in Poland. The art of book printing (in Cracow alone there were eight printing presses by 1580) and general school education spread. As many as one-quarter of the Polish population were able to read and write by 1550–80. Young Poles studied at major foreign universities, particularly at Padua, at Bologna, and at the Sorbonne, as well as at the Protestant universities of Wittenberg, Leipzig, Königsberg, Tübingen, and Basel. The department of astronomy at the University of Cracow achieved world renown through Nicolaus Copernicus (Mikołaj Kopernik; 1473–1543) and his work on the motions of the planets. Polish literary language came into its own, supplanting the use of Latin alone by scholars. The first Polish books were printed between 1514 and 1524, and the first Polish translation of the Bible appeared in 1534. Although still partly German, the burgher class was now integrated completely into the cultural mainstream of Poland. It was also of the greatest significance that the political science philosophy of Greco-Roman antiquity found general acceptance at this time, inspiring such works on the theory of political science as Andrzej Frycz-Modrzewski's *De Republica Emendanda* ("Of the reform of the Republic"; 1551), which was translated into almost every language spoken in Europe.

High level of education

The Reformation. The Reformation came to Poland from Germany, Italy, France, and Bohemia between the years 1523 and 1526. Lutheran and Calvinist denominations were established alongside the originally Hussite Bohemian Brethren and the Anti-Trinitarians, or Arians (from about 1562–65). Under the spiritual leadership of Laelius Socinus (1525–62) and Faustus Socinus (1539–1604) the Arians strove for both a rational secularization of religious life and a radical change in society, including the liberation of the peasantry. In spite of the first suppressive edicts of 1520–26, the Reformation gained strength, particularly after the Sejm suspended the secular execution of ecclesiastical sentences (1552). After this, Poland was the only country in Europe without religious persecutions for about the next 130 years. The Lutheran, Calvinist, and Hussite denominations consolidated in 1570 at the Concord of Sandomierz, but this soon disintegrated because of dogmatic differences. The Compact of Warsaw in 1573 removed the Catholic Church from its dominant position, introducing the constitutional equality of all religions—the first enactment in Europe of complete religious tolerance. The Reformation had affected about one-sixth of all parishes in the Polish and Lithuanian regions by 1562–91. The Eastern Orthodox Church was hardly touched by the Reformation, which received its greatest support from the nobility and the educated burgher classes, while the lower middle class and the peasantry in general remained Catholic. The effects of the Reformation persisted only among the German population of Great Poland and that of Royal Prussia (Gdańsk), in addition to a few larger cities, such as Warsaw and Wilno.

THE "SILVER AGE" OF THE ROYAL REPUBLIC, 1572–1648

The Interregnum and reform of the monarchy. *Constitutional reform.* The Interregnum, or period without a ruler, lasted from 1572 to 1575. During this time the republican constitution was further improved and extended. The election of Henry III of Valois (1573–74)—King Henry III of France from 1574—introduced and established the basic rule that not only the council of the aristocracy but also all nobles and squires should elect the king. This meant a formal victory for the lower nobility and the founding of the Polish rule by the nobility. The fundamental basis of the constitution, the "Henrician Articles" of 1573, required the king to swear an oath reducing his authority to no more than that of a contract partner in a sovereign nation of nobles. The king was also obliged to convoke the Sejm every two years; and in the periods between the sessions he was to be advised by a group of senators. Should the king fail to observe any of these articles, the nation was ipso facto obsolved from its allegiance.

Stephen Báthory (Stefan Batory), 1576–86. The next elected king was Stephen Báthory (Stefan Batory), who had defeated his opponent, the emperor Maximilian II. During his reign the leading statesman Jan Zamoyski

rose to the positions of grand chancellor (1578) and grand hetman (commander in chief; 1580). Zamoyski had been instrumental in gaining the victory for the lower nobility during the Interregnum. Now, Stephen Báthory and Zamoyski defeated Tsar Ivan IV with three brilliant campaigns (1578–81), forcing the Russians to return the occupied territories of Livonia and Połock by 1582.

Successful campaigns against Tsar Ivan IV

Sigismund III Vasa, 1587–1632. Bàthory was succeeded by Sigismund III Vasa, who defeated Maximilian of Austria. Since he was also the legitimate king of Sweden —as the son of John III Vasa of Sweden and of Catherine, daughter of Sigismund I—Sigismund established a brief Polish–Swedish union, but this soon fell apart as the result of Swedish-Lutheran opposition to the Catholic faith of their king.

The Swedish–Polish War of Succession. Revolting against Sigismund III in 1599–1600, Sweden pursued the Swedish–Polish war for 35 years, but Sigismund never relinquished his demands for the Swedish crown. The Polish grand hetmans Zamoyski and Jan Chodkiewicz were at first able to repel the attacks of the Swedes against Livonia (1600–09). They won a famous victory in the Battle of Kirkholm (1605), although outnumbered four to one by the Swedes. In the meantime, a Polish volunteer corps helped the False Dmitry to gain the tsar's throne in 1605–06. Sigismund found it necessary to openly intervene in Russia (1609–13) when a coup d'etat took place there. Under the leadership of Stanisław Żółkiewski, the Polish army won a brilliant victory at Kłuszyn (1610) against a sixfold Russian–Swedish majority. Polish troops occupied Moscow (1610–12), but they were driven out by the new tsar, Michael Romanov (1613–18). The important fort of Smoleńsk remained with Poland (1618–54).

The Thirty Years' War. At the outbreak of the Thirty Years' War (1618), Sigismund remained officially neutral but favoured the Austrian side. The Prince of Transylvania had advanced and occupied Vienna, but a decisive victory by the Polish army in 1619 prepared the way for the Austrian victory at the Bila Hora (Weisser Berg, or White Mountain) in 1620. Although the Poles won a decisive victory against the Turks also at the Battle of Chocim on the Dniester River in 1621, the Turkish attacks did not cease for another decade. Taking advantage of this Polish predicament, Sigismund's cousin, Gustavus II Adolphus of Sweden, occupied Livonia and its important Baltic seaport Riga (1621). At the Peace of Altmark, the Swedes temporarily gained possession of Livonia as well as of some Royal Prussian port cities (1629–35).

Swedish occupation of Livonia

Władysław IV Vasa, 1632–48. A highly talented field marshal, Sigismund's son Władysław IV (1632–48) assured the existence of Poland when he repelled the renewed attacks of the Turks, Russians, and Swedes (1633–34). He also reconquered, in 1635, the Prussian ports on the Baltic Sea that Sweden had occupied. But his plans to establish a Polish navy that would hold its own against the Swedish domination of the Baltic, to regain sovereign rights over Livonia (1639), and to prepare for an extensive war against the Ottoman Empire (1646–47) were all frustrated by the disinclination of the Polish nobles to wage wars. They wanted peace at any price in order to take advantage of the splendid opportunities opening up on the European market in the wake of the Thirty Years' War.

The Cossack revolt. The prominent powers in northern, eastern, and southeastern Europe had attacked Poland constantly and had forced the republic into repeated compromises on the question of sovereign rights over the Ukraine and the Duchy of Prussia. Meanwhile, the nomadic Ruthenian–Eastern Orthodox farmers—the Cossacks—had established themselves in the Ukraine, and their number was steadily growing with the addition of escaping peasants from Poland and Russia. The Polish landed estate owners could hardly keep them under control over the vastness of the barely populated steppe that the Cossacks inhabited. The Cossacks eventually rebelled against the constant attempts on the part of the Polish estate owners to reduce them to the state of bonded peasants, and their leaders demanded a position of equality with the Polish nobility. The Cossacks remained the foremost social danger in the republic, allying themselves with the Tatars in 1648.

Poland's access to the Baltic endangered. In 1618 John Sigismund, elector of Brandenburg (1608–20) also became duke in Prussia, and thus the two crowns were now in personal union, though the sovereignty over Ducal Prussia remained with the Polish crown. His grandson, however, the Great Elector Frederick William (1640–88), by clever manoeuvring between Sweden and Poland, succeeded in removing Ducal Prussia from Polish sovereignty by the Treaty of Welawa (Wehlau) in 1657. From then on, the Brandenburg state of Prussia became the most dangerous of Poland's neighbours, not least because Frederick William intended to establish a territorial connection between Western Pomerania and the Duchy of Prussia, henceforth a leading aim of Brandenburg–Prussian politics until the First Partition of Poland about 115 years later. It threatened to cut off Poland from its connections with the Baltic Sea.

The threat from Brandenburg

Economic prosperity. The booming years between 1577 and 1654 became the high point in the history of Polish economics. At that time, Poland was considered, appropriately, the "granary of Europe." Polish grain was exported to France, England, Spain, and sometimes even to Italy and the Near East via Amsterdam, where the most important grain stock exchange was located. Gdańsk soared in importance to the rank of a trade city of world renown. As a result of this foreign-trade boom, the landowners pushed the farmsteading economy to its very limits, developing estates into tremendous areas. In many cases the servitude of the peasantry become actual slavery. This caused a number of small rebellions by the peasants, many of whom escaped into the Ukraine.

The liberum veto. The economic power of the magnates encouraged the forming of groups of supporters among propertyless voters who would keep their votes at the disposal of one particular aristocrat, thus enabling the magnate to command entire districts of the provincial *sejm* and, if necessary, even to paralyze it. In this way the original, formal "democracy of nobles" based on about 150,000 voters had evolved into an oligarchy of about 300 families. This was to prove a decisive factor in the later disintegration of the Polish republic. The undermining of the power of the *sejm* culminated in a procedure that made it possible for just one delegate to disrupt it through the liberum veto. The liberum veto was based on the assumption of the political equality of every Polish gentleman, with the corollary that every measure introduced into the *sejm* must be adopted unanimously. Consequently, if any single deputy believed that a measure already approved of by the rest of the house might be injurious to his constituency, he had the right to exclaim "Nie pozwalam," ("I disapprove"), the measure in question falling at once to the ground. All efforts toward increasing the power of the central government were held to be against traditional freedom and were opposed. This principle was extended still further until a deputy, by interposing his individual veto, could at any time dissolve the *sejm*, and all measures previously passed had to be resubmitted for the consideration of the following *sejm*. The liberum veto was used for the first time during the *sejm* of 1652, but before the end of the 17th century it was used so recklessly that all business was frequently brought to a standstill. It thus became the chief instrument of foreign ambassadors or native magnates for dissolving inconvenient sessions, as a deputy could always be bribed to exercise his veto.

The Counter-Reformation. Poland experienced the effects of the Counter-Reformation after the Council of Trent (1545–63). Led by prominent scholars such as Cardinal Stanislaus Hosius (Stanisław Hozjusz), who introduced the Society of Jesus, or Jesuits, in Poland in 1564, a total of approximately 50 Jesuit establishments were founded in the republic between 1564 and 1654. The Jesuit colleges in Połock, Smoleńsk, and Černigov and the Jesuit Academy of Wilno (founded in 1578–80)

The Jesuits

were mainly intended for the conversion of Eastern Orthodox Russia to Catholicism. Through their colleges and schools, the Jesuits established a dominant influence on the education of the Polish people that would last for about two centuries. Piotr Skarga was the most prominent theologian and politician among the Jesuits. The Order of the Camaldolese also supported the Counter-Reformation. The Counter-Reformation led to religious disorders; many of the Protestant churches were closed, especially in the large royal cities (particularly between 1574 and 1612); and the number of Protestant parishes diminished, as many of the aristocratic dynasties reverted to Catholicism. By 1650 there were not more than 270 non-Catholic parishes left in the country. Only the established German–Lutheran Church in the city republics of Prussia (Gdańsk, Elbląg) and the Calvinist Church in Lithuania (approximately 140 churches) retained a certain importance. The most significant result of the Counter-Reformation was the Synod of Brześć in 1596, whereby six of the ten Eastern Orthodox eparchies acknowledged the authority of the Holy See in Rome. Declared illegal and schismatic in 1595, the Eastern Orthodox faith was again recognized in 1635. Its spiritual centre became the Academy of Kiev, which had been modelled after the colleges of the Jesuit order. The Protestant academies of Gdańsk and Leszno still retained their European distinction, however, and John Amos Comenius, the philosopher and pedagogue, taught in Leszno.

THE IRON ERA PERIOD OF WARS AND DISINTEGRATION, 1648–97

John II Casimir Vasa, 1648–68. The reign of the last of the Vasa kings in Poland, John II Casimir, is remembered in history as a period of bloody wars and disasters.

The Cossack–Russian invasion. The epoch began with a rebellion of the Ukrainian Cossacks, led by Bohdan Chmielnicki, who heavily defeated the Polish troops in 1648 and 1651, establishing their own military state (1651–54) with the armed assistance of the Tatars of the Crimea and the Ottomans. In the Union of Pereyaslavl, in 1654, the Cossacks acknowledged the authority of the Russian tsar Alexis Mikhaylovich. On the strength of Cossack aid, Alexis attacked Poland, conquering almost the entire eastern part of the country, as far as Lwów, in 1654–55.

The Swedish invasion. Charles X Gustav of Sweden took advantage of the Polish predicament and occupied the Polish and Lithuanian lands of the republic in 1655, receiving some support from the native aristocrats and from Frederick William of Brandenburg. John Casimir fled to Silesia, and the majority of the nobles (among them the future king John III Sobieski) recognized Charles as their king, particularly after he had promised to reconquer the eastern part of Poland from the Russians and Cossacks. The extraordinary brutality of the Swedish army, however, gave rise to a general revolt against Charles, and the Swedes were not able to take the two largest cities of Poland (Gdańsk and Lwów). The brilliant grand hetman Stefan Czarniecki eventually destroyed the Swedish and defeated Frederick William's Brandenburg army between 1655 and 1657. In the treaties of Welawa (Wehlau), Bromberg (Bydgoszcz), and Oliwa (Oliva, 1660), Poland recognized the "superior power of government" of Frederick William over the Duchy of Prussia but reserved the right to reversion with regard to the duchy and did not relinquish this right until 1773.

Flight of John Casimir

Settlements and social consequences of the wars. The Ukraine again entered into a union with Poland in 1658, and Russia was decisively defeated in 1660–62. Nevertheless, Russia obtained Smoleńsk and the eastern half of the Ukraine in the truce of Andruszów (Andrusovo; 1667), after the rebellion of Jerzy Lubomirski against the King of Poland. Having been instrumental in bringing about the greatest catastrophe in the history of Poland, John II Casimir finally abdicated in 1668. The war, the bubonic plague, slave raids, and mass murders had reduced the total population to approximately 4,000,000 people, or 45 percent of the former total population. (This was about twice the number lost in World War II.) The cities suffered worst of all, losing all manufacturing establishments and industrial enterprises along with three-quarters of all their inhabitants. The tremendous costs of the war caused the greatest inflation in the history of Poland. Religious feeling was fanatically inflamed since the war had been conducted in the spirit of a religious struggle, and the Protestant parishes almost totally disappeared. The constitutional maxim of religious tolerance was finally abandoned in 1648–58.

Michael (Korybut) Wiśniowiecki, 1669–73. The short reign of Michael (Korybut) Wiśniowiecki was dominated by internal fighting between the Habsburgs, led by the King, and the French-oriented faction that had gathered around John Sobieski, a military commander of rising fame. The Cossacks seceded again in 1667, allying themselves with the Ottoman Empire (1668), and in the succeeding Turkish attack in 1672–73, the Poles lost Podolia and two-thirds of the Ukraine.

John III Sobieski, 1674–96. A brilliant victory in 1673 established the fame of John Sobieski as the "vanquisher of the Turks," a title that brought him the crown of Poland in 1674. In spite of his many successes in the fight against the Ottomans (1675–76) and despite his liberation of Vienna in 1683—a crucial factor in the development of European history—John III Sobieski was not able to regain the regions in the southeast of the republic held by the Ottomans. He also failed in his attempts to secure the return of the Duchy of Prussia to Poland through treaties with France (1675) and Sweden (1677). Poland's participation in the Holy Alliance against the Ottoman Empire (1684) and the many Turkish campaigns of John III Sobieski (1684–92) eventually aided the development of Austria and Russia as new great European powers. With the Peace of Carlowitz (Karłowice; 1699), Poland again received Podolia and the Ukraine west of the Dnieper River. Given to Russia for two years in 1667 but never returned to Poland, the city of Kiev was recognized as part of Russia in the "perpetual peace" in 1686.

Peace of Carlowitz

THE SAXONIAN ERA AND THE RUSSIAN PROTECTORATE, 1697–1763

Augustus II the Strong, 1697–1733. On the death of John III, no fewer than 18 candidates for the vacant Polish throne presented themselves. The successful competitor was Frederick Augustus I, elector of Saxony, who renounced Lutheranism for the crown. Under his reign as Augustus II the Strong, Poland experienced a new wave of wars and catastrophes. The planned union between the industrially developed Saxony and raw material-producing Poland would have been advantageous for the economy of both countries, but that did not materialize since the King, as ambitious as he was lacking in talent, became involved in a war with Sweden through his alliances with Peter I the Great of Russia and King Frederick IV of Denmark.

The Northern War. These allies attacked Sweden and began the Northern War (1700–21). The Swedish king Charles XII repelled Denmark and Russia in 1700 and marched from Livonia into Poland (1701–02), the latter serving him as the base for his future military operations. Appointing Stanisław Leszczyński (Stanisław II) as puppet King (1704), Charles XII invaded Saxony in 1706 and forced Augustus to abdicate. During the civil war of 1704–10, Swedish troops totally devastated Poland, and the Saxonian and Russian armies fared little better. Cultural losses were enormous, and one-third of all Polish cities lay in ruins. Although by 1702 the population had recovered again, reaching about 8,000,000, war and then the bubonic plague of 1709 took their toll, and other disasters reduced the population to about 6,400,000. Poland was spared any further Swedish occupation when the Swedish troops advanced into the Ukraine, where they suffered a decisive defeat at the Battle of Poltava (1709). Stanisław Leszczyński escaped from Poland in 1710, and Augustus II again assumed the crown with the particular support of Peter the Great of Russia. Breaking all agreements with Poland, the Tsar annexed Swedish-held Livonia (1710), the very land that had given Augus-

Civil war of 1704–10

tus II the pretext to start the war. Then the Tsar turned east and put down the last Cossack rebellion in the Polish Ukraine (1702–04), which the Polish Sejm had provoked by despotically deciding to disband the Cossacks in 1699.

The Prussian situation. The Hohenzollern prince Frederick III had assumed the title of king of Prussia in 1701, with consent of Augustus but without the approval of the republic, which alone had the power to grant this title. In 1715 King Frederick Willaim I tried to acquire the Polish Prussian territory, again with the approval of Augustus. The intervention of Peter the Great, who resided in Gdańsk at the time, frustrated this attempt in 1716, and the Russian troops remained in control of the southern coast of the Baltic Sea. Peter the Great thus assumed the role of protector of the territorial integrity of the Polish republic. From then on, Poland was to all intents and purposes a protectorate of the Russian government, and this relationship lasted until the dissolution of the republic in 1795.

Augustus III, 1733–63. The French-supported candidate, Stanisław Leszczyński, was elected king for the second time after the death of Augustus II in 1733. The Russian and Saxonian armies interfered, however, forcing the election of his opponent, Augustus III, the son of Augustus II. It was in his reign that Prussia definitely and conclusively achieved the position of a European power under its king, Frederick II the Great (1740–86). He annexed Silesia between 1740 and 1745, securing control of the western boundaries of Poland as well as of Polish foreign trade at the points where it was shipped overland to central and western Europe. Inhabited mainly by Poles, the southeastern half of Silesia still retained close political and cultural ties with Poland, but the Prussian annexation ended the church sovereignty of the metropolitanate of Gniezno over Silesia.

The Seven Years' War. During the Seven Years' War (*q.v.*; 1756–63), the Russian army used the territories of Gdańsk, Toruń, and Poznań as operational bases in their war against Prussia. Frederick II ordered the counterfeiting of Polish money, a measure that severely damaged and inflated the monetary system of the republic.

Social, religious, and political change. During the long and peaceful era between 1716 and 1768, the population grew rapidly, due to both the steady immigration of Germans and the mass exodus of an enslaved peasantry from Russia. By 1772 Poland's population numbered approximately 11,420,000. Comprising more than one-half of all the Jews in the world, the Jewish population of Poland lived in all parts of the country. The Counter-Reformation reached its zenith under the spiritual leadership of the Jesuits, who trained 20,000 students of noble birth annually in their 51 greater colleges and other educational institutions. In 1717 and 1733, laws were passed that restricted the spiritual and secular rights of the dissident (non-Catholic) population. Popular education fell to its lowest level. Spreading through all the other parts of Europe, the Age of Reason affected Poland only by virtue of some individual achievements. Parliamentary life came to an almost complete standstill. Under the reign of Augustus II only four of a total of 13 *sejms* came to an orderly conclusion; under Augustus III only one out of 13 did so, as the result of the use of the liberum veto.

Population growth

REFORM AND PARTITION DURING THE REIGN OF STANISLAW II AUGUSTUS PONIATOWSKI, 1764–95

A former diplomat, Stanisław II August Poniatowski gained the crown of Poland with the help of Russian troops in 1764. Aided by his relatives, the Czartoryski, he tried to introduce political reforms, among other things the temporary abolition of the liberum veto in 1764–66, but his plans failed because of the objections of Catherine II the Great, the Russian empress. Taking advantage of the religious quarrels in Poland, the Empress sent Prince Nikolai V. Repnin as Russian minister to Warsaw with instructions that led to further discord in Polish affairs. Of Poland's population of 11,500,000, about 1,000,000 were dissidents, one-half Protestant and one-half Orthodox. For these people, who had been largely deprived of their rights by the laws of 1717 and 1773, Repnin, in the name of the Russian empress, demanded absolute religious and political equality with the Catholic population of Poland. He was well aware that an aristocratic and Catholic assembly like the Sejm would never concede such a demand.

Intervention by Catherine the Great of Russia

Early in 1767 a confederation was formed at Repnin's instigation to send a deputation to Catherine, petitioning her to guarantee the liberties of the republic. Subsequently, but not without a stubborn resistance, the Sejm accepted Catherine's authority, and the so-called fundamental laws were enacted, guaranteeing the liberum veto and all the other ancient abuses as unalterable parts of a Polish constitution ensured by Russia. All the restrictions against the dissidents were repealed at the same time.

Confederation of Bar. These events led to a Catholic uprising known as the Confederation of Bar, aided by the Turks. After four years of fighting (1768–72), the Russian troops were able to gain the upper hand over the confederates. Frederick II of Prussia tried to use this civil war to achieve a partition of Poland, but he met with the resistance of Catherine II. Only the threat of Austrian troops advancing against Russia and the Austrian annexation of some Polish territory in the Carpathian Mountains (1770) forced Catherine to seek help from the Prussian king on his terms—namely, the partition of Poland.

First Partition, 1772. With the First Partition of Poland in 1772, the republic lost about 28 percent of its territory, the Livonian and White Ruthenian regions north of the Dvina River and east of the Druć River falling to Russia. Austria received Little Poland south of the Vistula River and almost all of the Red Ruthenian territory under the name of the Kingdom of Galicia. Prussia obtained the smallest but most valuable property, namely, Royal Prussia, comprising Warmia (Ermland) and a part of Great Poland on both sides of the Noteć River, though without the cities of Gdańsk and Toruń. Through this annexation Prussia had not only acquired the desired land connection between Western Pomerania and East Prussia that it had tried to secure for almost 120 years, but it had also gained control over approximately four-fifths of the total foreign trade of Poland. By levying enormous custom duties on the Polish foreign trade going via this route, Prussia made this its most important source of income. In fact, the partition of Poland was of vital importance to Prussia, for it was now able to shake off the last vestiges of the old Polish sovereign rights. The treaty of 1773 established the full and complete sovereignty of Prussia over its lands.

Prussian control of foreign trade

The period of reform. The shock of the First Partition caused political and economic reforms in Poland—as far as Russia would permit. The taxation system and the army were thoroughly reorganized, and with the Permanent Council, in 1775, Poland installed its first real central government. Many landed estate owners carried out individual peasant emancipations, and almost 200,000 Germans and at least 300,000 Russians emigrated to Poland, a land that was considered free. Slowly, the cities began to flourish again, and the beginnings of an industrial revolution could be observed with the rise in mining activities, the advances of the textile industry, the founding of the first joint-stock companies, and the employment of the first machine equipment. Polish intellectual pursuit and reasoning received fresh impetus when the Age of Reason was finally accepted. The King promoted the political theories of such men as Edmund Burke and George Washington, while the educated Poles advanced the political theories of Montesquieu and Rousseau. But whatever the theory, the concept of modern democracy, including all ranks and classes of society, quickly became established in Poland. The first governmental department for public education in Europe was established in conjunction with the appointment of an education commission in Poland in 1773. Its task was the reorganization of the universities of Cracow and Wilno, as well as the supervision of approximately 80 gymnasiums. The printing of books and the publication of magazines and journals also flourished.

Improvements in education

The Constitution of May 3, 1791. The first codified constitution in Europe since antiquity and the second in

The partitions of Poland, 1772–95.

the world after the United States, the new Polish constitution passed by the "Four Years Sejm" embodied the following ideas: first, the precept of a "people's sovereignty," which included the nobility as well as the metropolitan bourgeoisie; second, the constitutional separation of powers between the executive, legislature, and judiciary; and third, the responsibility of the cabinet to parliament. The liberum veto and all the obstructive machinery of the anomalous old system were abolished. According to its own rules, this constitution had to be revised after 25 years at the latest. But Catherine II considered such a constitution dangerous to the existence and continuation of her own autocratic governmental system; she therefore ordered her troops to invade Poland in 1792, and the reforms were destroyed by force.

The Second and Third Partitions. The Russo–Prussian treaty of 1793 (the Second Partition) placed almost all the Red Ruthenian and White Ruthenian lands under Russian rule, while Prussia received Gdańsk, Toruń, Great Poland, and part of Mazovia. The reaction was inevitable, and in 1794 a general popular insurrection broke out under the leadership of Tadeusz Kościuszko against this latest Russo-Prussian humiliation. Kościuszko achieved a partial liberation of the peasant class and began a general armament of the people, mobilizing more than 150,000 men. At first the Polish forces were almost universally successful; but ultimately Kościuszko was defeated by the Russian troops under Aleksandr Suvorov at the Battle of Maciejowice, and Warsaw capitulated at the end of 1794. Now Russia and Austria—joined later also by Prussia—agreed to the Third Partition of Poland in 1795. Russia annexed the entire territory east of the Niemen and Bug rivers, Austria took almost all of Little Poland, including Cracow, and Prussia received the remaining lands, including Warsaw. Stanisław II abdicated officially in 1795. For all official purposes, at least, this was the end of the Republic of Poland, which was eradicated from the map of Europe for the next 123 years.

Kościuszko

III. Poland under partition, 1795–1914

FOREIGN RULE AND THE DUCHY OF WARSAW, 1795–1815

The Russian sector. With the Third Partition of Poland in 1795, the largest part of the territory fell to Russia. Officially, Catherine II called these partitions a return of Russian territory, even though such a claim dated back 450 years. Proclaiming the unity of all Russians, the largest part of the Uniate Church returned to the fold of the Eastern Orthodox faith. In spite of this, the Polish constitution and culture remained fairly unaffected at first in these "Russian" parts, where at least 1,800,000 Poles, including over 640,000 nobles, still held positions of influence. Because Russia's level of civilization was still extremely low under the reign of the tsars Paul I (1796–1801) and Alexander I (1801–25), the government was unable to administer the area without Polish help. The land had been divided into eight governmental units in 1801; and since the Poles retained basic administrative control, the municipal rights, control of the Polish county courts and of the Polish Sejm remained in force for a number of years (1796–1831). An added factor was that this region had the highest standard of civilization, culture, and education within the realm of the Russian Empire—with the exception of the Baltic Sea provinces—and the fundamental principles of the Russian educational system were based on the essential features of the Polish educational institutions of this region.

The Prussian sector. The Prussian area consisted of the three provinces of West Prussia, South Prussia, and New East Prussia. Together with the province of East Prussia, which had not been under Polish rule since 1657, the country came to be known officially as the Kingdom of Prussia, a part of the Prussian monarchy. Of its population of almost 4,000,000, however, about three-quarters were ethnic Poles.

The Austrian sector. The Kingdom of Galicia, as the Austrian section was known, was repeatedly reorganized administratively. Most of the native intellectuals in both the Prussian and the Austrian sections were replaced by German administrators who governed the lands in their customary autocratic fashion. It is therefore not surprising that in these areas numerous nationalist secret societies were established.

Patriotic and conspiratorial societies

The struggle of the patriots. As early as 1768, Polish emigrant groups were formed in Hamburg, Dresden, Constantinople, and particularly in Paris. The group of Polish Jacobins organized in Warsaw and Wilno (1792–94) had established connections with the French Revolution, especially through Józef Sułkowski, who had politically supervised Napoleon Bonaparte in his capacity as secret police inspector (1796) of the French Directoire. Branching out from their Jacobin origins, the conspiratorial Society of Polish Republicans, formed in Warsaw around 1798–1800, and the Warsaw Society of the Friends of Science, founded in Warsaw in 1800, served partially as a cover organization for Jacobin activities. The centre of the conspiratorial network was in Paris, but it gained a particularly strong hold in Galicia after the French–Austrian War of 1792–1801. Gen. Jan Henryk Dąbrowski, who had gained his fame from the defense of Warsaw in 1794, established Polish legions in northern Italy in 1797, recruiting men from Austrian prisoners of war of Polish nationality. The legions fought without any political success against Austria between 1797 and 1801.

Russian rule. Prince Adam Jerzy Czartoryski, the Russian foreign minister, tried to re-establish the Polish Republic from the sector occupied by Russia. He was aided in this by the tsar Alexander I. The plan was designed to create a buffer zone against Prussia, then allied with France. The idea lost its rationale, however, when Napoleon I of France attacked Prussia in 1806 and Russia came to the aid of Prussia. The French advance against Poznań and Warsaw paved the way for a general Polish insurrection against Prussia, led mainly by Jan Dąbrowski and Józef Wybicki.

The Duchy of Warsaw. Taking some purely Polish areas of the Kingdom of Prussia, Napoleon I created the Duchy of Warsaw, placing it under the rule of the king of Saxony, Frederick Augustus (1807). The constitution dictated by Napoleon I and the introduction of the Code Napoléon called for the personal liberation of the peasants. But the soil remained fundamentally with the landed nobility, and therefore this liberation promoted rather than alleviated the agrarian population surplus in Central Poland, a condition that had existed already for about 300 years. Józef Poniatowski (1763–1813), the nephew of the last king, distinguished himself as field marshal during the war of 1809, when the Duchy of Warsaw acquired the Austrian part of the Second Partition, including Cracow, as well as Zamość, annexed with Galicia in 1772. Thus, the Duchy of Warsaw had by this time grown to almost the same size as the Prussian monarchy. The failure of Napoleon's war against Russia in 1812, however, meant that by 1813 the Duchy of Warsaw had come under Russian administration.

Government under Napoleon

THE KINGDOM OF POLAND AND THE OTHER POLISH LANDS, 1815–31

The Congress of Vienna (1814–15) established the territorial division of Poland (within the boundaries of 1772) until 1918. In accordance with the Prussian demands, the Grand Duchy of Poznań was detached from the authority of the Duchy of Warsaw and incorporated into the Prussian monarchy. Cut off from the Duchy of Warsaw as well, the "Free City of Cracow" was designated to be the "symbolic capital of the divided Poland," though these intentions came to an end when Austria annexed the city in 1846. Galicia remained an Austrian hereditary land.

The Kingdom of Poland. The main part of the Duchy of Warsaw was given the title of Kingdom of Poland in 1815. Approximately four-fifths of its population (over 4,000,000 in 1827) were ethnic Poles, of whom as many as 325,000 were nobles. This area thus came to be considered as the Polish nucleus. After the Congress of Vienna, in 1815, this Congress Kingdom of Poland, or Congress Poland, as it often came to be called, was united with the Russian Empire, though it retained its own governmental system, its own Sejm, and its own army. Tsar Alexander I was now in command of about three-quarters of all the historically Polish territories and, being not only the tsar of Russia but also the king of Poland, he was well advised to try to win the loyalty of the Polish people.

The constitution of the Kingdom of Poland

The constitution of the Kingdom of Poland, passed between 1815 and 1831, was considered the most liberal in all of Europe. The population of the Congress Kingdom of Poland included more voters than France, whose population was six times greater. A severe impediment, however, was the fact that Alexander I reigned with the harshness of an absolute monarch from 1819 on, breaking the constitution several times. This again promoted the creation of secret societies, the most consequential of which was the National Freemasonry (1819–25) under the leadership of Walerian Łukasiński. Similar secret societies were founded in Cracow, Poznań, and especially in the University of Wilno, where the Society of the Philomats functioned as a front for several conspiratorial groups. Even Adam Mickiewicz, the greatest Polish Romantic poet, became involved in the affairs of the Philomats and was sent into exile for some time. The secret societies (such as the National Patriotic Society) continued and flourished, despite repression at the hands of the Russians.

The Rising of 1830. Alexander's successor, autocratic Tsar Nicholas I (1825–55), planned a military campaign against France and Belgium after the revolution in France in July 1830. He was going to send a Polish army to accomplish this, but most of the Polish ensigns banded together to create the November Insurrection on November 29, 1830, under their leader Piotr Wysocki. Almost the entire army and the majority of all Polish politicians joined in the insurrection, and the Sejm proclaimed the ousting of Tsar Nicholas I on January 25, 1831, an act that led to a formal war between Russia and Congress Poland. The war lasted from January to September 1831, the superior Russian forces finally defeating the Poles, who received no response to their appeal for western European protection. About 6,000 leaders of the rising were forced into exile during 1831–32, most of them emigrating to France in what has become known as the Great Emigration.

RUSSIAN REPRISALS AND THE JANUARY INSURRECTION, 1831–64

Repression of Poland. The suppression of the November Insurrection meant heavy reprisals in the Russian as well as in the Prussian Polish areas, even though the latter had no actual part in it. Extensive confiscations of estates, deportations, and enforced recruiting were designed to break the national patriotism of the Poles. The universities of Warsaw and Wilno were suppressed, and Polish students compelled to go to St. Petersburg (now Leningrad) and Kiev in Russian Poland. The remainder of the Uniate Church was abolished and converted to Eastern Orthodox between 1831 and 1839, though continuing to exist in Congress Poland until 1875 and in Galicia until 1945. The Organic Statute of 1832 replaced the constitution, the Sejm, and the army in the Kingdom of Poland; and the land was united with the Russian Empire in a true union, although officially the kingdom retained a few autonomous rights.

The Organic Statute

Polish nationalist groups. The conservative group of emigrants led by Adam J. Czartoryski, the "king in exile," tried to solve the Polish question through legal and diplomatic means. His minimum goal was the restoration

of the legal status of 1815, which had been violated from the very beginning. The radicals had splintered into many factions, but the Polish Democratic Society founded in 1832 soon emerged as the leading organization. Its Manifesto of Poitiers of 1836 was less realistic than the program set up by the conservative side, because its revolutionary agenda demanded an independent Poland within the borders of 1772. But the Manifesto proclaimed the idea of a land reform without compensation to the present owners, and this drew many supporters. In the years between 1833 and 1846, emissaries and leaders of the partisans of the "left" established secret revolutionary cells in all parts of Poland. These cells were persistently traced down by the authorities, and thousands of their members were deported or imprisoned.

The 1846 insurrection. The Polish Democratic Society gained a certain influence in the country with the installation of a committee in Poznań between 1839 and 1846. This committee drew up a plan for a general revolution, but the Prussian police discovered it in 1846. In spite of this, a central government in Cracow, under the revolutionary leaders Jan Tyssowski and Edward Dembowski, tried to get an insurrection started. The uprising spread to Galicia, where Austrian troops soon put it down, at the same time inciting the local population so that many Galician peasants turned against the revolutionaries. The failure of the 1846 revolt severely weakened Polish participation when a general revolutionary wave swept through Europe during the early spring of 1848–49. Originally, Prussia and Austria had nominally supported Polish demands for independence, but now attempts by the Poles to establish a real independence were resisted by armed force in both countries. The course of this revolutionary struggle showed clearly that the fight was no longer only about the ideal of a unified republic based on the boundaries of 1772 but also about the Romantic Idealism of the time, which favoured individualistic, linguistically and culturally separated nationalities. On the other hand, nationalist ambitions now extended beyond the borders of 1772 for the first time. The Polish question also gained more impetus on the international scene. Adam Mickiewicz founded a new Polish legion in Italy and a little later published the moderate socialist newspaper *La Tribune des Peuples* in Paris (1848–49). The landed gentry of Poznań financed the *Neue Rheinische Zeitung* ("The Newspaper of the Rhineland"), the journal through which Karl Marx and Friedrich Engels in 1849 proclaimed the national liberation of Poland to be the most important task of the workers' movement of Europe.

Romantic revolutionary Idealism

Alexander II and the rising of 1863. The Eastern Question and the Crimean War (1853–56) caused violent upheavals within the Russian Empire, which motivated Alexander II (1855–81) to take a more conciliatory stand toward the Kingdom of Poland. A series of reforms were implemented, in their later stages by the autocratic Count Aleksander Wielopolski, who was installed in high office and stood for a national policy of loyal union with Russia. His methods and character lost him the support of the moderate gentry, however, and aroused the outright enmity of the young patriotic radicals, who were influenced by ideas expressed by Napoleon III of France and by the national reunification of Italy (1859–60). (The left wing of these radicals became linked with the Russian liberal movement and the international emigrants in London centred around Karl Marx and Aleksandr Herzen.) Religious ceremonies became occasions of political demonstrations, rioting broke out in Warsaw, and the situation culminated in the widespread insurrection of January 22, 1863, sparked off by Wielopolski's plans to press the revolutionary youth of the cities into the Russian army. The revolutionaries had relied on French and Austrian support, but these hopes proved to be in vain; and to make matters worse, Prussia again cooperated with Russia. As before, the ethnic groups in the Russian sectors—Poles, Lithuanians, and the Catholic White Ruthenes—united in a common war against the Tsar that lasted for 15 months, though the insurrection was finally crushed when the rebel "National Government" was detected by the Russian administrative authorities on April 10–11, 1864. The defeat was followed by executions, confiscations, and deportations, and all hopes for the Polish people to establish an autonomous national state were ended for the next half century. The Russian government did proclaim, however, the liberation of its peasants on March 13, 1861, and it extended this to the Kingdom of Poland on March 2, 1864. By so doing, it took the most important traditional premise for the revolution out of the hands of the revolutionaries. The agrarian policy, however, was expressly calculated to stir up ill feeling between the peasants and the country gentry, whom Russia was determined to punish in every way for their leading part in the insurrection. Yet the agrarian reforms accelerated the growth of towns and industry and the new social structure produced both financiers who exploited the great possibilities of the Russian market and a new working class, among whom the first socialist organizations began their secret activity.

Liberation of the peasants

THE FOUNDING OF MODERN POLAND, 1864–1914

After the failure of the January Insurrection, a policy of harsh repression fell upon the Poles remaining in the Russian and Prussian sectors. The Russian sector was now offically named the Western Region of the Russian Empire, and its governor general, Mikhail Nikolayevich Muravyov (who became known as the "Hangman of Wilno"), made every effort to stamp out Polish culture altogether.

Russification. The Kingdom of Poland was reorganized into the Land of the Vistula under a purely Russian administration. The University of Warsaw became a Russian university in 1869. Russification of all secondary schools was implemented during the years 1869 to 1874 and of all other public schools after 1885: the Russians very successfully accomplished their aim of keeping illiteracy among the common people at as high a level as possible. Consequently, by 1905 there were relatively fewer schools and students in the Land of the Vistula than there had been in 1815. Nearly all private schools and all social and political activities were prohibited.

Prussian and Austrian Poland. Following the Russian example Otto von Bismarck, the German chancellor, instituted a similar policy, and the Prussian sector was incorporated into the newly founded German *Reich*. In 1872 the entire school system was Germanized. The Colonization Law of 1886 tried to integrate German peasants into the native Polish population. Polish autonomy was able to achieve some success only in the Austrian sector, where its most important agency was the Galician Provincial Sejm (Diet). The Poles in Austria became the country's second nationality, and they were allowed to participate in the government at Vienna and retained sovereignty over the Ruthenes in Galicia. Galicia itself became the haven of Polish culture, with the University of Cracow, the University of Lwów, and the Academy of Sciences attracting many Polish intellectuals.

Galicia

Industrial growth and social change. The development of modern industry, notably the textile and metal manufacturing industries, as well as mining, made Congress Poland after the abolition of the customs barrier with Russia the most dynamic, industrialized part of the Russian Empire until about 1890. In Congress Poland alone there were more than 400,000 industrial workers by 1910. It was mainly Polish intellectuals who stimulated industrialization in the Russian and Austrian sections, whereas German intellectuals led the industrialization program of the Prussian part—particularly in Upper Silesia, with its 200,000 Polish miners. Due to the many agrarian crises between 1846 and 1892, most of the 3,200,000 descendants of the former nobility moved to the cities in the Russian sector, where they formed the majority of the liberal professions. In the Polish regions of eastern Germany, Congress Poland, and West Galicia, the intellectual classes were mostly without property and therefore dependent on wages, whereas the Poles in the Western Region of the Russian Empire and in East Galicia were mainly wealthy landowners or belonged to the city bourgeoisie. One of the main features of the period

was the mass emigration of Poles from their native lands into the more industrialized parts of Germany, a movement that was to continue for decades to come. Thus, by 1910 more than 100,000 miners of Polish descent were working in the industrial Ruhr district. The rural population of Congress Poland and Galicia was mostly illiterate, and poverty increased there to such an extent that at least 3,500,000 people emigrated between 1890 and 1914, mainly to the United States.

Mass emigration to Germany

Development of political parties. The first permanent political parties were established in Congress Poland and in exile between 1891 and 1893. The Polish League (LP), founded in 1886–87, was reorganized as the National League (LN) by Roman Dmowski in 1892–93 and later became the nucleus of National Democracy (ND), which was the strongest bourgeois party between 1905 and 1939. The Polish Socialist Party (PPS) was founded in 1892–93 under the patronage of Bolesław Limanowski and subsequently, under the leadership of Józef Piłsudski, became the strongest socialist party (with about 50,000 members) in the entire Russian Empire during the Russian Revolution of 1905. The left-wing socialist party (SDKP; from 1900 SDKPiL, Social Democracy of the Kingdom of Poland and Lithuania), founded in 1893 and led by Rosa Luxemburg and Junian Marchlewski, remained a minor party in comparison. The 1905 revolution, which swept over Russia, changed political life in all the Polish regions. The National Democracy, led by Roman Dmowski and supported by the majority of the landed gentry and the bourgeoisie, restricted its national platform to the demand for Polish autonomy. For this reason it was allowed to operate legally not only in Congress Poland but in Russian Poland, too, after 1905. The same party also controlled the Polish faction in the Russian Duma, or Parliament (1905–17). The PPS split in 1905–06: the patriotic wing under Józef Piłsudski and Tomasz Arciszewski retained its "radical program for independence," in accordance with the teachings of Friedrich Engels, and took part in the abortive revolution of 1905 against the Russian government; the left wing adjusted its program to an internationalist standpoint and so found it easy later on to merge with the SDKPiL, on the extreme left. The introduction of universal suffrage in Austria, including the Austrian sector of Poland (Galicia), for the parliament in Vienna in 1907 promoted the founding of the agrarian Polish Peasant Party (PSL). This party soon spread its influence to southern Congress Poland, but it split in 1913 into a moderate majority and a radical left. Only in Prussia was the repression of Polish cultural and political life continued, and after 1905 this policy was pursued in an even more severe form. This was the main reason why the Polish National Democrats regarded the German *Reich* rightfully as their main opponent from 1905 on.

IV. Modern Poland, since 1914

THE FOUNDING OF THE SECOND REPUBLIC, 1914–21

Events during World War I. At the outbreak of World War I, the governments of Austria and Russia tried to use the Polish question as a political weapon. On August 16, 1914, the Austrian government allowed the formation of a Supreme National Committee (NKN) in Galicia, and the organization of a Polish legion recruited mainly from the membership of the followers of Józef Piłsudski. The ultimate goal of Austrian policy was the incorporation of Congress Poland into Galicia. On August 14, 1914, the Russian government recognized the basic right of the Poles to autonomy, particularly in the lands that the Russian troops hoped to conquer. The Polish National Committee (KNP) was formed in November 1914—its chief members coming from the National Democrats, led by Roman Dmowski. The KNP supported the Russian war effort, and Russian forces conquered almost all of Galicia in 1914.

Piłsudski and Dmowski

Division of Congress Poland. The troops of the Central Powers—Germany and Austria-Hungary—were able subsequently not only to retake Galicia but to advance deep into Congress Poland. The Central Powers divided it into two military occupation zones, with a German governor general in Warsaw and an Austro-Hungarian one in Lublin. The political groups in both of these zones separated into those who believed in adopting a passive stance and the activists. With the majority of the PPS and the left-wing intellectuals on their side, the activists established the Central National Committee (CKN) in December 1915, their goal being to re-establish a Polish republic with the help of the Central Powers.

Creation of a Kingdom of Poland. At the request of the German commander, Gen. Erich Ludendorff, and the German governor general, Hans Hartwig von Beseler, the German and Austrian emperors proclaimed a new Kingdom of Poland on November 5, 1916. The kingdom consisted of both the occupied zones but comprised only about one-sixth of the territory established in 1772. The hopes of both monarchs for more support among the Polish volunteer troops in the Austro-German fight against Russia were in vain, for German aspirations did not match the expectations of the Poles, who had envisioned an eastward expansion of the Kingdom of Poland. Ludendorff, in turn, tried to establish what he himself termed "a national kingdom of Lithuania" in the eastern regions. All these elements now gave the first incentive to an internationalization of the Polish question.

The Russian Revolution. The Russian Revolution in March 1917 brought about the two Poland proclamations of the Soviet of Petrograd and the provisional government of Russia. These recognized Poland's right to independence, while the latter insisted on a military alliance with Russia. After this, three Polish army corps were formed from the ranks of the Russian army between May 1917 and May 1918, and France also recruited a Polish volunteer army. Founded by Dmowski on August 15, 1917, in Lausanne, the Polish National Committee (KNP) worked closely with the governments of the Western Allies. In the Kingdom of Poland, Piłsudski and the Polish Legion, now reorganized as the Polish Auxiliary Corps, with about 20,000 men, clashed with the Central Powers. Piłsudski and the majority of his corps were interned in July 1917. The grant of a limited Polish self-government in the Kingdom of Poland and the installation of a Regency Council on September 12, 1917, came too late to overcome the distrust that now divided the Central Powers and the Poles.

The Polish National Committee

The fight for self-determination. The October Revolution in Russia, as well as the proclaimed principle of the "right for self-determination of all nations" as stated by both Lenin and the U.S. president Woodrow Wilson (though both with very different interpretations), gave the Polish question international significance. President Wilson demanded the creation of an "independent Polish state" with a free and secured access to the sea in his well-known "14-points speech" of January 8, 1918. This program was ratified as an integral part of the future peace settlement by the governments of France, Great Britain, and Italy on June 3, 1918. The Central Powers used the "right for self-determination of all nations" in the peace negotiations of Brest-Litovsk (now Brest, Belorussian Soviet Socialist Republic) in February–March 1918 as a pretext for the separation of the Kingdom of Poland from the Russian Empire, but they apportioned the Chełm province, with its predominantly Polish population, to the Ukraine on February 9, 1918. This infuriated Polish opinion.

Re-establishment of the state. The military collapse of Austria in October 1918 led to the formation of a Polish Liquidation Commission in Cracow on October 28, 1918, which assumed power in Western Galicia. On November 7 a Provisional Government of the Polish Republic was established in Lublin. With the collapse of the German *Reich* in November 1918, Piłsudski was freed from his internment in Germany. Returning to Warsaw, he took control of the whole of Poland on November 11, 1918. The administrations for the regions of Cracow and Lublin also put themselves under his command. November 11, 1918, has thus been generally recognized as the day of the founding of the Second Polish Republic.

Piłsudski's return to Poland

The Second Polish Republic. To begin with, the Second Polish Republic consisted of the Kingdom of Poland

as it existed in 1916, the Duchy of Cieszyn, and West Galicia. Poland's losses during World War I numbered about 800,000 dead as well as the destruction of the majority of industrial plants, communications, and the serious disruption of the Polish monetary system and economy.

Internal developments. Piłsudski secured his position of power in the country by reaching an agreement, in January 1919, with the Polish National Committee (KNP) in Paris, headed by Roman Dmowski. The KNP was the recognized official Polish delegation at the Paris Peace Conference. Ignacy Jan Paderewski, a close associate of Dmowski, formed a government in Warsaw in 1919, but the executive power remained in the hands of Piłsudski, as the Polish "chief of state," from November 22, 1918, until December 14, 1922. The succeeding democratic elections led to the formation of a constitutional Sejm, which operated both as the constituent and legislative assembly (1919–22) after the passing of the "Little Constitution" on February 20, 1919. The strongest parties in the country were the National Democrats and the Peasants (PSL), the latter for the most part cooperating with the National Democrats. The left-wing parties commanded only about one-quarter of the votes. The Communist Workers' Party of Poland was founded on December 16, 1918, and Workers' Councils were set up in November 1918. The Councils were broken up by the government in June 1919, and this established and secured a "bourgeois democracy" in Poland as opposed to the "Soviet democracy" in Russia.

The Treaty of Versailles. At the Paris Peace Conference the Polish delegation demanded the surrender of the formerly Prussian sector, Upper Silesia, and southern East Prussia (Mazuria) from Germany. The largest part of the province of Poznań was already under Polish authority because the December 1918 Polish uprising against the Germans in Poznań had engulfed almost the entire province. The Treaty of Versailles, signed on June 28, 1919, awarded Poland the main part of the Prussian sector, providing the desired direct access to the Baltic Sea, even though the port of Gdańsk (Danzig), to which the Poles had laid claim, became a "Free City." The plebiscite in Mazuria, held on July 11, 1920, resulted in a heavy defeat for Poland, partly because of the Polish–Soviet war, and it brought only a few border regions under Polish authority. The Polish population in Upper Silesia rebelled three times against the German administration. In the plebiscite of March 20, 1921, 682 communes voted for Poland and 792 for Germany, but the Poles secured preponderance in the southeastern plebiscite area, which was industrially the most important. The new frontier of October 20, 1921, divided this area: Poland was awarded 76 percent of the coal production, 22 out of 37 blast furnaces, and nine out of 14 steel works, with about 990,000 people. Populated by Poles, Czechs, and Germans, the former Duchy of Cieszyn was the subject of controversy between Poland and Czechoslovakia. On July 28, 1920, it was divided, but in a manner that left a considerable Polish minority in the Czechoslovakian sector.

Territorial disputes. Poland owed its rapid eastward expansion to its quickly recruited and effective army. Evacuation of the territories occupied in the east by the German troops had to be completed by the beginning of February 1919, but every strip of land left by the Germans was promptly taken over by the Red Army. Thus, between November 1918 and February 1919, that army moved westward from the Dnieper to the Bug River line. Piłsudski decided that it was imperative to throw back eastward the forces aiming at imposing a foreign form of government on restored Poland. The central part of historic Lithuania was occupied by the Poles in April 1919. On July 27 the Supreme Council approved a demarcation line between Poland and Lithuania, leaving Wilno on the Polish side. In eastern Galicia the West Ukrainian People's Republic had been established in November 1918, but Polish troops occupied it in June–July 1919. In addition, the Polish Army extended its sphere of influence over the largest part of White Ruthenia and over the western Ukraine—far beyond the boundary lines of the Second Partition of 1793—without meeting any serious resistance from the Red Army until December 1919, because the Russians were still embroiled in civil war. The Soviets launched a military offensive against Poland between February and May 1920. The militarily and politically ill-advised Polish advance against Kiev in June 1920 led to the Polish–Soviet war that had been brewing for the past one and a half years. The Red Army, under the command of Mikhail Tukhachevsky, advanced, reaching the vicinity of Toruń, Warsaw, and Lwów by July and August 1920. The Polish forces led by Piłsudski defeated the Red Army decisively, however, in a battle on the Vistula between August 16 and 28. This victory crushed the Bolsheviks' last chance of a widespread revolution in central and western Europe. The Polish Army reconquered Central Lithuania with Wilno (Lithuanian Vilnius), western White Ruthenia, western Wolhynia, and East Galicia before the armistice of October 12, 1920. The Soviet government finally recognized this boundary unconditionally in the Peace of Riga on March 18, 1921.

Defeat of the Red Army

POLAND BETWEEN THE WARS, 1921–39

The constitution of March 17, 1921, established a parliament consisting of two houses, the Senate and the Sejm. The political forces in the country had splintered up into numerous parties and groups, and this proved a hindrance to the development of a stable, unified parliamentary government.

Domestic policy. Between 1922 and 1926 Poland was governed by frequently changing cabinets that were based mainly on a coalition between the National Democrats, the Christian Democrats, and the moderate Peasant Party. The primary task of these governments was to attempt to eliminate the inflation that the destruction of World War I and the subsequent conflicts had caused. The government stabilized the situation through the introduction of a new currency, the złoty, on February 1, 1924. But the new currency was in danger again by 1925, mainly as the result of a tariff war instigated by the Germans. The financial crisis that followed led to high unemployment and severe unrest among the working people. This, in turn, gave the Communist Party a steadily rising influence, even though it had been declared illegal in 1923. Piłsudski had not been active on the political scene since 1923, but these new developments compelled him to organize a military coup on May 12–15, 1926, in order to take power. Supporting their former leader with a general strike, the PPS played a decisive role in Piłsudski's victory.

The Piłsudski coup

The Piłsudski government. Piłsudski headed the government from 1926 to 1930. His rule was a moral dictatorship with only a formal preservation of parliamentary authority. His administration aimed at the "moral cleansing" of society in Poland and at eliminating some of the widespread corruption. Piłsudski relied mainly on the army and the conservative nobility of eastern Poland for his support. Between 1926 and 1927 a right-wing opposition emerged, led by Dmowski. Piłsudski confronted them with his Non-Party Block for Cooperation with the Government (BBWR), which was a loose organization held together only by Piłsudski's personality. At any rate, in the elections to the Sejm held on March 4, 1928, the BBWR succeeded in obtaining one quarter of all the parliamentary seats, though a contributing factor for this political success was the increasing economic prosperity of 1926–29.

The Great Depression. The crisis in the world economy began to affect Poland in October 1929. Unemployment hit about 893,000 workers, excluding agricultural workers—or approximately one-third of those employed in 1931. Production sank between 1931 and 1933 to only 46 percent of the 1913 level. Under the pressure of the general misery and need, the PPS, the Polish Peasant Party (PSL), and some others united on November 1, 1929, to form a left-wing opposing coalition (Centrolew, or Centre-Left). Piłsudski employed harsh measures against his opponents, ordering the arrest of about 70 politicians. The Sejm elections of November 1930 gave

the BBWR its desired majority, but the genuine political parties now practically disappeared from the political scene. Piłsudski governed from 1930 to 1935 without holding an official public political office. His authority was based on the support given by the civil service and by his officers' corps and, in particular, the support of the colonels trained in the legions. Piłsudski tried to master the economic crisis through a program of non-intervention and thrift, but he was largely unsuccessful.

The 1935 constitution. A constitutional reform was introduced on April 23, 1935, strengthening the executive branch of government and giving the head of state the power to enact important laws without the approval of Parliament.

Piłsudski's successors. Piłsudski died on May 12, 1935, and the resulting struggle for power, complicated by strikes and demonstrations, soon reduced all parliamentary activity to a complete farce.

Opposition groups. The elections held in September 1935 and November 1938 showed this only too well, and a large part of the population and most of the opposition parties boycotted them. There were violent demonstrations and strikes in 1936 and 1938, and the beginnings of a popular front, bringing left and left-centre parties together, could be noted. The established radical workers' parties, the PPS and the KPP, found a new ally in the Peasant Party, which had now also become radical under its new leader Stanisław Mikołajczyk. Joseph Stalin's reaction to these signs of national unity was to have the Comintern dissolve the Communist Party of Poland in 1938, branding its leaders as provocateurs and capitalist agents. On the right wing, the National Radical Camp (ONR) generated some Fascist groups, but they were dissolved in 1934 and received hardly any support. Founded by the government on March 1, 1937, the Camp of National Unity (OZN) remained an authoritarian association that—like the BBWR—had no real social or political platform.

Dissolution of the Communist Party of Poland

Social problems. The important social questions of Poland remained unsolved in the time between World Wars I and II. Any permanent solution was beyond the reach of the country's economic resources. The surplus in the agrarian population could only have been eliminated by a comprehensive program of industrialization, but there was no capital to do this. Nevertheless, the agrarian reform based on the laws of July 15, 1920, started the distribution of approximately one-tenth of all arable land. Industrialization made some progress with, for example, the energetic promotion of the chemical industry and the building of the "coal-railroads" from Upper Silesia to the Baltic Sea coast, but the funds necessary for investment in these enterprises stretched Poland's national economy to its limits. The entire 1938 production barely reached the 1913 level. Poland remained an agrarian country, and about two-thirds of its total population depended either directly or indirectly on its agricultural produce. Only one-quarter of the country's inhabitants received their income from industry.

Foreign policy. In its foreign policy, Poland attempted to strengthen its position through alliances with France and Romania (1921). Endangered by political and military cooperation between Germany and the U.S.S.R., as well as by their concerted policy aiming at the revision of existing frontiers, Poland found itself in a hazardous position after the treaties of Locarno (1925) and the April 1926 treaty negotiated by Gustav Stresemann and Georgy Vasilyevich Chicherin of the Soviet Union stating that German–Soviet relations should continue to be based on the 1922 Treaty of Rapallo. Acting under Piłsudski's instruction, Józef Beck, Polish foreign minister, concluded a nonaggression pact with the U.S.S.R. in 1932, and a similar one with Germany in 1934—the latter preserving both Poland's alliance with France and its freedom of action as a member of the League of Nations. This safeguarded Poland's position, at least for a short time (1934–38). But the German *Reich* had by now annexed Austria and the largest part of Czechoslovakia, and it established control over the Slovakian and Lithuanian republics. This placed it in such a strategically favourable position toward Poland that Adolf Hitler now dispensed with all caution. His proposals for a global solution were aimed at placing Poland in a situation of complete dependence on Germany so that he would be able to make Poland into a base for his planned attack on the U.S.S.R. Observing the guarantee of March 31, 1939, the British government under Neville Chamberlain gave Poland diplomatic, but no military or financial, assistance. This did nothing to prevent the Germans from attacking Poland or to stop the outbreak of World War II. Hitler, on August 23, 1939, concluded with Stalin a nonaggression pact containing a secret protocol dividing Poland into German and Soviet spheres of interest, circumscribed by the Narew, Vistula, and San rivers. This "Fourth Partition of Poland" proved to be the decisive factor leading to the outbreak of World War II.

Beck's nonaggression pacts

POLAND DURING WORLD WAR II, 1939–45

Defeat by Germany. The fall of Poland came unexpectedly fast during the September campaign of 1939. Warsaw capitulated on September 27, 1939, after the defeat of the Polish Army. The last organized Polish resistance ended on October 5, 1939. Following German demands, the U.S.S.R. ordered two army corps to invade eastern Poland on September 17, 1939, breaking its earlier agreements of 1921 and 1932. On September 28, 1939, Hitler and Stalin again agreed on a new partition of Poland along the Narew, Bug, and San rivers. Hitler's plans for the creation of a Polish puppet state did not materialize because no collaborator could be found. On October 12, 1939, Hitler gave the order to annex outright the former Prussian section, parts of Mazovia, eastern Great Poland with Łódź, and a border strip in Little Poland.

The division of Poland

Soviet annexations. The regions in the Soviet sphere of interest were incorporated into the U.S.S.R. with the added help of supervised plebiscites held between October 22 and November 2, 1939. In contrast with German procedure, the U.S.S.R based its decisions, at least formally, on the "right for self-determination of the nationalities," hoping in this way to get its demands internationally legalized. The annexation carried out by the U.S.S.R. put the British government into an embarrassing situation. On the one hand, it had guaranteed the security of Poland, while, on the other hand, it did not want to risk a conflict with the U.S.S.R. It was for this reason that on October 26, 1939, the British foreign minister Lord Halifax pointed to the fact that the westward extension of the Soviet boundary approximated the earlier Curzon line of December 8, 1919, and of July 11, 1920. He was the first European statesman to do so, but this explanation became the basis for the later establishment of the boundary between Poland and the U.S.S.R. at the end of World War II.

Polish government-in-exile. The forming of a Polish "government-in-exile" in France, based on the 1935 constitution, assured the survival of the Polish Republic. Its leading statesman and supreme commander was Władysław Sikorski. The Polish government-in-exile moved to the United Kingdom after the defeat of France in June 1940. A civil and military resistance movement was also formed in occupied Poland in September 1939.

German repression. From the very beginning, in October 1939, the occupational policy of the Germans was designed to completely eradicate Polish culture. Almost the entire Polish school system was suppressed. Mass executions of Polish intellectuals were carried out, and the infamous concentration camp of Oświęcim (Auschwitz) was set up. The intention was to Germanize the territory, and mass deportations of Poles and mass settlings of Germans in their place were supposed to accomplish this. Germans from the Baltic states and eastern Poland were transferred to the western Polish lands incorporated into the German *Reich*. The Soviet government also participated in mass deportations of the Polish inhabitants from the eastern parts of their country incorporated into the U.S.S.R.

Alliance with the U.S.S.R. The German attack on the U.S.S.R. on June 22, 1941, changed the situation drasti-

cally for Poland since the Germans now began to occupy Soviet-held Poland. In addition, there now existed the possibility of an armed alliance between the Polish government-in-exile and the U.S.S.R. In accordance with the Polish–Soviet agreement of July 30, 1941, a Polish army was set up in the U.S.S.R. under Gen. Władysław Anders. But the Polish units were moved to Persia in 1941 and later fought in the Near East and North Africa. Stalin agreed to the annulment of the "Fourth Polish Partition" agreement between the German and the Soviet governments of 1939, but he declined the restitution of the Polish–Soviet border of 1921. In his debate with the British foreign minister Anthony Eden on December 16, 1941, he proposed the Curzon line as the basis for the future Polish–Soviet boundary.

After the outbreak of hostilities between Germany and Soviet Russia, the German government consolidated East Galicia with the rest of occupied Poland, even though the majority of the population in East Galicia was Ukrainian.

German policy of extermination. The extermination of the Polish intellectuals and the mass deportation of Poles, particularly from the areas around Poznań, Łódź, and Zamość, was vigorously pursued. The Polish citizens of Jewish descent, hundreds of thousands of whom had been interned in the ghettos of the large cities, were deported to extermination camps, such as Auschwitz and Treblinka, where they were killed, along with the Jewish population of the greater part of Europe. Neither the belated ghetto risings of Warsaw, Białystok, and Wilno (April–September 1943) nor the special actions taken by the Polish underground were effective enough to halt this extermination. According to the most careful estimates, about 3,350,000 Polish citizens of Jewish descent were slaughtered. Millions of Polish citizens were sent to forced labour camps in Germany, and hundreds of thousands were executed.

The ghetto risings

Polish resistance. It is not surprising that the Polish underground grew quickly since it considered itself primarily a national organization for self-protection.

From January 1942 on, the Communist and left-wing socialist groups again gained influence. The Polish Workers' Party (PPR) and its military wing, the People's Guard (GL; later the People's Army, or AL) developed from their ranks. One of the secretaries of the PPR was Władysław Gomułka (born in 1905), who was subsequently to become deputy premier of Poland and first secretary of the Polish Communist Party. The PPR became an important and powerful factor when the U.S.S.R. terminated its relationship with the government-in-exile in London after the Katyn affair of April 1943, involving allegations that the Soviet authorities had murdered about 13,400 Polish officers in April 1940. A second government-in-exile was subsequently set up in the U.S.S.R. by the Union of Polish Patriots. The turning point on the Russian front came between June and September 1943, when the Soviet forces began their westward advance. In January 1944 they crossed the frontier of the Riga peace treaty, pushing forward to the Curzon line. By July 31, 1944, the Polish territories all the way to the Narew, Vistula, and San rivers were under Soviet control. On July 21, 1944, the Polish Committee of National Liberation (PKWN) was established in Chełm (later in Lublin) representing the opposing faction to the government-in-exile in London.

The Warsaw uprising

The uprising of Warsaw on August 1, 1944, was staged by the Home Army (AK) to stabilize the administrative power of the London exile government in the capital, which was still occupied by German troops. This insurrection remained without British and Soviet support, however, and the AK had to capitulate. This, in turn, assured the pre-eminence of the Lublin Committee. On January 1, 1945, the Lublin Committee reorganized into a provisional government and exercised authoritarian control in all the territories west of the Curzon line, which had been occupied by the U.S.S.R.

German defeat. The Soviet and Polish armed forces, the latter recruited by the provisional government, began the great winter offensive in January 1945. Taking almost all the lands along the Oder and Neisse rivers by March 10, 1945, they established a decisive precedence over the non-Communist Polish troops fighting in Western Europe as to the making and implementing of political decisions in restored Poland. At the Yalta Conference (February 4–11, 1945), both Franklin D. Roosevelt and Winston Churchill sacrificed the legitimacy of the London government-in-exile to Stalin by consenting to the formation of a mixed interim government in Poland. With the consent of the Soviet government, the provisional Polish government officially assumed sovereign control over all German lands east of the Oder and the western Neisse rivers, in addition to the territory of the Free City of Gdańsk, between February 5 and May 24, 1945.

Emergence of the People's Republic. The provisional government signed a mutual pact with the U.S.S.R. on April 21, 1945. After many difficulties, the new Polish Government of National Unity was finally constituted on June 28, 1945. It included Western-oriented politicians such as Stanisław Mikołajczyk, who became vice premier. But at the same time it assured itself of the predominance of Soviet-inclined parties, especially the PPR, under Władysław Gomułka and Bolesław Bierut. Harry S. Truman and Winston Churchill appreciated this bias in the Polish government and decided on a policy of strong resistance to Stalin.

Potsdam and the Oder–Neisse line

With this policy in mind, they stipulated at the Potsdam Conference (July 17–August 2, 1945) that the Polish western boundary along the Oder and Neisse rivers should be recognized as a temporary boundary. Despite this, the Allied governments removed all ethnic Germans from the territory east of the Oder and Neisse rivers, thus securing Polish sovereignty. The Polish–Soviet treaty of August 16, 1945, confirmed the Polish eastern boundary along the Curzon line.

Effects of the war. About 6,000,000 Polish citizens, or 22 percent of the total population, died during World War II. Of these, only 600,000 were actual war casualties. The greatest loss, approximately 4,500,000, was due to mass extermination, deportation, exile, and emigration. The damage to industries, communications, housing, buildings, and to culture in general from the war has been impossible to estimate. The Germans were responsible for at least four-fifths of these losses; the rest was the responsibility of the U.S.S.R. World War II was thus the greatest catastrophe in Polish history in terms of total loss of life and property and as a result of the thorough and premeditated attempt at genocide.

POLAND AFTER WORLD WAR II

Formation of the People's Republic. Under the Polish Government of National Unity that was in power between June 28, 1945, and February 6, 1947, Poland was again a formal democratic republic, recognizing the constitution of March 17, 1921. But the nationalization of the large- and medium-size industries in 1946 and a few changes in the constitution, endorsed by a plebiscite on June 30, 1946, were a prelude to the reorganization of the Polish government into a People's Democracy. Strong resistance was raised against this, and only one-quarter of all the soldiers who had fought in the armies under British command actually returned to Poland. In Poland itself an effective opposition was organized against the often despotic measures taken by the government. Influential groups of the grand old parties, such as the National Party, PPS, SL, and SP, supported the resistance movement, which was founded on September 2, 1945. The resistance movement had as its aim a "democracy in a western European interpretation" and "Christian ideals." The Polish security corps, the police, and the Polish Army quelled the partisan war waged by the resistance movements with extreme harshness, particularly during the period between March 1945 and April 1947. This resistance later made it all the more difficult to establish legal bourgeois parties. The National Party and other right-wing associations were declared illegal from the very beginning, but the political groups that collaborated with the government formed a "bloc of democratic parties," led mainly by the PPR, under Bierut and Gomułka, and the left wing of the PPS, under Józef Cyrankiewicz and Adam Rapacki. In the elections for the legislative

Resistance to sovietization

National Assembly on January 19, 1947, this democratic bloc received 80.1 percent of all votes cast, according to official figures.

Socialist Poland. The gradual conversion of Poland to a purely socialist state took place under the presidency of Bierut (1947–52) and under the premiership of Józef Cyrankiewicz. Gomułka became deputy premier. The entire national economy was nationalized and brought under public ownership. The exception was the agricultural sector, which was only partially collectivized. On December 15, 1948, the PPR and the PPS merged to form the Polish United Worker's Party (PZPR). With the growing political hostility between the U.S.S.R. and the Western powers between 1947 and 1949, Stalin ordered the purging of those politicians who were considered "rightist-nationalist" deviationists. Being part of this group, Gomułka and his supporters were taken into custody (September 1948 to November 1949). This left Bierut as both president and first secretary of the PZPR (1948–56). The planned socialist economy was finally introduced with the establishment of the State Planning Commission on February 4, 1949, and the adoption of the six-year plan on July 21, 1950.

The purges ordered by Stalin

The new constitution. On July 22, 1952, a new Soviet-type constitution was passed and was slightly revised in 1972. This made Poland a People's Republic. Under this constitution the supreme organ of state authority was the Council of State; and the supreme organ of state administration was the Council of Ministers appointed by and responsible to the Sejm. In the elections of October 26, 1952, the PZPR received about 64 percent of all the seats in Parliament. The constitution remained purely formal, however, considering the factual dictatorship of the PZPR.

The post-Stalin period. After Stalin's death, Cyrankiewicz returned to the prime minister's office (1954–57). Political repression was relaxed, and about 100,000 political prisoners were freed in 1955 and 1956. But the real de-Stalinization was not implemented before the 20th congress of the Soviet Communist Party in 1956, after the sudden death of Bierut on March 12, 1956. The leadership of the PZPR considered the severe workers' unrests in Poznań in June 1956 a warning signal, and they therefore found it expedient to endorse a deep consideration of possible reforms. Reinstated on August 5, 1956, Gomułka again took over the leadership of the PZPR since he was the only man who could restore party unity and count on wide popular support.

Re-emergence of Gomułka

The leadership of Gomułka. The party leadership of Poland was still autocratic under Gomułka (1956–70), but the country experienced a much more liberal government than the other states in the eastern bloc. The administration allowed the return of private ownership in small businesses, great efforts were made for the construction of new homes, the collectivization of agriculture was revoked, and the freedom of the press was considerably extended. From 1956 to 1971 the PZPR maintained a steady 51 percent of all seats in Parliament due to predetermined selection of candidates, but a certain political codetermination of other parties or groups was now tolerated. There were power struggles within the PZPR from which the "partisans" under the leadership of Gen. Mieczysław Moczar, minister of the interior, emerged as the strongest faction in 1964. Moczar and his supporters suffered a setback in connection with the student unrests and with their policy of anti-Zionism in 1968, but they were not totally removed from their position until 1971.

Cultural developments. The scientific achievements and the general level of education reached a very high level under the Gomułka regime. The Catholic Church was able to expand its work relatively freely after an agreement reached in 1956. The Polish episcopacy was instrumental in preventing open rebellions and thus indirectly preventing Soviet military interventions, especially in October 1956 and in December 1970.

Agriculture and industry. The loss of human life during World War II, the land distributions in the western districts of Poland, and the agrarian reforms of 1944 and 1945 much improved the long-standing agrarian crisis in Poland. It was finally completely eliminated under Gomułka, who followed the principle of private ownership for the farmer. Consequently, an average of about 85 percent of the arable agricultural land was in private hands during the years 1956 to 1972. Growing industrialization, which had begun even before 1956, started a mass exodus of people from the rural areas into the metropolitan centres. The system of a centrally controlled economy proved too stifling and inhibiting as the industries began to expand. For this reason, the fifth convention of the PZPR in 1968 alleviated the restrictions. The single-handedness of Gomułka's decisions, his disregard for popular opinion, and finally the bad harvests in 1969 and 1970 led to severe unrest among the working people in the Baltic seaport cities in December of 1970. He was forced to resign on December 20, 1970. His successor, Edward Gierek, secured popular support through his policy of extending the consumer industries and through promoting public discussions and rehabilitating many members of the creative intellectual class, although he was unable to eliminate the danger of creeping unemployment.

In March 1972 Henryk Jablonski was named to the presidency, and Pyotr Jaroszewicz to the premiership.

Foreign policy. During the Cold War and due to the U.S. policy of disengagement in eastern Europe between 1949 and 1956, Poland's foreign policy remained closely tied to that of the U.S.S.R. In 1949 Poland joined the Council For Mutual Economic Assistance (Comecon); and it became a member of the Warsaw Pact in 1955. The central problem of Polish foreign policy has been the legal, international recognition of its western boundary (the Oder–Neisse line). The German Democratic Republic recognized this boundary in 1950, but the Federal Republic of Germany disputed it at least until 1963. The governments of the U.S., U.K., and France recognized this western border line tacitly after the gradual cessation of the Cold War from 1956 onward. The Polish–Soviet agreement of 1965 renewed the Soviet border guarantee that had existed since 1945. The Polish foreign minister Adam Rapacki tried to slowly break through the iron curtain with his plan for disarmament, put forth for the first time on October 2, 1957. After the nuclear test ban treaty, concluded in 1968, and the start (November 1969) of the strategic arms limitation talks between the U.S. and the U.S.S.R., the Rapacki plan again became the basis for serious negotiations toward a planned European security system. In connection with the policy of general relaxation, Gomułka, the West German chancellor Willy Brandt, and Cyrankiewicz signed in Warsaw on December 7, 1970, a treaty declaring that the existing German–Polish border line, determined at Potsdam on August 2, 1945, by the governments of the United States, Great Britain, and the Soviet Union, "forms the western state frontier of Poland"; the Federal German government "affirms the inviolability [of this frontier] now and in the future."

The Rapacki plan

A visit to Warsaw by U.S. president Richard Nixon (May 31, 1972) resulted in the establishment of closer trade contacts with the U.S.

BIBLIOGRAPHY. The standard work for the political history of Poland until 1936 is *The Cambridge History of Poland*, 2 vol. (1941–50), with chapters written by the acknowledged Polish and British scholars of the period between World Wars I and II. Contributions by leading historians of the People's Republic of Poland are included in ALEKSANDER GIEYSZTOR *et al.*, *History of Poland* (1968), which covers events until 1939. A group of scholars in exile have published the representative collection: HENRYK PASZKIEWICZ *et al.*, *Polska i jej dorobek dziejowy* (1956), recounting Polish history until 1918. Of further importance are the chapters on Poland in *The New Cambridge Modern History*, vol. 1 (1961). The results of recent historical research in Poland are available in essays and synoptic form in English, French, or German in the *Acta Poloniae Historica* (annual). Of considerable value also are the Polish contributions to the international congresses for historical research. For an evaluation of Polish history from the Catholic point of view, see OSKAR HALECKI, *La Pologne de 963 à 1914* (1933; Eng. trans., *A History of Poland*, rev. ed., 1960). The recognized standard work on Polish culture and its history of ideas is ALEXANDER BRUCK-

NER, *Dzieje kultury polskiej*, vol. 1–3, 3rd ed. (1957–58), and vol. 4, 2nd ed. (1946). Still absolutely necessary for the social sciences and the development of economics in Poland is JAN RUTKOWSKI, *Historia gospodarcza Polski*, 2 vol. (1947–53). The collective work *Miasta Polskie w tysiącleciu*, 2 vol. (1965–67), contains a wealth of material on the subject. For a concise history of the development of Polish government, the *Historia ustroju Polski w zarysie* by STANISLAW KUTRZEBA, completed by ADAM VETULANI, 8th ed. (1949), is still basic. It should be complemented by the more detailed work of the two scholars in constitutional history, JULIUSZ BARDACH and B. LESNODORSKI, *Historia państwa i prawa Polski*, 2nd ed., 2 vol. (1964–66), which also features an excellent bibliography. Polish church history is synthesized in *Kościół w Polsce*, 2 vol. (1968–69), written by a group of researchers of the Catholic University of Lublin under the editorship of JERZY KLOCZOWSKI. JAKUB SAWICKI has published numerous studies on the religious minorities in Poland, such as *Studia nad położeniem prawnym mniejszości religijnych w państwie polskim* (1937), on the legal position of religious minorities in Poland. The Polish government has recently republished the history of former eastern Poland and its minorities in single volumes. Beyond these are OSKAR HALECKI, *Borderlands of Western Civilization* (1952); and ADAM ZOŁTOWSKI, *Border of Europe* (1950). MARIAN KUKIEL, *Zarys historii wojskowości w Polsce*, 5th ed. (1949), is still fundamental for the country's military history. The era of the founding of the state and the time of the early Piasts has been most thoroughly researched after 1945, mainly as the result of new excavations. Important in this respect is WITOLD HENSEL, *Polska przed tysiącem lat*, 3rd ed. (1967; Eng. trans., *The Beginnings of the Polish State*, 1960). The Middle Ages and early modern times are all discussed in the above-mentioned works. The following monographs in western languages are currently available: HERBERT H. KAPLAN, *The First Partition of Poland* (1962); JEAN FABRE, *Stanislas-Auguste Poniatowski et l'Europe des lumières* (1952); WALERJAN KALINKA, *Der Vierjährige Polnische Reichstag 1788–1791*, 2 vol. (1896–98); R.H. LORD, *The Second Partition of Poland* (1915); M. HANDELSMAN, *Napoléon et la Pologne, 1806–1807* (1909), now somewhat dated; MARIAN KUKIEL, *Czartoryski and European Unity, 1770–1861* (1955); R.F. LESLIE, *Polish Politics and the Revolution of November 1830* (1956) and *Reform and Insurrection in Russian Poland, 1856–1865* (1963). Outstanding on the subject of the founding of the Second Republic is TITUS KOMARNICKI, *Rebirth of the Polish Republic* (1957), containing an extensive bibliography and documentation. A recent modern history of Poland is HANS ROOS, *Geschichte der polnischen Nation* (1961; Eng. trans., *A History of Modern Poland*, 1966).

(Ha.Ro.)

Polar Biomes

The polar regions comprise the Arctic, in the north, and the Antarctic, in the south, and although these two are apt to be confused, they are indeed "poles apart" as regards their animal and plant associations, or biomes. The few similarities that exist result chiefly from the coldness, widespread aridity, and level of latitudes. (Because of the latitude, day and night practically divide the year: the sun is continuously above the horizon in summer and below it in winter.) Even the criterion of coldness is elicited mainly in contrast with more hospitable regions, for in the Arctic there is probably no lowland area that does not enjoy for at least one month in each year a mean temperature appreciably above the freezing point, although in the Antarctic only the off-lying islands and the coast of Graham Land on the Antarctic Peninsula are favoured with this warming.

Boundaries of the polar regions

Because the arbitrary latitudinal Arctic and Antarctic circles have no meaning as natural boundaries for plants and animals, biologists regard the polar regions in general as lying poleward of the limits of tree growth. One generally recognized natural boundary of the Antarctic is the Antarctic Convergence—a delimitation in the sea, where cold surface-water layers spreading northward from the continent meet with and sink below warmer mixed sub-Antarctic waters. This boundary embraces to its south some of the sub-Antarctic islands, such as Heard Island and South Georgia.

In the present context, biomes are taken to be more or less climax formations of plants and animals considered together and comprising the biota—apart from recent introductions and other disturbances caused by man.

THE ENVIRONMENTAL SETTING

Fossil evidence indicates that in earlier geological ages many parts of the Arctic and Antarctic had temperate or warmer climates favouring quite luxuriant tree growth. Over millions of years the change to relative barrenness has occurred probably both through variations in world climate (the ice caps are no more than 4,500,000 years old) and through the drifting of landmasses poleward from lower latitudes. In any case the polar regions today —especially the Antarctic—are characterized by extremely harsh climates. Precipitation is generally so low —often only a few centimetres (a centimetre is about 0.4 inch) a year—in the highest latitudes that, coupled with the low temperatures and permanently frozen subsoil, there prevails a desert-like barrenness. Nevertheless, the availability of snow meltwater, often throughout the short growing season, and the long-lasting summer daylight favour some limited plant growth.

Desert-like barrenness

The Arctic. The highest latitudes in the north are occupied by the Arctic Ocean, the farthest north land being in Greenland and the Canadian Arctic Archipelago. To the south stretch islands or major landmasses, which in many sectors of the northern polar cap extend into the sub-Arctic and then temperate zones, thus affording more or less continuous dispersal routes for plants and animals from the south. The Arctic Ocean is deep, but the surface is largely covered by floating ice. The land area is commonly rugged, with widespread mountain ranges and glaciers descending to the sea—especially in Greenland, occupied by the world's second-largest ice cap (see ARCTIC OCEAN).

The Antarctic. The highest latitudes in the south are occupied by the continent of Antarctica, which is largely covered under the world's greatest ice cap. Only on projecting mountains (nunataks) and limited ice-free tracts near the shores, comprising about 4 percent of the total area, can land plants grow. The continent is far more isolated than is any Arctic land, being fully 800 kilometres (500 miles) from the nearest continental landmass, though scattered and usually small sub-Antarctic islands exist and very probably act as "stepping stones" for some limited plant and animal dispersal. Nevertheless, for practical purposes the Antarctic is isolated by formidable sea barriers that have made it extremely difficult for colonization by plants and animals since the last glacial period (see ANTARCTICA).

THE BIOTIC COMPONENT

Arctic and Antarctic plants and animals are extremely well adapted to their harsh and inhospitable environments. The form of adaptation is often similar in both polar regions, but rather few species are common to the two. While their terrestrial and freshwater ecosystems (ecological communities considered as a unit together with the nonliving factors of their environment) are widely different, the far more prolific marine ecosystems are comparable; indeed in both the Arctic and the Antarctic, it is chiefly in the seas that life abounds.

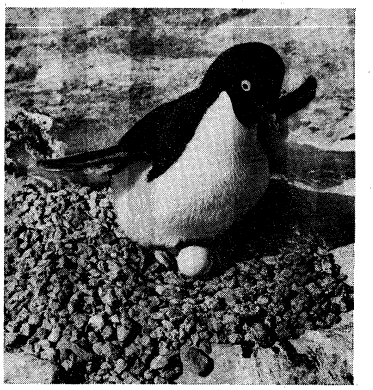
Richness of life in polar seas

Vegetation. Polar food cycles, from plant producers through various animal consumers, are relatively simple, with few organisms linked together. Unfavourable climatic and soil conditions combine to limit severely plant growth in the Antarctic. But in the Arctic, vegetation is often fairly luxuriant in the southern tundra ranges, and its component plants are very diverse—as also are the dependent animal species. Of Arctic flowering plants and ferns, about 1,000 different species are known from regions north of the tree line. Some of these are confined to the Arctic, but the vast majority range far southward—especially on mountains, in characteristic Arctic-Alpine distribution. The more primitive "lower" plants are less known but probably include almost as many species of mosses as of vascular plants and some 300 species of liverworts. Lichens are probably at least as numerous as the mosses, and the fungi are surely far more so, fully 850 species of fungi having been recorded from Greenland alone. Arctic algae are very numerous, —probably more than 2,000 different species, a considerable number of which are limited to the Arctic Ocean. The

bacteria of the Arctic have been insufficiently studied, but their numbers must be considerable, for a wide range of types occurs in both salt- and freshwaters, as well as in bottom deposits and soils.

In marked contrast to the Arctic, the Antarctic proper possesses only two native flowering plants: a grass, *Deschampsia antarctica,* and a relative of the pinks, *Colobanthus quitensis.* Though both of these are limited to favourable exposures in the Peninsula sector, they also occur on the sub-Antarctic islands and in southernmost South America. Apart from some algae and other relatively simple organisms, terrestrial life is restricted to the 4 percent of land area that is ice-free. There occur more than 70 species of mosses but relatively few liverworts. Lichens are the most successful and widespread group of plants in Antarctica because of their ability to colonize bare rock surfaces and their physiological adaptation to low temperatures and arid conditions; about 400 species have been recorded from the continent, although this number may be reduced by critical taxonomic study in the future. They extend to slightly over 86° S, and include *Verrucaria serpuloides,* the only known marine lichen, which passes its entire existence underwater. Of algae, approximately 360 nonmarine species have been recorded from Antarctic ice, snow, soils, and temporary summer ponds. The snow algae, which give rise to reddish, yellow, or green patches of snow, are found only in the coastal areas where permanent snowfields undergo extensive annual thawing.

Compared with the Arctic, fungi and bacteria are few in the Antarctic. Bacteria that were isolated from lakes, and yeasts of the genus *Candida* isolated from rock detritus and snow, proved remarkably well adapted to low temperatures. In the seas more than 200 species of algae have been recorded, the majority being diatoms; bottom-dwelling algae in shallow waters sometimes form extensive miniature "forests".



Animal life. Arctic animals tend to be far less numerous than plants, both in species and individuals. In North America the most notable among Arctic mammals on land are the Arctic hare, wolf, fox, collared lemming, polar bear (chiefly along coasts), short-tailed weasel, caribou, and musk-ox. Except for the musk-ox, these animals are all represented in Arctic Eurasia by the same or related species. All these mammals reach the far north, most of them practically to the northernmost limits of land, but some others, including the wolverine, shrews, ground squirrels, and some additional small rodents and weasels, range well into the Arctic without reaching so very far north. This is also the case with the brown bear, red fox, and ermine.

Range of animal life in the Arctic

The Arctic seas are the habitat of various seals, whales, walrus, and narwhals, while white whales (belugas) frequent narrow inlets and the mouths of rivers. (Man in ever-increasing numbers threatens to change the fragile ecosystems of the Arctic as never before; see CONSERVATION OF NATURAL RESOURCES.)

Although a few marine birds range over the Arctic Ocean north of the northernmost coasts, most Arctic birds are limited to the vicinity of land and southward. Almost all of them migrate south to spend the winter, but Arctic ptarmigan regularly and snowy owls sometimes remain in the far north. On land, numerous ducks, geese, and waders, particularly, come to nest and pass the summer, as do some swans, while pipits and ravens are widespread, as are various falcons and other birds of prey. Often nesting in vast numbers collectively on bird-cliffs or on the ground are various kinds of guillemots (murres) and terns, as well as puffins, little auk, and fulmar. Loons, or divers, call eerily from the numerous shallow lakes, and various kinds of gulls and skuas, or jaegers, screech from above. The Arctic, in fact, seems to abound in bird life in summer. At this time of year also the air inland (except in the far north) teems with insects, especially mosquitoes. Still farther south the insects probably contribute the greatest number of species to the total fauna; they diminish drastically in the far reaches of the north, except for the wingless springtails (Collembola), which occur even on snow and ice.

Animal life in Antarctica.

By courtesy of (top right and bottom) the U.S. Navy; photograph, (top left) Popperfoto

Freshwater fish also extend well into the Arctic, the northernmost apparently being the Arctic char (*Salvelinus alpinus*) found in lakes around 82° N. Other prominent Arctic fish include cods (Gadidae), eelpouts (Zoarcidae), sculpins (Cottidae), and lumpsuckers and related forms (Cyclopteridae); a few sharks also occur. The Arctic marine-invertebrate life is often particularly rich and includes many sizable Crustacea; this fauna is dependent for food on the seasonally abundant phytoplankton and in turn supports most of the vertebrate animals.

Like the land vegetation, the animal life of Antarctica is extremely poor. Truly terrestrial vertebrates are lacking, though various sea-feeding penguins and fulmar and other petrels come ashore to breed—as do also the great skua, Dominican gull, Antarctic tern, and Antarctic shag. There are four kinds of truly Antarctic seals, all belonging to different genera—the Weddell seal, the leopard seal, the Ross seal, and the crabeater seal, of which the last-named is the most abundant seal in the world, numbering an estimated 5,000,000 to 8,000,000 individuals. Several of the largest species of whale are still found in the open seas around Antarctica, though their populations have been drastically depleted by excessive hunting. By extreme contrast the largest terrestrial animals of these rigorous regions are two species of small midges, one of which is winged and the other wingless; these, in addition to a limited array of mites, springtails, micro-

Scarcity of animal life in the Antarctic

scopic rotifers, tardigrades, protozoans, nematodes, and rare enchytraeid worms, constitute the native land fauna. In the adjacent seas there is an abundance of the crustacean krill (*Euphausia superba*), constituting the greater part of the food of the blue, fin, and humpback whales, and a vast array of other zooplankton, often in great abundance, even at depths where the temperature is constantly below the freezing point of freshwater.

COMMUNITY STRUCTURE

Unlike the situation in most parts of the world where plants form the main embellishment on land, the Arctic and, to a far greater extent, the Antarctic tend to have the framework of their terrestrial ecosystems dominated by the physical structures that locally make up the earth's surface. In the Antarctic, nesting penguins, because of their accumulated mineral-rich guano (excrement), may create barrens on which no plant can grow; but, on the other hand, large seaweeds in the sublittoral (below tide) zones of the sea create suitable habitats for a wide range of marine animals. Thus on land it is chiefly in the low-Arctic and the sub-Antarctic islands that plants really affect the landscape.

In the polar regions the struggle of the totality of organisms tends to be more with the extremely exacting environments than with one another, though some competition for space and food does exist. This occurs among both animals and plants, but, in general, what one immediately sees of living materials in these regions consists almost entirely of plants, the greatest development of which is the Arctic tundra of low-growing species interspersed with lichen-covered rock fields and numberless ponds (see TUNDRA).

Besides marshy and other seaside vegetational types of limited extent, there may be extensive areas of sedges and cotton-grasses (*Eriophorum*), and of true grasses, such as *Arctophila* and *Arctagrostis*, around lakes and ponds in the Arctic. Luxuriant "patchwork quilt" communities of mixed mosses and lichens are often found around and above bird-cliffs, nourished by mineral-rich bird excrement. Where the snow drifts so deeply in winter that the growing season is drastically reduced by its late melting, zoned series of vegetation types develop. The seas abound in tiny free-drifting organisms, or plankton, of which the plant component, or phytoplankton, occur as deep as light penetration allows; these last support a wealth of crustacean and other zooplankton and, ultimately, fish and mammals (*e.g.*, seals and whales). Even floating ice bears a considerable population of diatoms on both its upper and lower surfaces, making the ice appear a dirty brown in summer.

Effect of snow on vegetation

The Antarctic, by contrast, is impoverished. There is no true tundra on the continent, but only occasional thin tracts of sparse mossy vegetation and algal and lichen patches in especially favoured places. These tracts are found along coasts where the climate is mildest; they contribute to the peat formations on the west side of the Antarctic Peninsula. Other terrestrial habitats include rocky coastlines, the slopes of mountains projecting above the continental ice cap, glacial moraines, summer meltwater channels, and warmed areas around volcanically active fumaroles (holes emitting hot gases and vapour). There are also some lakes and numerous freshwater ponds and puddles. In all such areas on land and in freshwaters, however, the biomass, or totality of living things, is such that vegetation appears to the uninitiated to be virtually lacking except in especially favoured areas that are merely tinted by it. By contrast, in shallow marine waters the biomass of living matter may be considerable, being often greater than in the Arctic. This richness of sea life results apparently in part from the upwelling of nutrient-rich waters in the Antarctic Ocean.

The sub-Antarctic islands south of the Antarctic Convergence show polar affinities and are commonly included as part of the Antarctic in the broad sense, though on the islands of Kerguelen, Heard, and South Georgia, there are commonly coastal tussocky grasslands of *Poa* or *Festuca* species and inland fields of herbaceous plants, with mainly lichens and mosses on higher land. Especially notable is the Kerguelen cabbage (*Pringlea antiscorbutica*), the sole representative of its genus. Some ferns and a club moss occur in protected habitats. Animal life on these islands is more prolific than on the Antarctic continent; insects and birds are numerous.

Antarctic islands' vegetation

COMMUNITY DEVELOPMENT AND PRODUCTIVITY

Although in and around the nesting rookeries of seabirds (except for the penguins as described earlier) the plants may to a considerable extent follow the animals, in general the opposite obtains. Vegetation develops how and where it can, and the animals follow—often becoming regular and important associates, doubtless helping to spread the plants by disseminating seeds and other plant parts. Thus, characteristic biomes develop, often in spite of cyclic or other changes in which the polar regions abound. As for successional (seral) changes in the Arctic, marshy and boggy formations, arid rock and other land formations, and flower slopes and herb fields, all theoretically develop into relatively stable communities, within which the organisms habitually group themselves into smaller units called microbiomes.

Except in the more favoured marine habitats, as already indicated, biological productivity in the polar regions is rather meagre at best, tending to be higher in the Arctic than in the Antarctic. The polar organisms, however, are usually well adapted to withstand rigorous conditions, an impressive instance being some Antarctic lichens, which, after artificial frost treatment by slow stages down to −198° C (−324.4° F) and then gradual warming, recovered normal activity within one day. Many lowly polar plants are capable of photosynthesizing at temperatures even several degrees below freezing point and can carry on vital activities even when the surrounding air temperature is far below 0° C (32° F); differentials as high as 25–30° C (45–55° F) between plant and air may be observed in both the Arctic and the Antarctic. In such circumstances, annual net production may reach the order of some hundreds of grams of dry weight per square metre in moss communities at favourable sites even in Antarctica. In the more favoured Arctic, although plant productivity is low daily production during the short growing season is comparable with that of many herbaceous communities of temperate regions.

Annual biological production

In the matters of productivity and food webs of polar and allied biomes, much work was under way in the early 1970s through the International Biological Programme, acting in several countries, which should yield further interesting results in due course. Preliminary reports indicate that in Char Lake on Cornwallis Island, the phytoplankton, consisting mainly of flagellates and diatoms, has an annual production of 5–7 grams per square metre (0.15–0.21 ounce per square yard) where the average depth is 10.4 metres. The average daily wet weight of phytoplankton and the mean chlorophyll content were surprisingly constant from April to October, though the surface of the lake was only ice-free from mid-August to mid-September. Only two species of zooplankton were present, but there were numerous Arctic char, which fed mainly on immature stages of midges.

(1970), a particularly valuable symposium of numerous specialist papers; NICHOLAS POLUNIN, *Botany of the Canadian Eastern Arctic, Part III: Vegetation and Ecology* (1948), and *Circumpolar Arctic Flora* (1959); see also his articles "Arctic Flora," "Arctic Vegetation," and "Tundra" in *Encyclopedia of the Biological Sciences*, 2nd ed. (1970).

(N.Po.)

Polemoniales

This order of flowering plants, consisting of eight families and over 4,000 species, includes some of the most handsome and favoured of garden and wild flowers. European and American gardens sparkle in spring and summer with the colours of *Phlox, Polemonium* (Jacob's ladder or Greek valerian), *Ipomoea* (morning glory), *Myosotis* (forget-me-not), and *Phacelia*. Woodlands, glades,

mountains, and deserts, particularly in North America, are often brilliantly coloured with their petals. Many other species, however, are often considered weeds, and a few justly deserve that appellation. Most members of the order are annual, biennial, or perennial herbs, many of which are delicate and ephemeral desert inhabitants. Several others, however, are woody trees, shrubs, or vines of great duration, but because of their limited size, number, and distribution are not important timber producers. Two families of the order are unusual in consisting of nonphotosynthetic parasites.

GENERAL FEATURES

Sweet potato the principal food plant

Economic importance. On the whole, the order is of minor economic importance. The one species of major importance as a food plant is the sweet potato, *Ipomoea batatas* (family Convolvulaceae). The nutritious tuberous roots of the plant have been an important food source since prehistoric time. Utilization is now worldwide, but long before European man began to eat the plant its use was well established in South America and in the Pacific Islands. The fact that it was well-known as a crop plant in two isolated geographical areas before botanists began to study it presented an interesting dilemma for students of the origin of cultivated plants. Was it originally American or Polynesian? Even though the sweet potato is not known as a wild plant, its apparent close wild relatives are found in South America. This, and other compelling reasons, led most botanists to the conclusion that the cultivated plant originated in South America and was transported at an early time to such diverse regions as New Zealand, Hawaii, and Easter Island. The mode of transport and the migration route of the sweet potato to these remote regions are matters not yet resolved.

Other members of the family Convolvulaceae (morning glories) have aroused recent interest because their seeds contain significant quantities of the hallucinogenic chemical substances lysergic acid amide and isolysergic acid amide, which are similar to the drug LSD. This psychotomimetic attribute was known to the Aztecs, and certain Mexican Indians still use the seeds for divinatory purposes. Species of the genera *Ipomoea* and *Rivea* possess significant quantities of the drugs, the different species varying in their potency. The natural quantitative variation in the drug content of the seeds leads to public-health problems among illicit drug users because it is difficult to determine the drug content of a seed before it is eaten. Serious psychic effects and even death have resulted from uncontrolled use of the seeds. Since many *Ipomoea* species are common weeds, it is unlikely that legislation would be effective in controlling the use of morning glory seeds for psychotomimetic purposes.

Garden ornamentals

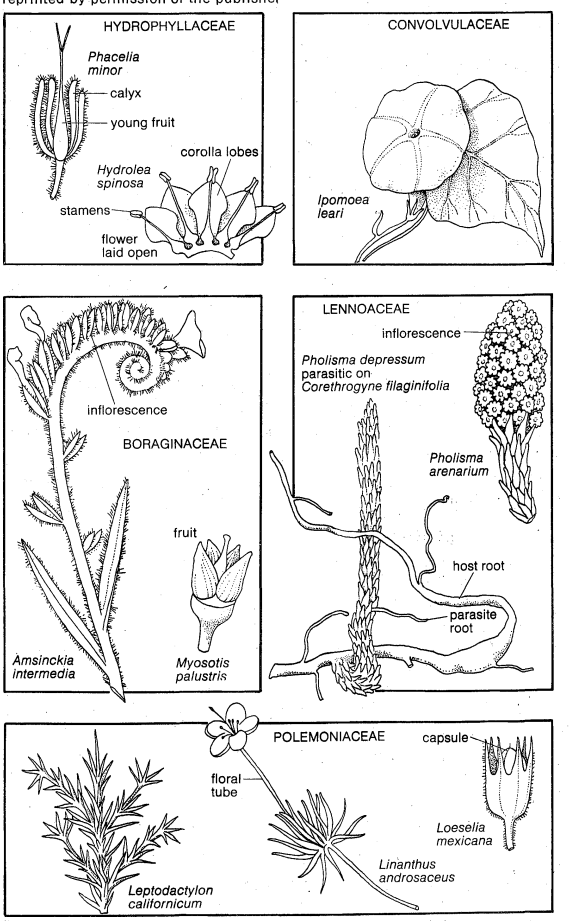
Use of members of the order for aesthetic purposes as garden ornamentals is another economic application of these plants. Compared with the cash value of sweet potatoes, the commercial value of these plants as ornamentals is not very great, but the annual spring perusal of seed catalogs is a much richer experience because of the inclusion of members of the families Convolvulaceae, Polemoniaceae, Hydrophyllaceae, and Boraginaceae. Species of the genus *Dichondra* (Convolvulaceae) have unique value as turf plants in tropical and subtropical regions. They are tough, low-growing, small-leaved, small-flowered plants that grow appressed to the ground, qualities that enable them to compete successfully with grasses. They are superior to grasses in one respect—they need little or no mowing. A vigorous stand of *Dichondra* provides one of the most beautiful lawns possible.

Size range and diversity of structure. As treated here, the eight families of the order Polemoniales can be grouped into two categories. The three small families, Cuscutaceae, Lennoaceae, and Hoplestigmataceae, are sufficiently distinct individually that each will be discussed separately. The five larger families, Polemoniaceae, Convolvulaceae, Hydrophyllaceae, Boraginaceae, and Loasaceae, however, show a similar range of variation so that one family may serve as a model to portray the whole group of five. The family Polemoniaceae is ideally suited for this, since it is large enough to illustrate most of the variation encountered in the other families, yet small enough to have undergone critical study.

Growth forms. The form of members of the family Polemoniaceae and the entire order includes a great range of morphological (structural) diversity. Large shrubs and small trees grow in the Andes in South America. In North America, the nearest approach to this growth habit is seen in some Mexican plants, but most others are at best low shrubs or woody-based perennial herbs. The latter constitute a significant part of the family in western North America. Large herbaceous perennials with extensive underground stems are another important growth form in the family. There are other plants that may be weakly perennial, but that tend for the most part to be biennials. Such plants often attain large size. By far the largest number of species in the family are annuals. Some tend to grow for many months when conditions are favourable, but many others are desert annuals, whose growth is rapid and usually complete in just a few weeks. Some annual members of the family are extreme dwarfs that flower while seemingly mere seedlings. Some of the latter rarely produce true foliage leaves but exist on the produce of their cotyledons ("seed leaves"), photosynthetic stems, and floral bracts.

Stems. Stem growth varies from extensive in the trees and shrubs to very little in desert annuals. The patterns of stem growth include underground rhizomes (rootlike stems), thickened woody crowns, typically branched aerial stems, and vines.

Leaves. Leaf form is similarly varied, ranging from pinnately (lateral leaflets arranged along a central axis, comblike) or palmately (all leaflets radiate from a common point) compound to simple needles and from large to nearly lacking. In a few cases, the tips of compound leaves grow out into tendrils, which provide support in the climbing vines. The general outline of the leaf includes those that are broadly elliptical or lance-shaped, those that are elongate but narrow, and small needles or scales. Leaf margins may be lobed, toothed, or smooth. Veins may be extensive, branched, and prominent or so poorly developed as to be nearly lacking in some leaves. Leaves are often clothed with a hairy covering that may often consist of cobwebby, prickly, or glandular plant hairs. In most members of the family the leaf arrangement is alternate along the stem but in two genera it tends to be opposite.



Plant hairs

Flowers and fruits. Flowers of the order Polemoniales are usually disposed in clusters in which the first flower to bloom is the apical one; thus, they are cymose. The cluster may be loose or, in a few cases, a compact head. Some species have clusters consisting of hundreds of flowers whose period of bloom may last many days. Others have only a few flowers per inflorescence (flower cluster), and a few species have a solitary flower at each branch tip. In these, the flowers are either very large, or, if smaller, the plant is so compact that it may literally be covered with flowers—each flower solitary at the end of a crowded branch. The flowers of the order Polemoniales are highly varied in structure, form, size, and colour; however, they share a basic plan, consisting of hypogyny (sepals, petals, and stamens attaching at the base of the ovary), five united sepals, and five united petals, to which the filaments of the five stamens are fused; they generally have three carpels (ovary wall structures) united into a three-locular (chambered) compound pistil (female structure). Nectar, produced by special glands at the base of the pistil, often collects in the corolla base. The sepals vary in shape from a large saucer-shaped structure to a constricted tube. The tissue along the midrib of each sepal tends to be green and dense, but the tissue between the lobes is thin and membranous. The membrane may be flat, corrugated, or prominently ridged. In some genera, the calyx (all sepals considered together) enlarges bladderlike in fruit, whereas in other cases the membranes are ruptured as the enclosed fruit enlarges. The most striking variation in flowers is seen in the petals or corolla. Usually the corolla is radially symmetrical, but in some genera it tends to be bilabiate (two-lipped). In other aspects of form it may be described as rotate (round, wheellike),

Flower shapes

campanulate (bell-shaped), tubular, funnelform, or salverform (trumpet-shaped). The individual corolla lobes may be rounded, truncate, pointed, or erose (with eroded margins, as if gnawed). In size the corolla may be minute or up to several centimetres long or broad. Colours vary from white to yellow through orange, pink, red, mauve, or blue. The flowers may be uniform or multicoloured, often with conspicuous spots or streaks arranged in definite patterns. Stamens (male reproductive organs) likewise vary in numerous parameters. They may be large or small, set deeply within the flower, variously disposed upon the petals, set at the orifice of the corolla, or strongly exserted (extended beyond the opening of the corolla tube). Flowers of the Polemoniaceae family are typically protandrous; *i.e.*, the stamens mature before the stigma (tip of the female organ, where pollen is deposited) is receptive to pollen. The pistil and resulting fruit may bear one seed, a few seeds, or many seeds. Generally, the mature fruit is a dry capsule that is often dehiscent (capable of splitting along definite lines) into three parts. The stigma, as is the case with the stamens, may be set deeply within the flower or long exserted. The seeds vary in size, weight, colour, markings, in the presence or absence of a mucilaginous coat, and may have a broad wing, especially in the tropical woody species. Pollen grains, elaborately sculptured, show variations that may exceed the variations in other features of the plants.

Representative plants and structures of five of the eight families of the order Polemoniales.

Other variations. The previous examples, taken mostly from the family Polemoniaceae, reflect some of the basic features of the order as a whole. There are, however, some outstanding specializations found in other families that deserve additional mention. In the matter of floral biology, the family Boraginaceae shows heterostyly. This is the condition of the flower in which members of a species population differ in the length of the stigma relative to the length of the stamens. Most often encountered is the distylous condition, wherein the style is very short and the anthers stand near the throat of the corolla (a condition known as thrum form), or the styles are elongate, with the stigma standing in the throat of the corolla and the anthers disposed in the base of the flower (pin form). This is an arrangement that enhances crossing because pollen from a thrum plant normally leads to fertilization in a pin flower, and pollen from pin leads to fertilization in thrum. In regard to seed dispersal, many unusual modifications related to dispersal by fur-bearing animals are found in the Boraginaceae. In most members of the family the two-carpellary ovary divides into four nutlets at maturity—the fruit wall of each nutlet tightly embracing a single seed. The outer surfaces of the nutlets bear hooks, barbs, bristles, and similar structures that adhere to fur. The family Loasaceae, which is usually not placed in this order, differs in having an inferior ovary (*i.e.*, the sepals, petals, and stamens appear to attach at the upper end of the ovary, their basal portions enclosing it). Along with certain members of the families Boraginaceae and Hydrophyllaceae, they usually have harsh, often stinging, trichomes (plant hairs).

NATURAL HISTORY

Pollination. Variation in floral features within the order is matched by variation in pollination mechanisms. The range of pollinators known in the order includes bees, hummingbirds, flies, beetles, butterflies, moths, and bats. Many species are self-pollinated. Floral structure is closely correlated with mode of pollination, and the order exhibits nearly all the floral modifications associated with such a diversity of pollinators (see POLLINATION).

Dispersal. Seed-dispersal mechanisms in the Polemoniales order are varied but not nearly so diversified as the pollination mechanisms. In nearly all species the fruit is a dehiscent capsule, the rupturing of which allows a slow sifting of seeds from it, or else an explosive split scatters the seeds forcibly. In a few cases the fruit does not split and it (and its seed or seeds) is dispersed as a unit. Once liberated from the capsule, the seeds may simply fall to the ground immediately about the parent plant, but those with explosive capsules may eject the seeds a metre or more. In both of these cases the seeds are subject to being carried about by animals, wind, water, or other agents. The tropical members of the order with winged seeds may be dispersed great distances by strong winds. A peculiar adaptation of many annual species is the development of a mucilaginous layer on the outside of the seed coat. When wet, this layer may increase in thickness to the diameter of the seed itself and is very sticky. These sticky seeds may be eaten, especially by birds, and may, by chance, stick to their feet or beaks and thus be carried great distances. Some North American species are represented by disjunct (widely separated) populations in South America, and it is reasoned that they may have been established there by transport on migratory birds. This must be thought of as the extreme form of dispersal, and most movement is probably the result of fitful small jumps repeated over thousands of generations.

Agents of seed dispersal

Physiology. The physiological diversity in the family is evident from the ecologically diverse habitats occupied by some populations. The perennials of Arctic or Alpine regions are adjusted to short, cold growing seasons and long dormant seasons. In contrast, some tropical species may grow the year around, with only slight variations in growth brought on by fluctuations in available moisture. Seasonal adjustment is very evident in the perennial plants of eastern North America, where a succession of species develop and flower, starting in the early spring, through summer, and, finally, to a species whose last flowers are killed by the first autumnal frost. The desert annuals have perhaps the most rigorously programmed

Life cycle of desert annuals

physiological systems. Their seeds germinate only when certain minimal moisture and temperature requirements have been satisfied. Then they grow rapidly to flowering and fruiting before the onset of the next drought period. Most populations vary in their requirements for germination, so that not all seeds germinate every year. Many seeds, in fact, may remain dormant for several years before germination occurs. This variation ensures that some seeds will always be available in the event of a crop failure caused by the extreme rigours of the fluctuating desert environment.

Parasitism. Two families in the order, Cuscutaceae and Lennoaceae, consist of totally parasitic plants. With the exception of certain species of *Cuscuta* (dodder or love vine), they are rarely observed. The dodders are thought to be closely related to, and derived from, the twining members of the family Convolvulaceae. In *Convolvulus* the advantage of twining seems to be purely mechanical; whereas in the nearly leafless and achlorophyllous (*i.e.*, without chlorophyll—nonphotosynthetic) *Cuscuta*, twining brings the stem of the parasite into intimate contact with the host plant, where specialized organs (haustoria) penetrate the nutritive as well as the water-conducting tissue of the host, withdrawing sustaining substances. Dodder plants flower and produce an abundance of seeds with ample reserve food in the endosperm (starchy nutrient tissues). Typically, the seeds germinate in soil, producing first a club-shaped rootlike structure and later a wiry stem that may establish a new parasitic relationship with a suitable host. Soon the root dies, leaving only the haustorial connections established between parasite and host. Since dodder plants are lacking in the usual photosynthetic machinery, they die unless a satisfactory parasitic union is established. Seedlings, however, may live for several weeks and grow many centimetres before their successful establishment or their starvation occurs.

The family Lennoaceae shows no obvious resemblance to *Cuscuta* in its general morphology or mode of parasitism. Usually only the flowering portion of the plant emerges from the sandy soil where it grows, but an extensive underground root system is present. This system apparently ramifies randomly until host root systems are encountered. When a root of the parasite approaches a host root, a haustorial type of root system develops that penetrates into, and absorbs from, an appropriate host root. The mechanisms of lateral rather than vertical root growth and the sensing of an appropriate host plant are unresolved questions regarding the physiology of these plants.

EVOLUTION

There is very little fossil evidence that would be helpful in understanding the relationships of the order. The few fossils known are isolated organs scattered geographically and stratigraphically. Consequently, phylogenetic relationships must be deduced by comparing modern species.

It is conceded by phylogenists that the order Polemoniales is an advanced plant group. Its high level of specialization is evident in the flowers, fruits, vegetative morphology, and physiological adaptations. Because of its advanced state, however, it is difficult to deduce a group ancestral to the order and to demark clear lines of relationship within the order. These are problems common among many flowering plant orders. Taxonomic groups referred to as Polemoniales, or that have included all or most of the families appearing here, range in size from three families to 26 families. The eight families here comprising the order bear a relationship to the order Gentianales (*q.v.*), especially in several floral and anatomical characters. It is difficult, however, to conceive of one of these living orders as having been derived from the other. The two orders could better be thought of as having been derived from a common ancestor. Some of the more primitive members of the groups within—or closely related to—the orders Rosales and Dilleniales, such as the family Pittosporaceae, have been suggested as possible ancestors from which both the orders Gentianales and Polemoniales arose.

Relationships to other plant orders

The lines of relationship within the order are also obscure, since most of the families show parallel specializations. It seems, therefore, unrealistic to attempt a sequential arrangement of the families Convolvulaceae, Polemoniaceae, Boraginaceae, Hydrophyllaceae, and Loasaceae, when surely none exists. On the other hand, the family Cuscutaceae seems clearly to be a parasitic derivative of the family Convolvulaceae, whereas the families Hoplestigmataceae and Lennoaceae show a strong similarity to either or both of the families Boraginaceae and Hydrophyllaceae.

CLASSIFICATION

Distinguishing taxonomic features. The families of the Polemoniales order are delimited primarily on the basis of flower and fruit characters, their vegetative, chemical, and ecological considerations being of secondary importance. Most families have gynoecia (female apparatus—stigma, style, and ovary) of two carpels, but the family Lennoaceae is exceptional in having six to 14 carpels, the family Polemoniaceae regularly has three, and the family Loasaceae may have as many as five. In the latter family, the ovary is inferior, but in the rest of the order the ovary is superior. The petal number (or lobes of the corolla) is mostly five in the order, but the family Loasaceae often has from four to ten, and the family Hoplestigmataceae has from 11 to 14. Occasional individuals or even some unusual species may have either four or six petals in other families. In the families Hydrophyllaceae and Boraginaceae the petals often bear appendages or crests. Nearly all members of the order have five stamens per flower, but the family Loasaceae often has many, and the Hoplestigmataceae family has from 20 to 30 stamens. The tendency in the Boraginaceae for the fruit to ripen as four-dividing nutlets is unique to that family within this order, as is the gynobasic style (*i.e.*, the style arises from the base of the four-parted ovary). Vegetatively, the Hydrophyllaceae, Boraginaceae, and Loasaceae families often possess harsh epidermal trichomes (plant hairs) that, in some species, have stinging capability. Woodiness is lacking only in the parasites, the families Lennoaceae and Cuscutaceae. Both species of the family Hoplestigmataceae are trees. In the remaining five families, trees and shrubs or woody vines occur, along with herbaceous species.

Annotated classification. The classification presented here includes only a small portion of the families usually treated together as an order in most former classification systems, along with three families of doubtful affinity. On practical and theoretical grounds, the first five families presented below are difficult to separate from the remainder of the approximately 26 families of those systems. The other three families (Lennoaceae, Hoplestigmataceae, Loasaceae) have rarely been included with them. They do bear some relationship to the families Boraginaceae and Hydrophyllaceae, however, so they may rest about as comfortably in the Polemoniales as they would in other orders.

Scope of classification system

ORDER POLEMONIALES

Flowering plants with mostly sympetalous (fused) corollas. Flowers generally 5-merous (in parts of 5—5 sepals, 5 petals, etc.), actinomorphic (radially symmetrical), stamens 5 and alternate with corolla lobes, or numerous. Fruit a capsule or of 1 to 4 nutlets. Plants typically trees, shrubs, vines, or herbs, except for a twining parasite and a few root parasites. Primarily in North and South America, but some also in Eurasia and in Africa as well. There are eight families, 208 genera, and 4,446 species.

Family Polemoniaceae (phlox family)

Herbs, shrubs, small trees, or vines; leaves mostly alternate, rarely opposite, simple or compound. Flowers bisexual, regular or rarely bilabiate (2-lipped), 5-merous, inflorescence a cyme or head, flowers rarely solitary; sepals 5, united; petals 5, united, often rotate (wheel-shaped, often flat and circular in outline), campanulate (bell-shaped), salverform (trumpet-shaped), or tubular, contorted in bud. Stamens 5, adnate (fused) to corolla, sometimes with unequal insertion (*i.e.*, they arise at different points along the corolla tube), exserted (extending past the corolla opening), or included in corolla tube. Ovary superior, carpels 3 or rarely 1 or 2 by reduction, surrounded by a nectariferous (nectar producing) disk, style 1, stigmas 3, rarely 1 or 2. Fruit a dehiscent capsule; seeds 1 to

numerous, large or small, sometimes winged, mostly small, often mucilaginous when wet; endosperm present; embryo straight or slightly curved. Eighteen genera, over 300 species, mostly in North and South America, but a few species in Eurasia. Some prominent examples include the genera *Polemonium, Phlox, Gilia,* and *Linanthus.*

Family Convolvulaceae (morning glory family)

Herbs, shrubs, trees, or vines; chiefly twining or trailing, with milky juice. Leaves alternate, simple, entire, or lobed. Flowers bisexual, regular, rarely irregular, 5-merous, inflorescence a cyme (a flower cluster that matures from the apex downward) or flowers solitary; sepals 5, united; petals 5, united, often campanulate or cylindrical, contorted in bud; stamens 5, adnate to corolla, exserted or included in corolla tube. Ovary superior, carpels 1 to 4, mostly 2, surrounded by a nectariferous disk, style 1, stigmas 1 or 2; fruit a dehiscent capsule. Seeds few, large, often hairy; endosperm present; embryo curved, cotyledons large and crumpled. Fifty genera, over 1,400 species, widely distributed in the tropics and temperate regions. *Convolvulus, Ipomoea, Dichondra.*

Family Cuscutaceae (dodder family)

Parasitic herbs lacking chlorophyll. Stems slender, twining, threadlike, often in great masses, with haustorial connections to host, but rootless after seedling stage. Leaves reduced minute scales. Flowers bisexual, regular, 5-merous (rarely 4-merous), white or waxy, inflorescence a compact cyme; sepals 5, united; petals 5, rarely 4, united, corolla campanulate or cylindrical, often appendaged, lobes imbricate (overlapped) in bud. Stamens 5, inserted at corolla throat, alternate with corolla lobes. Ovary superior, carpels 2, styles 2 or united basally; fruit a capsule, circumscissile (opening by a regular transverse circular line of division) or irregularly dehiscent. Seeds 1 to 4, embryo coiled within the endosperm, cotyledons minute or lacking. One genus (*Cuscuta*) of over 150 species, widely distributed, occasionally a noxious pest of agricultural crops or indigenous flora.

Family Hydrophyllaceae (waterleaf family)

Herbs or shrubs. Leaves usually alternate, but often opposite or in a rosette, simple or deeply lobed to compound, coarsely hairy, sometimes with stinging hairs. Flowers bisexual, regular, 5-merous; inflorescence, usually of coiled cymes. Sepals 5, united, often with appendages between the lobes; petals 5, united, rotate, campanulate, or tubular. Stamens 5, adnate to base of corolla, often associated with corolla appendages, exserted or included. Ovary superior, carpels 2, style 1, stigmas 2. Fruit a dehiscent capsule; seeds numerous, highly ornamented; endosperm present; embryo small and straight. Twenty genera, nearly 300 species, mostly in North America, with a few on other continents but none in Europe or Australia. Important examples of genera include *Hydrophyllum, Phacelia, Nemophila, Nama,* and *Eriodictyon.*

Family Boraginaceae (borage family)

Herbs, shrubs, or large trees. Leaves usually simple, entire, opposite, alternate, or whorled, often coarsely hairy or scabrous (scaly). Flowers bisexual, regular, 5-merous; inflorescence often a coiled cyme. Sepals 5, united, slightly irregular, petals 5, united, crested or appendaged, rotate, campanulate, salverform, or tubular. Stamens 5, adnate to corolla, usually included in corolla, but may be long-exserted in a few, sometimes heterostylous (differing lengths of stamens and styles in different flowers—the "thrum" and "pin" forms mentioned in the article). Ovary superior, carpels 2, often deeply lobed and style gynobasic, style and stigma usually 1. Fruit usually of 1 to 4 smooth or highly ornamented nutlets; endosperm present or absent; embryo straight or curved. One hundred genera and 2,000 species, with worldwide distribution but prominent in North America and the Mediterranean region. *Cordia, Ehretia, Heliotropium, Lithospermum, Echium, Cryptantha,* and *Cynoglossum* are some important genera.

Family Lennoaceae (sand food family)

Fleshy erect parasitic herbs, lacking chlorophyll, attached to roots of other plants. Leaves simple bractlike scales. Flowers bisexual, regular, 5- to 8-merous; inflorescence a compact spike or head. Sepals 5 to 8 linear, united at base; petals 5 to 8, united into a flaring tubular corolla. Stamens 5 to 8, inserted at corolla throat, anthers barely exserted. Carpels 5 to 15, united, placental column (the area of ovule attachment) massive, style 1, stigma 1, but with several small lobes. Fruit capsule-like but eventually separating into several nutlets; seeds small; endosperm present; embryo undifferentiated. Three genera (*Lennoa, Ammobroma, Pholisma*), 4 species, distributed in western North America.

Family Hoplestigmataceae

Trees. Leaves large, simple, entire alternate. Flowers bisexual, regular, number of floral organs indeterminate, inflorescence cymose. Sepals united, splitting irregularly at anthesis (time at which ovules are fertilized); petals 11–14, united basally, irregularly imbricate. Stamens numerous, irregularly arranged, not adnate to corolla. Ovary superior, carpels 2, united; placentae parietal (ovule attachment on the inner wall of ovary); style 1, short; stigmas 2, elongate. Fruit a drupe; seed with endosperm; embryo large, straight. One genus (*Hoplestigma*), 2 species, in western tropical Africa.

Family Loasaceae (loasa family)

Herbs or shrubs. Leaves opposite or alternate, simple or divided, often coarsely hairy, sometimes stinging. Flowers bisexual, regular, 4- to 5-merous; inflorescence a cyme or head, or flowers solitary; floral tube adnate to ovary; sepal lobes 4 to 5, usually persistent on fruit; petals 4 to 5, often prominently clawed. Stamens 5 to many, often in 5 bundles opposite the petals. Ovary inferior, carpels united, style 1, stigmas 1 to 5, placentas parietal; fruit a capsule; seeds 1 to many; endosperm prominent; embryo straight. Fifteen genera and 250 species, in North and South America, except for 1 genus (*Kissenia*) in Africa. *Mentzelia, Loasa,* and *Cajophora* are important examples of genera.

Critical appraisal. The families grouped here as the order Polemoniales have been treated in a variety of contexts in different systems. Most systems, however, include the families Convolvulaceae, Cuscutaceae, Polemoniaceae, Hydrophyllaceae, and Boraginaceae in the same order, whether it is designated Polemoniales, Tubiflorae, Solanales, or by some other name. In addition, several families such as Solanaceae, Nolanaceae, Verbenaceae, Scrophulariaceae, and other families with tubular corollas and superior ovaries are often included in an ordinal group along with more typical Polemoniales. The family Lennoaceae has sometimes been placed in the order Ericales, but its relationship to the Hydrophyllaceae and Boraginaceae families now seems firmly established. The arrangement presented here deviates most from other proposed systems in the inclusion of the families Hoplestigmataceae and Loasaceae. That the relationship of the first is uncertain is clearly exemplified by its inclusion in the orders Lamiales, Violales, Bixales, and Ebenales by various authorities. Similarly, the family Loasaceae has been placed in the orders Cistales, Violales, and Loasales by different workers. It seems particularly out of place in the Polemoniales because of its inferior ovary, separate petals, and multiple stamens; however, its resemblance to the families Hydrophyllaceae and Boraginaceae in characters of indument (covering of plant hairs), seed, embryo, and endosperm is considered adequate to permit its placement in the Polemoniales order as defined here.

Uncertain status of some families

These variations in treatment of the families are the result of having inadequate data and also disparate opinions about the value of certain characters in phylogenetic taxonomy. Until more data are available, particularly additions of critical material to the fossil record, concepts of the primitive condition of angiosperms (flowering plants) will have to remain theoretical. In view of the variations in thought on this subject, there is certain to be a continuing disparity in the evaluation of the evolutionary significance of plant characters and their utilization in the construction of classifications purporting to be phylogenetic (*i.e.*, reflecting actual evolutionary relationships).

(D.M.Sm.)

Police

The term police is now used to denote a body of people organized to maintain civil order and to investigate breaches of the law. In the 18th and 19th centuries the term was used more generally to denote the internal civil administration of a state or a town, including (to quote Adam Smith) "the domestic regulation of such matters as taxes, bounties, monopolies and the exclusive privileges of corporations." In France and countries influenced by the Napoleonic style of administration, the duties of the police have been more widely defined to include the enforcement of regulations concerning public health, the erection of buildings, and so forth.

All societies need some means whereby order is maintained. In the smallest societies lacking written laws, informal sanctions discourage deviation. In the simplest forms of state organization, the ruler has agents to enforce his decisions. The police function is universal in society, though it is only in the larger and more complex states of modern times that full-time officials are appointed with special police responsibilities regulated by law. In modern industrial societies most policemen are enrolled in state, provincial, or municipal forces concerned with criminal investigation, traffic regulation, and preventive patrol. A central government generally has special sections of personnel responsible for the collection of political information, counterespionage, the protection of important persons, and so forth; and not all of this work can be accounted policing in its modern connotation. The ordinary police services are often supplemented by special police forces, separately organized, for the supervision of railways, harbours, docks, airports, and government establishments. Recent years have also seen a rapid growth in private security organizations, though countries differ in the extent to which they accord legal recognition to the creation of private police forces for the supervision of commercial establishments, university campuses, and the like.

POLICE AND SOCIETY

The diversity of police activities. There is a remarkable historical, geographical, and organizational diversity in the activities of persons who are, or have been, counted as policemen. Within any one country the work of policemen today is very different from what it was 200 years ago. There are also major differences between countries—policing New York City is bound to have little in common with policing the Solomon Islands. The police forces of some countries, having been created by the central government for its own purposes, have grown from the centre outward. Elsewhere, communities have maintained local police arrangements, and the central government has stepped in to consolidate and coordinate them so that growth has been from the outside inward. The diversity is so great that the onlooker may wonder if the different kinds of activity and organization have sufficient in common to be classified together.

Principles of police accountability and adaptation

The principle of police accountability is helpful in explaining the diversity noted above. The problem is summarized in a Latin question: *Quis custodiet ipsos custodes?* ("Who guards the guardians?"). From one point of view, it is desirable that a police force should be as efficient as possible. It should be rationally and economically organized so that specialist services can be developed without any overlap or conflict between the responsibilities of different units. Such considerations favour the establishment of national police forces, which can take advantage of the economies of scale in training, promotion schemes, specialist organization, and so on. But it often has been felt that the existence of a national force places too much power in the hands of those who direct it; that there is a danger that the government will use its control of the police to keep itself in office; and that the police will not be accountable to the public. Therefore, some countries favour a local basis for police organization.

A second principle that helps explain the diversity of police activities in different societies is that of police adaptation. If the society is agricultural, as in rural India, the police will be concerned with the state of the crops, irrigation of fields, the conditions of roads and paths, private feuds and quarrels, the registration of births and deaths, feasts, fairs, and all manner of private and public events. If local landowners are influential, as they were in 19th-century England, much police effort will be expended in the enforcement of laws against poaching, and much less in the investigation of ways in which the behaviour of employers infringes the rights of employees. If offenses are committed in moving vehicles, then the police must be motorized. If criminals use firearms, then the police are likely to be armed. Police activity must be adapted to the society that is being policed. The spread of industrialization in the 20th century has meant that otherwise different societies have adopted similar modes of production and have experienced similar problems. The control of automobile traffic has aspects common to Los Angeles, Tokyo, and Leningrad. Police organizations in different countries therefore tend to respond in increasingly similar ways. A later section will outline constant features in the activity of policemen in industrial societies.

Social control in small communities. Most people obey most laws willingly, whether or not there is a policeman looking on. They comply with the laws because they believe them right and perceive that in the long run it is in everybody's interest to observe them. But this voluntary compliance is more general in certain kinds of community and with respect to certain kinds of law. In small communities in which everyone knows everyone else, people who live up to the shared ideals are rewarded by the esteem of their fellows. If they fall short of other people's expectations, life is made more difficult because others are no longer so ready to help them in times of trouble. This pattern of informal rewards and punishments is, in all kinds of society, the most potent force in law enforcement, but it is stronger in the small community because there people meet one another in different roles. The village grocer may represent his district on the county council; and he may meet his neighbour, the schoolteacher, in his capacity of councillor, or of grocer, or of parent of a school child, or of neighbour, or in one of many other roles. Should there be two grocers, people may feel obliged to patronize the one who attends the same church as they do. Thus, in the village there is a relatively dense network of social ties, which imposes more restraint upon social deviance of any kind.

The forces that order the life of the small community make the policeman's task much easier. Instead of imposing requirements, he has only to lubricate the mechanisms inherent in social relations, and police action is needed only when the informal controls have proven insufficient. The ideal of the well-integrated local community has, therefore, had a romantic appeal for some social philosophers, and many policemen sometimes think nostalgically of the life of the village constable. Though it is an unreal abstraction—like the idea of a frictionless pendulum—the notion of a self-policing community can serve as a model when studying what is required of the police. And the notion need not be limited to local communities. Professions such as law and medicine also form communities of practitioners who are able to police themselves with respect to the practice of professional skill, but, naturally, the members cannot police one another's conduct in respect to nonprofessional matters such as motoring offenses.

Social control in large societies. The bigger a society becomes, the weaker its self-policing elements are likely to be. In the first place, when people are involved with those whom they are unlikely ever to meet again, there may seem to be less reward for honest dealing; and, if one party feels he has been cheated, there is less chance of his being able to bring informal pressures to bear upon the offender. Most contacts are impersonal, and since the parties do not meet in other capacities, the informal controls cannot play so great a part. In the second place, with technological progress there comes a need for new laws. With the growth of automobile traffic, for example, many new laws governing vehicle construction, licensing, and

manner of driving become necessary. Because many such laws do not have the same moral significance as laws penalizing personal violence or dishonesty, the reporting of offenses cannot be left to members of the public. Formal controls are needed in the shape of trained inspectors, officials, and traffic police. When the legislature declares that certain actions are in the future to count as offenses, it increases the amount of crime. There is a danger here that people who are convicted of the one offense—say, a motoring offense—may feel aggrieved and in the future be less willing to cooperate with the police or to obey the law when they are not being observed. The self-policing element is therefore weakened. In the third place, as societies grow it becomes more difficult to relate public interests and private interests. If an employer catches a group of his employees committing an offense within the workplace, he may not wish to call in the police. He may believe that, if he deals with it in his own way, production and profit may suffer less; the public interest, however, is not served thereby. Similarly, if valuable property is stolen, an insurance company may be willing to pay for its return without obtaining the information that would make it possible for the criminals to be prosecuted. Supervision of the way private bodies respond to crime is necessary if the total level of crime is to be reduced.

The hazards of centralized policing. For these and other reasons, it would appear that communities cannot wholly be left to police themselves, and that a central government should impose its standards upon local communities. If, however, the central government itself is corrupt or self-seeking, the outcome will be worse than if communities were left to enforce law and order according to their own lights. Moreover, good intentions on the part of the central government are in themselves obviously not sufficient. Much will depend upon whether it can induce its agents to use their powers in desired ways.

French police in the ancien régime

A striking example of action by a central government to enforce its own standards is provided by the French political police. Though some writers have looked critically at the use of police by French kings to effect a personal rule, the fact is that community controls could not have achieved the same end, and there would seem to be little doubt that in the 18th century the citizen of Paris was far better protected from crime than, for instance, the citizen of London. Louis XIV had 40 inspectors of police and many paid agents, who supplied the king with masses of detailed information about the conduct of private persons. Louis then issued *lettres de cachet*, ordering the imprisonment of persons of whose guilt he was satisfied even though there was insufficient evidence to bring them to trial; returning to their hometowns noble ladies who had been misbehaving; and, generally, exercising a kind of summary justice. The attendant influx of criminal information and salacious anecdotes concerning all orders in society helped to create the image of an omniscient political police. Indeed, at one time it was estimated that one-quarter of all the housemaids and lackeys in Paris were receiving money from the police in return for information about their employers and acquaintances. The police chief Sartine once boasted to Louis XV, "Sire, whenever three people speak to one another in the street, one of them will be mine." At the same time the ordinary police took an active part in many aspects of the city's life. The lieutenants general of police built markets, paved and constructed streets, founded the Bourse (stock exchange), moved a cemetery, provided street lighting, established a system of state pawnshops, created a hospital for children, founded a veterinary college, built schools for children of the poor, sought work for the unemployed, and organized fire and river rescue services. The police took stock of the city's food supplies and forbade wine sellers to have leaden counters and milkmen to use copper vessels. They censored posters and regulated the employment of foster mothers. They persecuted Protestants, controlled the sale of lottery tickets, and inspected drains. They had the streets cleaned. They supervised cabdrivers, made regulations about dogs, checked food prices, surveyed dangerous buildings, read people's letters in the course of post, and even stopped fishmongers from selling oysters between April 30 and September 10. The police inspected prisons, read theological works for signs of heresy, and had a financial agency for the encouragement of overseas trade.

French police after the Revolution

When the Revolution came, the French police made not one effective move against the revolutionaries; they identified themselves with the revolutionary government rather than with the old law. In 1796 a new Ministry of the General Police of the Republic was created and soon came under the control of Joseph Fouché, who used his position to establish a political police making extensive use of paid informers. As a consequence, a separate police body, the Prefecture of Police of Paris, had to be created to take responsibility for more conventional duties. One agent within the Prefecture, François-Eugène Vidocq, became head of the Police Judiciaire (the department for criminal investigations) and was celebrated for his disguises. Generations after his death his name was still execrated by ordinary Frenchmen as the epitome of police espionage. Though the legend bears little relation to Vidocq's actual history, it testifies to the fears of citizens that the state may use the police to serve the ends of those in power rather than the community as a whole.

Present-day schemes of police administration. Although the belief still persists that decentralization favours police accountability (and thus serves to steer clear of the abuses exemplified by the French police of an earlier day), some centralization is required for economic and operational efficiency. As the period of training needed for effective police work has grown longer and work hours have been reduced, police manpower has become more expensive; and it has become important to see that men are not employed on tasks for which less highly trained employees could be used. Consequently, policemen in most industrial countries are now assisted by a host of auxiliaries: typists, photographers, mechanics, fingerprinting technicians, forensic scientists, traffic wardens, and so on. It has become advantageous to have national schemes for fixing the pay scales of both policemen and auxiliaries; for recruiting; for seeing that similar standards are employed all over the nation; for establishing a common system of criminal records; for developing national facilities for higher training and the selection of top administrators; for forming specialist squads to investigate particular kinds of crime; for research; and, generally, for seeing that the police service keeps abreast of the changing pattern of criminal activity. Such tendencies make for increased centralization, and they operate in a similar fashion in all industrialized countries. As a result, regardless of the way in which police services have started out—whether, like the French, they have been highly centralized or, like the British, have taken community policing as their model—all have tended to develop common features; and within apparently different systems there are comparable devices for balancing central and local interests.

Police reorganization in West Germany and Japan

The examples of police reorganization in West Germany and Japan illustrate the way in which demands for economic rationality serve to offset the belief that decentralization favours police accountability. In 1949 the Council of the Allied High Commission in West Germany ruled that the police were to be administered at the level of municipalities and rural districts. There were to be no provincial police or national police, lest they assume a paramilitary character or otherwise threaten either democratic government or the security of the occupation forces. The police were to be responsible for the maintenance of public order and safety, the prevention of crime, and the bringing of offenders to justice. But in 1950 provision was made for provincial (*länder*) police forces. Subsequently the Federal Criminal Police Bureau (Bundeskriminalamt) was set up in Wiesbaden to coordinate the detective work of local police forces and prosecute criminals whose activities were not confined to one province. A national Frontier Police Force (Bundesgrenzschutz) was established and became the biggest police force in the republic. Organized in companies, it is controlled by the minister of the interior. An Emergency

Police (Bereitschaftspolizei) was created to deal with disasters, such as floods and landslides, and with riots and other emergencies. The arms available to this force include machine guns. Though the provincial governments are responsible for personnel costs, the federal government provides the equipment and appoints the inspector general. Since the inspector general, on behalf of the federal government, is responsible for inspecting the provincial police, and, since the Emergency Police also has to enlist and train recruits, the central government has considerable influence over the entire police service. The training function is particularly important. Recruits first attend basic training courses at state police schools and then serve in the Emergency Police for approximately two years before returning to a local force. At the same time, the provinces watch very carefully to see that their prerogatives in respect to police control are not impugned. Apart from the period of the Third Reich, local control has strong roots in German police tradition.

In Japan, in 1947, U.S. Gen. Douglas MacArthur introduced a new organization to decentralize the police and subject them to democratic control. A national rural police was established, but all towns and cities of over 5,000 inhabitants were to have their own police forces. In this way 1,605 communities acquired their own police. Because this multiplicity led to overlapping jurisdiction and confusion, however, all police forces in 1954 were amalgamated into a single national service administered in 45 prefectural districts. At the same time, the chairman of the National Public Safety Commission was given the status of a minister of state so that the government might assume responsibility for public peace and order.

MAJOR MODELS OF POLICE ADMINISTRATIVE ORGANIZATION

Systems with established police forces. *France.* In France, there are two national police forces: there is the Police Nationale, with units in each *département* commanded by the prefect of the *département*, who, in turn, is responsible in police matters to the director general of the Police Nationale; and there is the Gendarmerie Nationale. The Police Nationale was formed in July 1966 by the amalgamation of the Prefecture of Police of Paris and the Sûreté Nationale, which had been responsible for policing the provincial towns and for certain specialized work. The director general's headquarters includes seven divisions covering general intelligence, judicial police, public safety, security, regulations, training, and personnel. The National Police has a strength of some 91,000, the Gendarmerie 61,000. In the larger towns there are *Gardiens de la Paix* who serve as municipal police, responsible for preventive patrol and the control of traffic.

The Paris police has five sections: municipal police; the Police Judiciaire (for criminal investigation); an intelligence unit; a technical unit; a unit for economic, financial, and commercial offenses; and a section responsible for the safety of the president and of other important persons. Within Paris there are 20,000 Gardiens de la Paix (guardians of the peace) who serve as municipal police, responsible for preventive patrol and the control of traffic. In the provincial *départements*, while the commissaire de police is responsible to the prefect, he is expected to cooperate with the mayor and the municipal administration. For preventive work and the maintenance of order (traffic, patrols, meetings, and so on), the commissaire has at his disposal a Corps Urbain composed of uniformed Gardiens de la Paix and higher ranking officers; for criminal investigation and administrative work he has plain-clothed Officiers de Police and Inspecteurs who form the Sûreté Urbain. Major decisions on working methods and administration are, however, taken at the Paris headquarters.

The Police Nationale also has several specialized divisions. One is the provincial Police Judiciaire, which is organized in 17 regional branches. Others include intelligence and counterintelligence services; mobile reserves, or riot police; the Republican Security Companies (CRS), whose 13,500 men, organized in companies of about 200 Gardiens each, are housed in barracks. They became notorious as a result of brutality in dealing with student demonstrators in Paris in May 1968.

Gendarmerie Nationale

The Gendarmerie Nationale is composed of soldiers formed in strictly disciplined units and quartered in barracks. The force includes the Mobile Gendarmerie and the Departmental Gendarmerie, a section of which covers each military area (several *départements*) under the command of a general. The central headquarters for the Gendarmerie, under the direct control of the minister for the armed forces, is charged with planning, staff organization, and administration. The mayors of certain communes have communal or rural policemen at their disposal; but, as a rule, police work in country districts and in towns with less than 10,000 inhabitants is undertaken by gendarmes. They also police certain main roads. Some are appointed as officers of the judicial police and are thereby empowered to inquire into and deal with all types of crime, including murder, kidnapping, wounding, and the like.

These divisions within the French police service, and the separate ties that units have with local administrators, suggest that, though centralized, the French police is far from monolithic. There are many opportunities for one police body to check upon the activities of another and to prevent any one organization from being unduly corrupted by its powers.

Belgium. Belgium, another country with an outwardly centralized police system, displays similar features. There, a Judicial Police, responsible to the minister of justice, is staffed by civil servants and concerned with the investigation of crimes and with bringing offenders before the courts and takes no part in administrative police work. Separate police forces exist for the railways, state security, the military, and the protection of atomic research establishments. The Gendarmerie is part of the kingdom's armed forces; it is responsible to the minister of the interior for its duties as administrative police, the execution of laws and arrests, and the maintenance of public order; to the minister of justice for its duties as judicial police, including the national security; and to the minister of national defense for duties concerning military deserters and mobilization arrangements. Unlike the Communal Police, who are appointed by the various towns and communities, members of the Gendarmerie have power to act in all territories of the kingdom. Though financed by local communes, these policemen are subject to controls exercised by the minister of the interior.

Italy. Italy, too, has several national police forces. The Public Security Guards (Guardia di Pubblica Sicurezza), which is part of the armed forces, is charged with the maintenance of internal public security and order, with the protection of life and property, and with preventing and checking crime and gathering evidence in criminal matters. Although the force is of a semimilitary character, it performs all normal police functions and is responsible to the minister of the interior. The Corps of Carabinieri is a military-like body housed in barracks; it is responsible to the minister of defense in certain matters, but to the minister of the interior in regard to police duties. As an executive organization for the detection of crime, the corps carries out duties assigned to it by law, under the direction of judicial authorities to whom it reports on investigated crimes. At every level, commanders of the corps must maintain liaison with the army, political, judicial, and police authorities. A Guardia di Finanza is charged principally with protecting the national frontiers from activities connected with smuggling, counterfeiting, illegal entry, and tax evasions. In addition to the national forces, municipalities maintain their own police, the Vigili Urbani, which undertake certain kinds of municipal administration but are increasingly concerned with traffic control. Frequent attempts have been made to amalgamate the Vigili with the Public Security police, but the municipalities have resisted such proposals.

Carabinieri

Spain. Spain also has several police forces with interlocking responsibilities. The two principal forces, organized on military lines, are equipped with arms and are

closely associated with the armed forces. The Civil Guard (Guardia Civil) is responsible for maintaining security and order and repressing crime in the rural areas. The Armed and Traffic Police (Policía Armada y de Tráfico) has similar responsibilities in the towns. The Civil Guard operates with detachments assigned to local posts, being supplemented by mobile reserves that keep order on the highways. The Armed Police patrol the towns. Superior "agents" belonging to a third State Police Corps (Cuerpo General de Policía) operate from stations of the Armed Police. They are civil servants who work in plain clothes on criminal investigation duties. In the towns there are also unarmed municipal police, paid out of the municipal budget, who are responsible to the mayor. If they arrest a criminal they hand him over to the Armed Police.

Japan. Japan's police force was a centralized, national organization under the minister of home affairs from 1871 to 1947, when, as noted above, the U.S. occupation forces initiated a plan to decentralize and "democratize" the police. When the experiment failed, all police forces were amalgamated in 1954 and placed under the direction of the National Public Safety Commission (NPSC) and the National Police Agency (NPA). Today, branches of the NPSC and the NPA operate in all the nation's 46 prefectures.

The NPA is responsible for directing general police activities, though each prefecture enjoys considerable autonomy. On the other hand, the NPSC exists primarily to guarantee the democratic administration and the political neutrality of the police. It has power to intervene in the operation, administration, financing, and personnel appointment of police forces in the various prefectures. The chairman of the NPSC is a minister of state directly responsible to the prime minister. (The latter may, with the Diet's approval, control all or sections of the police during a state of national emergency.) Likewise, the director general of the NPA is appointed by the NPSC with the prime minister's approval.

Thus, Japan's police, which in 1970 consisted of about 175,000 officers, is, on the one hand, a decentralized, autonomous force and, on the other, a national, government-directed force. In addition to the general police charged with law enforcement, there are various agencies that carry out specialized work. These include the riot police (numbering 9,700 in 1970).

Scandinavian countries. The advantages of a unified police service can most easily be combined with accountability to the public in small homogeneous nations with a relatively high level of civic education. In the Scandinavian countries—for instance, Denmark, Finland, Norway, and Sweden—all have national police forces and no separate forces for railways, docks, or similar establishments. In Finland the police is an organ of the central government and is financed by the state. In Norway only about 10 percent of police costs are met by the municipalities; each of 54 police areas is under the command of a Politimester, who must hold a degree in law and who is responsible to the minister of justice and police. Before appointment as a constable, a person must have served as a police aspirant in one of the major forces, have successfully completed a ten-month course at the police school, and have undergone four months local training. In Denmark the central government appoints a commissioner of police, but the 72 local chief constables are independent commanders of the personnel placed at their disposal by the state.

Administrative reform in Sweden

The pressures for rationalization are well exemplified by the reform of police administration in Sweden. Because of its technological and social development, the country is experiencing an acute shortage of labour coupled with a high level of urbanization, leaving large provincial regions with very low population density. Since 1965 the police have been nationally administered, the number of local police districts has been reduced to 119, and the number of police stations to 510. This has been made possible by greatly increased use of motor vehicles and the expansion of the radio and telephone networks. But, because nearly 50 districts can muster fewer than 50 police officers, further rationalization is likely. Responsibilities for prosecuting and seizing the property of debtors have been removed from the police. The internal organization of the police now divides into two principal divisions responsible for patrol work and criminal investigation. Local police committees have been established on an advisory basis. The intention has been to create a forum in which the police chief can discuss law enforcement with representatives of local government. Local police budgets are considered by these committees. The police chiefs are responsible to the National Police Board, which reports to the Ministry of Justice.

Decentralized systems. *United Kingdom.* The United Kingdom of Great Britain and Northern Ireland has no national police force, although, in several important respects, the central government exercises strong controls over all police forces; and there has been a continuing tendency to eliminate small forces by amalgamating them with larger units. Different arrangements still obtain in various parts of the kingdom. Since 1829 the home secretary has been answerable to Parliament for the Metropolitan Police (21,000 officers in 1970), who patrol the London area. Other police forces in England and Wales numbered 226 in 1860, but by 1969 they had been reduced to 46 (78,000 officers). The home secretary can, if necessary, require a chief constable of one of these forces to retire in the interests of efficiency, but he cannot give them orders, and they are answerable in operational matters only to the laws of England. In Scotland in 1969 there were 22 forces (11,000 officers), and their position was in many respects similar to that of English provincial forces, with one major exception. In England anyone may prosecute in the courts; and, although the police often prosecute in many cities, the municipality employs its own lawyers to take in court all except minor traffic cases. In Scotland responsibility for deciding whether or not to prosecute lies with the lord advocate, one of the government's law officers, and with his local subordinates (procurators fiscal), to whom the police are accountable in regard to criminal investigation. In Northern Ireland there is a state police, the Royal Ulster Constabulary (3,000 officers), and its senior officer is responsible to the minister of home affairs. Within the United Kingdom there are a number of special police forces for docks, railways, and defense establishments, the members of which are sworn constables with police powers of arrest. Chief among these is the power to arrest a person on suspicion that he has committed a felony. Civilians are entitled to arrest persons whom they know to have committed a felony. The various factory police units and private security services have only civilian powers of arrest.

Combined local and central controls

One aspect of British police administration most likely to be of general interest is the way in which the centralization of certain services is combined with forms of local independence. A Royal Commission on the Police reported in 1962:

> There is a substantial case for creating a national police service. Its organization would be more logical, and a number of us think that it would prove to be a more effective instrument for fighting crime and handling road traffic. . . . We do not regard the creation of a national police service as constitutionally objectionable or politically dangerous.

One of the commission's members added:

> The danger in a democracy does not lie in a central police that is too strong, but in local forces that are too weak.

The commission recommended the continuance of separate local police forces. In defense of its decision it can probably be argued that the local system does provide a measure of democratic control, and that such control, once lost, probably could not be regained without a terrible struggle. Localism obliges police chiefs to seek the support of local councils and, therefore, makes them more responsive to public opinion than they might otherwise be. Provided that the inspector of constabulary certifies that a force is efficient, the central government meets half its cost. The chief constable is, therefore, encouraged to collaborate not only with local government but also with the central government, which can establish uniform standards and conditions of service and with-

hold its share of the finances if these are not met. Chief constables are appointed by committees representative of the relevant local government councils, but their nomination requires the approval of the home secretary. This will be withheld unless the nominee has a period of recent service in some other police force. This, and similar provisions, indicate the growth and spread of national standards in police work.

New Scotland Yard

The British police, through the Home Office, operate certain common services that lead to better cooperation between forces. These include recruit training, advanced training at a police college, research and planning, forensic-science laboratories, wireless depots, central and regional criminal records offices, and regional crime squads. Local forces can solicit assistance from New Scotland Yard in the investigation of murder or from the City of London and the Metropolitan Police in the investigation of serious company frauds. New Scotland Yard is the headquarters of the Metropolitan Police; and, thus, unlike the Federal Bureau of Investigation (FBI) in the United States, it is not a national police agency.

British police experience is of general interest with respect to the question of whether policemen should be permitted to join trade unions. At the end of World War I, there was considerable unrest because rates of police pay had been allowed to fall to a level at which it was difficult for a man to feed his family. Some London and Liverpool policemen went on strike. Pay scales were improved, and the 1919 Police Act was passed declaring, in effect, that no police officer had the right to strike, and that those who did would be dismissed and subject to imprisonment. Every constable, sergeant, and inspector became automatically a member of the Police Federation, which is a representative body with many of the characteristics of a trade union. Acting either locally through branch boards or centrally through the police council or its own conferences, the federation can make representations to a chief officer or the home secretary on matters affecting the welfare and efficiency of members of police forces generally, but not on matters of discipline and promotion affecting individuals. Higher ranks are represented by the Superintendents' Association and the Chief Officers' Association.

The regular police are complemented by special constables (volunteers who perform short periods of police duty in spare time from their normal occupations), a First Police Reserve composed of former or pensioned policemen, and traffic wardens (civilians who work under the direction of the police in the enforcement of parking laws and the direction of traffic). It is important to note that the uniformed, detective, and other branches of the police are not separate career lines. Men are transferred from one to the other, and an officer who is ambitious for promotion will seek to broaden his experience.

British police concept

At the heart of the British conception of uniformed police work is the idea of the constable patrolling his beat. He is regarded as the main instrument of crime prevention in a police service that, since 1829, has believed that "the primary object of an efficient Police is the prevention of crime." Most police officers are employed in the uniformed branch. Up to 10 percent of any force will be in the Criminal Investigation Department, or detective branch, whose members work usually in plain clothes and undertake the investigation and classification of crime reports, the collection of information relating to crime or suspected crime, and the preparation of crime statistics. The constable on patrol carries a short and unobtrusive truncheon. British policemen do not carry firearms, though on special occasions when there is reason to fear that the police may be fired at, trained officers are issued weapons for very limited periods. Firearms control in Britain is strict, and it is difficult for the ordinary citizen to purchase arms.

The United States. The United States provides a picture of what may be the most decentralized police system in the world, accompanied by an extraordinary degree of duplication and conflicting jurisdiction. Since there is no federal government control to ensure uniform standards, every community is entitled to run its own police department but cannot exclude federal or state officials from investigating offenses over which they have jurisdiction. There are five major types of police agency: (1) the federal system, consisting of police officers attached to the Department of Justice (the Federal Bureau of Investigation, together with 700 United States marshals), the Bureau of Internal Revenue (investigating tax evasion), the Secret Service Division, the Narcotics Bureau, the Post Office, and many others; (2) police forces and criminal investigation agencies established by each of the 50 states of the union; (3) sheriffs and deputy sheriffs in over 3,000 counties, plus a few county police forces that either duplicate their police jurisdictions or displace them; (4) the police forces of about 1,000 cities and over 20,000 townships and New England towns; and (5) the police of about 15,000 villages, boroughs, and incorporated towns. To this list must be added some special categories, such as the police of the District of Columbia; various forces attached to authorities governing bridges, tunnels, parks, and parkways; the university, or "campus," police forces; and some units for policing special districts formed for fire protection, soil conservation, and other diverse purposes. The usual estimate is that there are about 40,000 separate, public police agencies in the United States and that the majority of them consist of units of one, two, or three men who are not employed full time. Many are not paid wages but are compensated by the payment of fees for duties undertaken.

These police forces are controlled in different ways. The federal bodies are responsible to the federal authorities, and the state forces to the governors of their states. At local levels there are variations. States are divided into counties, and every county has its sheriff, usually elected for a term of two to four years and with responsibilities for the prosecution of crime and the supervision of the custody of prisoners. He may have deputies performing duties as uniformed policemen. In some states there are county police forces under the control of county boards, whereas, elsewhere, appointments are made by state governors on the recommendation of the county authorities. In some places county police forces are completely independent of the sheriff's office.

Police commissioners

In a major American city, like New York City, the administration, government, disposition, and discipline of the police department are in the hands of a police commissioner, who is appointed by the mayor for a fixed term of years and is likely to be someone with considerable career experience as a policeman. There are deputy commissioners with responsibility for legal matters, policy, public relations, administration, licensing, and juvenile aid. The police department budget is part of the city budget, for which annual appropriations are made out of general tax returns. Whether or not other cities utilize this sort of structure for governing the police depends, in part, upon whether executive responsibility is held by a mayor, a city manager, or a council. Even if a mayor holds executive responsibility, the chief of police may, as in Atlanta, Georgia, be responsible to the police committee of the board of aldermen. In Atlanta, when a disciplinary charge is made against an officer, the chief suspends him; the charge is heard at the next meeting of the police committee, which decides both the verdict and the sentence. Elsewhere, the administrative structure has been supplemented by special citizen review boards charged with investigating citizen accusations against the police. These boards have achieved only limited success and are disliked by the police, who point out that lawyers and doctors do not have similar bodies and that, if a colleague misbehaves, he should be disciplined by a body of fellow professionals, who are the best placed to assess the factors involved. This argument is rejected by those who maintain that American police have failed to discipline those of their number who behave unlawfully. In New York City a proposal for the creation of a civilian review board was rejected in the 1966 citizen referendum.

Many American cities have failed to pay salaries that would attract to police employment the sort of men capable eventually of taking charge of large organizations. In such cities there have been few policemen with manageri-

al talent. Morale has often suffered because serving officers have supported political groups in the hope of promotion if the group is successful at an election. The Detroit department had thirteen police commissioners in the period 1941–71, and there are many other cities in which the turnover has been equally rapid. Some cities appoint as commissioner of police someone who is not a serving policeman but a part-time administrator, who can supervise the managerial side and relate police operations to the political structure. He can then be replaced after an election without upsetting the pattern of relations within the police force. Recent studies have shown that enforcement patterns vary widely when the police are dependent upon the local government. For example, business interests may not want parking regulations enforced strictly, and in the desire to obtain local support, the police may be willing to adapt their activities to community expectations.

American police officers have no national police union or federation to serve as a watchdog over such matters as wages, hours, working conditions, and grievances. Many belong to the Fraternal Order of Police and similar social organizations. In about 45 of the major cities, bodies resembling unions have been formed that appeal to public opinion and use persuasion and arbitration to advance their members' interests. There has been no formal police strike since the one in Boston in 1919, although, as in some Canadian and Scandinavian cities, there have been occasions when large numbers of men have simultaneously reported "sick" as an informal act of protest.

The Tenth Amendment of the U.S. Constitution reserves to the states and to the people those powers not delegated to the federal government. Consequently, state, county, city, and township governments can enact laws and employ policemen to enforce them, provided, of course, that there is no conflict with the Fourteenth Amendment guaranteeing citizens protection by due process of law and equal protection of the law. For this reason, citizens' conduct is regulated by the enactments of different bodies. If a civil rights worker is murdered in a Southern state and the local police are unwilling to investigate the matter properly, the FBI may be sent to investigate whether anyone attempted unlawfully to deprive the dead man of his civil rights. This is a less serious charge than murder, but it is a federal offense and gives federal agents rights of jurisdiction. Similarly, if a European visiting the University of California were one weekend to go to Nevada and bring back with him a girl whom he took to his office and murdered, he could find the case being investigated by the university police, the city police, the local county sheriff, the FBI, the immigration authorities, and, if the girl were a drug user, the Narcotics Bureau. In such circumstances, the different investigating bodies often compete with one another instead of cooperating.

The existing American police structure to some extent reflects public opposition to any concentration of police power. It has been argued that the nation would suffer should all offenses become federal offenses and should power be transferred to Washington and local government be enfeebled. Local problems require local remedies, and the weaknesses of big government are all too apparent. On the other hand, it is argued that the integration and consolidation of police forces could result in an improved service that would reduce costs, increase efficiency, and eliminate the evils of overlapping jurisdictions. The first steps in this direction have been taken in respect to training. Since 1960 no police officer in the state of New York has been able to assume his duties until he has received a certificate for successfully completing basic training. California has introduced grants-in-aid for training that are so attractive that most municipalities are taking advantage of them. Other states have adopted similar schemes. More recently the federal government has made available to the police, through the Law Enforcement Assistance Administration, substantial funds for improving police resources and their management.

Certain other countries with a federal political structure have federal police forces complementing state forces, but the principles involved are no different from those exemplified by the United States. In Australia, for example, each of the six states has its own laws but does not legislate in matters pertaining to federal organizations and cannot pass laws at variance with those of the commonwealth. Each state has its police force. The federal attorney general controls the Commonwealth Police Force responsible for the enforcement of federal legislation. Other police forces under federal control are responsible for overseas territories, the northern territory of the subcontinent, and the capital territory.

The U.S.S.R. In many countries, recent changes in the structure of police administration have been in the direction of greater centralization; so it is of interest to consider a country where the change has been in the reverse direction. After the death of Joseph Stalin the police force of the Ministry of State Security of the Soviet Union was absorbed into the force of the Ministry of Internal Affairs (MVD) under Beria, who was arrested a year later. This force was then divided. The organization dealing with state security was transferred to a Committee of State Security under the Council of Ministers of the U.S.S.R.; known by the initials KGB, it is understood to be primarily a counterintelligence agency. The body that carries out duties performed elsewhere by the normal uniformed police is the militia. Prior to 1956 it was centralized under the Ministry of the Interior, but in December of that year the administration was decentralized. Units are now subject to control by the higher organizations of the militia, by the soviet of the local administrative area, by the local representative of the procurator general of the U.S.S.R., and by the courts. In 1960 the MVD was abolished, and in some areas the militia was itself replaced by Public Order Detachments made up of workers, builders, farmers, teachers, and students. Two and a half million citizens were enrolled into these detachments as voluntary militia. Two years later these new detachments were being criticized in the Soviet press for using their powers in too high-handed a way. To the outsider it would seem as if the Soviet Union found that a highly centralized police service was not accountable to the public and that better responsiveness required drastic decentralization, even to the extent of occasionally relying upon citizen volunteers.

POLICE WORK AND LAW ENFORCEMENT

Routine police activities. Earlier reference was made to the way in which police activity is adapted to the kind of society that is to be policed. There are features common to the work of policemen in differing societies that are founded upon similar technology. Yet within the same society, at times within the same police force, there are variations in the policies of police chiefs. One police administrator, because of his personal beliefs or because of his perception of public opinion, may allocate more men for the investigation of vice than of fraud, may allocate more or fewer men for traffic control or crime prevention. A police chief may instruct his men not to bother about prostitution, provided it is confined to a given locality. Thus, the police in different neighbourhoods may follow different patterns of law enforcement. One study of six American cities identified three such patterns, or styles: a *watchman* style found in departments that use the law more as a means of keeping the peace than for giving effect to the intentions of the legislators; a *legalistic* style, found in a department that acts as if there were a single standard of community conduct, so that all laws are to be enforced, and each policeman may be expected to produce a quota of charges; a *service* style, which is an adaptation to the wants of homogeneous middle class suburban communities, so that, in dealing with minor offenses by local people, the police prefer to activate informal controls rather than invoke the law. These three styles are to some extent associated with city size, population composition, community power structure, and so forth; but they also depend upon the personal decisions of the police chief.

Watchman, legalistic, and service styles of law enforcement

Within the framework of enforcement policy, police work is divided into various branches. The largest num-

ber of men is usually allocated to uniformed patrol, either on foot or with motor transport. Studies of the activities of policemen on patrol indicate that only a small portion of their time goes to the making of arrests or to initiating formal actions under the criminal law. A study of the calls received by a police station in suburban Boston revealed that over half did not involve matters of a police nature, many being simply requests for information. A study in New York City found that less than one recorded incident in 40 led to arrest. Nevertheless, the patrol officer is performing a valuable crime-prevention function by dealing with potentially troublesome situations that, if unattended, could lead to something more serious. Domestic disturbances often culminate in assault, sometimes in homicide or a broken home that can foster juvenile delinquency. The man who is drunk and incapable of looking after himself may be robbed. The prostitute may engage or cooperate in the robbery of her patrons. But, though policemen insist that the heart of police work is preventive patrolling, this activity is not so easily adapted to a motorized age. Policemen in cars are removed from most ordinary contacts with members of the public, and in a big city it becomes increasingly difficult for the policeman to keep a finger on the pulse of his neighbourhood.

"Unit beat policing"

An interesting attempt to come to terms with the problems of policing industrial cities is a scheme of "unit beat policing," first introduced in England in 1966. To each patrol area there is allocated a team that provides for each of three daily shifts—two area constables, one small, conspicuously marked police car and driver, a detective, and a collator. The applications of unit beat policing may vary in accordance with local circumstances and it still has an experimental quality, but a general characterization is possible. The area constable, who is expected to reside within or near his beat, normally works in uniform and is allowed to work out his own plans for covering his area, though he may be expected to spend some of his time patrolling shopping precincts or other areas where the public expects to see a policeman. He is required to maintain personal contact with members of the public, like the old-style village "bobby"; and he should be the "eyes and ears" of the other members of the team. He is the local contact man in any investigation of complaints about the police coming from people in the neighbourhood. The area constable maintains radio contact with these other officers, with his sergeant, and with headquarters. The driver is regarded as another patrolman who has the use of an automobile to take him from one part of the area to another and can therefore attend incidents more quickly than the men on foot. He is not expected to spend his time driving about, and, in one force at least, the optimum mileage for a six-hour tour of duty is regarded as 25 miles (40 kilometres). The collator is a sergeant at headquarters who, with assistants, records all the information sent in by the patrol teams so that he has a daily record of all information relevant to crime, an index of criminals or suspects living or working in the area, an index of such persons' motor vehicles, with additional records for persons subject to driving disqualifications or convicted of drug offenses; there are further records of premises requiring special watch, of the *modus operandi*, or methods, employed in local crimes and of methods used by local criminals, together with a monthly analysis of the pattern of crime in the area. The collator prepares a daily bulletin on local happenings for the benefit of the area team. Because the success of unit beat policing depends in part upon the availability of up-to-date information of this kind, the effectiveness of the area constable is judged by the quality and quantity of information he sends to the collator. The scheme is also dependent upon the use of new methods to establish good communication between members of the patrol team; special conferences attended by the local detectives may be held at regular intervals to bring together as many as possible of the police officers concerned with the patrol area.

The work of police detectives and their new techniques of investigation (such as scene-of-crime fingerprint identification) is relatively well known. It is useful to mention, however, that police forces in many countries have, in recent years, been devoting more and more resources to new departures; *e.g.*, crime-prevention campaigns. Businessmen and householders are advised about weak points in their security and remedies suggested.

Police speakers visit meetings and conferences to educate the public in what needs to be done to combat crime. Police visit schools and talk to students about what the law requires; they may stage mock crimes and trials to give their teaching more impact. In many cities policemen on special duty keep in touch with juveniles considered risks with respect to delinquency, and many officers help with youth clubs in their spare time. If the police are to be active in preventive work, they need men additional to those employed on other duties. This raises the question of what is a reasonable police strength for a given population. Comparisons are difficult, but in most industrial countries there is a police officer for every 600 of population (United States 1:591; United Kingdom 1:571; Japan 1:653). In nonindustrial societies the ratio is higher. Countries like Belgium, France, and Spain have a low ratio if the gendarmerie is included in the calculation; otherwise they are within the normal distribution.

Police and courts. One of the most important ways in which the police are held accountable for the manner in which they perform their duties is through the courts. In France (and in countries with similar juridical procedures) the police making inquiries are under the direction of the investigating magistrate, whose task it is to decide whether there is a case for trial and, if so, what it is. The French think it improper that policemen should inquire into a citizen's activities without his knowledge that they are doing so and without these investigations being under judicial control. The English and American procedure is very different. Anyone may prosecute. The judge listens to the prosecution's argument and evidence that the accused has broken a particular law, and he listens to the defense. Then he decides between them. If he finds the case proved, he then inquires into the accused's previous record and determines the sentence. Should it transpire that the defendant has broken a law but not the one he is accused of having broken, the case must be dismissed.

Police discretion in arrest and prosecution

If the accusatorial system is to function justly, the police must bring all cases of lawbreaking before the courts. It is for the court to decide whether they merit punishment. But, in practice, the police exercise considerable discretion as to whom they will prosecute; and, although their use of this discretion is not at present very well controlled by any agency, the principle of police discretion can be defended on several grounds. In several American cities, for instance, police chiefs who have instructed their men to bear down on offenses and bring offenders to court have had to revert to previous, less stringent practices, because the rate of reported offenses had increased so much that the courts had been unable to cope with the pressure of cases. Apart from such considerations, there are three chief arguments in favour of police discretion. First, it has not yet been possible to draft and keep up-to-date a criminal code that unambiguously encompasses all conduct intended to be made criminal and none other; there will always be technical offenses or offenses that public opinion no longer regards as culpable. Second, those charged with enforcing the law do not have sufficient resources to enforce all the laws all the time, so that enforcement must be selective. Third, to bring a technical offender to court may, in practice, damage a man's reputation.

The second of these arguments was well illustrated in 1966–68 in London, where the law governing gaming houses held that gambling games must be so conducted that the chances would be equally favourable to all players. Casino operators attempted to find ways around this law by such means as using roulette wheels with a zero to increase slightly the odds in the favour of the house. Offenders were convicted but appealed. Believing the law to be uncertain and believing that the expense involved in providing detectives to watch such clubs was not justified

unless there were complaints of cheating or reason to believe that a particular club had become a haunt of criminals, the police commissioner issued instructions in which he said:

> For the time being all applications for authority for an inside observation in licensed or registered clubs for the purpose of detecting gaming are to be submitted for my approval.

A private citizen went to the courts to complain that the law was not being enforced. The court of appeal recognized that police chiefs have a discretion with which the law will not interfere, covering such matters as the disposition of their resources and the decision on whether to prosecute in particular cases. But this instance did not fall within that range. It revealed what one judge called a deplorable state of affairs. Had the commissioner not already withdrawn his instruction, the court very likely would have ruled in favour of the complainant.

There are circumstances in which the police overenforce the law, as when they prefer a "holding charge" to detain someone against whom they are preparing more serious charges. More usually, they underenforce the law by failing to prosecute when they believe that the ends of justice would not be served by so doing. For example, they are usually less ready to prosecute for drunkenness on Christmas Eve. Also, policemen in many countries have decided that if a wife complains on a Saturday night that her husband came home drunk and assaulted her, it is unwise to arrest the husband, lest the wife, who has to live with him when the trouble is over, later asks for the charge to be withdrawn. If the case does go to trial and the man is fined or imprisoned, as much of the burden falls upon the wife and children as upon the offender. In such circumstances, legal sanctions are often clumsy weapons.

Rights of the accused

The courts control police activities in other ways. In England a set of publicized "Judges' Rules" outlines safeguards for accused persons while under investigation. If, in court, it can be proved, for example, that the police failed at the proper points to warn a man that he was under suspicion of having committed a particular offense and that any statement he might make could be given in evidence, then the prosecution might fail. In the United States, the Supreme Court has held that an accused need not answer police questions and that he has a right to consult a lawyer before questioning; if he cannot afford to hire a lawyer, one must be provided. In other decisions, policemen have been prevented from submitting at a trial any evidence that was obtained by unreasonable search and seizure, and, until abolished by Congress, another rule held that, if a person arrested by a federal officer was not taken promptly before a judicial officer and charged with a criminal offense, no confession obtained during a period of delay could be used against him. American police officers have maintained that such rulings hamper them in preparing cases against criminals, and it has been pointed out that one danger in such a situation may be that the police will seek ways around the law.

British and American criminal procedures favour public trials so that all evidence can be challenged. Sometimes offenders are punished more severely by the publicity attached to a trial than by the sentence of the court. According to one point of view, this is, in general, beneficial, since concern for reputation is a powerful sanction on deviation, and it follows that, if offenders receive private trials, they will be less deterred from illegal behaviour. According to the other point of view, publicity may for some people be double punishment and a denial of equal justice. It is worth noting, therefore, the procedure known in Norway as the *forelegg* and in Sweden as the *polisförhör*. This is employed only in connection with minor offenses, such as might be dealt with by financial penalties. On the basis of the police evidence, the public prosecutor notifies the accused that, if the case goes to trial, he will ask the court to impose a certain fine. If the accused pleads guilty and pays the fine, the case need not go to court at all. A similar procedure is adopted elsewhere for on-the-spot fines for motoring offenses. It reduces the burden upon the courts; but, on the other hand, this procedure introduces a new and difficult element into the control of the discretion to prosecute by policemen or by public officials.

Crowds and riots. The first problem in dealing with large masses of people is that of mobilizing police strength. A distinction is therefore to be drawn between the planned assembly for which the police have been able to make preparations and the unanticipated gathering, especially the riot, when the police find themselves unprepared and under strength. The London police have developed great skill with crowds but have no experience of urban rioting on the scale with which American police were confronted in the 1960s. Both crowds and riots, however, require patrol officers to adopt a very different approach from that to which they are accustomed. Normally, policemen are free to handle members of the public in an individual manner. But the control of civil disturbances requires large numbers of disciplined personnel working as a team under unified command. They must not arrest offenders unless it is essential, for, if they do, they will have to guard the arrestee or take him away and cannot then be available for controlling the crowd.

The "new police" were introduced in London in 1829 because the army had been ineffective in controlling mobs. From the beginning, they were careful not to overreact when handling crowds. In Britain, if the police fail to control a riot, recompense for the damage has to be paid by the police authority for the district. Were the police to use, say, water cannon, an injured onlooker could sue the police for assault. The London police use no riot squads, no protective clothing, no arms, no riot gas, and no barriers for crowd control. Constables are drawn from ordinary duties when there is a big parade or demonstration. The police line has always to be in close contact with the crowd, preventing the stone throwing and violence that occurs when there is a gap between them and the citizenry. The advantages of the passive police stance encouraged by their legal accountability were exemplified by four London demonstrations in 1967–68 against United States policy in Vietnam. At the fourth of these, in an atmosphere made tense by press apprehensions of revolution, some 50,000 people marched through the city. In February 1971 a demonstration of some 140,000 individual workers passed off without one arrest. Police efforts have been directed to preserving the citizen's right to demonstrate peacefully while isolating any trouble-making minority and preventing their spoiling the occasion.

Disturbances that erupted in more than 50 American cities in 1967 posed serious problems for the police. Most of these began during the evening watch, when a police department normally has about 13 percent of its uniformed force on duty. At this time, a city like Cincinnati, with a population of about 500,000 and an area of 77 square miles (199 square kilometres), would have about 95 uniformed policemen on duty. The National Advisory Commission on Civil Disorders found that many of the disturbances began when allegedly abusive or discriminatory police actions set sparks among the grievances of Negro ghetto dwellers. The police responded to the disorders cautiously, trying to disperse crowds, observing developments or cordoning off the area. In more than half the cases studied by the commission, rumours significantly aggravated the tensions. Some ghetto dwellers seized the opportunity to raid stores believed to charge high prices. In 13 cases the police were unable to control the resulting situation and the National Guard, composed of private citizens who undertake military duty for at least two weeks during the year, was summoned. The commission concluded that they were inadequately trained for riot duties and that their performance in 1967 raised doubts about their capabilities for such assignments. The rumours running through Negro communities were matched by rumours among the whites of widespread sniper fire. In Newark, N.J., National Guardsmen and police fired 13,326 rounds of ammunition in three days. By contrast, regular troops restored order in Detroit by calm discipline and little use of firearms.

The experience of the 1967 disorders suggests that giv-

ing the police more destructive weapons is not sufficient to maintain order when a substantial section of the population is disaffected. Repressive tactics cannot deal effectively with roving bands of rioters engaged in window breaking, looting, and fire bombing. Nor do policemen think it fair that they should have to shoulder the consequences of society's failure to solve long-standing problems.

Police and private security. Recent years have seen a rapid growth in private security companies, because the police in most countries are not able to provide as much protection as is often desired for private industrial premises or the transport of valuable goods or money. Coupled with this development, and in part responsible for it, has been the increase in the opportunity for theft within industrial concerns. Some firms now assume that at least 2 percent of the goods they handle will be stolen at some point by their own personnel or their customers. The security companies themselves provide opportunities for crime, and the police are concerned that these companies sometimes in good faith employ men whom the police know to have been involved in crime. In Sweden private security companies may apply for official registration, in which case, personnel appointed to sensitive positions have first to be given police approval. It is likely that the question of delimiting the responsibilities of police and private security bodies will attract increasing attention, not least in view of the activities of organizations that inquire into the credit worthiness of private citizens. In Britain, security men carry weapons that are not available to the police and wear uniforms of a kind that sometimes leads people to mistake them for police officers. Some managers discharge employees who have been stealing from the company instead of reporting them for prosecution. But this may be unfair to other employers who may subsequently offer them employment without knowing their background. It is also contrary to the public interest that crime should go unpunished. How private bodies can be made to attend to the public interest is of growing concern to police officers.

Public relations. Since the end of World War II, police forces in many industrial countries have feared that their relations with the public have been deteriorating and that this was having an adverse effect upon their work. Many policemen see the public as having become more ready to question authority of any kind. They believe that the increase in motor traffic has brought citizens who would otherwise be well disposed toward the police into relationships that easily generate friction and resentment. Accordingly, the police have launched public relations campaigns, appointed press officers, and devised new procedures for investigating public complaints. The changes in public attitudes, however, are far more complex than the foregoing would suggest; many individuals will express favourable sentiments toward the police in one situation and hostile ones in another. There may be grounds for believing that the key to this problem lies not in any generalized public attitude or in formal controls upon police conduct, but in the informal relations with the public that stem from the way in which the policeman's role in society is defined.

The policeman in society

Because of the special powers vested in him, a policeman is bound to be set apart, to some extent, from other members of society. In many countries, policemen, in theory at least, are never off duty. They are expected to take police action whenever necessary, even if they are out with their families seeking recreation. Police regulations usually imply that a policeman when out of uniform must do nothing to bring the force into disrepute and may stipulate that officers may have no connection with people licensed to sell alcohol, provide entertainment, run gaming houses, and so forth. Policemen dislike unnecessary restrictions upon their social lives and argue that they can do their jobs better if they can be on easy terms with members of the public, so that the latter see them simply as men with duties to perform like anyone else. It is probable that the more a policeman is hindered from participating in the community, the less he will understand public sentiment, the less he will exercise his discretion, and the weaker will be the informal controls over his conduct. If this is true, then members of the public may be more likely to be irritated by his behaviour and to treat him differently in social contacts—thus tending to isolate him even more. Hostility and isolation feed upon one another. This proposition can be illustrated from colonial territories in Africa, where policemen were at times required to enforce laws not meeting the moral approbation of the population, were isolated from the people, and exploited their powers. In some of the northern cities in the United States, police departments have been demoralized by political control, poor leadership, and low rates of pay; the men have come to feel themselves pariahs. The dangers of social isolation are now more widely recognized.

Police work as an occupation. As has been seen (for example, in the reference to the police in Italy), some police bodies are constituted as part of the armed services. In some European countries, it has been normal to recruit as policemen men who have served as regular soldiers or sailors. It has been even more common to appoint retired army, navy, or air force officers to command police forces. Since World War II the trend has been in the contrary direction.

Police work is seen as a specialist career, and it is argued that the senior positions should go to men who have learned the work by practice. This poses certain problems of recruitment. It is argued that the police should be able to offer appointments as cadets to young school leavers who are keen to become policemen. If they have to wait until they are 21 years or so before they are eligible for appointment, they may be lost to the police. On the other hand, it is said that a youth who has come straight into the police from school has had too little experience of life and is likely to be too narrow in his outlook. Cadet-training schemes therefore seek to give such entrants a wider experience by sending them to social-service agencies and other bodies.

A similar problem is that of officer entry. Many young entrants to the police have the physique and outlook to do the work but have not been among the able scholars and are unlikely to make good administrators. It is not clear whether police should recruit university graduates with the promise that they will be appointed to supervisory positions. The French recruit graduates to the Police Judiciaire by examination, and in Norway only men with legal qualifications are eligible for appointment as police chiefs. In the United States many universities offer courses in police science, and those who obtain qualifications in this field have a certain but limited career advantage. In Britain, graduates are welcomed, but have to compete with other entrants for promotion. The most able among the younger officers are selected for a 12-month course at the national Police College at Bramshill; they divide their time so that half is devoted to professional and half to general studies, by contrast with the rather shorter courses at the Federal Bureau of Investigation Academy at Quantico, Virginia, where all the teaching concentrates upon police subjects.

Police work as a profession

There is a strong movement in the United States to define police work as a profession. There are respects in which policemen exercise a professional skill and provide a service comparable to that furnished by doctors and lawyers. On the other hand, a disciplined body of men incorporated in a strongly hierarchical organization can never have clients of their own or the same kind of obligation toward clients that doctors and lawyers have. The model of a profession does not appear really to fit the police, and, when police chiefs advocate professionalism, they are really using this expression as a slogan in the struggle to improve police standards and win more recognition from the public. It is easier to see the policemen's job as the practice of a craft, for the policeman acquires his skills in the course of an experience that is limited to him and those fellows of his who are bound to the same occupation. Conscious of having a special part to play, members of a craft see the occupation as one that aspirants can enter only through a selective apprenticeship. Unlike professionals, policemen are subject to close con-

trols by superiors, they have no serious professional society, and they do not yet contribute new knowledge about their craft in systematic written form.

INTERNATIONAL ORGANIZATION

The International Criminal Police Organization (Interpol) has a history going back to 1914, though its present constitution dates from 1956. Each member nation has established a bureau that maintains relations with the General Secretariat in Paris. The bureaus transmit criminal information that may be of interest to other countries; they undertake, within their own countries, inquiries, searches, and arrests requested by other countries; and they take steps to implement resolutions voted by the annual assembly. Interpol can act only within the framework of national laws; criminals can be returned only if an extradition treaty is in force and the offender is a national of the country requesting return. The International Association of Chiefs of Police, with headquarters in Washington, draws its members largely from the United States and is the leading voice in America for professional police standards. It is active in training, research, and public relations. There is a parallel body bringing together the representatives of the lower ranks, known as the International Conference of Police Associations. The International Police Association was founded in 1950 as a social organization. Its membership of over 40,000 is strongest in Europe. The Association grants scholarships for study travel and arranges annual conferences.

BIBLIOGRAPHY. JAMES CRAMER, *The World's Police* (1964), provides a remarkably comprehensive survey of modes of police administration. Regrettably there is no reference book listing current changes in this field, and the reader will need to refer to national reports prepared in the countries concerned. THE INTERNATIONAL POLICE ASSOCIATION has published a useful *International Bibliography of Selected Police Literature*, 2nd ed. (1968). There are histories of the police forces of many countries: T.A. CRITCHLEY, *A History of the Police in England and Wales* (1967); M. LECLERE, *Histoire de la Police*, 3rd ed. (1964); JAMES RICHARDSON, *A History of the New York Police from Colonial Times to 1901* (1970); PAUL RIEGE, *Kleine Polizei-Geschichte*, 3rd ed. (1966); PHILIP JOHN STEAD, *The Police of Paris* (1957). For popular accounts of police work and the problems of accountability two recent British books deserve mention: BEN WHITAKER, *The Police* (1964); and PETER LAURIE, *Scotland Yard* (1970). MICHAEL BANTON, *The Policeman in the Community* (1964), is a sociological comparison of the police role in Scotland and the United States. JAMES Q. WILSON, *Varieties of Police Behavior* (1968), compares the enforcement policies of eight American police departments, while JOHN A. GARDINER, *Traffic and the Police* (1969), reports on a more restricted comparative study. JEROME H. SKOLNICK, *Justice Without Trial* (1966), discusses the detective's role in California and is sensitive to the legal as well as the sociological issues. ARTHUR NIEDERHOFFER, *Behind the Shield* (1967), gives a sociological viewpoint from a former New York policeman. The current problems of police operations and accountability are also featured in the U.S. President's Commission on Law Enforcement and Administration reports, *The Challenge of Crime in a Free Society* (1967), *Task Force Report: The Police* (1967); and the *Report of the National Advisory Commission on Civil Disorders* (1968). Comparable studies for countries other than Britain and the United States are scarce, but reference may be made to DAVID H. BAYLEY, *The Police and Political Development in India* (1969); and D. CHAPPELL and P.R. WILSON, *The Police and the Public in Australia and New Zealand* (1969).

(M.P.B.)

Police Technology

Police technology covers the methods and techniques of, and the equipment available to, the law-enforcement agencies of the world. Through the 20th century, improvements and innovations have been made in police transportation, communications, weaponry, laboratory facilities, and other areas; but these have scarcely more than kept pace with the pressures generated by denser urban populations, greater sophistication on the part of criminals, social disturbances, and new types of crime made possible by new economic or technological developments—*e.g.*, aircraft hijacking.

Police technology increasingly involves borrowings from the physical and social sciences, as well as from the disciplines of jurisprudence and education. Professional publications, educational programs, workshops, and international conferences of police reveal the growing importance attached in recent years to the technical side of police work. Tomorrow's policeman will unquestionably be impressively equipped and educated; yet it was only in the 1960s that police technology became recognized as a distinct discipline in its own right. The present article is concerned with police technology in surveillance and crime fighting; traffic-control technology is described in the article TRAFFIC CONTROL. The technology of prison systems is described in PRISONS AND PENOLOGY.

HISTORY

Many examples of an incipient police technology can be found in the ancient and medieval world.

Long before the birth of Christ, Egyptians used detailed word descriptions of individuals, a concept known today as "portrait parle." The Babylonians pressed fingerprints into clay to identify the author of cuneiform writings and to protect against forgery. Fingerprints were also used by the Chinese at an early date for purposes of identification. The concept of comparison and identification of handwriting was established in Roman times, as is evidenced by the Justinian Code of the Eastern Roman Empire, enacted in AD 539. Branding and mutilation were used from time immemorial to identify convicted criminals. Trial by ordeal and by combat were medieval methods of interrogation of suspects, with the survivors judged innocent. A more humane medieval method, and a step toward modern concepts, was compurgation, in which the disputants took oaths on sacred relics.

Precursors of the modern lie detector

An Asian interrogation method involved scientific principles based on the lessening of salivation under nervous tension. The mouths of several suspects were filled with dry rice; the suspect exhibiting the greatest difficulty in spitting out the rice was judged guilty. Another precursor of the modern lie detector was employed in India. Suspects were sent into a dark room where a sacred ass was stabled and directed to pull the animal's tail. They were warned that if the ass brayed it was a sign of guilt. The ass's tail had been dusted with black powder; those with a clear conscience pulled the tail, whereas the guilty person did not; an examination of the suspects' hands revealed the person with the guilty conscience.

Modern police methods were beginning to develop in Europe by the 18th century and, in the 19th, were reinforced by a great number of technological advances. When the British Parliament enacted the reforms of Robert Peel in 1829, the importance of keeping good police records was recognized. In principle, Peel stated that police records were indispensable for the proper distribution of police strength. His reforms laid the foundation for the development of the modern police communications system and provided for a coherent police organization.

Until the mid-19th century, however, police signal systems consisted of whistles, raps on the pavement with a nightstick or baton, and flashing of lights. In 1849 the central police station at Scotland Yard and the district police stations of London were connected by a telegraph line. Other cities followed, and telegraph boxes placed at points on patrolmen's beats permitted swift calls to headquarters when assistance was needed.

The telephone was first installed in a police station in Washington, D.C., in 1878. Two years later Chicago took the important step of installing telephone boxes on patrolmen's beats.

In the area of identification, the late 19th century brought important advances. In 1882, Alphonse Bertillon of France introduced a means of identifying suspects by using measurements of the body, head, and limbs. This system was largely supplanted by fingerprinting, which dates from about the same period. The Henry system of classifying fingerprints (by patterns and shapes) was adopted by Scotland Yard in 1901, and this system, or variants of it, soon became standard all over the world.

The idea of tracing and identifying an individual typewriter by means of the peculiarities of its type characters probably first appeared in Arthur Conan Doyle's story "A Case of Identity," written in 1891, three years before the first mention of the subject in technical literature.

First use of the automobile

The automobile, first used in police work in Akron, Ohio, in 1899, became the basis of police transportation in the 20th century. Closely linked with it was the adoption of radio communication. Other communications innovations were the teletypewriter and facsimile. The teletypewriter evolved from printing telegraphs and developed rapidly during World War I; in the 1920s it became the workhorse of police communications in most countries. Facsimile transmission (telephotography) dates from the early 1900s, and, as early as 1908, a criminal was captured as a result of his photo being transmitted by facsimile from Paris to London. After World War I this technique also became widespread.

Perhaps the single most important invention in the development of police communications was the transistor, which in the 1950s provided small, lightweight, reliable radio transmitter-receivers.

In the 1920s the technique of identification of firearms on the basis of striated markings on bullet jackets was introduced. As these and other new techniques became familiar, the first police crime laboratories were instituted in Europe and the U.S. One of the earliest was that established at Lyons, France.

There have been few innovations in weaponry. The nightstick (club) and firearm, invariably an adaptation of a military weapon, remained virtually unchallenged in the police arsenal until the 1960s, when chemicals, tranquillizing darts, light- and sound-energy techniques, and other devices began appearing.

MODERN SURVEILLANCE SYSTEMS

Police have a number of surveillance techniques available, but chief reliance is almost universally placed on patrolling.

Patrol systems. Patrols vary in methodology, assignments, structure, and mobility. Their flexibility has been significantly enhanced by improved methods of communication, especially the two-way radio and by the availability of numerous types of vehicles; the automobile and motorcycle are the most prominent, but the bicycle remains valued in many countries. The mobility provided by modern communications and transportation techniques is particularly useful in dealing with civil disorders.

The areas covered by metropolitan police patrols vary enormously in population density, character of commerce and industry, terrain, and roads. The helicopter, whose value in traffic surveillance was established in the 1960s, promises in the 1970s to be used for general patrol work in metropolitan and rural areas. In some countries the short-takeoff-and-landing aircraft has been adopted for patrol and rescue work.

Police dogs. The training of dogs for police work was originally developed in Ghent, Belgium, about 1900 and was soon copied elsewhere. Though certain breeds with especially keen senses are used for special purposes, such as detecting caches of illegal drugs or for tracking fugitives and missing persons, the most widely trained dog for regular patrol work is the German shepherd, or Alsatian. Other breeds sometimes used include boxers, Doberman pinschers, Airedale terriers, rottweilers, schnauzers, and bloodhounds. Selection and training has become highly specialized. Selection involves use of standard criteria relating to breeding and physical measurements, and training is rigorous.

Electrical protection systems. Electrical protection (alarm) systems substantially reduce burglaries and contribute to capture of many criminals. The development of alarm equipment and the evolution of operating procedures in the U.S., Canada, and western Europe has been significantly influenced by the published standards of Underwriters' Laboratories, Inc. (UL). Central-station systems and local-alarm systems are the two basic categories of UL-regulated burglar-alarm systems.

Central stations

Central stations are commercially operated control centres serving metropolitan and surrounding areas. Burglar-alarm protective circuits and devices automatically transmit signals to these centres. Armed guards are in attendance at all times and are dispatched to conduct immediate investigations of unauthorized entry of protected properties. Central stations generally have direct communication channels to police control centres. Some such centralized operations in large European cities control several completely automatic satellite stations in nearby cities; the local police are dispatched by the central station.

Local burglar-alarm systems are used primarily in small cities and towns where central-station services are not available. Sensitive warning mechanisms are connected to loud alarms attached to outside walls of buildings and, often, to a signal system in local police stations. (A description of proprietary detection and warning systems is given in SECURITY AND PROTECTION SYSTEMS.)

Technical surveillance. The application of technology to surveillance operations has greatly expanded the capabilities of law-enforcement agencies and has led to creation of a special field of police technology known as technical surveillance.

Audial surveillance. Audial surveillance, or electronic eavesdropping, became practical for obtaining evidence and investigative leads as a result of intensive development of the magnetic tape recorder and solid-state electronic components during World War II and subsequent years. The field has two technically and legally distinct areas: the surreptitious interception of oral communications, commonly known as "bugging," and the surreptitious interception of wire communications, commonly known as "wiretapping." Typical devices used include miniature microphones, miniature radio transmitters, and a variety of radio-receiving and voice-recording equipment.

Microphones, of course, are always required for the interception of oral communications and may be connected by cables directly to recorders located at remote locations or may be connected to transmitters. Excellent quality microphones of very small size are available throughout the world. Microphones located in the handsets of telephones may be used to intercept nearby conversations through modifications and the use of companion equipment connected to telephone lines.

Radio transmitters of cigarette-package size, equipped with integral batteries and microphones, are commonly known as "wireless mikes." Most radio transmitters used for audio surveillance operate within the very high frequency (VHF) range.

The most common wire-communication-interception activity consists of monitoring telephonic conversations. Equipment used for telephone tapping ranges from the telephone repairman's handset to automatic voice recorders connected to target telephone lines.

Optical surveillance. This type of surveillance makes use of such devices as binoculars and telescopes; cameras with long-focal-length, or telephoto, lenses; closed-circuit television; and videotape recorders. Closed-circuit television is a versatile surveillance method that has become widely used both by police and by private security systems. From a central location, a supervisor can monitor events at one or several remote locations. Cameras may be fixed or oscillated to sweep a large area.

Devices for low light levels

Recently available low-light-level devices have greatly extended passive optical-surveillance capabilities. Practical low-light-level television systems are manufactured for optical surveillance operations under light intensities as low as 10^{-8} lumens per square metre, or virtual darkness. Night-vision telescopes using two and three light-amplification stages are also in use.

Tagging and tracking. Object tagging and signal tracking comprise a third category of police technical-surveillance operations. Devices emitting a unique signal are attached to vehicles or implanted in target objects. Compatible receiving or activating equipment is used to track the tagged objects. A typical device used in tracking is a miniature radio transmitter using distinctive tone modu-

lation, commonly known as a "bumper beeper," which is surreptitiously attached to a vehicle. The target is discreetly tracked with one or more surveillance vehicles equipped with appropriate receiving equipment.

CRIME REPORTING AND RECORDS

The efficiency and effectiveness of a police department depend in large degree on complete, readily available, and up-to-date record keeping.

Information must be reported, collected, classified, analyzed, processed, and stored. Numerous files must be kept, of which the most important include fingerprints, *modus operandi* of criminals, and various investigation and reference files. There should be as much cross-filing as possible.

Fingerprint classification. Fingerprint records are among the most significant files that are maintained. Inked fingerprints from all ten fingers of an individual can be classified; *i.e.*, put into narrow categories for file purposes and ultimate retrieval (see illustration). In the United States, the Henry extension system is used. This system is a modification of the Henry system, which was developed prior to 1900 in England. These two systems vary greatly in presentation but are similar in content. In parts of South America, the Vucetich system is used. In the Henry extension system, each of the ten individual fingerprints of a person is classified as to arches, loops, whorls, or composite style prints. The type of design, plus subclassification based on locating certain fixed points and counting the ridges lying between the points, is used to make the classification.

By courtesy of the New York State Identification and Intelligence System

Classification of a fingerprint for computer search and storage from a facsimile copy of a suspect's fingerprints.

Fingerprints obtained from individuals are classified and compared with the fingerprints of other individuals having the same classification. With this system, personnel in a police centre need not compare a set of fingerprints with all the millions of cards on file but only with the few in the same classification. (For the technique of fingerprint photography and identification, see below *Laboratory procedures.*)

Modus operandi. If a criminal has been successful in the use of certain methods and techniques, he tends to repeat the same operational procedure. Thus, evidence of a definitely characteristic behaviour and procedure at the crime scene can serve to identify the offender if the pattern is recognized by the police. Although classification of criminals according to operational method and manner had, by midcentury, lost a good deal of its effectiveness in the investigation of burglaries, large law-enforcement agencies still maintained *modus operandi* files to recognize a pattern of behaviour, to associate a group of crimes with a single perpetrator, and to enable them to approximately predict the next target of the criminal. The *modus operandi* file is most effective in crimes involving personal contact, such as felonies against the person, confidence games, and forgery.

Investigation and reference files. Informational files are maintained by law-enforcement agencies. The primary purpose of these records is to identify the source of evidence discovered in connection with a crime. For example, a file of automotive paint samples will assist in identifying the make and model of a vehicle involved in a hit-and-run case. Automotive registrations and records of firearms will assist in establishing ownership. In addition to their own files, the police have access to the records of many governmental agencies that record titles, contracts, vital statistics, significant events, and official acts in general. Among other files maintained by the police the following prove exceptionally useful.

Missing persons. Each year many thousands of persons are reported missing to the police. In addition, the police must investigate cases of unidentified persons, living and dead. Descriptive files are maintained of missing persons under the age of approximately 19, unidentified dead, and unidentified persons who are physically and mentally afflicted.

Laundry and dry cleaners' marks. A valuable clue to the identity of an unknown person can be found in the mark or marked tag placed in his clothing by the laundry, dry cleaner, or tailor. The mark usually consists of a set of numbers or letters identifying the retail store for the wholesale processor. Samples of these marks are filed systematically by larger police departments for the purpose of tracing a lost, dead, or wanted person.

Lost or stolen property. Many cases of burglary and larceny are solved simply by tracing stolen property to the possession of the criminal. For this purpose, police maintain a central cross-indexed file of property lost or stolen and of articles pledged at pawnbrokers or sold to secondhand dealers. The common objects of larceny—automobiles, watches, jewelry, furs, and cameras—are identified by means of an accurate physical description, including serial marks and personal inscriptions.

Computerized records. The record-keeping tasks of police work were long handled by individuals using a diversity of manual systems. Quick nationwide or international utilization of records and files was impossible. Now, however, electronic data processing has revolutionized information-handling techniques. Manual filing systems have been superseded by computers that operate from central geographic points, storing data and making it instantaneously and accurately available to many police constituents. Furthermore, the computer can be linked with other computers in the same country or in different countries.

Electronic data processing

In addition to serving as a depository and dispenser of information, the computer can provide statistical analysis for research and management, develop intelligence data bases and analysis systems, assist in the analysis of physical evidence, facilitate swift document retrieval, and help in such areas as identification of fingerprints. In the analysis of fingerprints, the computer is not yet economically effective because there is no simple means by which single prints can be directly identified, but promising research is underway to develop automatic scanning and classification systems.

COMMUNICATIONS

A total police communication system can be extremely complex, but its complexity varies with the needs associated with particular police organizations and their operational environmental situations. Each police function or situation calls for its own subsystem of communication.

In a large city, the sources of information that must be fed into the central system are remarkably varied. Police may be on foot or motorcycles, in patrol cars, in patrol boats, or in aircraft. In addition, the system must encompass links to fire stations, ambulance services, traffic-control systems, rescue teams, alarm systems, emergency utility services, crime-information systems, and crime

laboratories. A variety of fixed and mobile systems are in use, including radio, television (including closed-circuit), telephone, teletypewriters, and facsimile transmission. Research and development are active in such areas as more effective use of available radio frequencies, improved mobile teletypewriters, improved facsimile systems for fingerprints and documents, and direct vehicle-to-computer communications systems.

Police radio-communications systems, which profited considerably from the advances in electronics during and after World War II, also profited from the development of computers, which made possible the quick retrieval of information on stolen property, wanted persons, and other police intelligence for patrolmen as well as headquarters. The augmented flow of information has placed an added burden on existing communications systems, which have consequently grown more complex. Among numerous technological innovations, the development of the modern police communications centre merits particular mention.

Functions of a police communications centre

A communications centre performs several functions: (1) it receives and processes police calls from the public; (2) it audits and dispatches police resources in response to police calls; (3) it receives and responds to information inquiries as well as calls for assistance from police patrols; (4) it maintains moment-to-moment status information on police resources for command and control purposes.

The geographic distribution of police communication centres has been broadened to include locations in many countries of the world. These centres facilitate police work needed to deal with the international mobility of modern criminals. The extensive radio network maintained through Interpol serves to promote international cooperation among world police organizations.

INTERROGATION METHODS AND EQUIPMENT

Policemen and other investigators continue to depend on interrogation as a principal means of determining facts and resolving issues. Reliance on interrogation, however, involves certain problems: ascertaining when a suspect or witness is telling the truth, evaluating memory, allowing for the physical and mental condition of a witness or suspect, and understanding the problems created by an individual's perspective.

Interrogation methods and equipment have evolved in response to these problem areas. The psychological, psychophysical, and physical sciences have played vital roles in police interrogation techniques.

The polygraph. The most dramatic gains in interrogation technology have come through the polygraph, or so-called lie detector. The polygraph monitors and records selected body changes that are affected by a person's emotional condition. The recorded changes are then studied, analyzed, and correlated in respect to specific questions or other stimuli.

The first modern polygraph was constructed in 1921 by John A. Larson, a medical student at the University of California, working with a member of the local police department. Larson's instrument was capable of continuously recording blood pressure, pulse, and respiration; since it recorded these conditions simultaneously, it was called a polygraph. A later development provided for the recording of the psychogalvanic skin reflex (electrodermal response), the flow of current between two different parts of the body. Research is continuing on both the instrumentation and the psychological techniques necessary for its effective use by the police.

Even though the polygraph has been formally and successfully utilized in police intelligence and security investigation since 1924, there is still no complete agreement on its validity among leading psychologists. Furthermore, the results of a polygraph test are not always judicially acceptable. Despite these qualifications, the polygraph has proved an invaluable aid to police interrogation and the development of investigative leads.

Detection of narcotics and dangerous drugs. Portable field chemical kits have been developed for the detection of narcotics and dangerous drugs. These kits are designed to provide a practical method for initial tests in the field and are not intended to replace the more thorough laboratory examinations.

Drug tests. Tests for determining that a suspect has consumed a narcotic or dangerous drug must be performed in a forensic laboratory. These tests require the taking of a urine or blood sample from the suspect and, therefore, require close medical supervision. Many new techniques for the detection of both caches and small amounts of drugs are under development, ranging from the use of specially trained police dogs to electronic odour-detection equipment.

Alcohol tests. In view of many studies linking traffic fatalities with alcohol use, the determination of the amount of alcohol in a driver's blood has received increasing attention from police researchers in many countries.

For many years, the basic test for legally determining a driver's blood-alcohol content involved taking a blood sample and sending it to a laboratory for analysis. This method, although accurate, is not practical for law-enforcement purposes because many people object to having a blood sample taken, and test results are not immediately available. The development of the breath analyzer for the determination of blood-alcohol content has given the police a more practical tool. This instrument permits a precise amount of the suspect's breath to pass through a chemical solution (potassium dichromate and sulfuric acid), resulting in a colour density change proportional to the amount of alcohol in the air sample. The percentage of alcohol in a given air sample is determined and equated to a certain percentage of blood-alcohol content. In cases where the suspect is not conscious or requires serious medical attention, a blood test may be the only recourse. Blood-test and breath-analyzer techniques, however, are not accepted as evidence in all courts.

The breath analyzer

WEAPONS AND RELATED DEVICES

To contend with the wide diversity of criminal situations, police require a variety of weapons and restraining and protective devices. Science and technology have contributed to the development of increasingly practical and effective equipment of this type.

Standard weapons. Standard equipment varies. The London policeman carries only a small baton; the New York City policeman carries a large-calibre revolver and a baton; the Paris policeman carries a small-calibre semiautomatic pistol, a baton and a leaded cape; and the Cairo (Egypt) policeman carries a submachine gun or automatic rifle.

The most universal physical weapon and certainly the most frequently used weapon over the years has been the baton, nightstick, or billy. The baton has been the subject of study and research, and there now exists a family of batons which includes, in addition to the original wood or plastic baton, devices that contain firearms, aerosols or tear-gas cartridges, and electric-shock systems. Some batons are made to break at a certain degree of impact, in order to avoid serious injury.

Pistols, including the automatic pistol and the revolver, are the second most widely used police weapons. In the United States the revolver (.38 special to .45 calibre) is the primary pistol, whereas in Europe and Asia the automatic (.25 to .38 calibre 9 mm) finds extensive use.

Shotguns, rifles, and automatic weapons are usually included in the police arsenal but are issued only when essential.

Chemical and other nonlethal weapons. The most universally used chemical weapons are those that deliver compounds that cause either severe weeping or tearing at the eyes (lacrimators) or extreme discomfort or sickness (nauseators). The three most universally used chemicals are known by the initials CN and CS, both lacrimators, and DM, a nauseator. Among the systems used to dispense the chemicals are riot shotguns, fog generators, and grenades. The most commonly used new weapon is the handheld aerosol tear-gas projector (MACE). Of convenient size, it can be carried in a holster; it is easily aimed and is instantly effective. Its viable range is about 15 feet and it delivers about 40 one-second bursts.

Lacrimators and nauseators

Other nonlethal weapons include sound and light devices which cause confusion, pain, or temporary blindness.

Restraining and protective devices. Criminal restraining and police protective systems have been subjects of much study and research. The developments in restraining devices or systems include lighter, more effective handcuffs, with improved locking systems; lightweight thumb cuffs; pressure-twisting devices that are applied to wrists; lighter and stronger straitjackets; and lighter and stronger leg irons.

A recently developed restraining device is the disposable handcuff. It consists of a 22-inch-long nylon plastic strap with a slotted head at one end and a tapered tail at the other. A stainless steel barb in the head allows the tail to be pulled through the head in one direction and locks the strap so it cannot be withdrawn. To remove these plastic cuffs, the policeman merely cuts them off. This development is particularly useful in mass arrests, as in riot situations.

Significant developments in the technology of protective devices include heavy plastic shields to ward off rocks and other missiles; lightweight nylon clothing resistant to pistol bullets; bullet-proof shields; and bullet-proof armor made of nylon and ceramic materials, which can withstand high-powered rifle bullets.

LABORATORY PROCEDURES

Crime laboratories may be either specialized, such as those that handle principally documentary evidence, or they may be broad in coverage, as is the case with most national police laboratories. The fundamental purposes include the collection and preservation of physical evidence, its examination, and the preparation and presentation of accurate, objective testimony regarding it.

Personnel include specialists such as document examiners, generalists such as criminologists, and technicians and other supporting personnel. They are usually employed by a government unit and must pass rigid examinations.

Facilities and equipment. Crime laboratories usually are equipped with a wide array of scientific instruments and facilities. Instruments are constantly being developed and introduced, and the resources of individual laboratories vary. Some are equipped with expensive and highly sophisticated analytical instruments, such as the mass spectrograph, the electron microprobe, and the scanning electron microscope. Close cooperation among laboratories makes possible the sharing of specialized equipment when needed.

Value of photography

The largest category of laboratory equipment relates to photography. The usefulness of the medium extends from straightforward photography of, for example, car accidents and sites of crimes to specialized work of various kinds. Colour photography is increasingly used to obtain more realistic and informative representations of the crime scene. Ultraviolet and infrared photography aid in detecting stains, invisible writing, and alterations on documents. Radiography is also used to provide details that would otherwise be invisible. Photography through the microscope (photomicrography) is a common technique, a special case being the examination of bullets. Fingerprint photography is an area of specialization that may involve conventional methods or any of a number of special techniques to recover useful prints from different types of surfaces.

Among the more common facilities are chemical laboratories, with a range of reagents and analytical instruments, including spectrographs and chromatographs. Optical equipment includes a full range of magnifying devices, from magnifying glasses to specialized microscopes of various kinds, including stereomicroscopes and comparison microscopes.

Evidence and its examination. An investigation at the scene of a crime, particularly in crimes of violence, is the first phase of the laboratory function. Some jurisdictions have mobile crime laboratories, in which some of the regular laboratory tests can be performed.

Crime sites must be searched to locate pertinent physical evidence, which may range from latent fingerprints to bloodstains to pieces of a broken automobile headlight. Evidence must be marked for identification, preserved, and protectively packaged for transportation to the laboratory. In addition, records (written or photographic) must be made of each piece of evidence and its exact location with respect to the crime.

Certain laboratory procedures and tests are carried out in the field when time is limited or when there is a possibility that the evidence might be disturbed. Among such procedures or tests are: dusting for fingerprints, making casts of footprints and car tracks, making blood tests, and collecting specimens of organic and inorganic materials from the environment.

Classes of evidence. Evidence can be categorized according to potential value as proof. Certain types of evidence can be individualized or associated with a unique source, whereas other types cannot be pinpointed but can aid in identification because they fall into particular classes. Types of evidence that can be individualized are handwriting, typewriting, fingerprints, footprints, tire marks, impressions or casts of nonstandard items, striated markings on bullets, tool marks, objects with random fractures or tears, and substances that have undergone an alteration that makes them unique among others of the same class. Among evidence that only identifies a certain class are blood and other body fluids, narcotics, toxicological materials, fibres, soils, inks, and many kinds of materials produced in batches.

Examinations can be either unilateral or comparative in nature. Blood-typing and establishing the distance from which a weapon was fired are unilateral examinations, whereas studies of handwriting or spent bullets involve comparisons with other examples.

Pathological examinations. Although pathological examinations are not ordinarily conducted by a crime laboratory, they are part of forensic science. Definitive statements relating to the cause of death and time of death are made by the coroner or medical examiner of the jurisdiction in which the death took place. Observations by crime laboratory personnel of the conditions at a crime scene, plus toxicological analysis by a crime laboratory, are utilized in concluding whether a death was by accident, suicide, or murder. In most jurisdictions, an autopsy is conducted if a physician was not in attendance or if the cause of death is not obvious, as in cases involving poisoning, electrocution, asphyxiation, heart attack, or stroke. In cases involving identification of a decedent, crime laboratory personnel may work with a coroner or medical examiner to establish identity by such methods as comparison of fingerprints and handwriting.

Fingerprints, palm prints, and footprints. Fingerprints found at the scene of a crime can be very significant as evidence connecting an individual with a crime scene. Fingerprints can be either visible or latent. Visible prints —formed by dirt or blood, for example—or three-dimensional prints formed in soft matrices, can be photographed directly. Latent fingerprints, which are not ordinarily visible, can be brought out by dusting techniques when the surface is hard and by chemical techniques when the surface is porous. In dusting for fingerprints, a fine powder of contrasting colour is applied with a fine brush. The powder clings to the residual oils and fats in the print and the excess powder is removed with the brush. On porous surfaces (such as paper) fuming iodine, silver nitrate, or ninhydrin solutions are used to develop the latent fingerprints. The most effective developer of latent fingerprints is ninhydrin, which can reveal prints that are several years old.

Fingerprint "points"

Individual fingerprints are identified on the basis of agreements in a significant number of individualities, commonly known as "points." These are the bifurcations, ending ridges, and dots in the fingerprint pattern. If sufficient points are found with spatial relationship to other points, then a basis exists for identifying a fingerprint. It has been considered necessary to have 12 points to identify a fingerprint, but in current practice, a lesser number can be used under certain circumstances. Palm prints and footprints are identified in the same manner as fingerprints.

Document examination. The work of the "questioned document examiner" encompasses the examination of handwriting, typewriting, ink, paper, and typography and covers such problems as the identification of handwriting and typewriting, the sequence of events involved in the preparation and handling of a document, the alteration of a document, and the age of a document.

Handwriting, like all other evidence, is identified on the basis of individuality. Children are taught specific ways of forming letters, but they rapidly begin to inject their own individuality into letter forms and writing execution. By the time a person reaches maturity, his writing has acquired peculiarities which serve to identify him. Naturally, there is some variation in each person's writing from sample to sample, but any sample containing sufficient evidence of the individuality of its author can be identified.

A forged signature presents other problems. Simulated signatures based upon recollection contain a combination of the forger's own writing habits and his recollection of the victim's habits. In many cases, such simulations can be identified. On the other hand, when the perpetrator makes a careful drawing of the victim's signature or traces an authentic signature, the forgery can be exposed but cannot be identified with the handwriting of the perpetrator. Two different individuals making careful tracings of the same model signature would produce virtually identical drawings.

Typewriter identification

The make and model of typewriter used to prepare a document can be determined by examining typeface designs and comparing them with information contained in reference files and differentiation charts. The work of a specific typewriter can be identified if it contains sufficient identifying individuality, based on broken or tilting characters, badly aligned characters, characters that print more heavily on one side than on another, and rebounding characters. Mechanical conditions affecting the type basket or the escapement may also have identifying value. Since it is impossible to reinsert a document into a typewriter in its exact former position, it is possible, using a ruled screen, to determine if a document has been prepared at one sitting or has been re-inserted.

Ink comparisons provide class evidence that is frequently of value, but it is not possible to individualize ink; *i.e.*, identify it as coming from a unique source. Chemical tests of various kinds are used for ink comparisons.

Papers can be differentiated on the basis of fibre, filler, and sizing constituents. Fibres can be identified by differential staining and microscopic examination. Fillers can be identified by X-ray diffraction because they are crystalline substances. Chemical tests are used for the identification of sizing constituents. Research with neutron activation analysis, a technique involving chemical analysis by radioactivity, indicates that it may even be possible to identify paper by batches.

Questions concerning the sequence of writing—*i.e.*, whether the ink signature is over or under the typewritten portion of a document—can be important in proving or disproving the authenticity of a document. In this and related problems, such as deciphering and restoration of eradicated or erased writing, examinations are carried out using stereomicroscopes, ultraviolet and infrared techniques, or chemical tests, depending on the specific problem.

Ballistics techniques. Firearms examinations involve such problems as ascertaining the type of weapon and the specific weapon used to fire a bullet, determining the distance between the weapon and the target, and establishing whether or not a particular individual fired a weapon.

The identification of a particular weapon is based upon the comparison of minute striations, or striae, left on bullets as they pass through the rifled barrel. Each barrel leaves a different combination of striae on the side of bullets. A bullet recovered from the scene of a crime can be compared with a test bullet fired from a suspect weapon. The striated markings on both bullets are brought into juxtaposition under a comparison microscope. If there is agreement in the width, depth, and spacing of a significant number of striae in both bullets, an identification can be made. (The same principle is used in the identification of tool marks.) The extractor and ejector markings on rifle and automatic-pistol cartridges can be identified in the same manner. In some cases, the firing pins and breechblocks leave individual markings on the face of a cartridge.

The distance from which a weapon was fired can be determined, up to several feet, by examination of the form and size of the hole in a target, the extent of the burned area around the hole, the amount of embedded powder grains, and the presence of mercury or lead from primers. The effects vary with the weapon and the type of ammunition. Such information may be vital in determining whether or not a gunshot wound was self-inflicted. Infrared, X-ray, and chemical tests are used in determining the extent of powder residues.

The best means of determining whether or not an individual has recently fired a gun has been the subject of much controversy. In the dermal nitrate test, melted paraffin is used to pick up traces of nitrates and nitrites on the hand, after which a chemical test is made for such compounds. This method has been discredited because it can give incorrectly positive test results. Use of the neutron-activation technique to detect the presence on the hand of antimony and barium from cartridge primers is much more definitive.

Individualization of paint

Paint. Under certain circumstances, paint evidence can be individualized. If a jagged edge of a paint fleck found on a suspect can be matched with the edges of the matrix from which it came, a basis exists to connect a suspect with a crime scene. Multilayered paint chips can sometimes be individualized if the discrete layers possess sufficient individuality. Under other circumstances, paint must be considered class evidence. Examination of paint for class characteristics involves the use of chemical tests to determine constituency, as well as examination with instruments such as the infrared spectrophotometer, emission spectrograph, or electron microprobe.

Inorganic materials. Soil, safe insulation, and other inorganic evidence can also be compared to determine common origin. It is not possible to individualize the evidence, but the fact that the same type of mineral matter was found on a suspect and at a crime scene is usually considered significant. Inorganic materials can be compared in terms of metallic element constituents, density of constituents, and microscopic structure.

Blood, blood spots, and semen. Bloodstains are a natural consequence of many crimes of violence; examinations usually concern the position, extent, and nature of suspected bloodstains. In most cases, the blood is dry. Preliminary chemical tests indicate only that the stain in question may be blood. The Teichmann and Takiyama tests, both of which rely on a reaction with hemoglobin, are confirmatory tests for blood. Human blood can be differentiated from the blood of other species by the precipitin test, which involves the reaction between blood and antihuman rabbit serum. Blood can also be categorized as to group: A, B, O, or AB.

The shape, position, and extent of bloodstains often give valuable information about the circumstances surrounding the commission of a crime. Blood falling from different heights forms stains of different shapes, which are further modified by the angle at which the blood drop hits the surface. Rough estimates can be made as to the age of bloodstains.

Ultraviolet light and the acid phosphatase test are used for the presumptive identification of semen. Positive identification for semen relies on identifying spermatozoa in the suspected sample.

Hairs and fibres. Hairs and fibres found at the scene of a crime can also be important evidence. It is not possible to trace hair to a specific individual, but narrow classes having probative value can be established. Human hair can be distinguished microscopically from other animal hairs. Hairs from various portions of the body vary in structure. Microscopic examination can reveal if hair has been recently cut, burned, or split. Chemical tests can demonstrate the presence of bleached or tinted hair. Neu-

tron activation analysis has been used in recent years to identify specific trace elements in hair and to measure the quantities of such trace elements.

The various fibres used in clothing, rope, furniture, etc., are of vegetable, animal, or synthetic origin. They can be differentiated by microscopic study and by simple chemical tests for solubility and other properties. Colour comparisons can be conducted using a comparison microscope or by spectrophotometric evaluation. Because they are mass-produced, fibres cannot be individualized.

Drugs and poisons. Toxicological examinations concern the identification of drugs and poisons, either in the form of pills and powders or as materials recovered from body organs. Among drugs or narcotics or both, of interest to crime laboratories are marijuana, morphine, heroin, and other narcotic alkaloids, amphetamines, barbiturates, tranquillizers, and LSD. These substances must be differentiated from nonprescription drugs. In the case of pills, the exact shape, colour, and external marking may serve as aids in identification. Laboratory test methods for specific chemical substances include colour reaction tests, crystal tests, chromatography, and infrared spectrophotometry. Normally, several tests are performed for the sake of confirmation.

Examination of body organs for the presence of poisonous material of any type requires an involved extraction procedure with a series of tests to confirm or eliminate the presence of a number of toxic materials. In addition to the drugs previously mentioned, other possible poisonous substances include gaseous and liquid poisons, metallic and inorganic poisons, organic poisons, vegetable and animal poisons, and bacterial poisons. The extraction procedures serve to separate volatile and nonvolatile substances, metallic and nonmetallic substances, and alkaline and acid-soluble substances.

Voice identification. The use of the sound spectrograph for voice identification is a relatively new development. The sound spectrograph is an instrument that graphically presents the time, frequency, and intensity of speech sound waves. The graphic forms for a sound such as *you*, as spoken by one person, can be compared with those produced by the speech of a second person and thus differentiated. The accuracy of the technique in identifying individuals is still in some doubt among speech scientists, even though voicegraphs, or voiceprints, have been used in courtroom proceedings.

Political Parties

Political parties are groups organized for the purpose of achieving and exercising power within a political system. They originated in their modern form in Europe and the United States in the 19th century, along with the electoral and parliamentary systems whose development is reflected in their own evolution. The term party has since come to be applied to all organized groups seeking political power, whether by democratic elections or by revolution.

In earlier, prerevolutionary, aristocratic and monarchical regimes, the political process unfolded within restricted circles in which cliques and factions, grouped around particular noblemen or influential personalities, were opposed to one another. The establishment of parliamentary regimes and the appearance of parties at first scarcely changed this situation. To cliques formed around princes, dukes, counts, or marquesses there were added cliques formed around bankers, merchants, industrialists, and businessmen. Regimes supported by nobles were succeeded by regimes supported by other elites, whose political power was derived from industrial and mercantile wealth and who organized themselves into so-called cadre or brokerage parties in order to acquire the political power that their newfound wealth put within their reach. These narrowly based parties were later transformed to a greater or lesser extent, for the 19th century saw the emergence in Europe and America of parties depending on mass support.

Ubiquity of parties in the 20th century

The 20th century saw the spread of political parties throughout the entire world. In Africa large parties have sometimes been formed in which a modern organization has a more traditional ethnic or tribal basis; in such cases the party leadership is frequently made up of tribal chiefs. In certain areas of Asia, membership in modern political parties is often determined largely by religious factors or by affiliation with ritual brotherhoods. Many political parties in the developing countries are partly political, partly military; they are equally capable of participating in the electoral process and of inspiring guerrilla or revolutionary action. Certain Socialist and Communist parties in Europe had the same tendencies several decades earlier.

These last-mentioned European parties have demonstrated an equal aptitude for functioning within multiparty democracies and as the sole political party in a dictatorship. Developing originally within the framework of liberal democracy in the 19th century, political parties have been used in the 20th century by dictatorships for entirely undemocratic purposes. The point, then, is that political parties are institutions that can function in widely divergent political situations.

TYPES OF POLITICAL PARTY

A fundamental distinction can be made between cadre parties and mass-based parties. The two forms coexist in

many countries, particularly in western Europe, where Communist and Socialist parties have emerged alongside the older conservative and liberal parties. Many parties do not fall exactly into either category but combine some characteristics of both.

Cadre parties. Cadre parties—*i.e.*, parties dominated by politically elite groups of activists—developed in Europe and America during the 19th century. Except in some of the states of the United States, France from 1848, and the German Empire from 1871, the suffrage was largely restricted to taxpayers and property owners, and, even when the right to vote was given to larger numbers of people, political influence was essentially limited to a very small segment of the population. The mass of people were limited to the role of spectators rather than that of active participants.

The cadre parties of the 19th century reflected a fundamental conflict between two classes: the aristocracy on the one hand and the bourgeoisie on the other. The former, composed of landowners, depended upon rural estates on which a generally unlettered peasantry was held back by a traditionalist clergy. The bourgeoisie, made up of industrialists, merchants, tradesmen, bankers, financiers, and professional people, depended upon the lower classes of clerks and industrial workers in the cities. Both aristocracy and bourgeoisie evolved its own ideology. Bourgeois liberal ideology developed first, originating at the time of the English revolution of the 17th century in the writings of John Locke, an English philosopher. It was then developed by French philosophers of the 18th century. In its clamouring for formal legal equality and acceptance of the inequities of circumstance, liberal ideology reflected the interests of the bourgeoisie, who wished to destroy the privileges of the aristocracy and eliminate the lingering economic restraints of feudalism and mercantilism. But, insofar as it set forth an egalitarian ideal and a demand for liberty, bourgeois classical liberalism expressed aspirations common to all men. Conservative ideology, on the other hand, never succeeded in defining themes that would prove as attractive, for it appeared to be more closely allied to the interests of the aristocracy. For a considerable period, however, conservative sentiment did maintain a considerable impact among the people, since it was presented as the expression of the will of God. In Catholic countries, in which religion was based upon a hierarchically structured and authoritarian clergy, the conservative parties were often the clerical parties, as in France, Italy, and Belgium.

Conservative and liberal cadre parties dominated European politics in the 19th century. Developing during a period of great social and economic upheaval, they exercised power largely through electoral and parliamentary activity. Once in power, their leaders used the power of the army or of the police; the party itself was not generally organized for violent activity. Its local units were charged with assuring moral and financial backing to candidates at election time, as well as with maintaining continual contact between elected officials and the electorate. The national organization endeavoured to unify the party members who had been elected to the assemblies. In general, the local committees maintained a basic autonomy and each legislator a large measure of independence. The party discipline in voting established by the British parties—which were older because of the fact that the British Parliament was long established—was imitated on the Continent hardly at all.

United States parties in the 19th century

The first United States political parties of the 19th century were not particularly different from European cadre parties, except that their confrontations were less violent and based less on ideology. The first United States form of the struggle between the aristocracy and the bourgeoisie, between conservative and liberal, was carried out in the form of the Revolutionary War, in which Great Britain embodied the power of the king and the nobility, and the insurgents that of bourgeoisie and liberalism. Such an interpretation is, of course, simplified. There were some aristocrats in the South and, in particular, an aristocratic spirit based on the institutions of slaveholding and paternalistic ownership of land. In this sense, the Civil War could be considered as a second phase of violent conflict between the conservatives and the liberals. Nevertheless, the United States was from the beginning an essentially bourgeois civilization, based on a deep sense of equality and of individual freedom. Federalists and Anti-Federalists, Republicans and Democrats—all belonged to the liberal family since all shared the same basic ideology and the same system of fundamental values and differed only in the means by which they would realize their beliefs.

In terms of party structure, United States parties in the beginning differed little from their European counterparts. Like them, the United States parties were composed of local notables. The ties of a local committee to a national organization were even weaker than in Europe. At the state level there was some effective coordination of local party organizations, but at the national level such coordination did not exist. A more original structure was developed after the Civil War—in the South to exploit the vote of the blacks and along the East Coast to control the votes of immigrants. The extreme decentralization in the United States enabled a party to establish a local quasi-dictatorship in a city or county by capturing all of the key posts in an election. Not only the position of mayor but also the police, finances, and the courts came under the control of the party machine, and the machine was thus a development of the original cadre parties. The local party committee came typically to be composed of adventurers or gangsters who wanted to control the distribution of wealth and to ensure the continuation of their control. These men were themselves controlled by the power of the boss, the political leader who controlled the machine at the city, county, or state levels. At the direction of the committee, each constituency was carefully divided, and every precinct was watched closely by an agent of the party, the captain, who was responsible for securing votes for the party. Various rewards were offered to voters in return for the promise of their votes. The machine could offer such inducements as union jobs, trader's licences, immunity from the police, and the like. Operating in this manner, a party could frequently guarantee a majority in an election to the candidates of its choosing, and, once it was in control of local government, of the police, the courts, and public finances, etc., the machine and its clients were assured of impunity in illicit activities such as prostitution and gambling rings and of the granting of public contracts to favoured businessmen.

The degeneration of the party mechanism was not without benefits. The European immigrant who arrived in the United States lost and isolated in a huge and different world might find work and lodging in return for his commitment to the party. In a system of almost pure capitalism and at a time when social services were practically nonexistent, machines and bosses took upon themselves responsibilities that were indispensable to community life. But the moral and material cost of such a system was very high, and the machine was often a purely exploitative mechanism, performing no services to the community whatever.

By the end of the 19th century the excesses of the machines and the bosses and the closed character of the parties led to the development of primary elections, in which party nominees for office were selected. The primary movement deprived party leaders of the right to dictate candidates for election. A majority of the states adopted the primary system in one form or another between 1900 and 1920. The aim of the system was to make the parties more democratic by opening them up to the general public in the hope of counterbalancing the influence of the party committees. In practice, the aim was not realized, for the committees retained the upper hand in the selection of candidates for the primaries.

The British Labour Party

In its original form the British Labour Party constituted a new type of cadre party, forming an intermediate link with the mass-based parties. It was formed with the support of trade unions and left-wing intellectuals. At the base, each local organization sent representatives to a district labour committee, which was in turn represented at the national congress.

The early (pre-1918) Labour Party was thus structured of many local and regional organizations. It was not possible to join the party directly; membership came only through an affiliated body, such as a trade union. It thus represented a new type of party, depending not upon highly political individuals brought together as a result of their desire to acquire and wield power but upon the organized representatives of a broader interest—the working class. Certain Christian Democrat parties—the Belgian Social Christian Party between the two world wars and the Austrian Popular Party, for example—had an analogous structure: a federation of unions, agricultural organizations, middle class movements, employers' associations, etc. After 1918, the Labour Party developed a policy of direct membership on the model of the continental Socialist parties, individual members being permitted to join local-constituency branches. The majority of its membership, however, continued to be affiliated rather than direct.

Mass-based parties. Cadre parties normally organize a relatively small number of party adherents. Mass-based parties, on the other hand, unite hundreds of thousands of followers, sometimes millions. But the number of members is not the only criterion of a mass-based party. The essential factor is that such a party attempts to base itself on an appeal to the masses. It attempts to organize not only those who are influential or well known or those who represent special interest groups but rather any citizen who is willing to join the party. If such a party succeeds in gathering only a few adherents, then it is mass based only in potential. It remains, nevertheless, different from the cadre-type parties.

Socialist mass-based parties

At the end of the 19th century the Socialist parties of continental Europe organized themselves on a mass basis in order to educate and to organize the growing population of labourers and wage earners, which industrialization was making increasingly large and which was becoming more important politically because of extensions of the suffrage, and to gather the money necessary for propaganda by mobilizing in a regular fashion the resources of those who, although poor, were numerous. Membership campaigns were conducted, and each member paid party dues. If its members became sufficiently numerous, the party emerged as a powerful organization, managing large funds and diffusing its ideas among an important segment of the population. Such was the case with the German Social Democratic Party, which by 1913 had more than 1,000,000 members.

Such organizations were necessarily rigidly structured. The party required an exact registration of membership, treasurers to collect dues, secretaries to call and lead local meetings, and a hierarchical framework for the coordination of the thousands of local sections. A tradition of collective action and group discipline, more developed among workers as a result of their participation in strikes and other union activity, favoured the development and centralization of party organization.

A complex party organization tends to give a great deal of influence to those who have responsibility at various levels in the hierarchy, resulting in certain oligarchical tendencies. The Socialist parties made an effort to control this tendency by developing democratic procedures in the choice of leaders. At every level those in responsible positions were elected by members of the party. Every local party group would elect delegates to regional and national congresses, at which party candidates and party leaders would be chosen and party policy decided.

The type of mass-based party described above was imitated by many non-Socialist parties. Some cadre-type parties in Europe, both conservative and liberal, attempted to transform themselves along similar lines. The Christian Democrat parties often developed organizations copied even more directly from the mass-based model. But non-Socialist parties were generally less successful in establishing rigid and disciplined organizations.

The first Communist parties were splinter groups of existing Socialist parties and at first adopted the organization of these parties. After 1924, as a result of a decision of the Comintern (the Third International, or federation of working class parties), all Communist parties were transformed along the lines of the Soviet model, becoming mass parties based on the membership of the largest possible number of citizens, although membership was and is limited to those who embraced and espoused the ideology of Marxism–Leninism.

Communist mass-based parties

The Communist parties developed a new structural organization: whereas the local committees of cadre and Socialist parties focussed their organizing efforts and drew their support from a particular geographical area, Communist groups formed their cells in the place of work. The work-place cell was the first original element in Communist party organization. It grouped together all party members who depended upon the same firm, workshop, or store or the same professional institution (school or university, for example). Party members thus tended to be tightly organized, their solidarity, resulting from a common occupation, being stronger than that based upon residence.

The work-place-cell system proved to be effective, and other parties tried to imitate it, generally without success. Such an organization leads each cell to concern itself with problems of a corporate and professional nature rather than with those of a more political nature. These basic groups, however, smaller and, therefore, more numerous than the Socialist sections, tend to go their separate way. It is necessary to have a very strong party structure and for party leaders to have extensive authority if the groups are to resist such centrifugal pressure.

This has resulted in a second distinctive characteristic of the Communist parties: a high degree of centralization. Although all mass-based parties tend to be centralized, Communist parties are more so than others. There is, in principle, free discussion, which is supposedly developed at every level before a decision is made, but afterward all must adhere to the decision that has been made by the central body. The splintering that has from time to time divided or paralyzed the Socialist parties is forbidden in Communist parties, which have generally succeeded in maintaining their unity. A further distinctive characteristic of Communist parties is the importance given to ideology. All parties have a doctrine or at least a platform. The European Socialist parties, which were doctrinaire before 1914 and between the two wars, later became more pragmatic, not to say opportunistic. But, in Communist parties, ideology occupies a much more fundamental place, a primary concern of the party being to indoctrinate its members with Marxism.

The Fascist model

The 1920s and '30s saw the emergence of Fascist parties that attempted, as do the Communist and Socialist parties, to organize the maximum number of members but that did not claim to represent the great masses of people. Their teaching was authoritarian and elitist. They thought that societies should be directed by the most talented and capable people—by an elite. The party leadership, grouped under the absolute authority of a supreme head, constituted such an elite. Party structure had as its goal the assurance of the obedience of the elite.

This structure resembled that of armies, which are also organized in such a way as to ensure, by means of rigorous discipline, the obedience of a large number of men to an elite leadership. The party structure, therefore, made use of a military-type organization, consisting of a pyramid made up of units that at the base were very tiny but that, when joined with other units, formed groups that got larger and larger. Uniforms, ranks, orders, salutes, marches, and unquestioning obedience were all aspects of Fascist parties. This similarity rests upon another factor; namely, that Fascist doctrine taught that power must be seized by organized minorities making use of force. The party thus made use of a militia intended to assure victory in the struggle for control over the unorganized masses.

Large parties built upon the Fascist model developed between the two wars in Italy and Germany, where they actually came into power. Fascist parties appeared also in most other countries of western Europe during this period but were unable to achieve power. The less-developed nations of eastern Europe and Latin America were equally infected by the movement. The victory of the Allies in

1945, as well as the revelation of the horrors of Nazism, stopped the growth of the Fascists and provoked their decline, but Fascist-type party organization and doctrine remains a potent means of exercising power.

PARTIES AND POLITICAL POWER

Whether they are conservative or revolutionary, whether they are a union of notables or an organization of the masses, whether they function in a pluralistic democracy or in a monolithic dictatorship, parties have one function in common: they all participate to some extent in the exercise of political power, whether by forming a government or by exercising the function of opposition, a function that is often of crucial importance in the determination of national policy.

The struggle for power. It is possible in theory to distinguish revolutionary parties, which attempt to gain power by violence (conspiracies, guerrilla warfare, etc.), from those parties working within the legal framework of elections. But the distinction is not always easy to make, because the same parties may sometimes make use of both procedures, either simultaneously or successively, depending upon the circumstances. In the 1920s, for example, Communist parties sought power through elections at the same time that they were developing an underground activity of a revolutionary nature. In the 19th century, liberal parties were in the same situation, sometimes employing the techniques of conspiracy, as in Italy, Austria, Germany, Poland, and Russia, and sometimes confining their struggles to the ballot box, as in Great Britain and France.

Revolutionary methods vary greatly. Clandestine plots by which minority groups seize the centres of power presuppose monarchies or dictatorships in which the masses of people have little say in government. But terrorist and disruptive activity can serve to mobilize citizens and to demonstrate the powerlessness of any government. At the beginning of the 20th century leftist trade unionists extolled the revolutionary general strike, a total stoppage of all economic activity that would paralyze society completely and put the government at the revolutionaries' mercy. Rural guerrilla activity has often been used in countries with a predominantly agrarian society; urban guerrilla warfare was effective in the European revolutions of the 19th century, but the development of techniques of police and military control has made such activity more difficult.

Functions of parties within a democracy

Revolutionary parties are less numerous than parties that work within the law: the contest at election time is the means normally used in the struggle for power. Such activity corresponds, moreover, to the original nature of political parties and involves three factors: the organization of propaganda, the selection of candidates, and the financing of campaigns. The first function is the most visible. The party first of all gives the candidate a label that serves to introduce him to the voters and to identify his position. Because of this party label the voters are better able to distinguish the candidates. The promises and declarations of individuals are seldom taken with too much seriousness, and it means more to indicate that one candidate is a Communist, another a Socialist, a third a Fascist, and a fourth a liberal. Finally, the party also furnishes the candidate with workers to raise funds, put up his posters, distribute his literature, organize his meetings, and canvass from door to door.

The function of selecting candidates is exercised in three ways. In cadre parties, candidates are selected by committees of the party activists who make up the party—the caucus system, as it is known in the United States. In general, local committees play essential roles in this regard. In some countries, however, the selection is centralized by a national caucus, as, for example, by the Conservative Party in Britain and the Union of Democrats in France. In mass-based parties, selection is made by members of the regional and national congresses according to apparently democratic procedures; in actual practice, the governing committees play an essential role, the local constituency members generally ratifying their choice. Thirdly, in the United States the mechanism of primary elections has established a system for selecting candidates by means of the votes of all party members or all voters within a particular electoral district.

The various processes of selecting candidates do not, however, differ significantly in their results, for it is almost always the party leaders who play the essential role. This introduces an oligarchical tendency into party politics, a tendency that has not been overcome by the congresses of the mass-based parties or the United States primaries, which provide only a partial limitation on the power of the governing committees.

An important aspect of the struggle for power between political parties is the financing of campaigns. Cadre parties always have in their committees some key figure having connections with businessmen who is responsible for collecting gifts from them. In mass-based parties, rather than looking for large sums of money from a few people, leaders gather smaller sums from a large number of people who usually give on a monthly or annual basis. This method has been viewed as one of the distinguishing characteristics of mass-based parties. Sometimes the law intervenes in the financing of elections and of parties. Laws often limit campaign expenses and attempt to restrict the resources of the parties, but they are generally inoperative because it is quite easy to circumvent them. In some countries the state contributes public funds to the parties. At first, such financial participation was limited to expenses for campaigns and was based on the uniform treatment of candidates (as in France), but in Sweden and Finland the state contributes to the general finances of parties.

Participation in power. Only the functions of parties in democratic regimes will be considered at this time. The role of the single party in a dictatorship will be analyzed separately.

Once a political party has achieved electoral victory, the question arises of how much influence the party is to have on the government. The influence of the party on members in elective office is frequently quite weak. It defines the general lines of their activity, but these lines can be quite hazy, and few decisions are taken in the periodic meetings between officeholders and their party. Each member of the legislature retains personal freedom of action in his participation in debates, in his participation in government, and, especially, in his voting. The party may, of course, attempt to enforce the party line, but parliamentary or congressional members cannot be compelled to vote the way the party wants them to. Such is the situation in the United States, within most of the liberal and conservative European parties, and within cadre parties in general.

Flexible and rigid parties

The question of how disciplined a party is, of the extent to which it will always present a united front, enables a distinction to be made between what may be termed rigid and flexible parties; that is, between those that attempt always to be united and disciplined, following what is most often an ideologically based party line, and those that, representing a broader range of interests and points of view, form legislatures that are assemblies of individuals rather than of parties.

Whether the parties operating within a particular system will be rigid or flexible depends largely on the constitutional provisions that determine the circumstances in which a government may continue in office. This is clearly illustrated by comparing the situation in the United States with that in Great Britain. In the United States the president and his government continue in office for the constitutionally defined period of four years, regardless of whether a majority in the legislature supports him or not. Since a united party is thus not crucial to the immediate survival of the government, both major parties are able to contain broad coalitions of interests, and votes on issues of major importance frequently split each party. In the United Kingdom the situation is quite different. There, government can continue in office only so long as it commands a majority in the legislature. A single adverse vote can result in the dissolution of Parliament and a general election. Party discipline and unity are thus of crucial importance, and this fact has far-reaching conse-

quences for the composition, organization, and policies of each party. The consequences of party disunity within such a constitutional framework are well illustrated by the weakness and instability of the governments of the Third and Fourth French republics.

The distinction between flexible and rigid parties applies equally to parties in power and to those forming the opposition. Votes of censure or of lack of confidence, votes on proposed legislation or on the budget, questions put to ministers or challenges made to them—in short, all the functions of an opposition party—are worked out differently in flexible and rigid party systems.

In flexible party systems the absence of strong discipline is often of great consequence to the opposition party because only rigid parties can constitute an opposition force sufficiently strong to counterbalance the strength of the party in power. At the same time, party discipline permits the opposition to present the public with an alternative to the majority party; the logical consequence of such a situation is Britain's "shadow cabinet," which accustoms the electorate to the idea that a new group is ready to take over the reins of government.

Parties provide, moreover, a channel of communication between opposition legislators and the public. The governing party performs a similar service for the government, although it is less necessary, since the government has at its disposal numerous means of communicating with the public. Opposition parties thus provide a means of expressing negative reaction to decisions of government and proposing alternatives. This role justifies the official recognition given to opposition parties, as is the case in Great Britain and Scandinavia.

Power and representation. It is difficult to envisage how representative democracy could function in a large industrialized society without political parties. In order for citizens to be able to make an intelligent choice of representative or president, it is necessary for them to know the real political orientation of each candidate. Party membership provides the clearest indication of this.

Individual candidates and the party

The programs and promises of each individual candidate are not too significant or informative, because most candidates, in their attempt to gain the most votes, try to avoid difficult subjects; they all tend to speak the same language; that is, to camouflage their real opinions. The fact that one is a Socialist, another a conservative, a third a liberal, and a fourth a Communist provides a far better clue as to how the candidate will perform when in office. In the legislature the discipline of the party limits the possibility that elected representatives will change their minds and their politics, and thus the party label acts as a sort of guarantee that there will be at least some correspondence between promise and performance. Parties make possible the representation of varying shades of opinion by synthesizing different positions into a stance that each representative adopts to a greater or lesser extent.

But parties, like all organizations, tend to manipulate their members, to bring them under the control of an inner circle of leaders that often perpetuates itself by cooptation. In cadre parties, members are manipulated by powerful committees containing cliques of influential party leaders. In mass-based parties, leaders are chosen by the members, but incumbents are very often re-elected because they control the party apparatus, using it to ensure their continuation in power.

Democratic political systems, while performing the function of representation, thus rest more or less on the competition of rival oligarchies. But these oligarchies consist of political elites that are open to all with political ambition. No modern democracy could function without parties, the oligarchical tendencies of which are best regarded as a necessary evil.

PARTY SYSTEMS

Party systems may be broken down into three broad categories: two-party, multiparty, and single-party. Such a classification is based not merely on the number of parties operating within a particular country but on a variety of distinctive features that the three systems exhibit. Two-party and multiparty systems represent means of organizing political conflict within pluralistic societies and are thus part of the apparatus of democracy. Single parties usually operate in situations in which genuine political conflict is not tolerated. This broad statement is, however, subject to qualification, for, although single parties do not usually permit the expression of points of view that are fundamentally opposed to the party line or ideology, there may well be intense conflict within these limits over policy within the party itself. And even within a two-party or a multiparty system, debate may become so stymied and a particular coalition of interests so entrenched that the democratic process is seriously compromised.

The distinction between two-party and multiparty systems is not as easily made as it might appear. In any two-party system there are invariably some tiny parties in addition to the two major parties, and there is always the possibility that such small parties might prevent one of the two main parties from gaining a majority of seats in the legislature. This is the case with regard to the Liberal Party in Great Britain, for example. Other countries do not fall clearly into either category; thus, Austria and the Federal Republic of Germany only approximate the two-party system. It is not simply a question of the number of parties that determines the nature of the two-party system; many other elements are of importance, the extent of party discipline in particular.

The multiparty system. In Anglo-Saxon countries there is a tendency to consider the two-party system as normal and the multiparty system as the exceptional case. But, in fact, the two-party system that operates in Great Britain, the United States, and New Zealand is much rarer than the multiparty system, which is found in almost all of western Europe.

In western Europe, three major categories of parties have developed since the beginning of the 19th century: conservative, liberal, and Socialist. Each reflects the interests of a particular social class and expounds a particular political ideology. After World War I other categories of parties developed that were partly the result of divisions or transformations of older parties. Communist parties began as splinter groups of Socialist parties, and Christian Democrat parties attempted to weld together moderate Socialists and conservatives and some liberals. Other distinctive types of party emerged in some countries. In Scandinavia, liberal rural parties developed in the 19th century, reflecting a long tradition of separate representation of the rural population. In many countries ethnic minorities formed the basis of nationalist parties, which then either joined existing parties or divided them.

The appearance of Socialism in the 19th century upset the earlier lines of battle between conservatives and liberals and tended to throw the latter two groups into a common defense of capitalism. Logically, this situation should have led to the fusion of conservatives and liberals into one bourgeois party that would have presented a united stand against Socialism. This is, in fact, what happened in Great Britain after World War I.

Influence of the electoral system on the number of parties

One of the most important factors determining the number of parties operating within a particular country is the electoral system (see ELECTORAL PROCESSES). Proportional representation tends to favour the development of multiparty systems because it ensures representation in the legislature for even small parties. The majority, single-ballot system tends to produce a two-party system, because it excludes parties that may gain substantial numbers of votes but not the majority of votes necessary to elect a representative within a constituency. The majority system with a second ballot favours a multiparty system tempered by alliances between parties. Such a system is very rare, found only in the German Empire (1871–1914) and in the French Third (1870–1940) and Fifth (since 1958) republics. Voters choose between the parties that did best in a first ballot. This leaves small parties at a disadvantge but, nevertheless, gives them opportunity to strengthen their role during the second balloting as long as they are willing to enter into alliances with the leading parties.

Another factor producing multiparty systems is the intensity of political conflicts. If, within a given political movement, extremists are numerous, then it is difficult for the moderates in that party to join with them in a united front. Two rival parties are likely to be formed. Thus, the power of the Jacobins among 19th-century French liberals contributed to the inability of the moderates to form one great liberal party, as was successfully achieved in Great Britain. Likewise, the power of the extremists among the conservatives was an obstacle to the development of a strong conservative party.

The distinction between the multiparty system and the two-party system corresponds largely to a distinction between two types of Western political regime. In a two-party situation the administration has, in effect, an assurance of a majority in the legislature, deriving from the predominance of one party; it has, therefore, a guarantee of continuance and effectiveness. Such a system is often referred to as majority parliamentarianism. In a multiparty situation, on the other hand, it is quite rare for one party to have a majority in the legislature; governments must, therefore, be founded on coalitions, which are always more heterogeneous and more fragile than a single party. The result is less stability and less political power. Such systems may be referred to as nonmajority parliamentarianism.

In practice, majority and nonmajority parliamentary systems do not coincide exactly with two-party systems and multiparty systems. For, if each of the two parties is flexible and does not control the voting patterns of its members (as is the case in the United States), the numerical majority of one of the parties matters little. It can happen, moreover, that one party in a multiparty system will hold an absolute majority of seats in the legislature so that no coalition is required. Such a situation is unusual but has occurred in West Germany, Italy, and Belgium at various times since 1945.

Ordinarily, however, a coalition will be the only means of attaining a parliamentary majority within the framework of the multiparty system. Coalitions are by nature more heterogeneous and more unstable than a grouping made up of one party, but their effectiveness varies greatly according to the discipline and organization of the parties involved. In the case of flexible parties that are undisciplined and that allow each legislator to vote on his own, the coalition will be weak and probably short-lived. The instability and weakness of governments is at its maximum in such situations, of which the Third French Republic provides a good example.

If, on the other hand, the parties involved in a coalition are rigid and disciplined, it is possible for a system quite similar to the two-party system to develop. This is often the case when two opposing alliances are formed, one on the left and one on the right, and when both are strong enough to endure through the legislative session. This type of coalition, referred to as bipolarized, introduces elements of the two-party system into a multiparty framework. A situation of this type has developed in Sweden, where conservative, liberal, and agrarian parties have been aligned against the Social Democrat Party, which eventually allied itself with the Communist Party (1970).

The system of bipolar alliances may be contrasted with the system of a centrist alliance. Rather than the parties on the right forming a centre–right coalition to oppose a centre–left coalition, there is the possibility that the centre–left and the centre–right will join forces and reject the extremes at both ends of the political spectrum. Such a situation occurred in Germany during the Weimar Republic, when the government rested on a majority formed of a coalition of Catholic Centrists and Social Democrats, with opposition coming from the Communists and the nationalists on the extreme left and right.

Benefits and disadvantages of coalition politics

Centrist coalitions all tend to give the average citizen a sense of political alienation. In rejecting both extremes, coalitions may well be isolating the radical, unstable elements, but the governing coalition may tend to be unresponsive to new ideas, uninspiringly pragmatic, and too ready to compromise. This situation gives rise to a more or less permanent breach between practical politics and political ideals. An advantage of bipolarization or of the two-party system is that the moderates of both sides must collaborate with those who are more extreme in their views, and the extremists must be willing to work with those who are more moderate; the pressure from the extremists prevents the moderates from getting bogged down, while collaboration with the moderates lends a touch of realism to the policies of the extremists.

The two-party system. A fundamental distinction must be made between the two-party system as it is found in the United States and as it is found in Great Britain. Although two major parties dominate political life in the two countries, the system operates in quite different ways.

The American two-party system. The United States has always had a two-party system, first in the opposition between the Federalists and the Anti-Federalists, then in the competition between the Republicans and the Democrats. There have been frequent third-party movements in the history of the country, but they have always failed. Presidential elections seem to have played an important role in the formation of this type of two-party system. The mechanism of a national election in so large a country has necessitated very large political organizations and, at the same time, relatively simplified choices for the voter.

American parties are different from their counterparts in other Western countries. They are not tied in the same way to the great social and ideological movements that have so influenced the development of political life in Europe during the last two centuries. There have been Socialist parties at various times in the history of the United States, but they have never challenged the dominance of the two major parties. It can be argued that the main reason for the failure of Socialist parties in America has been the high degree of upward mobility permitted by a rich and continually expanding economy. The consequence of this mobility has been that class consciousness has never developed in the United States in a manner that would encourage the formation of large Socialist or Communist parties.

In comparison with European political movements, therefore, American parties have appeared as two varieties of one liberal party, and within each party can be found a wide range of opinion, going from the right to the left.

The American parties have a flexible and decentralized structure, marked by the absence of discipline and rigid hierarchy. This was the structure of most of the cadre-type parties of the 19th century, a structure that most liberal parties have retained. Federalism and a concern for local autonomy accentuate the lack of rigid structure and the weakness of lines of authority in the parties. Organization may be relatively strong and homogeneous at the local level, but such control is much weaker on the state level and practically nonexistent on the national level. There is some truth to the observation that the United States has not two parties but 100—that is, two in each state. But it is also true that each party develops a certain degree of national unity for the presidential election and that the leadership of the president within his party gives the victorious party some cohesion.

Coalition voting patterns in the U.S. Congress

In voting, Republicans and Democrats are usually found on both sides. An alliance between liberal Republicans and Democrats against conservative Republicans and Democrats tends to develop. But neither bloc is stable, and the alignment varies from one vote to another. As a consequence, despite the existence of a two-party system, no stable legislative majority is possible. In order to have his budget adopted and his legislation passed, the president of the United States must patiently try to gather the necessary votes on every question; like Penelope, he has the wearisome task of beginning anew each day. The American two-party system is thus a pseudo-two-party system, because each party provides only a loose framework within which shifting coalitions are formed.

The British two-party system. Another form of the two-party system is operative in Great Britain and in New Zealand. The situation in Australia is affected somewhat by the presence of a third party, the Country Party.

A tight alliance between the Australian Liberal Party and the Country Party introduces, however, a rather rigid bipolarization with the Labour Party. The system thus tends to operate on a two-party basis. Canada also possesses what is essentially a two-party system, Liberals or Conservatives usually being able to form a working majority without the help of the small, regionally based parties.

Great Britain has had two successive two-party alignments: Conservative and Liberal prior to 1914 and Conservative and Labour since 1935. The period from 1920 to 1935 constituted an intermediate phase between the two. Britain's Conservative Party is actually a Conservative–Liberal Party, resulting from a fusion of the essential elements of the two great 19th-century parties. Despite the name Conservative, its ideology corresponds to political and economic liberalism. A similar observation could be made about the other major European conservative parties, such as the German Christian Democratic Party and the Belgian Social Christian Party.

Importance of rigid party lines in the British system

The British two-party system depends on the existence of rigid parties; that is, parties in which there is effective discipline regarding parliamentary voting patterns. In every important vote, all party members are required to vote as a bloc and to follow to the letter the directives that they agreed upon in common or that were decided for them by the party leaders. A relative flexibility may at times be tolerated, but only to the extent that such a policy does not compromise the action of the government. It may be admissible for some party members to abstain from voting if their abstention does not alter the results of the vote. Thus, the leader of the majority party (who is at the same time the prime minister) is sure to remain in power throughout the session of Parliament, and the legislation he proposes will be adopted. There is no longer any real separation of power between the executive and legislative branches, for the government and its parliamentary majority form a homogeneous and solid bloc before which the opposition has no power other than to make its criticisms known. During the four or five years for which a Parliament meets, the majority in power is completely in control, and only internal difficulties within the majority party can limit its power.

Since each party is made up of a disciplined group with a recognized leader who becomes prime minister if his party wins the legislative elections, these elections perform the function of selecting both the legislature and the government. In voting to make one of the party leaders the head of the government, the British assure him of a disciplined parliamentary majority. The net result is a political system that is at once stable, democratic, and strong; Many would argue that it is more stable, more democratic, and stronger than systems anywhere else in the world.

This situation presupposes that both parties are in agreement with regard to the fundamental rules of a democracy. If a Fascist party and a Communist party were opposed to one another in Great Britain, the two-party system would not last very long. The winner would zealously suppress the opponent and rule alone.

The system, of course, does have its weak points, especially insofar as it tends to frustrate the innovative elements within both parties. But it is possible that this situation is preferable to what would happen if the more extreme elements within the parties were permitted to engage in unrealistic policies. The risk of immobility is in fact a problem for any party in a modern industrial society, and not just for those in a two-party situation. The problem is related to the difficulties involved in creating new organizations capable of being taken seriously by an important segment of the population and in revitalizing long-standing organizations encumbered by established practices and entrenched interests.

Single-party systems. There have been three historical forms of the single-party system: Communist, Fascist, and that found in the developing countries.

The Communist model. In Communist countries the party is considered to be the spearhead of the urban working class and of other workers united with it (peasants, intellectuals, etc.). Its role is to aid in the building of a Socialist regime during the transitory phase between capitalism and pure Socialism, called the dictatorship of the proletariat. An understanding of the exact role of the party requires an appreciation of the Marxist conception of the evolution of the state. In countries based on private ownership of the means of production, the power of the state, according to the Marxist point of view, is used to further the interests of the controlling capitalists. In the first stage of revolution the power of the state is broken. Power, however, still has to be wielded to prevent counterrevolution and to facilitate the transition to Communism, at which stage coercion will no longer be necessary. Thus, the party, in effect, assumes the coercive functions of the state during the dictatorship of the proletariat or, to be more accurate, during the dictatorship of the party in the name of the proletariat.

Role of the party in Communist states

It is thus the party hierarchy and not the official state hierarchy that has the real power. The first secretary of the party is the most important figure in the government, and, whether the party leadership is in the hands of one man or several, the party remains the centre of political power.

In China the role of the party has been modified to some extent. The Great Cultural Revolution (1966–69) seems to have been a device used by Mao Tse-tung to reduce the power of the party, over which he was losing control. He sought support instead from the masses of fanatical youth and the army. Since then, the party has been gradually reorganized, but it is no longer as dominant as it was or as is usual within Communist states. The role of the army appears to be preponderant; moreover, it is an army that has been very politicized and that has always maintained close contact with the population.

In all Communist countries, the structure of the party has been determined largely by the need for it to govern firmly while at the same time maintaining its contact with the masses of the people. Party members are a part of the general public, of which they are the most active and most politically conscious members. They remain in contact with the masses by means of a network of party cells that are present everywhere. Party leaders are thus always "listening in on the masses," and the masses are always informed of decisions of party leaders, as long as the communication network is working in both directions.

The party is not only a permanent means of contact between the people and party leaders; it is also a propaganda instrument. Political indoctrination is essential to the survival of Communist parties, and many resources are devoted to it. Indoctrination is accomplished in training schools, by means of "education" campaigns, carefully censored newspapers, periodicals, and books, and the untiring efforts of militants, who play a role similar to that of the clergy in organized religion. The party is thus the guardian of orthodoxy and has the power to condemn and to excommunicate.

The Fascist model. Fascist parties in a single-party state have never played as important a role as Communist parties in an analogous situation. In Italy, the Fascist party was never the single most important element in the regime, and its influence was often secondary. In Spain the Falange never played a crucial role, and in Portugal the National Union was a very weak organization even at the height of dictator António Salazar's strength. Only in Germany did the National Socialist Party have a great influence on the state. But, in the end, Hitler's dictatorship was dependent on his private army, the SS (Schutzstaffel), which formed a separate element within the party and which was closed to outside influences, and on the Gestapo, which was a state organization and not an organization of the party. The Fascist party in the single-party state has a policing or military function rather than an ideological one.

After their rise to power, the Fascist parties in both Germany and Italy gradually ceased to perform the function of maintaining contact between the people and the government, a function that is usually performed by the party in a single-party situation. It was possible to ob-

serve a tendency for the party to close in upon itself while suppressing its deviant members. The renewal of the party was then assured through recruitment from youth organizations, from which the most fanatical elements, the products of a gradual selection process starting at a very early age, entered the party. The party tended, therefore, to constitute a closed order.

The single party in the developing countries. Some of the Communist parties in power in developing countries do not differ significantly from their counterparts in industrialized countries. This is certainly true of the Communist Party of the Democratic Republic of Vietnam and the Communist Party of North Korea. There are, however, countries in Africa, Asia, and Latin America in which the single party in power cannot be characterized in terms of a European counterpart. This observation applies to, for example, the Arab Socialist Union in Egypt, the Neo-Destour Party in Tunisia, and the National Liberation Front in Algeria, as well as many parties in black Africa.

Most of these parties claim to be more or less Socialist or at least progressive, while remaining far removed from Communism and, in some cases, ardent foes of Communism. President Nasser attempted to establish a moderate and nationalistic Socialism in Egypt. In Tunisia the Neo-Destour Party is more republican than Socialist and is inspired more by the example of the reforms in Turkey under Kemal Atatürk than by Nasserism. In black Africa, single parties often claim to be Socialist, but with few exceptions they rarely are in practice. But, while they may not be revolutionary, they are reform oriented.

Single parties in developing countries are rarely as well organized as Communist parties. In Turkey the Peoples' Republican Party was more a cadre party than a mass-based party. In Egypt it has been necessary to organize a core of professional politicians within the framework of a pseudoparty of the masses. In black Africa the parties are most often genuinely mass based, but the membership appears to be motivated primarily by personal attachment to the leader or by tribal loyalties, and organization is not usually very strong. It is this weakness in organization that explains the secondary role played by such parties in government.

Some regimes, however, have endeavoured to develop the role of the party to the fullest extent possible. The politics of Atatürk in Turkey were an interesting case study in this regard. It was also Nasser's goal to increase the influence of the Arab Socialist Union, thereby making it the backbone of the regime. This process is significant in that it represents an attempt to move away from the old-fashioned dictatorship, supported by the army or based on tribal traditions or on charismatic leadership, toward a modern dictatorship, supported by one political party. Single-party systems can institutionalize dictatorships by making them survive the life of one dominant figure.

The necessity of parties in democratic systems

It has often been said in the West that political parties are in a state of decline. Actually, this has been a long-standing opinion in certain conservative circles, arising largely out of a latent hostility to parties, which are viewed as a divisive force among citizens, a threat to national unity, and an enticement to corruption and demagoguery. In certain European countries—France, for example—right-wing political organizations have even refused to call themselves parties, using instead such terms as movement, union, federation, and centre. And it cannot be denied that to some extent the major European and American parties of the 1970s do appear old and rigid in comparison with their condition at the turn of the century or immediately following World War I. Even relatively new parties, such as the Christian Democratic parties of Germany and Italy (founded in 1945), seem somewhat lifeless.

In terms of size and number, however, political parties are not declining but growing. At the turn of the century they were confined mainly to Europe and North America; elsewhere they were quite weak or nonexistent. In the second half of the 20th century, parties are found practically everywhere in the world. And in Europe and North America there are generally far more people holding membership in parties than prior to 1914. Parties of the 1970s are larger, stronger, and better organized than those of the late 19th century. In the industrialized nations, especially in western Europe, parties have become less revolutionary and innovative, and this factor may explain the rigid and worn-out image that they sometimes present. But even this phenomenon is found only in a limited area and may, perhaps, pass.

The growth of parties into very large organizations may be responsible for the feelings of powerlessness on the part of many individuals who are involved in them. This is a problem experienced by people who find themselves part of any large organization, whether it be a political party, business enterprise, corporation, or union. The difficulties involved in reforming or changing political parties that have become large and institutionalized, coupled with the next-to-impossible task of creating new parties likely to reach sufficient strength to be taken seriously by the electorate, have resulted in much frustration and impatience with the party system. But it is difficult to imagine how democracy could function in a large industrialized country without political parties. In the modern world, democracy and political parties are two facets of the same reality, the inside and outside of the same fabric.

BIBLIOGRAPHY. ROBERT MICHELS, *Les Partis politiques: essai sur les tendances oligarchiques des democraties* (1914; Eng. trans., *Political Parties: A Sociological Study of the Oligarchical Tendencies of Modern Democracies,* 1915), provides the first modern theory of political parties, stemming from the doctrines of the "elite," or "ruling class," of Gaetano Mosca. The book is based largely on the example of German social democracy. MAURICE DUVERGER, *Les Partis Politiques* (1951; Eng. trans., *Political Parties: Their Organization and Activity in the Modern State,* 2nd ed., 1964), gives a comparative and systematic study of political parties, emphasizing the experience of the European countries. JOSEPH G. LAPALOMBARA and MYRON WEINER (eds.), *Political Parties and Political Development* (1966), is a collection of contributions by various authors and is the best recent comparative explication of problems concerning political parties. D.W. RAE, *The Political Consequences of Electoral Laws* (1967), provides, on the basis of an examination of the balloting in numerous countries since 1945, an analysis of the relationship between the electoral system and political parties. It is a model of comparative study. Works about American parties are very numerous. Recommended are SAMUEL J. ELDERSVELD, *Political Parties: A Behavioral Analysis* (1964); and WILLIAM N. CHAMBERS and WALTER D. BURNHAM (eds.), *The American Party Systems* (1967). There are very few works that study European political parties comparatively. STANLEY HENIG and JOHN PINDER (eds.), *European Political Parties* (1969), however, provides much factual information in a concise and systematic format. On Great Britain, SAMUEL H. BEER, *Modern British Politics: A Study of Parties and Pressure Groups* (1965); and R.T. MCKENZIE, *British Political Parties: The Distribution of Power Within the Conservative and Labour Parties,* 2nd rev. ed. (1963), are particularly useful. D.E. APTER, *The Politics of Modernization* (1965); THOMAS L. HODGKIN, *African Political Parties* (1961); and A. MAHIOU, *L'Avènement du parti unique en Afrique noire* (1969), provide accounts of the operations of political parties in developing countries.

(M.Du./Ed.)

Political Philosophy

The central problem of political philosophy is how to deploy or limit public power so as to maintain the survival and enhance the quality of human life. Like all aspects of human experience, it is conditioned by environment and by the scope and limitations of mind; and the answers given by successive political philosophers to perennial problems reflect the knowledge and the assumptions of their times. Political philosophy, as distinct from the study of political and administrative organization, is more theoretical and normative than descriptive. It is inevitably related to general philosophy and is itself a subject of social anthropology, sociology, and the sociology of knowledge. As a normative discipline it is thus concerned with what ought, on various assumptions, to be and how this purpose can be promoted, rather than with a description of facts—although any realistic political theory is necessarily related to these facts. The politi-

cal philosopher is thus not concerned so much, for example, with how pressure groups work or how by various systems of voting decisions are arrived at, as with what the aims of the whole political process should be in the light of a particular philosophy of life.

There is thus a distinction between political philosophy, which reflects the world outlook of successive theorists and which demands an appreciation of their historical settings, and modern political science proper, which, insofar as it can be called a science, is empirical and descriptive. Political philosophy, however, is not merely unpractical speculation, though it may give rise to highly impractical myths: it is a vitally important aspect of life, and one that, for good or evil, has had decisive results on political action; for the assumptions on which political life is conducted clearly must influence what actually happens. Political philosophy may thus be viewed as one of the most important intellectual disciplines, for it sets standards of judgment and defines constructive purposes for the use of public power. Such consideration of the purposes for which power should be used are in a very real sense more urgent today than they have been in any earlier historical period, for mankind has at its disposal the power either to create a world civilization in which modern technology can immeasurably benefit the human race, or to destroy itself in pursuit of political myths. In this situation the scope for political philosophy is great, the clarification of its purpose and limitations urgent—an aspect, indeed, of civilization's survival.

Significance of political philosophy

Despite this unique aspect of the contemporary situation and although ancient political philosophies were formulated under very different conditions, their study still illuminates questions vital today. Questions concerning the aims of government, the grounds of political obligation, the rights of individuals against the state, the basis of sovereignty, the relation of executive to legislative power, and the nature of political liberty and social justice have been asked and answered in many ways over the centuries. They are all fundamental to political philosophy and demand answers in terms of modern knowledge and opinion.

The central purpose of this article is to describe how these questions have been asked and answered by representative and influential political philosophers, from Greco-Roman antiquity through the Middle Ages, early modern times, and the 19th and early 20th centuries. During so long a time span the historical context of these formulations has changed profoundly, and an understanding of the political philosophers selected demands some account of their background. Because of limitations of space, only political philosophers of outstanding importance have been at all fully described, although many minor figures also are briefly discussed.

The article is divided into the following sections:

I. The history of political philosophy in the West to the end of the 19th century
- Antiquity
  - Plato
  - Aristotle
  - Cicero and the Stoics
  - St. Augustine
- The Middle Ages
  - John of Salisbury
  - Aquinas
  - Dante
- The 16th to the 18th centuries
  - Machiavelli
  - Hobbes
  - Spinoza
  - Richard Hooker's adapted Thomism
  - Locke
  - Burke
  - Vico
  - Montesquieu
  - Rousseau
- The 19th century
  - Utilitarianism
  - Tocqueville
  - T.H. Green
  - Liberal nationalism
  - American constitutionalism
  - Anarchism and utopianism
  - Saint-Simon and Comte
  - Hegel
  - Marx and Engels

II. Political philosophy in the 20th century
- Political pragmatism
- Religious and Existentialist approaches
- Revolutionary doctrines
  - Lenin
  - Other Marxist approaches

III. Conclusion

I. The history of political philosophy in the West to the end of the 19th century

ANTIQUITY

Although in antiquity great civilizations arose in Egypt and Mesopotamia, in the Indus Valley, and in China, there was little speculation about the problems of political philosophy as formulated in the West and since predominant. The laws of Hammurabi of Babylon (*c.* 1750 BC) are rules propounded by the monarch as a representative of God on Earth and are mainly concerned with order, trade, and irrigation; the *Admonitions* of the Egyptian vizier Ptahhotep (*c.* 2300 BC) are shrewd advice on how to prosper in a bureaucracy; and the *Arthaśāstra* of Kauṭilya, grand vizier to the Indian Candragupta Maurya in the late 4th century BC, are Machiavellian precepts on how to survive under an arbitrary power. To be sure, the Buddhist concept of *dharma* (social custom and duty), which inspired the Indian emperor Aśoka in the 3rd century BC, implies a moralization of public power, and the teachings of Confucius in the 6th century BC are a code of conduct designed to stabilize society; but there is not, outside Europe, much speculation about the basis of political obligation and the purpose of the state, with both of which Western political philosophy is mainly concerned. An authoritarian society is taken for granted, backed by religious sanctions, and a conservative and arbitrary power is generally accepted.

In contrast to this overwhelming conservatism, paralleled by the rule of custom and tribal elders in most primitive societies, the political philosophers of ancient Greece question the basis and purpose of government; and, though they do not separate political speculation from shrewd observations that today would be regarded as empirical political science, they created the vocabulary of Western political thought.

Plato. The first elaborate work of European political philosophy is *The Republic* of Plato (*c.* 378 BC), a masterpiece of insight and feeling, superbly expressed in dialogue form and probably meant for recitation. Further development of Plato's ideas is undertaken in his *Statesman* and *Laws,* the latter prescribing the ruthless methods whereby they might be imposed. Plato grew up during the great war between Athens and Sparta in which Athens suffered defeat and, like many political philosophers, tried to find remedies for prevalent political injustice and decline. Indeed, *The Republic* is the first of the utopias, though not one of the more attractive; and it is the first classic attempt of a European philosopher to moralize political life.

Cast as a lively discussion between Socrates, whose wisdom Plato is recounting, and various leisured Athenians, Books V, VII–VIII, and IX of *The Republic* state the major themes of political philosophy with poetic power. Plato's work has been criticized as static and class bound, reflecting the moral and aesthetic assumptions of an elite in a slave-owning civilization and bound by the narrow limits of the city-state. The work is indeed a classic example of a philosopher's vivisection of society, imposing by relatively humane means the rule of a high-minded minority.

Epistemological assumptions in *The Republic*

The Republic is a criticism of current Hellenic politics —often an indictment. It is based upon a metaphysical act of faith, for Plato believes that a world of permanent Forms exists beyond the limitations of human experience and that morality and the good life, which the state should promote, are reflections of these ideal Forms (see PLATO). The point is best made in the famous simile of the cave, in which men are chained with their faces to the

wall and their backs to the light, so that they see only the shadows of reality. So constrained, they shrink from what is truly "real" and permanent and need to be forced to face it. This Idealistic doctrine, known misleadingly as Realism (in nontechnical language it is hardly realistic), pervades all Plato's philosophy: its opposite doctrine, Nominalism, declares that only particular and observed "named" data are accessible to the mind. On his Realist assumption, Plato, who was perhaps influenced by Indian thought, regards most ordinary life as illusion and the current evils of politics as the result of men pursuing brute instinct. It follows that

> unless philosophers bear kingly rule in cities or those who are now called kings and princes become genuine and adequate philosophers, and political power and philosophy are brought together . . . there will be no respite from evil for cities.

Only philosopher-statesmen can apprehend permanent and transcendant Forms and turn to "face the brightest blaze of being" outside the cave, and only philosophically minded men of action can be the saviours and helpers of the people.

Plato is thus indirectly the pioneer of modern beliefs that only a party organization, inspired by correct and "scientific" doctrines, formulated by the written word and interpreted by authority, can rightly guide the state. His rulers would form an elite, not responsible to the mass of the people. Thus, in spite of his high moral purpose, he has been called an enemy of the open society and the father of totalitarian lies. But he is also an anatomist of the evils of unbridled appetite and political corruption and insists on the need to use public power to moral ends.

Having described his utopia, Plato turns to analyze the existing types of government in human terms with great insight. Kingly government is the best but impracticable; in oligarchies the rule of the few and the pursuit of wealth divide societies—the rich become demoralized and the poor envious, and there is no harmony in the state. In democracy, in which the poor get the upper hand, demagogues distribute "a peculiar kind of equality to equals and unequals impartially," and the old flatter the young, fawning on their juniors to avoid the appearance of being sour or despotic. The leaders plunder the propertied classes and divide the spoils among themselves and the people until confusion and corruption lead to tyranny, a worse form of government. For the tyrant becomes a wolf instead of a man and "lops off" potential rivals and starts wars to distract the people from their discontent. "Then, by Zeus," Plato concludes, "the public learns what a monster they have begotten."

Plato's *Statesman* and *Laws*

In the *Statesman* Plato admits that, although there is a correct science of government, like geometry, it cannot be realized, and he stresses the need for the rule of law, since no man can be trusted with unbridled power. He then examines which of the current forms of government is the least difficult to live with, for the ruler, after all, is an artist who has to work within the limits of his medium. In the *Laws,* purporting to be a discussion of how best to found a polis in Crete, he presents a detailed program in which a state with some 5,000 citizens is ruled by 37 curators of laws and a council of 360. But the keystone of the arch is a sinister and secret Nocturnal Council to be "the sheet anchor of the state," established in its "central fortress as guardian." Poets and musicians will be discouraged and the young subjected to a rigid, austere, and exacting education. The stark consequence of Plato's political philosophy here becomes apparent. He had, nonetheless, stated, in the dawn of European political thought, the normative principle that the state should aim at promoting the good life and social harmony and that the rule of law, in the absence of the rule of philosopher-kings, is essential to this purpose.

Aristotle. Aristotle, who was a pupil in the Academy of Plato, remarks that "all the writings of Plato are original: they show ingenuity, novelty of view and a spirit of enquiry. But perfection in everything is perhaps a difficult thing." Aristotle was a scientist, not a prophet, and his *Politics* (*c.* 335–322 BC), written while he was teaching at the Lyceum at Athens, is only part of an encyclopaedic account of nature and society, in which he analyzes society as if he were a doctor and prescribes remedies for its ills. Political behaviour is here regarded as a branch of biology, as well as of ethics; in contrast to Plato, Aristotle was an empirical political philosopher. He criticizes many of Plato's ideas as impracticable, but, like Plato, he admires balance and moderation and aims at a harmonious city under the rule of law. The book is composed of lecture notes and is arranged in a confusing way—a quarry of arguments and definitions of great value but hard to master. The first book, though probably the last written, is a general introduction; Books II, III, and VII–VIII, probably the earliest, deal with the ideal state; and Books IV–VII analyze actual states and politics. The treatise is thus, in modern terms, a mixture of political philosophy and political science.

Like Plato, Aristotle naturally thinks in terms of the city-state, which he regards as the natural form of civilized life, social and political, and the best medium in which men's capacities can be realized. Hence his famous definition of man as a "political animal," distinguished from the other animals by his gift of speech and power of moral judgment. "Man, when perfected", he writes,

> is the best of animals, but when separated from law and justice he is the worst of all, since armed injustice is the most dangerous, and he is equipped at birth with the arms of intelligence and wit, moral qualities which he may use for the worst ends.

Since all nature is pervaded by purpose and since men "aim at the good," the city-state, which is the highest form of human community, aims at the highest good. Like sailors with their separate functions, who yet have a common object in safety in navigation, citizens, too, have a common aim—in modern terms survival, security, and the enhancement of the quality of life. In the context of the city-state, this high quality of life can be realized only by a minority, and Aristotle, like Plato, excludes those who are not full citizens or who are slaves; indeed, he says that some men are "slaves by nature" and deserve their status. Plato and Aristotle aim at an aristocratic and exacting way of life, reflecting, in more sophisticated forms, the ideas of the warrior aristocracies depicted by Homer.

Aristotle's view of the role of law in the city-state

Having stated that the aim of the city-state is to promote the good life, Aristotle insists that it can be achieved only under the rule of law.

> The rule of law is preferable to that of a single citizen; if it be the better course to have individuals ruling, they should be made law guardians or ministers of the laws.

The rule of law is better than that even of the best men, for "he who bids law rule may be deemed to bid God and reason alone rule, but he who bids men rule adds the element of the beast; for desire is a wild beast, and passion perverts the minds of rulers, even if they are the best of men." This doctrine, which distinguishes between lawful government and tyranny, survived the Middle Ages and, by subjecting the ruler to law, became the theoretical sanction of modern constitutional government.

Aristotle also vindicates the rule of custom and justifies the obligations accepted by members of society: the solitary man, he writes, "is either a beast or a God." This outlook at once reflects the respect for custom and solidarity that have promoted survival, in primitive tribal societies, even at the price of sacrificing individuals, and gives a theoretical justification for the acceptance of political obligation.

Like Plato, Aristotle analyzes the different kinds of city-states. While states are bound, like animals, to be different, he considers a balanced "mixed" constitution the best—it reflects the ideal of justice (*dikē*) and fair dealing, which gives every man his due in a conservative social order in which citizens of the middle condition preponderate. And he attacks oligarchy, democracy, and tyranny. Under democracy, he argues, demagogues attain power by bribing the electorate and waste accumulated wealth. But it is tyranny that Aristotle most detests; the arbitrary power of an individual above the law who is "responsible to no-one and who governs all alike with a view to his own advantage and not of his subjects, and therefore against their will. No free man can endure such a government."

The *Politics* contains not only a firm statement of these principles but also a penetrating analysis of how city-states are governed, as well as of the causes of revolutions, in which "inferiors revolt in order that they may be equal, and equals that they may be superior." The treatise concludes with an elaborate plan for educating the citizens to attain the "mean," the "possible," and the "becoming." The first implies a balanced development of body and mind, ability and imagination; the second, the recognition of the limits of mind and the range of limitations of talent; the third, an outcome of the other two, is the style and self-assurance that come from the resulting self-control and confidence.

While, therefore, Aristotle accepts a conservative and hierarchic social order, he states firmly that public power should aim at promoting the good life and that only through the rule of law and justice can the good life be attained. These principles were novel in the context of his time, when the great extra-European civilizations were ruled, justly or unjustly, by the arbitrary power of semidivine rulers and when other peoples, though respecting tribal custom and the authority of tribal elders, were increasingly organized under war leaders for depredation.

Cicero and the Stoics. Both Plato and Aristotle had thought in terms of the city-state. But Aristotle's pupil Alexander the Great swamped the cities of old Greece and brought them into a vast empire that included Egypt, Iran, and the Levant. Though the civilization of antiquity remained concentrated in city-states, they became part of an imperial power that broke up into kingdoms under Alexander's successors. This imperial power was reasserted on an even greater scale by Rome, whose empire at its greatest extent reached from central Scotland to the Euphrates and from Spain to eastern Anatolia. Civilization itself became identified with empire, and the development of eastern and western Europe was conditioned by it.

Emergence of universal philosophies

Since the city-state was no longer self-sufficient, universal philosophies developed that gave men something to live by in a wider world. Of these philosophies, Stoicism and Epicureanism were the most influential. The former inspired a rather grim self-sufficiency and sense of duty, as exemplified by the writings of the Roman emperor Marcus Aurelius; the latter, a prudent withdrawal from the world of affairs.

The setting for political philosophy thus became much wider, relating individuals to universal empire, thought of, as in China, as coterminous with the civilization itself. Its inspiration remained Hellenic; but derivative Roman philosophers reinterpreted it, and Roman legists enclosed the old concepts of political justice in a carapace of legal definitions, capable of surviving their civilization's decline.

Cicero lived in a time of political confusion during which the old institutions of the republic were breaking down before military dictators. His *De re publica* and *Laws* are both dialogues and reflect the classical sense of purpose: "to make human life better by our thought and effort." Cicero defined the *res publica* (commonwealth) as an association held together by law; he further asserted, as Plato had maintained with his doctrine of Forms manifest in the just city, that government was sanctioned by a universal natural law that reflected the cosmic order. Cicero expresses the pre-Christian Stoic attempt to moralize public power, apparent in the exacting sense of public responsibility shown by Hadrian and Marcus Aurelius in the 2nd century AD.

St. Augustine. With the conversion of the emperor Constantine (AD 312), when Christianity, long influential, became the predominant creed of the empire, and, under Theodosius (379–395), the sole official religion, political philosophy changed profoundly. St. Augustine's *City of God* (413–426), written when the empire was under attack by barbarians within and without, sums up and defines a new division between church and state and a conflict between "matter" and "spirit" resulting from the Fall of man and original sin.

St. Augustine, whose *Confessiones* are a record of a new sort of introspection, combined a classical and Hebraic dualism. From the Stoics and Virgil he inherited an austere sense of duty, from Plato and the Neoplatonists a contempt for the illusions of appetite, and from the Pauline and patristic interpretation of Christianity a sense of the conflict between Light and Darkness that reflects Zoroastrian and Manichaean doctrines emanating from Iran. In this context worldly interests and government itself are dwarfed by the importance of attaining salvation and of escaping from an astrologically determined fate and from the demons who embody the darkness. Life becomes illuminated for the elect minority by the prospect of eternal salvation or, for those without grace, shrivels under the glare of eternal fires.

St. Augustine regarded salvation as predestinate and the cosmic process as designed to "gather" an elect to fill the places of the fallen angels and so "preserve and perhaps augment the number of the heavenly inhabitants." The role of government and indeed of society itself becomes subordinated into a "secular arm," part of an earthly city, as opposed to the "City of God." The function of government is to keep order in a world intrinsically evil.

Augustine's view of the role of government

Since Christianity had long played the main role in defense of the veneer of a precarious urban civilization in antiquity, this claim is not surprising. Constantine came of crude Balkan origins, a soldier putting to rights a breakdown in government that would continue in the West with the abdication of the last Western emperor in 476, though in the East the empire would carry on with great wealth and power, centred in the new capital of Constantinople (Byzantium).

St. Augustine thus no longer assumed, as did Plato and Aristotle, that a harmonious and self-sufficient good life could be achieved within a properly organized city-state; he projected his political philosophy into a cosmic and lurid drama working out to a predestinate end. The normal interests and amenities of life became insignificant or disgusting, and the Christian Church alone exercised a spiritual authority that could sanction government. This outlook, reinforced by other patristic writings, would long dominate medieval thought, for with the decline of civilization in the West the church became more completely the repository of learning and of the remnants of the old civilized life.

THE MIDDLE AGES

The decline of ancient civilization in the West was severe; not, indeed, in technology, for the horse collar, the stirrup, and the heavy plow now came in; but political philosophy, like other intellectual interests, became elementary. In the Byzantine Empire, on the other hand, Justinian's lawyers in 529–533 produced the Codex Justinianus, the Digest, and the *Institutes,* which defined and condensed Roman law. The Byzantine *basileus,* or autocrat, had moral responsibility for guarding and harmonizing an elaborate state, a "colony" of heaven in which reason and not mere will ought to rule. And this autocracy and the orthodox form of Christianity were inherited by the Christianized rulers of the Balkans, of Kievan Russia, and of Muscovy.

In the West, two essential principles of Hellenic and Christian political philosophy were transmitted, if only in elementary definitions, in rudimentary encyclopaedias. Isidore of Seville in his 7th-century *Etymologiae,* for example, asserts that kings rule only on condition of doing right and that the rule reflects a Ciceronic law of nature "common to all people and mankind everywhere by natural instinct." Further, the barbarians respected the civilization they took over and exploited. When converted, they revered the papacy, and in 800 the Frankish Charlemagne even revived the Western Empire as holy and Roman. The idea of Christian empire coterminous with civilization thus survived in Western as well as Eastern Christendom.

John of Salisbury. After Augustine, not until the 12th-century Renaissance did another full-length speculative work of political philosophy appear in the West. The *Policraticus* of John of Salisbury (*c.* 1159) is the work of a man experienced in politics who became bishop of Chartres. Based on wide classical reading, it centres on

the ideal ruler, who represents a "public power." John admired Augustus and the Roman emperor Trajan, and, in a still predominantly feudal world, his book carried on the Roman tradition of centralized authority, though without its Byzantine autocracy. The prince, he insists, is he who rules in accordance with law, while a tyrant is one who oppresses the people by irresponsible power. This distinction, which derives from the Greeks, Cicero, and St. Augustine, is fundamental to Western concepts of liberty and the trusteeship of power.

John did not know Aristotle's *Politics,* but his learning is nevertheless remarkable, even if his political similes are unsophisticated. His favourite metaphor for the body politic is the human body: the place of the head is filled by the prince, who is subject only to God; the place of the heart by the senate; the eyes, ears, and tongue are the judges, provincial governors, and soldiers; and the officials are the hands. The tax gatherers are the intestines and ought not to retain their accumulations too long; and the farmers and peasants are the feet. John also compares a commonwealth to a hive and even to a centipede.

This vision of a centralized government, more appropriate to the memory of the Roman Empire than to a medieval monarchy operating in a still semifeudal world, is a landmark of the 12th-century revival of speculative thought and reflects the better organized monarchy that Henry II was then building up.

Aquinas. It is a far cry from this practical 12th-century treatise by a man of affairs to the elaborate justification of Christian kingship and natural law created by St. Thomas Aquinas in the 13th century, during the climax of medieval Western civilization. His political philosophy is only part of a metaphysical construction of Aristotelean range—for Aristotle had now been assimilated from Arabic sources and given a new Christian content, with the added universality of the Stoic and Augustinian world outlook. Aquinas' *Summa theologiae* purports to answer all the major questions of existence, including those of political philosophy. Like Aristotle, Aquinas thinks in terms of an ethical purpose. Natural law is discussed in the first part of the second book as part of the discussion of original sin and what would now be termed psychology, while war comes under the second part of the second book as an aspect of virtue and vice. Law is defined as "that which is regulation and measure." It is designed to promote the "felicity and beatitude" that are the ends of human life. Aquinas agrees with Aristotle that "the city is the perfection of community" and that the purpose of public power should be to promote the common good. The only legitimate power is from the community, which is the sole medium of man's well being. In his *De regimine* he compares society to a ship in need of a helmsman and repeats Aristotle's definition of man as a social and political animal. Again following Aristotle, he considers oligarchy unjust and democracy evil. Rulers should aim to make the "life of the multitude good in accordance with the purpose of life which is heavenly happiness." They should also create peace, conserve life, and preserve the state—a threefold responsibility. Here is a complete program for a hierarchical society within a cosmic order. It combines the Hellenic sense of purpose with Christian aims and asserts that, under God, power resides in the community, embodied in the ruler but only for so long as he does right. Hence the comment that "St. Thomas Aquinas was the first Whig"—a pioneer of the theory of constitutional government. The society he envisages, however, is medieval, static, hierarchical, conservative, and based on limited agriculture and even more limited technology. Nonetheless, Thomism remains the most complete and lasting political doctrine of the Catholic Church, since modified and adapted but not in principle superseded.

Aquinas' political views in the *Summa theologiae*

Dante. By the early 14th century the great European institutions, empire and papacy, were breaking down through mutual conflict and the emergence of national realms. But this conflict gave rise to the most complete political theory of universal and secular empire formulated in the medieval West. Dante's *De monarchia* (*c.* 1313), still in principle highly relevant, insists that only through universal peace can human faculties come to their full compass. But only "temporal Monarchy" can achieve this: "a unique princedom extending over all persons in time." The aim of civilization is to actualize human potentalities, and to achieve that "fullness of life which comes from the fulfillment of our being."

Monarchy, Dante argues, is necessary as a means to this end. The imperial authority of the Holy Roman emperor, moreover, comes direct from God and not through the pope. The empire is the direct heir of the Roman Empire, a legitimate authority, or Christ would not have chosen to be born under it. In subjecting the world to itself, the Roman Empire had contemplated the public good.

This high-flown argument, part of the political warfare between the partisans of the emperor and pope that was then affecting Italy, drives to essentials: that world peace can be secure only under a world authority. That Dante's argument was impractical did not concern this medieval genius, who was writing more the epitaph than the prospectus of the Holy Roman Empire; he was concerned, like St. Thomas, to create a political philosophy with a clear-cut aim and a universal view.

Out of the grand but impractical visions of the High Middle Ages in the 13th-century climax of Christian civilization there emerged by early modern times the idea of a well-governed realm, its authority derived from the community itself, with a program designed to ensure the solvency and administrative efficiency of a secular state. In spite of the decline of the civilization of antiquity in the West, the Greco-Roman sense of purpose, of the rule of law, and of the responsibility of power survived in Christian form.

THE 16TH TO THE 18TH CENTURIES

Machiavelli. In the thought of the Italian political philosopher Niccolò Machiavelli may be seen a complete secularization of political philosophy. Machiavelli was an experienced diplomat and administrator, and, since he stated flatly how the power struggle was conducted in Renaissance Italy, he won a shocking reputation. He was not, however, without idealism about the old Roman republic, and he admired the independent spirit of the German and Swiss cities. This idealism made him all the more disgusted with Italian politics, of which he makes a disillusioned and objective analysis. Writing in retirement after political disgrace, Machiavelli states firmly that,

Machiavelli's view of human nature

> Since this is to be asserted in general of men, that they are ungrateful, fickle, false, cowards, covetous, and as long as you succeed they are yours entirely: they will offer you their blood, property, life, and children . . . when the need is far distant; but when it approaches they turn against you.

And again,

> since the desires of men are insatiable, nature prompting them to desire all things and fortune permitting them to enjoy but few, there results a constant discontent in their minds, and a loathing of what they possess.

This view of human nature, already expressed by Plato and St. Augustine, is here unredeemed by Plato's doctrine of form and illusion or by St. Augustine's dogma of salvation through grace. Machiavelli accepts the facts and advises the ruler to act accordingly. The prince, he states, must combine the strength of the lion with the cunning of the fox: he must always be vigilant, ruthless, and prompt, striking down or neutralizing his adversaries without warning. And when he does an injury it must be total. For "men ought to be either well treated or crushed, because they can avenge themselves of lighter injuries, of more serious ones they cannot." Moreover, "irresolute princes who follow a neutral path are generally ruined." He advises that it is best to come down at the right moment on the winning side and that conquered cities ought to be either governed directly by the tyrant himself residing there or destroyed. Princes, furthermore, unlike private men, need not keep faith: since politics reflects the law of the jungle, the state is a law unto itself, and normal moral rules do not apply to it.

Machiavelli had stated with unblinking realism how, in fact, tyrants behave; and, far from criticizing their conduct or distinguishing between the just prince who rules

by law and the tyrant whose laws are in his own breast, he considers that the successful ruler has to be beyond morality since the safety of and expansion of the state are the supreme objective. In this myopic view, the cosmic visions of Aquinas and Dante are disregarded, and politics becomes a fight for survival. Within his terms of reference, Machiavelli made a convincing case, although as an experienced diplomat he might have realized that dependability in fact pays and that systematic deceit, treachery, and violence usually bring about their own nemesis.

Hobbes. The 17th-century English political philosopher Thomas Hobbes, who spent his life as a tutor and companion to great noblemen, was a writer of genius with a greater power of phrase than any other English political philosopher. He was not, as he is sometimes misrepresented, a prophet of "bourgeois" individualism, advocating free competition in a capitalistic free market. On the contrary, he was writing in a preindustrial, if increasingly commercial, society and did not much admire wealth as such but rather "honours." He was socially conservative and anxious to give a new philosophical sanction to a hierarchical, if businesslike, commonwealth in which family authority was most important.

Philosophical influences on Hobbes

Philosophically, Hobbes was influenced by nominalist scholastic philosophy, which had discarded Thomist metaphysics and had accepted a strict limitation of mind. He therefore based his conclusions on the rudimentary mathematical physics and psychology of his day and aimed at practical objectives—order and stability. He believed that the fundamental physical law of life was motion and that the predominant human impulses were fear and, among those above the poverty level, pride and vanity. Men, Hobbes argued, are strictly conditioned and limited by these laws, and he tried to create a science of politics that would reflect them. "The skill of making, and maintaining Common-wealths," therefore, "consisteth in certain Rules, as doth Arithmetique and Geometry; not (as Tennis play) on Practise onely: which Rules, neither poor men have the leisure, nor men that have had the leisure, have hitherto had the curiosity, or the method to find out."

Hobbes ignores the classical and Thomist concepts of a transcendent law of nature, itself reflecting divine law, and of a "chain of being" whereby the universe is held harmoniously together and, following Descartes's practical method of investigation, states plainly that power creates law, not law power. For law is only law if it can be enforced, and the price of security is one supreme sovereign public power. For, without it, such is the competitive nature of men, once more than subsistence has been achieved they are actuated by vanity and ambition, and there is a war of all against all. The true law of nature is self-preservation, he argues, which can be achieved only if the citizens make a compact among themselves to transfer their individual power to the "leviathan" (ruler), who alone can preserve them in security. Such a commonwealth has no intrinsic supernatural or moral sanction: it derives its original authority from the people and can command loyalty only so long as it succeeds in keeping the peace. He thus uses both the old concepts of natural law and contract, often invoked to justify resistance to authority, as a sanction for it.

Hobbes, like Machiavelli, starts from an assumption of basic human folly, competitiveness, and depravity, and contradicts Aristotle's assumption that man is by nature a "political animal." On the contrary, he is naturally antisocial; and, even when men meet for business and profit, only "a certain market-fellowship" is engendered. All society is only for gain or glory, and the only true equality among men is their power to kill each other. Hobbes sees and desires no other equality. Indeed, he specifically discouraged "men of low degree from a saucy behaviour towards their betters."

Significance of the *Leviathan*

The *Leviathan* horrified most of his contemporaries; Hobbes was accused of atheism and of "maligning the Human Nature." But, if his remedies were tactically impractical, in political philosophy he had gone very deep by providing the sovereign nation-state with a pragmatic justification and directing it to utilitarian ends.

Spinoza. The 17th-century Dutch philosopher Benedict de Spinoza also tried to make a scientific political theory, but it was more humane and more modern. Hobbes assumes a preindustrial and economically conservative society, but Spinoza, a Portuguese Jew born in Amsterdam, assumes a more urban setting. Like Hobbes, he is Cartesian, aiming at a scientific basis for political philosophy; but, whereas Hobbes was dogmatic and authoritarian, Spinoza desired toleration and intellectual liberty, by which alone human life achieves its highest quality. Spinoza, reacting against the ideological wars of religion and skeptical of both metaphysics and religious dogma, was a scientific humanist who justified political power solely by its usefulness. If state power breaks down and can no longer protect him or if it turns against him, frustrates, or ruins his life, then any man is justified in resisting it, since it no longer fulfills its purpose. It has no intrinsic divine or metaphysical authority.

In *Tractatus Theologico-Politicus* and the *Tractatus Politicus* Spinoza develops this theme. He intends, he writes, "not to laugh at men or weep over them or hate them, but to understand them." In contrast to St. Augustine, he glorifies life and holds that governments should not try to "change men from rational beings into beasts or puppets, but enable them to develop their minds and bodies in security and to employ their reason unshackled." The more life is enjoyed, he declares, the more the individual participates in the divine nature. God is immanent in the entire process of nature, in which all creatures follow the laws of their own being to the limit of their powers. All are bound by their own consciousness, and man creates his own values.

It seems that Spinoza thought good government approximated to that of the free burgesses of Amsterdam, a city in which religious toleration and relative political liberty had been realized. He is thus a pioneer of a scientific humanist view of government and of the neutrality of the state in matters of belief.

Richard Hooker's adapted Thomism. While out of the breakup of the medieval social order there emerged the humanist but sceptical outlook of Machiavelli, then the scientific humanist principles of Descartes, Hobbes, and Spinoza, from which the utilitarian and pragmatic outlook of modern times derives, another influential and politically important strain of political philosophy also emerged. During the Reformation and Counter-Reformation, Protestant and Catholic dogmatists denounced each other and even attacked the authority of princes who, from interest or conviction, supported one side or the other. Political assassination became endemic, for both Protestant and Catholic divines declared that it was legitimate to kill an heretical ruler. Appeal was made to rival religious authority as well as to conscience. Men would resist authority and suffer execution rather than risk damnation, and in the resulting welter Hobbes and Spinoza advocated a sovereign state as the remedy. But other political philosophers salvaged the old Thomist concept of a divine cosmic order and of natural and human laws sanctioning the state. They also put forth the classical and medieval idea of the derivation of public power from the commonwealth as a whole and the responsibility of princes to the law. When Hobbes wrote that might makes right, he outraged such critics, who continued to assert that public power was responsible to God and the laws and that it was right to resist a tyrant who declared that the laws were in his own breast. This political theory was most influentially developed in England, where it inspired the constitutionalism that would also predominate in the United States.

Richard Hooker, an Anglican divine who wrote *The Lawes of Ecclesiasticall Poline* (1593–97), reconciled Thomist doctrines of transcendent and natural law, binding on all men, with the authority of the Elizabethan Anglican Church, which he defended against the Puritan appeal to conscience. Society, he argued, is itself the fulfillment of natural law, of which human and positive law are reflections, adapted to society. And public power is not something personal, for it derives from the community under law. Thus,

> The lawful power of making laws to command whole politic societies of men belongeth so properly unto the same entire societies, that for any prince . . . to exercise the same of himself . . . is no better than mere tyranny.

Such power can derive either directly from God or else from the people. The prince is responsible to God and the community; he is not, like Hobbes's ruler, a law unto himself. Law makes the king, not the king law.

Hooker, indeed, insisted that "the prince has a delegated power, from the Parliament of England, together with the convocation (of clergy) annexed thereto . . . whereupon the very essence of all government doth depend." This is the power of the crown in parliament in a balanced constitution. Hence an idea of harmonious government by consent. The Thomist medieval universal harmony had been adapted to the nation-state.

Locke. It was John Locke, politically the most influential English philosopher, who further developed this doctrine. His *Two Treatises of Government* (1690) were written to justify the Glorious Revolution of 1688–89, and his *Letter Concerning Toleration* (1689) was written with a plain and easy urbanity, in contrast to the baroque eloquence of Hobbes. Locke was a scholar, physician, and man of affairs, well-experienced in politics and business. As a philosopher he accepted strict limitations for mind, and his political philosophy is moderate and sensible, aimed at a balance among executive, judicial, and legislative powers, although with a bias toward the last.

His first *Treatise* was devoted to confuting the Royalist doctrine of patriarchal divine right by descent from Adam, an argument then taken very seriously and reflecting the idea of government as an aspect of a divinely ordained chain of being. If this order were broken, chaos would come about. The argument was part of the contemporary conflict of the ancients and the moderns.

Locke's view of the role and limits of public power

Locke tried to provide an answer by defining a limited purpose for political power, which purpose he considered to be "a right of making laws with penalties of death, and consequently all less penalties, for the regulating and preserving of property, and of employing the force of the community in execution of such laws, and in the defense of the commonwealth from foreign injury, and all this only for the public good." The authority of government derives from a contract between the rulers and the people, and the contract binds both parties. It is thus a limited power, proceeding according to established laws and "directed to no other end but the peace, safety, and public good of the people."

Whatever its form, government, to be legitimate, must govern by "declared and reasoned laws," and, since every man has a "property" in his own person and has "mixed his labour" with what he owns, government has no right to take it from him without his consent. It was the threat of attack on the laws, property, and the Protestant religion that had roused resistance to James II. Locke is expressing the concerns and interests of the landed and moneyed men by whose consent James's successor, William III, came to the throne, and his commonwealth is strictly conservative, limiting the franchise and the preponderant power to the propertied classes. Locke was thus no democrat in the modern sense and was much concerned to make the poor work harder. Like Hooker, he assumes a conservative social hierarchy with a relatively weak executive power and defends the propertied classes both against a ruler by divine right and against radicals. In advocating toleration in religion he was more liberal: freedom of conscience, like property, he argued, is a natural right of all men. Within the possibilities of the time, Locke thus advocated a constitutional mixed government, limited by parliamentary control of the armed forces and of supply. Designed mainly to protect the rights of property, it was deprived of the right of arbitrary taxation or imprisonment without trial and was in theory responsible to all the people through the politically conscious minority who were thought to represent them.

Though he was socially conservative, Locke's writings are very important in the rise of liberal political philosophy. He vindicates the responsibility of government to the governed, the rule of law through impartial judges, and the toleration of religious and speculative opinion. He is an enemy of the totalitarian state, drawing on medieval arguments and deploying them in practical, modern terms.

Burke. The Irishman Edmund Burke, while elaborating Whig constitutional doctrine expressed with such common sense by Locke, wrote with more emotion and took more account of time and tradition. While reiterating that government is responsible to the governed and distinguishing between a political society and a mere mob, he thought that governments were trustees for previous generations and for posterity. He made the predominant political philosophy of the 18th-century establishment appear more attractive and moral, but he wrote no great single work of political philosophy, expressing himself instead in numerous pamphlets and speeches.

In his early *Vindication of Natural Society* Burke is critical of the sufferings imposed by government, but his "Thoughts on the Cause of the Present Discontents" defines and defends the principles of the Whig establishment. He invoked a transcendent morality to sanction a constitutional commonwealth, but he detested abstract political theories in whose name men are likely to vivisect society. He set great store by ordered liberty and denounced the arbitrary power of the Jacobins who had captured the French Revolution. In his *Reflections on the Revolution in France* (1790) and *An Appeal from the New, to the Old Whigs* (1791), he discerned in the doctrine of sovereignty of the people, in whose name the revolutionaries were destroying the old order, another and worse form of arbitrary power. No one generation has the right to destroy the agreed and inherited fabric of society, and "Neither the few nor the many have the right to govern by their will". A country is not a mere physical locality, he argued, but a community in time into which men are born, and only within the existing constitution and by the consent of its representatives can changes legitimately be made. Once the frame of society is smashed and its law violated, the people become a "mere multitude told by the head," at the mercy of any dictator who can seize power. He was realistic in predicting the consequences of violent revolution, which usually ends up in some kind of dictatorship. Burke, in sophisticated accents, spoke for the ancient and worldwide rule of custom and conservatism and supplied a needed romanticism to the calculating good sense of Locke.

Burke's concept of an obligation to posterity

Vico. The political philosophies hitherto surveyed contained little idea of progress. In antiquity the idea of cyclic recurrence predominated, and even 18th-century Christians believed that the world had been created in 4004 BC and would end in the Second Coming of Christ and a judgment. The 14th-century Arab philosopher of history Ibn Khaldūn of Tunis, in the *Muqaddimah* to his *Kitāb al-ʿibar*, had pioneered a vast sociological view of the historical process; but in western Europe it was a neglected Neapolitan philosopher, Giambattista Vico (1668–1744), who first interpreted the past in terms of the changing consciousness of mankind. His *Scienza nuova* (1725; revised edition 1744) interpreted history as an organic process involving language, literature, and religion and attempted to reveal the mentality or ethos of earlier ages: the age of the gods, the heroic age, and the human age, its climax and decadence. These ages recur, and each is distinguished by mythology, heroic poetry, and rational speculation respectively. In contrast to the legalistic, contractual, and static political philosophies then prevalent, Vico had discerned new horizons.

Montesquieu. This sort of vision was developed and elegantly popularized by the cosmopolitan French savant Charles-Louis de Secondat, Baron de Montesquieu, whose work *The Spirit of the Laws* (Eng. trans., 1750) won immense influence. It was an ambitious treatise on human institutions and a pioneer work of anthropology and sociology. Believing in an ordered universe—for "how could blind fate have produced intelligent beings?" —Montesquieu examined the varieties of natural law, varying customs, laws, and civilizations in different

environments. He made the pedestrian good sense of Locke seem provincial, although he admired him and the British constitution. Unfortunately, he overemphasized the separation of executive, judicial, and legislative powers, considerable in Locke's day but by his own time tending to be concentrated in the sovereignty of Parliament. This doctrine much influenced the founders of the United States and the early French Revolutionaries.

Rousseau. The revolutionary romanticism of the Swiss-French philosopher Jean-Jacques Rousseau may be interpreted in part as a reaction to the analytic rationalism of the Enlightenment. He was trying to escape the aridity of a purely empirical and utilitarian outlook and attempting to create a substitute for revealed religion. Rousseau's *Émile* (1762) and *Du contrat social* (1763) proved revolutionary documents, and his posthumous *Considérations sur le gouvernement de Pologne* ("Considerations on the Government of Poland") contains desultory but often valuable reflections on specific problems.

There had been radical political slogans coined in medieval peasant revolts and in the 17th century, as in the Putney debates (1647) in the Cromwellian army, when a Puritan officer declared that "the poorest hee that is in England hath a life to live as the greatest hee," but the inspiration of these movements had been religion. Now Rousseau proclaimed a secular egalitarianism and a romantic cult of the common man. His famous sentence, "man is born free, but he is everywhere in chains," called into question the traditional social hierarchy: hitherto, political philosophers had thought in terms of elites, but now the mass of the people had found a champion and were becoming politically conscious.

Rousseau's idea of the general will

Rousseau was a romantic, given to weeping under the willows on Lake Geneva, and the *Social Contract and Discourses* is hypnotically readable, a flaming protest by one who found the hard rationality of the 18th century too exacting. But man is not, as Rousseau claims, born free. Man is born into society, which imposes restraints on him. Casting about to reconcile his artificial antithesis between man's purported natural state of freedom and his condition in society, Rousseau utilizes the old theories of contract and transforms them into the concept of the "general will." This general will, a moral will that aims at the common good and in which all participate directly, reconciles the individual and the community by representing the will of the community as deriving from the will of moral individuals, so that to obey the laws of such a community is in a sense to follow one's own will, assuming that one is a moral individual.

Similar ideas to that of the general will became accepted as a basis for both the social-democratic welfare state and for totalitarian dictatorships. And, since the idea was misapplied from small village or civic communities to great sovereign nation-states, Rousseau was also a prophet of a nationalism that he never advocated. Rousseau himself wanted a federal Europe. He never wrote the proposed sequel to the *Du contrat social* in which he meant to deal with international politics, but he declared that existing governments lived in a state of nature, that their obsession with conquest was imbecilic, and that "if we could realize a European republic for one day, it would be enough to make it last for ever" (*Political Writings* I, pp. 365–388). But, with a flash of realism, he thinks the project impracticable, owing to the folly of men.

The incursion of this revolutionary romantic into political philosophy changed the climate of political opinion, for it coincided with the breakdown of the old dynastic order and the emergence first of the middle classes and then of the masses to political consciousness and power.

That the concept of general will was vague only increased its adaptability and prestige: it would both make constitutionalism more liberal and dynamic and give demagogues and dictators the excuse for "forcing people to be free" (that is, forcing people to follow the general will, as interpreted by the ruling forces). Rousseau could inspire liberals, such as the 19th-century English philosopher T.H. Green, to a creative view of a state helping people to make the best of their potential through a variety of free institutions. It could also play into the hands of demagogues claiming to represent the general will and bent on molding society according to their own abstractions.

THE 19TH CENTURY

Utilitarianism. A major force in the political and social thought of the 19th century was Utilitarianism, the doctrine that the actions of governments should be judged simply by the extent to which they promoted the "greatest happiness of the greatest number." The founder of the Utilitarian school was Jeremy Bentham, an eccentric Englishman trained in the law.

Bentham judged all laws and institutions by their utility thus defined. "The Fabric of Felicity," he wrote, "must be reared by the hands of reason and Law."

Bentham's *Fragment, on government* (1776) and *Introduction to the Principles of Morals and Legislation* (1789) elaborated a Utilitarian political philosophy. Bentham was an atheist and an exponent of the new laissez-faire economics of Adam Smith and David Ricardo, but he inspired the spate of legislation that, after the Reform Bill of 1832, had tackled the worst consequences of 18th-century inefficiency and of the Industrial Revolution. His influence, moreover, spread widely abroad. At first a simple reformer of law, Bentham attacked notions of contract and natural law as superfluous, "The indestructible prerogatives of mankind," he wrote, "have no need to be supported upon the sandy foundation of a fiction." The justification of government is pragmatic, its aim improvement and to release the free choice of individuals and the play of market forces that will create prosperity. Bentham thought men far more reasonable and calculating than they are and brushed aside all the Christian and humanist ideas rationalizing instinctive loyalty and awe. He thought society could advance by calculation of pleasure and pain, and his *Introduction* even tries to work out "the value of a lot of pleasure and pain, how now to be measured." He compared the relative gratifications of health, wealth, power, friendship, and benevolence, as well as those of "irascible appetite" and "antipathy." He also thought of punishment purely as a deterrent, not as retribution, and graded offenses on the harm they did to happiness, not on how much they offended God or tradition.

Bentham's calculation of pain and pleasure

If Bentham's psychology was naïve, that of his disciple James Mill was philistine. Mill postulated an economic man whose decisions, if freely taken, would always be in his own interest, and he believed that universal suffrage, along with Utilitarian legislation by a sovereign parliament, would produce the kind of happiness and well-being that Bentham desired. In his *Essay on Government* (1828) Mill thus shows a doctrinaire faith in a literate electorate as the means to good government and in laissez-faire economics as a means to social harmony.

This Utilitarian tradition was humanized by James Mill's son, John Stuart Mill, the most influential of mid-Victorian liberals.

Whereas James Mill had been entirely pragmatic, his son tried to enhance more sophisticated values. He thought that civilization depended on a tiny minority of creative minds and on the free play of speculative intelligence. He detested conventional public opinion and feared that complete democracy, far from emancipating opinion, would make it more restrictive. Amid the dogmatic and strident voices of mid-19th-century nationalists, utopians, and revolutionaries, the quiet, if sometimes priggish, voice of mid-Victorian liberalism proved extremely influential in the ruling circles of Victorian England.

Accepting democracy as inevitable, J.S. Mill expressed the still optimistic and progressive views of an intellectual elite. Without complete liberty of opinion, he insisted, civilizations ossify. The quality of progress results not merely from the blind forces of economic competition but from the free play of mind. The worth of the state in the long run is only the worth of the individual's composing it, and without men of genius society would become a "stagnant pool." This militant humanist, unlike his father,

was aware of the dangers of even benevolent bureaucratic power and declared that a state that "dwarfs its men" is culturally insignificant.

Mill also advocated the legal and social emancipation of women, holding that ability was wasted by mid-Victorian conventions. He believed that the masses could be educated into accepting the values of liberal civilization, but he defended private property and was as wary of rapid extensions of the franchise as of bureaucratic power.

Tocqueville. Mill's friend Alexis de Tocqueville, whose *De la démocratie en Amérique* (*Democracy in America*) appeared in 1835–40, was a French civil servant also concerned with maintaining the standards and creativeness of civilization in face of the rising tide of mass democracy. Since the United States was then the only large-scale democracy extant, Tocqueville decided to go there, and as a result of his visit wrote a classic account of early 19th-century American civilization. "We cannot," he wrote, "prevent the conditions of men from becoming equal, but it depends upon ourselves whether the principle of equality will lead them to servitude or freedom, to knowledge or barbarism, to prosperity or wretchedness." He feared the possible abuse of power by centralized government, unrestrained by the power of the old privileged classes, and thought it essential to "educate democracy" so that, although it would never have the "wild virtues" of the old regimes, it would have its own dignity, good sense, and even benevolence. Tocqueville greatly admired American representative institutions and made a penetrating analysis of the new power of the press. He realized, as few people then did, that the United States and Russia would become world powers, and he contrasted the freedom of the one and the despotism of the other. He also foresaw that under democracy education would be respected more as a ladder to success than for its intrinsic content and might thus become mediocre. He was alive to the dangers of uniform mediocrity but believed, like Mill, that democracy could be permeated by creative ideas.

T.H. Green. This kind of humanism was given a more elaborate philosophical content by the English philosopher T.H. Green, whose *Lectures on the Principles of Political Obligation* (1895; reprinted from *Philosophical Works*, vol. 2, 1885) greatly influenced the Liberals in the British governments of the period 1905–15. Green, like J.S. Mill and Tocqueville, wished to extend the minority culture to the people and even to use state power to "hinder hindrances to the good life." He had absorbed from Aristotle, Spinoza, Rousseau, and Hegel an organic theory of the state. The latter, by promoting the free play of spontaneous institutions, ought to help individuals both to "secure the common good of society [and] enable them to make the best of themselves."

While hostile to the abuse of landed property, Green was not a Socialist. He accepted the idea that property should be private and unequally distributed and thought the operation of the free market the best way to benefit the whole society; for free trade would, he thought, diminish the inequalities of wealth in a common prosperity. But Green would have extended the power of the state over education, health, housing and town planning, and the relief of unemployment—a new departure in Liberal thought. These recommendations are embedded in the most elaborate and close-knit intellectual construction made by any modern British political philosopher, and they laid the foundation of the British welfare state.

Green's writing on social reform

Liberal nationalism. Whereas Green shirked the extension of liberal and constitutional principles into international affairs, the Italian patriot and revolutionary prophet Giuseppe Mazzini made it his vision and became the most influential prophet of liberal nationalism. In his *The Duties of Man* and *Essays* he envisaged a harmony of free peoples—a "sisterhood of nations," in which the rule of military empires would be thrown off, the destruction of clerical and feudal privileges accomplished, and in which the emancipated peoples would be regenerated by means of education and universal suffrage. This vision inspired the more idealistic aspects of the Italian Risorgimento (national revival or resurrection) and of nationalistic revolts in Europe and beyond. Though, in fact, fervid nationalism proved destructive, Mazzini advocated a united Europe of free peoples, in which national singularities would be transcended in a pan-European harmony. This sort of liberal democratic idealism was catching, and even if it frequently inspired Machiavellian policies, it also inspired President Woodrow Wilson of the United States, who had he not been thwarted by domestic opposition, might well have made a Mazzinian type League of Nations a success. Moreover, the Europe of the Common Market owes much to the apparently impractical liberal idealism of Mazzini (see NATIONALISM).

American constitutionalism. The United States was founded by men deeply influenced by republicanism, by Locke, and by the optimism of the French Enlightenment. George Washington, John Adams, and Thomas Jefferson all concurred that laws, rather than men, should be the final sanction and that government should be responsible to the governed. But the influence of Locke and the Enlightenment was not entirely happy. John Adams, who followed Washington as president, prescribed a constitution with a balance of executive and legislative power checked by an independent judiciary. The federal constitution, moreover, could be amended only by a unanimous vote of the states. Anxious to safeguard state liberties and the rights of property, the founding fathers gave the federal government insufficient revenues and coercive powers, as a result of which the constitution was stigmatized as being "no more than a Treaty of Alliance." Yet the federal union was preserved. The civil power controlled the military, and there was religious toleration and freedom of the press and of economic enterprise. Most significantly, the concept of natural rights had found expression in the Declaration of Independence and was to influence markedly political and legal developments in the ensuing decades, as well as inspire the French Declaration of the Rights of Man.

Natural rights in American constitutional thought

Anarchism and utopianism. While a liberal political philosophy within a framework of capitalistic free trade and constitutional self-government dominated the greatest Western powers, mounting criticism developed against centralized government itself. Radical utopian and anarchist views, previously expounded mainly by religious sects, became secularized in such works as William Godwin's *Political Justice* (1793), Robert Owen's *New View of Society* (1813), and Pierre-Joseph Proudhon's voluminous and anticlerical writings (see ANARCHISM).

The English philosopher William Godwin, an extreme individualist, shared Bentham's confidence in the reasonableness of mankind. He denounced the wars accepted by most political philosophers and all centralized coercive states. The tyranny of demagogues and of "multitudes drunk with power" he regarded as being as bad as that of kings and oligarchs. The remedy, he thought, was not violent revolution, which produces tyranny, but education and freedom, including sexual freedom. His was a program of high-minded, atheistic anarchy.

The English Socialist Robert Owen, a cotton spinner who had made a fortune, also insisted that bad institutions, not original sin or intrinsic folly, caused the evils of society, and he sought to remedy them by changing the economic and educational system. He thus devised a scheme of model cooperative communities that would increase production, permit humane education, and release the naturally benevolent qualities of mankind.

The French moralist and advocate of social reform Pierre-Joseph Proudhon attacked the "tentacular" nation-state and aimed at a classless society in which major capitalism would be abolished. Self-governing producers, no longer slaves of bureaucrats and capitalists, would permit the realization of an intrinsic human dignity, and federation would replace the accepted condition of war between sovereign states. Proudhon tried to transform society by rousing the mass of the people to cooperative humanitarian consciousness.

Saint-Simon and Comte. Another revolt against the prevalent establishment, national and international, was made by the French social philosopher Henri de Saint-Simon. Saint-Simon wanted to develop the Industrial

Revolution so as to ameliorate the condition of the poorest class. This would be achieved not through political revolution, but through a government of bankers and administrators who would supersede kings, aristocrats, and politicians. If France were suddenly deprived of three thousand leading scientists, engineers, bankers, painters, poets, and writers, he argued, the result would be catastrophic; but if all the courtiers and bishops and 10,000 landowners vanished, the loss, though deplorable, would be much less severe. Saint-Simon also demanded a united Europe, superseding the warring nation-states, with a European parliament and a joint development of industry and communication. He also invented a synthetic religion appropriate to a scientific phase of history, with a cult of Newton and the great men of science.

Comte's "religion of humanity"

Saint-Simon's disciple Auguste Comte went further. His *Course of Positive Philosophy* (1830–42) and *System of Positive Polity* (1851–54) elaborated a "religion of humanity," with ritual, calendar, and a priesthood of scientists, and secular saints, including Julius Caesar, Dante, and Joan of Arc. Society would be ruled by bankers and technocrats and Europe united into a Western republic. This doctrine, backed by pioneering sociology, won much influence among intellectuals. Yet Comte, like Saint-Simon, tackled the essential questions: how to deploy the power of modern technology for the benefit of all mankind; how to avoid wars between sovereign states; and how to fill the void left by the waning of Christian beliefs.

Hegel. Whereas the utopian reformers had discarded metaphysical arguments, the German philosopher G.W.F. Hegel claimed to apprehend the totality of the cosmos by speculative cognition. Like Vico, he saw the past in terms of changing consciousness, but he viewed the historical process as one of "becoming" rather than as one of eternal recurrence. Hegel had no adequate historical data for his intuitions, since the whole of world history was even less known then than it is today, but his novel sweep and range of theory proved an intoxicating substitute for religion. He divided world history into four epochs: the patriarchal Eastern empire, the brilliant Greek boyhood, the severe manhood of Rome, and the Germanic phase after the Reformation. The "Absolute," like a conductor, summons each people to their finest hour, and neither individuals nor states have any rights against them during their historically determined period of supremacy. Many felt some sense of anticlimax, however, when he claimed that the Prussian state embodied the hitherto highest self-realization of the "Absolute" (see HEGELIANISM). Not since St. Augustine had so compelling a drama been adumbrated. Hegel's drama, moreover, culminates in this world, for "the state is the divine idea as it exists on earth."

Marx and Engels. Hegel was a conservative, but his influence on the revolutionaries Karl Marx and his collaborator Friedrich Engels was profound. They inherited the Hegelian claim to understand the "totality" of history and life as it progressed through a dialectic of thesis, antithesis, and synthesis. But, whereas Hegel envisaged a conflict of nation-states, Marx and Engels thought that the dynamism of history was generated by inevitable class conflict economically determined. This was an idea even more dynamic than Hegel's and more relevant to the social upheavals that were a consequence of the Industrial Revolution. Marx was a formidable prophet whose writings lead up to an apocalypse and redemption. A deeply learned humanist, his ideal was the fullest development of the human personality. But, whereas Plato was concerned with an elite, Marx cared passionately for the elevation of whole peoples.

The Marxist credo was all the more effective as it expressed with eloquent ferocity the grievances of the poor, while prophesying retribution and a happy ending. For the state, once captured by the class-conscious vanguard of the proletariat, would take over the means of production from the capitalists, and a brief "dictatorship of the proletariat" would establish a truly communist society. The state would then wither away and man at last become "fully human" in a classless society.

The powerful slogans of Marx and Engels were a natural result of the unbridled capitalism of laissez faire, but politically they were naïve. In classical, medieval, and humanistic political philosophy the essential problem is the control of power, and to imagine that a dictatorship, once established, will wither away is utopian. As even Marx's fellow revolutionary the Russian anarchist M.A. Bakunin observed,

Marx's naïveté regarding the dictatorship of the proletariat

> The revolutionary dictatorship of the doctrinaires who put science before life would differ from the established state only in external trappings. The substance of both are a tyranny of the minority over the majority—in the name of the many and the supreme wisdom of the few.

The revolutionaries would vivisect society in the name of dogmas and "destroy the present order, only to erect their own rigid dictatorship among its ruins." For a full account of Marxist philosophy, see MARXISM.

II. Political philosophy in the 20th century

Nineteenth-century European civilization had been the first to dominate and pervade the whole world and to create a new self-sustaining productivity in which all eventually might share. But, as Saint-Simon had pointed out, this civilization had a fatal flaw. The rule of law, accepted within the politically advanced states, had never been achieved among them. Heavily armed nations and empires remained in a Hobbesian "posture of war," and classical and medieval ideals of world order had long been discarded. Within states, also, laissez-faire capitalism had exacerbated class conflicts, while the decline of religious belief had undermined traditional solidarity. And in 1914, when a general European war broke out, the peoples, contrary to the hopes of cosmopolitan revolutionaries, rallied behind their national governments. When the victorious powers failed to promote world order through the League of Nations, a second global conflict followed, during which were developed weapons so destructive as to threaten life everywhere.

In the aftermath of these catastrophes and the worldwide revulsion they occasioned, not least against the European colonial powers, three mainstreams of mid-20th-century political philosophy may be discerned.

In liberal-constitutional states, with modified, managerial capitalism and various degrees of public welfare, a political pragmatism has emerged, still maintaining the Aristotelian distinction between the rule of law and government by consent, on the one hand, and tyranny on the other. Second, there has been a reaffirmation of religious or quasi-religious values appealing to conscience and the inner man, expressed most persuasively in Existentialist writings. Third, revolutionary ideas have also developed, most of them along Marxist lines. Other revolutionary doctrines appeal to anarchist traditions and are elaborated with neo-Marxist and neo-Freudian insights. Within these categories many shades of opinion are expressed, and only a sampling of representative views is presented here.

POLITICAL PRAGMATISM

The first, pragmatist approach has been most powerfully asserted in the United States and Great Britain. The American writer Lewis Mumford, for example, has advocated a militant humanism, defending people against the alienations of megalapolitan life and attacking mechanization and materialism. Like the Greek philosophers and like Tocqueville, whom he admires, Mumford declares, "In the end, all our contrivances have but one object; the continued growth of human personalities and the cultivation of the best life possible." The American philosopher and educationist John Dewey, on the other hand, sought to counteract the dehumanization of industrial mass society by a freer form of education, liberating the personality.

Both these writers criticize the existing structure of society and its modified capitalism, but try to work within it. Another humanist, the English philosopher Bertrand Russell, was more radical. Russell carried into political philosophy an artistocratic individualism, campaigning for toleration, sexual freedom, compassion, and common sense. He broadcast elite values to a mass society and

attacked materialism, crass bureaucracy, and war. He twice went to prison in pacifist protest and was obsessed with the universal menace of nuclear weapons. He denounced warlike political theories: "Remember your humanity," he said, "and forget the rest." On political tactics often inept, Russell won wide influence as a man of principle, concerned to adapt archaic institutions to the changed environment of mankind.

The Austrian-born British philosopher Karl Popper has demonstrated the pretensions of the 19th-century determinist philosophies such as those of Hegel and Marx, while an English historian and philosopher, Sir Isaiah Berlin, has ridiculed the idea of a supposedly objective march of history. Berlin also rejects the Marxist belief that all values are conditioned by the place men occupy on the "moving stair of time." Marx, he points out, was as romantic as Hegel in envisaging a "world which moves from explosion to explosion in order to fulfil the great cosmic design." Moral values, he insists, are not just a "subjective gloss unworthy of consideration on the great hard edifice of historical construction." No single formula can be found, Berlin argues, whereby the various objectives of men can be harmoniously realized. There are many human goals, which may well be in conflict with one another.

This empirical, pluralist, and liberal political philosophy has much in common with the approach of the Frenchman Émile Durkheim and the Englishman Graham Wallas, both founding fathers of modern sociology. Statesmen and political philosophers, they contend, should not play the part of prophets but rather confine themselves to investigating social patterns and the ideas that are part of them. Ways might thus be found of promoting the survival and vitality of a given society in its particular setting.

Scientific humanism of Graham Wallas

Graham Wallas was concerned to adapt constitutional societies by consent. He wanted to nationalize many essential means of production, including transport and communications, and through increased taxation strengthen social democracy by greater economic and social equality. He was not a revolutionary but a reformer, who understood the precariousness of civilization and the dangers of nationalism, which could only bring, he prophesied, centuries of warfare and regression. He advocated a worldwide and constitutionalist scientific humanism, inspired by the idea of the solidarity of the whole species, for "the master task of civilized mankind is to promote the conditions leading to the good life."

Other political sociologists who accepted the established order did not expect to improve it. The Italian Vilfredo Pareto, and Gaetano Mosca, a Sicilian-born lawyer, set themselves not to state what they wanted but to record what occurs in society. Pareto's *Mind and Society* (1916) is an elaborate, quasi-mathematical classification of nonlogical political myths. Its form is daunting, but its insights are penetrating, especially a hilarious dissection of Rousseau's *General Will,* of which, Pareto concludes, "the intrinsic logico-experimental value . . . is zero." Ranging sardonically over history, Pareto insists that elites will always manipulate society, power merely shifting from one set of rulers to another.

Mosca, in *The Ruling Class* (1939), analyzed how political myths are exploited. He also concluded that elites everywhere are bound to rule and that the least bad government occurs when abuse of power is checked by legal means; that is, by the rule of law. Mosca admired the liberal constitutionalism of the 19th century, although he was aware of its precariousness and limitations. He argued that there is no total explanation of history, which has always been the unpredictable outcome of competing and interacting interests. One thing is certain, nevertheless: in various forms there will always be a struggle for predominance. Mosca's views, more clearly set out than Pareto's, have a salutary realism.

The American philosopher and critic James Burnham also analyzed shifts of power. In *The Managerial Revolution* (1941) he propounded a theory of bureaucratic revolution: the rulers of the new society, the class with power and privilege, will be the bureaucratic managers of "super states." In *The Machiavellians, Defenders of Freedom* (1943), he reinterprets Machiavelli and cites Mosca as a modern Machiavellian. Following Pareto's idea of the "circulation of elites," he asserts that, when a ruling class becomes inadequate, frivolous, or bored, loses confidence in itself and its myths, and becomes irresolute in deploying necessary force, new elites are bound to take over—as in the managerial revolution of the 20th century.

RELIGIOUS AND EXISTENTIALIST APPROACHES

In the second, religious and quasi-religious group of political philosophies, the Catholic hierarchy has reiterated its ancient neo-Thomist doctrine of original sin and redemption. Pope Leo XIII, in the encyclicals *Inscrutabili Dei Consilio* (1878), *Immortale Dei* (1885), and *Rerum Novarum* (1891), dismissed all anthropocentric political philosophies as new versions of old heresies. The world, "through an insatiable craving for things perishable," was "rushing wildly upon the straight road to destruction." Society is intelligible only in the light of the Christian revelation and a future life:

> exclude the idea of futurity and forthwith the very notion of what is good and right would perish, nay, the whole scheme of the universe would become a dark and unfathomable mystery.

Such is the human condition that visionary innovations are fruitless, and "venomous" teachings can only bring "death-bearing fruit." Society, as St. Augustine had declared, if organized without God, can only be a present hell. Hierarchy, authority, and censorship can alone "control the excesses of the unbridled intellect, which unfailingly end in the oppression of the untutored multitude." Property is essential to the family, on which the social order depends, and inequality is inherent in all human societies. Only a harmonious Christian commonwealth can assuage the consequences of sin, and within that social order the state should therefore encourage Christian trade unions and promote the welfare of the poor. Thus, the papacy, maintaining its monopoly of revelation, tried to come to terms with the demands of industrial civilization.

During the rise of 19th-century nationalism and of Communist, Fascist, and Nazi dictatorships, and in face of the increasing dominance of governments and large-scale industry in all mass societies, the importance of individual responsibility with regard to moral issues was emphasized by a divergent group of thinkers who have come to be described as Existentialists. Søren Kierkegaard (died 1855), a Danish Neo-Kantian, declared that "truth is subjectivity" and that only by means of inward revelation can man know God. Jean-Paul Sartre, a brilliant French Existentialist, tried to come to terms with dialectical Materialism. His *Existentialism and Humanism* (1948) comprises an affirmation of human dignity. "If," he writes, "I have excluded God the Father, there must be someone to invent values." Man, who has abandoned God, "must liberate himself by some practical commitment," for only then can he become fully human. Sartre's elaborate *L'Etre et le néant* (1943; Eng. trans., *Being and Nothingness,* 1956) is at once Cartesian and laborious, complete with a "key" to its special and pedantic terms. It investigates the loneliness of the human condition, attitudes to others, love, masochism, indifference, desire, and hate. This intense introspection is even more vividly expressed in his fiction and drama. The Algerian-born Albert Camus in *The Myth of Sisyphus* (1942) and *The Rebel* (1951) also agonizes brilliantly over the current human condition, and in *Man in Revolt* he discards hope of pragmatic improvement.

Sartre's view of human dignity

REVOLUTIONARY DOCTRINES

The third stream of contemporary political philosophy is Marxist–Leninist totalitarian and neo-Marxist anarchist. Many of Marx's original insights into the socio-economic process and its effect on ideas are now generally accepted. His prophecies, on the other hand, have not been fulfilled. The proletarian revolution, for example, came not in an economically advanced country but in one of the most backward; and the state, far from withering away or

Doctrinal assumptions of latter-day Marxists

being diminished by inexorable economic trends, has in fact become more powerful both in Communist and in social-democratic countries. Those who have accepted the total Marxist revelation as superseding all else have had thus to adapt and revise it. Hence, much tortuous and artificial debate has ensued. All Marxists of legitimate descent accept the Hegelian position that one can get beyond empirical knowledge and perceive the historically revealed installments of a total explanation. They also start from Marx's 19th-century belief that economically determined conflicts among feudal, bourgeois, and proletarian classes are the dynamic of history and that the rule of law is not a safeguard for the whole society against arbitrary power but merely the expression of class interest.

Lenin. The first and by far the most significant interpretation of Marx's doctrine as realized in the Soviet Union was made by Lenin and developed by Stalin and is entirely authoritarian. According to Marx and Engels, the revolution could occur only after the bourgeois phase of production had "contradicted" the tsarist order, but Lenin determined to take advantage of the opportunities provided by World War I and settle accounts directly with the "accursed heritage of serfdom, of Asiatic barbarism . . . an insult to mankind," and in 1917 he engineered a coup that secured the support of the peasantry and the industrial workers. He also adopted the revolutionary theorist Leon Trotsky's idea of a "permanent revolution" from above by a small revolutionary elite, using the existing Russian bureaucracy.

Already in *What Is To Be Done?* (1902), Lenin had argued that an educated elite must direct the proletarian revolution, and when he came to power he dissolved the recalcitrant constituent assembly and ruled through a "revolutionary and democratic dictatorship supported by the state power of the armed workers." In asserting the need for a self-constituted elite of professional revolutionaries to seize power, Lenin reverted to Marx's program in *The Communist Manifesto*, rather than conforming to the fated pattern of economic development worked out in *Das Kapital*.

In 1921 he further adapted theory to the times. His new economic policy sanctioned the development of a class of prosperous "kulak" peasantry to keep the economy viable. For Lenin thought always in terms of world revolution; and in spite of the failure of the Marxists in central Europe and the defeat of the Red armies in Poland, he died in the expectation of a global sequel. Thus, in *Imperialism, the Last Stage of Capitalism* (1917), he had extended the class war into an inevitable conflict between European imperialism and the colonial peoples involved. He had been influenced by the English historian J.A. Hobson's *Imperialism, a Study* (1902), which alleged that decadent capitalism was bound to turn from glutted markets at home to exploit the toil of "reluctant and unassimilated peoples."

But, as observed by classical, medieval, and modern constitutionalist political philosophers, authoritarian regimes suffer the tensions of all autocracies. Marx himself might have thought that such planned autocracies had made the worst of his revelation, which was to lead to an unplanned, classless utopia.

Other Marxist approaches. Many Marxist revisionists tend toward anarchism, stressing the Hegelian and utopian elements of his theory. The Hungarian György Lukács, for example, and the German Herbert Marcuse, who fled from the Nazis to the United States, have won some following among those in revolt against both authoritarian "peoples' democracies" and the diffused capitalism and meritocracy of the managerial welfare state. Lukács' "History and Class Consciousness" (published in Hungarian, 1922), a neo-Hegelian work, claims that only the intuition of the proletariat can properly apprehend the totality of history. But world revolution is contingent, not inevitable, and Marxism is an instrument, not a prediction. Lukács renounced this heresy after residence in the Soviet Union under Stalin, but he maintained influence through literary and dramatic criticism. After Khrushchev's denunciation of Stalin, Lukács advocated peaceful coexistence and intellectual rather than political subversion. In *The Meaning of Contemporary Realism* (trans. 1963), he again relates Marx to Hegel and even to Aristotle, against the Stalinist claim that Marx made a radically new departure. Lukács' neo-Marxist literary criticism can be tendentious, but his neo-Hegelian insights, strikingly expressed, have appealed to those anxious to salvage the more humane aspects of Marxism and to promote revolution, even against a modified capitalism and social democracy, by intellectual rather than by political means.

Marcuse's assessment of revolutionary prospects

Marcuse also reached back to the more utopian Marx. Now that most of the proletariat has been absorbed into a conformist managerial capitalism or has been regimented into bureaucratic peoples' democracies, freedom, argues Marcuse, is in retreat. In Western affluent societies most employers and workers are equally philistine, dominated by the commercialized mass media, or "cogs in a culture machine." The Soviet Union has reverted to an even more philistine monolithic repression, distorting art and literature. This enslavement of man by his own industrial productivity has been clinched by the colossal power of governments, which renders the old brief and brisk class warfare a romantic, impracticable idea. Marcuse attacked all establishments and transferred the redeeming mission of the proletariat to a fringe of alienated minorities—radical students and the exponents of the "hippie" way of life—as well as to Viet Cong guerillas and Black Power militants. Such groups, he declared, could apparently form liberating elites and destroy the managerial society. Thus reappeared the old Marxist–Hebraic pattern of redemption through struggle by a chosen people.

The Italian Communist Antonio Gramsci deployed a vivid rhetorical talent in attacking existing society. Like Marcuse, Gramsci was alarmed that the proletariat was being assimilated by the capitalist order and flung himself into the current controversy between social democrats and the radical revolutionaries. He took his stand on the already obsolescent Marxist doctrine of irreconcilable class war between bourgeois and proletariat. He aimed to unmask the bourgeois idea of liberty and to replace parliaments by an "implacable machine" of workers' councils, which would destroy the current social order through a dictatorship of the proletariat. "Democracy," he wrote, "is our worst enemy. We must be ready to fight it because it blurs the clear separation of classes."

Not only would parliamentary democracy and established law be unmasked, but culture, too, would be transformed. A workers' civilization, with its great industry, large cities, and "tumultuous and intense life," would create a new civilization with new poetry, art, drama, fashions, and language. Gramsci insisted that the old culture should be destroyed and that education should be wrenched from the grip of the ruling classes and the church and run under the direction of workers' councils.

But this militant revolutionary was also a utopian. He turned bitterly hostile to Stalin's regime, for he believed, like Engels, that the dictatorship of the workers' state would wither away. "We do not wish," he wrote, "to freeze the dictatorship." Following world revolution, a classless society would emerge, and mankind would be free to master nature instead of being involved in a class war.

Since World War II, Gramsci's notions have enjoyed a minor revival. They appeal to the fringe of revolutionaries who admire Marcuse and detest the embourgeoisement of an idealized proletariat. But, in a civilization in which, if total war can be avoided, material prospects are good, the destruction of the old culture out of rage, envy, and naïve idealism appears to be a pointless program. Like Marcuse's doctrine, it is a cry of pain, typical of the 1920s in Italy.

III. Conclusion

The history of political philosophy from Plato until the present day makes plain that modern political philosophy is still faced with the basic problems defined by the Greeks. The need to redeploy public power in order to maintain the survival and enhance the quality of human

life, for example, has never been so essential. And if the opportunities for promoting well-being are now far greater, the penalties of the abuse of power are nothing less than the destruction or gross degradation of all life on the planet.

In these circumstances it is of no great importance that some analytical philosophers have declared themselves neutral; they have at least often discredited pretentious metaphysical myths. On the empirical evidence, constitutionalism and the rule of law, with the ancient classic, medieval, and humanist traditions behind them, have proved themselves a more successful response to the environment than tyranny and repression. In the current and more sophisticated view, there are no shortcuts to the millennium. As Mosca points out, utopian ideas become

> dangerous when they succeed in bringing a large mass of intellectual and moral energies to bear upon an end that can never be achieved, and that in the day of purported achievement can mean nothing more than the triumph of the worst people and distress and disappointment for the good.

There will perhaps always be a struggle for pre-eminence in any society, and public laws are necessary to regulate it. Too much cannot be hoped of government, and the best society is that in which tyranny and caprice of power are prevented and in which men are free to create diverse and spontaneous institutions within the framework of law. Only within such a framework of a tolerably well-organized constitutionalism, gradually extended to relations between states, can the swiftly mounting opportunities provided by applied science be taken and the pattern of social life adjusted, so that the human species, instead of being thwarted and deformed by its institutions, can realize its full potentialities.

BIBLIOGRAPHY. The following editions of standard works and commentaries may be consulted.

Classical: PLATO: *The Republic*, trans. with an introduction by A.D. LINDSAY (1957); *The Statesman* (Loeb edition, 1925); *The Laws*, ed. by A.E. TAYLOR (1934). *The Politics of Aristotle*, trans. with introduction by ERNEST BARKER is still the best edition (1946). For the social background of Greek thought, see MAURICE BOWRA, *The Greek Experience* (1957). CICERO, *On the Commonwealth* (*De re publica*) is available in translation by G.H. SABINE and S.B. SMITH (1929). For *De legibus*, see the Loeb edition (1928, reprinted 1966). ST. AUGUSTINE, *The City of God* has been translated by JOHN HEALEY, with an introduction by ERNEST BARKER (1931). For the background, see PETER BROWN, *Augustine of Hippo* (1967) and *The World of Late Antiquity* (1971). C.N. COCHRANE, *Christianity and Classical Culture* (1940), is worth consultation; and H. OSBORN TAYLOR, *The Medieval Mind*, 4th ed., vol. 2 (1925), is still valuable for patristic and medieval thought.

Medieval: The most convenient edition of John of Salisbury is *The Statesman's Book of John Salisbury*, trans. and selected by J. DICKSON (1927). For St. Thomas Aquinas, see the *Selected Political Writings*, ed. by A.P. D'ENTREVES (1959). The full texts are in *The "Summa Theologiae" of St. Thomas Aquinas*, 2nd ed., 22 vol., trans. by the FATHERS OF THE ENGLISH DOMINICAN PROVINCE (1921–32). For DANTE'S *Monarchia*, see P.H. WICKSTEED'S translation in *The Latin Works of Dante* (1904), and that by D. NICHOLL (1954). See also A.P. D'ENTREVES, *Dante As a Political Thinker* (1952). The best general survey is R.W. and A.J. CARLYLE, *A History of Medieval Political Theory in the West*, 6 vol. (1903–36). A.L. SMITH, *Church and State in the Middle Ages* (1913); and C.H. MCILWAIN, *The Growth of Political Thought in the West, from the Greeks to the End of the Middle Ages* (1932), are still valuable.

Sixteenth–eighteenth centuries: NICCOLO MACHIAVELLI, *The Prince* and *Discourses on the First Decade of Titus Livius* are edited with an introduction by MAX LERNER (1950); his *Literary Works* are edited and translated by J.R. HALE (1961). See also ALLAN H. GILBERT, *Machiavelli's Prince and Its Forerunners* (1938); HERBERT BUTTERFIELD, *The Statecraft of Machiavelli* (1962); and FELIX RAAB, *The English Face of Machiavelli* (1964). THOMAS HOBBES, *The Leviathan, or the Matter, Forme and Power of a Commonwealth, Ecclesiastical and Civil* is edited by A.D. LINDSEY (1950); see also *The Complete Works*, ed. by WILLIAM MOLESWORTH, 11 vol. (1839–45). K.V. THOMAS, "The Social Origins of Hobbes's Political Thought," in *Hobbes Studies*, ed. by K.C. BROWN (1965), is the best account. JOHN BOWLE, *Hobbes and His Critics* (1951), describes Hobbes's political impact and the contemporary reaction to it. SPINOZA'S *Tractatus Theologico-Politicus* (in part) and the full *Tractatus Politicus* have been edited by A.G. WERNHAM (1958). See also STUART HAMPSHIRE, *Spinoza* (1951). For general background, see ALFRED NORTH WHITEHEAD, *Science and the Modern World* (1925). RICHARD HOOKER, *The Laws of Ecclesiastical Polity*, ed. by JOHN KEBLE, 3 vol. (1836), was revised by R.W. CHURCH and F. PAGET (1888). See also C.J. SISSON, *The Judicious Marriage of Mr. Hooker and the Birth of The Laws of Ecclesiastical Polity* (1940). JOHN LOCKE, *Two Treatises on Civil Government* has been edited by PETER LASLETT (1960); *The Second Treatise of Civil Government and A Letter Concerning Toleration* by J.W. GOUGH (1947). For EDMUND BURKE, see his *Complete Works* (Bohn's Classics, 1853) and *Selected Writings*, ed. by R.J.S. HOFFMAN and P. LEVACK (1949). See also PHILIP MAGNUS, *Edmund Burke: A Life* (1939); and ALFRED COBBAN, *Edmund Burke and the Revolt Against the Eighteenth Century*, 2nd ed. (1960). GIOVANNI BATTISTA VICO, *The New Science* is translated by T.G. BERGIN and M.A. FISCH (1961). See HENRY P. ADAMS, *The Life and Writings of Giambattista Vico* (1935); and BENEDETTO CROCE, *The Philosophy of Gianbattista Vico*, trans. by T.G. COLLINGWOOD (1964); also CHARLES LOUIS DE SECONDAT, *Oeuvres choisis*, trans. by J. CHAIX-RUY (1946). MONTESQUIEU, *The Spirit of the Laws* is translated by THOMAS NUGENT, with an introduction by FRANZ NEUMAN (1949). For the French Enlightenment generally, see J.B. BURY, *The Idea of Progress* (1921); and CARL BECKER, *The Heavenly City of the Eighteenth Century Philosophers* (1933). The best translation of JEAN-JACQUES ROUSSEAU'S *Social Contract*, with an introduction, is that of ERNEST BARKER (1947). See also *The Political Writings of Jean Jacques Rousseau*, ed. by C.E. VAUGHAN, 2 vol. (1915). WILLIAM H. BLANCHARD, *Rousseau and the Spirit of Revolt* (1967); and J. MCMANNERS, *The Social Contract* and *Rousseau's Revolt Against Society* (1968), are both illuminating. DAVID HUME, "Of the Original Contract" is available in *Social Contract*, ed. by BARKER (*op. cit.*)

The nineteenth century: JEREMY BENTHAM, *A Fragment on Government* and *An Introduction to the Principles of Morals and Legislation* are edited by WILFRED HARRISON (1948). See also JOHN PLAMENATZ, *The English Utilitarians*, 2nd rev. ed. (1948), particularly for Mill. J.S. MILL, *On Liberty* and *Considerations on Representative Government* are edited by R.B. MCCALLUM (1946). ALEXIS DE TOCQUEVILLE, *De la démocratie en Amérique* (Eng. trans., *Democracy in America*), ed. by PHILIPS BRADLEY, 2 vol. (1945), is the best edition. For a good abridgment, see H. REEVES's translation, ed. by H.S. COMMAGER (1946). *L'Ancien Régime* was edited by G.W. HEADLAM (1904). AUGUSTE COMTE, *Système de politique positive (System of Positive Polity)* is translated by J.H. BRIDGES, 4 vol. (1875–77). See J.S. MILL, *Auguste Comte and Positivism* (1865); and EDWARD CAIRD, *The Social Philosophy and Religion of Comte* (1885). BASIL WILLEY in *Nineteenth Century Studies* (1949), has a good essay. *Hegel's Philosophy of Right* is translated by T.M. KNOX (1942); his *Philosophy of History* by J. SIBREE, rev. ed. (1944). HERBERT MARCUSE, *Reason and Revolution: Hegel and the Rise of Social Theory*, 2nd ed. (1960), makes a new interpretation. ROBERT OWEN, *A New View of Society and Other Writings* are edited by G.D.H. COLE (1927). PIERRE-JOSEPH PROUDHON, *Qu'est-ce que la propriété? (What Is Property? An Enquiry into the Principles of Right and Government)* is edited by J.A. LANGLOIS (1966). See his *Oeuvres complètes*, ed. by C. BOUGLE and H. MOYSSET, 15 vol. (1923–36)—also D.W. BROGAN, *Proudhon* (1934). KARL MARX, *A Contribution to the Critique of Political Economy* was translated by N.T. STONE, 2nd rev. ed. (1904). See also *The Communist Manifesto*, ed. by HAROLD J. LASKI (1948); *Capital: A Critique of Political Economy*, trans. by E. and C. PAUL (1928); *Capital: The Process of Capitalist Production As a Whole* and *The Process of Circulation of Capital*, trans. by ERNEST UNTERMANN (1909); *The Holy Family* (1956); and *Selected Writings in Sociology and Social Philosophy*, ed. by T.B. BOTTOMORE and M. RUBEL (1964). Studies of Marx particularly recommended are FRANZ MEHRING, *Karl Marx: Geschichte seines Lebens* (1933; Eng. trans., *Karl Marx: The Story of His Life*, 1948); and ISAIAH BERLIN, *Karl Marx: His Life and Environment*, 4th ed. reprinted with corrections (1960). JOHN PLAMENATZ, *German Marxism and Russian Communism* (1954), is illuminating. FRIEDRICH ENGELS' works in translation include *The Condition of the Working Classes in England in 1844* (1958); *The Anti-Dühring: Herr Eugen Dühring's Revolution in Science* (1959); and *The Origin of the Family, Private Property and the State* (1884). The standard biography is by GUSTAV MAYER, *Friedrich Engels*, 2 vol. (1934; Eng. trans., 1936). GEORGES SOREL, *Reflectons sur la violence* (1912; *Reflections on Violence*), was translated by T.E. HULME (1915), and by J. ROTH (1950). See also *Les Illusions du progrès*

(1908; 5th ed., 1947); and P.L. PERRON, *Les Idées sociales de George Sorel* (1935).

The twentieth century: ISAIAH BERLIN, *Historical Inevitability* (1954) and *Two Concepts of Liberty* (1958); EMILE DURKHEIM, *The Rules of Sociological Method*, trans. by S.A. SOLVAY and J.H. MUELLER, ed. by C.E.G. CATLIN (1938); VILFREDO PARETO, *Trattato di sociologia generale*, 2nd ed. (1923; Eng. trans., *The Mind and Society*, ed. by A. LIVINGSTON, trans. by A. BONGIONNO and A. LIVINGSTON, 4 vol., 1935); GAETANO MOSCA, *Elementi di scienza politica*, 2nd ed. (1923; Eng. trans., *The Ruling Class*, ed. by A. LIVINGSTON and trans. by H.D. KHAN, 1939); LEO XIII, *The Pope and the People: Select Letters and Addresses on Social Questions* (1929); JEAN-PAUL SARTRE, *L'Être et le néant (Being and Nothingness: An Essay in Phenomenological Ontology)*, trans. and ed. by H.E. BARNES (1957); *Existentialism and Humanism*, trans. and ed. by PHILIP MAIRET (1948); LENIN, *The Development of Capitalism in Russia* (1899); *Collected Works*, 4th ed. (1960), vol. 3, *What Is To Be Done?*, vol. 5, *The State and Revolution*, vol. 25, *Imperialism: The Highest Stage of Capitalism* (1916); see also his *Selected Works*, 12 vol. (1936–39). GEORGE LICHTHEIM, *Marxism: An Historical and Critical Study*, 2nd rev. ed. (1964), is a good short account. See also HERBERT MARCUSE, *Reason and Revolution: Hegel and the Rise of Social Theory*, 2nd ed. (1960), *Eros and Civilization* (1955), *Soviet Marxism: A Critical Analysis* (1958), and *One Dimensional Man* (1964); ALASDAIR MACINTYRE, *Marcuse* (1970); GYORGY LUKACS, *Goethe und seine Zeit* (1947; *Goethe and His Age*, trans. by ROBERT ANCHOR, 1968); *Der historische Roman* (1955; *The Historical Novel*, trans. by H. and G. MITCHELL, 1962); and JAMES JOLL, *The Anarchists* (1965). For A. Gramsci, see *The Modern Prince and Other Writings*, trans. and introduced by L. MARKS (1957); J.M. CAMERETT, *Antonio Gramsci and the Origins of Italian Communism* (1967); A. POZZOLINI, *Antonio Gramsci: An Introduction to His Thought* (1970).

General histories of political philosophy: G.H. SABINE, *A History of Political Theory*, 3rd ed. (1961), is the most comprehensive survey. W.A. DUNNING, *A History of Political Theories*, vol. 1, *Ancient and Medieval*, vol. 2, *From Luther to Montesquieu*, vol. 3, *From Rousseau to Spencer* (1902–20, reprinted 1936–38), is still valuable. See also KARL POPPER, *The Open Society and Its Enemies*, 5th rev. ed., vol. 1, *The Spell of Plato* and vol. 2, *The High Tide of Prophecy: Hegel, Marx and the Aftermath* (1966). ERNEST BARKER, *The Principles of Social and Political Theory* (1951), analyses essential problems. JOHN BOWLE, *Politics and Opinion in the Nineteenth Century* (1954, paperback 1964); and WILLIAM EBENSTEIN, *Modern Political Thought: The Great Issues*, 2nd ed. (1960), are valuable, as is HAROLD D. LASSWELL, *The Future of Political Science* (1963).

(J.E.B.)

Political Power

Power, conceived broadly as man's influence over man, has been a deep and self-conscious human concern for more than 2,000 years. From Aristotle, Machiavelli, and Marx to modern political writers and activists, political philosophy and political conflict have revolved basically around who should have power over whom. But despite over two thousand years of conjecture, and at least occasional attempts at systematic analysis, scientific understanding of power phenomena has emerged only in the 20th century. The topic has been as elusive and formidable as it is vital.

The concept of power is employed widely in all the social sciences. Anthropologists study power, authority, and leadership in small communities ranging from primitive tribes to peasant villages and urban neighbourhoods. Sociologists investigate power as a ubiquitous aspect of social stratification, involving classes, elites, status groups, legal systems, social movements, and organizations, such as bureaucracies and parties. Psychiatrists and psychologists probe human motivations toward power and human reactions to its use. Economists analyze power in the market—monopolistic, duopolistic, oligopolistic, and perfectly competitive—as well as the influence of international firms and economic forces. Management specialists from various disciplines investigate the processes of power and control within organizations, while social psychologists concentrate on the same phenomena in small groups. Lastly, political scientists frequently take the study of power to be the very focus of their discipline. Having traditionally approached the topic through an examination of the formally authoritative institutions of power, such as constitutions and governments, they moved on to immediately related agencies, such as political parties and interest groups. Subsequently, political scientists have investigated power phenomena in virtually any significant setting, including families, occupations, and voluntary associations. The analysis of power remains a basic concern of social sciences.

CONCEPTS OF POWER

Analyses of power in the social sciences

In very fundamental terms, analysts of power have confronted three initial problems: (1) the concept of power itself; *i.e.*, what should be meant by the term power; (2) what aspects and types of power and power structures need to be distinguished; and (3) how power, so defined and elaborated, can be located and measured. The first two problems only will be described in this article; the third is a problem of social-scientific methodology.

Meaning and characteristics of power. The etymology of the term power is traced back to a Latin root (*potere*, *potesse*, or *posse*) essentially meaning "to be able to," or having the capacity to do something. One common meaning of "power"—now a rather ambiguous term—is, therefore, the "ability to act," "capacity to produce a result," or simply "strength." In politics, this meaning became more specialized, referring to the ability to affect the actions of others; that is, to produce alterations in their behaviour.

Political power is frequently distinguished from other forms of power, such as economic, social, and religious. The power that is political is defined in terms of an institution such as the government or the state. Political power then becomes power wielded in relation to the government or the state, either by it, or to affect it, or both. It is power directly or indirectly of and over government or the state.

A less common way of viewing political power is to regard it as power employed in relation to collective actions, governmental or other. Collective acts require the cooperation of more than one person and are a means by which the goals of collectivities are realized. As the American sociologist Talcott Parsons saw it, for example,

> The political process then is the process by which the necessary organization [for collective action] is built up and operated, the goals of action are determined and the resources requisite to it are mobilized.

Political power thus becomes defined in terms of actors' effects on this process, sometimes broadly interpreted to include all kinds of effects and sometimes more narrowly limited in terms of legitimacy and other considerations.

A third view of political power is stated or implied by those who define what is "political" in terms of power. Though at first it might appear that "political power" would then be a redundant expression, this is not true. Rather, political power is basically defined as "power over the allocation and distribution of power." Political power is thus power over power; the more a particular power relation affects other power relations, the more political it is. The power of the president of the United States over the Senate majority leader, for example, presumably includes much more political power than that of a local machine "boss" over a party hack even though the actual amount of direct control between the first pair may be less than that between the second pair.

Working definition of power

In the remainder of this article, unless otherwise indicated, power will be defined as a relationship in which the behaviour of one or more persons alters the behaviour of another or others. Political power will be construed as power over the allocation and distribution of power in some social unit (nation, city, organization) that must always be specified.

General aspects of power relationships. Various aspects of power have been found to be of critical importance in virtually all power relations. One is simply the matter of the actors involved. Any power relationship minimally involves two actors—one who influences and another who is influenced. Often there are several of each along with intermediaries who link the original influencer and ultimate influencee in a power chain.

Actors involved. A crucial feature of any power analysis is the choice of actors and actor characterizations. The power structure of a city, for example, may look quite different depending on who the main actors in the analysis are. They could be the formal governmental leaders such as the mayor, the councilmen, or the sheriff, on the one hand, or they could be the "old political hands" and the "young Turks"; the "Establishment" and the "People"; or liberals, radicals, and conservatives. When analyses of political power seem to disagree, it is frequently because they focussed on different political actors. Conclusions about political power thus must be interpreted in light of the adequacy of the choice and description of the actors selected.

Since power is a behavioral relationship among actors, description of the specific actions of all of them is important. Few actors influence everything another actor does, and few are affected by everything done to them. Studies of political power generally stress certain kinds of action on the part of the influencer (called his "influential behaviour") and certain kinds of response by the actor influenced (usually called the "scope" of the relationship). To paraphrase the American political scientist Harold Lasswell, power descriptions attempt to answer the question, "Who does what to whom with what effect?"

Recognition. In many settings, the more ample and accurate that an actor's perception is of the power relations around him, the greater his own power is likely to be. For this reason, many power struggles centre about control over information. Also, it often seems that an actor who newly recognizes that he is being influenced by another actor tends to strive to reduce that influence if possible. Hence the attractiveness to the influencer of "manipulation"—a power relation that is intended and recognized by the influencer, but is unrecognized by the actor who is influenced. Some analysts consider that manipulative power is rising in modern societies. One of the best means of destroying manipulative power is to make the person influenced aware that he is being manipulated.

Rapidity and power sequencing. Timing plays a prime role in political power. Two of the several facets of timing are of particular importance. One can be called "rapidity" or "response lag," the other, "power sequencing" (see below). Rapidity refers to the time that elapses between the influential behaviour of the influencer and the response (scope) of the one influenced. Many power conflicts seem to be exacerbated by discrepant interpretations of rapidity. University students, for example, attempting to influence their school's administration, may regard four months as an inordinately long response time, probably indicative of stalling. Administrators and faculty, on the other hand, may view such a response lag as extremely rapid—about as fast as the institution can be expected to react—and a clear manifestation of good faith.

The element of rapidity is extremely important to some types of organizations. The response lag is shortened when power is patterned in certain ways—especially hierarchically, unilaterally, and directly—and when certain types of power, such as absolute authority, are employed. Military units in combat, for example, require great rapidity of response and correspondingly adopt a hierarchical and authoritative power structure. Surgeons performing operations have similar needs and work within similarly concentrated and authoritative structures. In other types of organizations, however, rapidity of response is not as crucial. Filibustering and certain other forms of stalling in legislatures, for example, can be viewed as deliberate, legally permitted efforts to lengthen the response lag so as to deter the influencer from his attempt.

"Power sequencing"

Many power relations are not one-shot affairs. In the second facet of timing, "power sequencing," an original influence attempt may be followed by refusal, partial compliance, or evasion on the part of the one intended to be influenced; then another influence attempt is made, followed by another response, and so on. During such exchanges both parties often engage in contingency planning. The government, for example, must not only pass legislation, but it must also indicate what is to happen if citizens violate the legislation, what appeals can be made, how the violation is to be discovered. Actors vary significantly in the richness of their power repertoires, in the sophistication of the influence sequences they can handle. Some actors lapse quickly into violence and other fairly extreme responses, while others display great ingenuity in constructing alternative tactics. Some political systems expect quicker compliance and less sequencing than others. Explosions often occur when the sequencing expectations of the participants in a power relation are conspicuously divergent.

Resistance and cost. In attempting to compare the power of various actors, resistance and cost must be considered. Though very difficult and only imprecisely worked out, these important notions refer crudely to how hard or easy it is to get the influenced actor to respond (his resistance) and how much of a sacrifice, if any, it will be for the influencer to engage in the influential behaviour (his cost). Two groups may each get three bills through a legislature, but if one set of bills is noncontroversial or trivial while the others are faced with strong opposition but important, the difference in resistance shows the second lobby exerted greater power.

Indirect power. Some power relations are direct and some are indirect. In an indirect relation, intermediaries come between the original influencer and the ultimate influencee. Such indirect relations have not been well studied, but they seem to offer certain advantages and disadvantages. Indirect relations, for example, are less likely to be recognized. Thus, when governments or political parties wish to influence public opinion but know that a direct communication from them would be suspect, they frequently work through various agents. Indirect relations—very long chains of them, in fact—are inevitable in any large and complicated power structure. Such complicated patterns of power are part of the basic fabric of all modern societies.

Some indirect relations, on the other hand, often prove to be relatively fragile, offering opportunities to intermediaries to take power into their own hands. Indirectness masks the influencer's ability to observe compliance just as it masks recognition by the actor influenced, sometimes to the point that no one accurately perceives the true nature of the power patterns. Responsibility is then hard to assess.

The mask of power in indirectness

Reciprocity. A further important aspect of power relations is called reciprocity. Often power relations get reversed, so the original influencer is in turn influenced by the influencee. Such reciprocity phenomena appear to be especially significant. Democracy, for example, exhibits a relatively high incidence of reciprocal relations in the political power structure, in which the government influences the people but the people also influence the government. Several basic kinds of reciprocity can be observed, and students of political power investigate the causes and consequences of each.

Types of power. *Bases for classification.* Probably the most common classification of power would divide it into economic, social, and political categories—an essentially institutional classification. Political power pertains to the state or government, economic power to the financial and production establishments, and social power to the remaining institutions. Similar, but more elaborate, classifications that have been suggested would include religious, military, judicial, informational, and international power along with economic, social and political power.

Power and values

From another perspective, these various types of power can be regarded as referring to control over different kinds of valued resources. Political scientists who have pursued this line of thought most explicitly list eight types of human values: power, respect, rectitude, affection, well-being, wealth, skill, and enlightenment. Since power can be based on control over any of these values, there are eight basic types of power ("forms of influence"): political power, councillorship, mentorship, personal influence, violence, economic power, expertness, and advisory influence, respectively.

Another approach is to classify power relations in terms of types of behaviour—that is, according to kinds of influential behaviour (the behaviour of the influencer), or of scope (the behaviour of the one influenced). The former requires a classification of the types of behaviour an influencer can use to affect the others' responses; the latter requires a classification of the main dimensions along which an influencee can be affected.

Amitai Etzioni, a political sociologist, has analyzed complex organizations using a typology of power based on influential behaviour. The kind of question he is concerned with is essentially, "What kinds of things can actors do to influence other actors," and he discerns three main types of power: coercive (the use or threat of physical sanctions), remunerative (the use of material resources as rewards and punishments), and normative (the use of symbolic resources as rewards and punishments). Etzioni argues that although most organizations employ all three types of power, they tend to stress one more than the others. The military thus stress coercive power, business firms stress remunerative power, and churches stress normative power. He contends further that the basic type of power used by an organization is associated with differences in such factors as organizational goals, leadership characteristics, the kind and degree of consensus within the organization, recruitment patterns, and processes of training and socialization.

The last fundamental approach to classifying power relations focusses on the scope of the relationship. This approach poses the question: "In what ways can any actor's behaviour be affected by other actors?" This in turn requires a model of the state of an actor at any given time. In the same way that alterations in a physical object can be determined only by reference to regular descriptive categories, such as colour, shape, and hardness, in order to determine changes in influenced actors in a power relation, it is necessary to have categories for describing the various kinds of change that can occur.

Many typologies of power are based on such an analysis, either explicitly or implicitly. The English philosopher Bertrand Russell, for example, suggested three main types of power: direct physical power over the bodies of individuals, rewards and punishments, and influence on opinions. Within this framework, he noted further subtypes, such as priestly, kingly, naked, revolutionary, and economic power. But the basic typology centres on the scope of the power relationship, suggesting that human actors can be influenced physically, or through rewards and punishments, or through opinion change. More recent thought distinguishes physical power, in which actors are influenced merely as physical entities, from psychological power, in which behavioral effects are produced through first influencing the mind. Psychological power is divided into cognitive and motivational categories. Cognitive power (influencing an actor by changing his perceptions) mainly consists of threats of punishment and promises of reward. Motivational power (influencing an actor by altering his drives) consists of the inculcation of ethics and the generation of desires.

Problems of power classification. One outstanding problem with all attempts to classify power is that the categories developed are not mutually exclusive in an empirical sense. In other words, a given concrete power relationship rarely falls exclusively into any single category. If the government imprisons a man, it is simultaneously using physical power, cognitive power, and motivational power.

Power and authority

One of the most important types of power is authority. The interpretations of authority are many, but two conceptions seem uppermost. One views authority as compulsive power—power which brooks no refusal, which is binding on the actor influenced. He does not pause to ask why; when confronted with an authoritative imperative, he obeys. The other main notion of authority is more limited and is based on legitimacy. People learn conceptions of what constitutes proper, ethically desirable power relations. The actual relations that conform to these conceptions of what ought to be are said to have legitimacy for the perceiver. He is under strong moral pressure to obey legitimate influence assertions. Authority is a power relation involving the legitimate power of one role over another, for authority is not vested in particular idiosyncratic individuals, but in roles, offices, and positions. Virtually all political systems endeavour to establish the authority of crucial roles and institutions. It is uncertain, however, how long pure authority endures if it is not reinforced by other types of power.

Power structures. Theoretically, for any clearly specified social unit, such as a nation, community, or organization, and for any appropriate time period, one can designate the set of actors in the unit and the set of power relations among those actors. Together, these constitute the power structure of the unit.

Assuming sufficient information about actors and their power relations, structural analysis is concerned with three main questions: (1) how to provide a summary description of the power structure of the unit; (2) how to explain the particular structural configurations found; and (3) how to ascertain the consequences of those structural patternings for other variables such as the distribution of scarce resources, the unit's effectiveness at performing certain tasks or functions, and the morale of the actors in the unit.

Terms describing power structure

The analysis here will be confined to the first problem, that of describing the power structure of the unit. Many terms in ordinary language offer useful distinctions: oligarchy, autocracy, polyarchy, democracy, totalitarianism, plutocracy, anarchy, dictatorship, pluralism. The Greek endings "-archy" and "-cracy," from *archōn* ("ruler") and *kratos* ("rule, power"), have been attached to scores of stems to form structural power terms. Examination of such terms brings out three important aspects of power structures. The first and most basic is the distribution of power within the unit; that is, how widely shared the existing power relations are among the members. Does power tend to be concentrated in a few hands or dispersed? Aristotle, for instance, distinguished three fundamental types of power structures based on the distribution of power. These were, in their pure forms, kingship, aristocracy, and democracy; and in their corrupt forms, dictatorship, oligarchy, and ochlocracy (mob rule). They refer, respectively, to rule by one actor, rule by a few actors, and rule by many or all actors.

The second aspect of power structures, *who* rules, is reflected in ordinary language. The type of actor in the system with greatest power is in a plutocracy, the rich; in a gerontocracy, the aged; and in a timocracy, the propertied class.

The third structural aspect commonly noted in ordinary language describes the extent of the ruling element's power—"total," as in totalitarian systems, or limited and fragmented, as in pluralistic, democratic societies.

POWER IN VARIOUS SETTINGS

There is a vast lore about political power as it is exercised in various settings, little of which is organized into coherent theory and much of which is either contradictory or false. Nevertheless, enough is known about power at different levels of social organization to summarize the dynamics of its exercise at three levels: in groups, organizations, and communities.

Small groups. The small group is the setting for much of political life. Cabinets, party-executive committees, supreme courts, legislative committees, revolutionary juntas, town-finance committees, bureaucratic staffs, personal entourages, party cells, and even friendships all come to mind. In addition to its intrinsic importance, the small group is the building block from which larger political organizations are constructed. Hence, they are sometimes called "primary groups."

The most visible political actors are those occupying prominent organizational roles, such as the chief executive of the government, the leader of the opposition, or the spokesman for an interest group. Organizational roles, however, only set rough possibilities and limits for the actual exercise of power, which is always personal. The particular person playing the role must activate the potential power inherent in his organizational authority,

operating within the context of a small group much of the time. Some analysts, in fact, assert that most significant political decisions are made in small groups. An understanding of the dynamics of small groups is thus essential to an understanding of power.

Many definitions of the small group have been offered. All seem to revolve not about absolute size but around the notion of direct, face-to-face interaction. In the small group, each member knows and interacts directly with every other member. In contrast to the relatively large, indirect and impersonal organization, the small group tends to be relatively personal, direct, and intimate. Individual style, personal liking and disliking, and face-to-face interaction skills, which are much less important in the larger context, are crucial in the small group.

Leadership roles in small groups

The face-to-face interaction that characterizes the small group brings the emotional, affective or expressive features of relationships into greater prominence. Experimental studies, in fact, have suggested a bifurcation of group leadership along these lines. An instrumental, or task, leader moves the group toward realization of its manifest goals. Such leadership, however, is likely to generate tension and dissatisfaction. The instrumental leader, moreover, is usually somewhat distant from other group members. Hence an expressive leader also frequently emerges, acting to assuage the tensions and conflicts arising from pressure toward task completion.

Compelling emotional ties are frequently formed in the small group context—ties not merely to specific members but to the group itself as a symbolic entity. The member's need for acceptance and solidarity, his need for the cooperation of others in achieving many personal goals—all are disproportionately met in small-group settings. Satisfying these needs gives such groups great power over the individual. It is no accident that political organizations that make extremely difficult demands on their members are especially likely to be organized into relatively small, tight, and totally involving cells. Similarly, some argue that the more crucial the political decision, the smaller the unit handling it and the simpler its role structures. It has even been suggested that, as a general principle, other things being equal, the control of a social unit over its members is inversely related to its size.

Though the small groups of a political organization can be a major source of organizational power, supporting the formal structure in critical ways, they can also be a challenging and disruptive force. If individual members who oppose the larger unit can band together in a small group, they can frequently reinforce each other and blunt the otherwise potent pressures to conform. Extreme deviance such as criminality, attempts at coups and cabals, die-hard resistance, or even "family circles" of mutual protection against party informers (as in the Soviet Union) is almost always incubated in a supportive small-group atmosphere. Awareness of this potential for power in small groups has led many totalitarian regimes to try to atomize interpersonal relations below the level of the state, except in carefully controlled regime-supporting organizations such as the Hitler Youth of Nazi Germany, or the Pioneers of Stalin's Russia.

Organizations. Most positions of great political power are obtained by moving into established roles. Any new power holder creates for himself only a tiny fraction of the enormous web of power relations he commands when he moves into an existing structure of authority and power resources.

The modern world is distinctly an organizational world; modern power is organizational power, and modern man is, unavoidably, an organization man. Complex organizations are indeed built up from small groups, but those complex organizational arrangements in turn frequently determine what sort of small groups will be formed —where, when, how and among whom. Contemporary political power, in particular, is most conspicuously revealed in organizational settings and in the clash of organizational actors.

Basically, organizations can be regarded as devices for coordinating the behaviour of individuals and groups. Bureaucracies coordinate the behaviour of officials, presumably to implement governmental policies. Political parties concert the behaviour of partisans in order to increase their chances of gaining control over the government. By organizing and coordinating their actions, individuals and small groups can accomplish goals that otherwise would be unlikely or impossible.

Goals and power. The power position and activities of an organization are fundamentally related to its goals. Other things being equal, the greater the consensus within the organization on goals and means, the less the need for the internal exertion of power. The more the members spontaneously want to coordinate their behaviour and agree on how to do so, the less need there is to provide organizational influences toward that end. For this reason, many organizations expend much effort on maximizing consensus in areas of activity regarded as critical. The two main instruments for obtaining consensus are recruitment (or, more broadly, the selection, promotion, and release of personnel) and socialization (the teaching of attitudes and behaviour to members). The more the organization selects people who already have an appropriate viewpoint or the more it trains existing members to adopt such an outlook, the less it needs to use force, authority, reward, punishment, and other forms of power to induce appropriate behaviour.

The role of consensus on goals and means

Theories of political power assign a central position to distinctions among crucial types of goals. Probably the most basic distinction is that between power itself as a goal and other substantive goals. "Political man" has often been regarded as the actor dominated by the pursuit of power in the same way that "economic man" is dominated by the pursuit of pecuniary profit. The detailed implications of such an assumption have never been elaborated for political man as carefully as they have for economic man. The main proposition that emerges from such a concept may be that the goal of power itself is in many respects "unbounded," a goal never fully satisfied. On the other hand, many substantive goals can be reached and extinguished; they do not motivate the political actor to seek power across the board but only in certain limited areas.

Distribution of power. Much research indicates that it is usually misleading to think of the power structure of an organization. Structural arrangements differ according to activity. The distribution of power over personnel policies may vary considerably from that over public relations. If so, it is important to ascertain whether power is more likely to be concentrated in some areas than in others, and whether an individual actor in the organization can transfer some kinds of power to other areas more easily than he can transfer other kinds. Thus far, the answers to both questions seem to be affirmative and similar. There appears to be a remarkably general tendency for most organizations—political, business, social —to concentrate power most narrowly in three basic areas: (1) control over major resource allocations; (2) control over high-level personnel decisions; and (3) control over important interactions with critical external actors, such as main competitors or allies.

Concentrations of power in organizations

Other analytic structures of organizations. Power is not the only analytic structural aspect of an organization. Patterns of prestige, communication, wealth, friendship, and so on can also be distinguished. A major theoretical concern is to comprehend the relationships among these analytic structures. The most conspicuous finding to date would seem to be the tendency toward isomorphism, or similarity, among these various structures. It appears difficult, for example, to maintain a highly democratic power structure in the face of a highly concentrated prestige or status structure. Great inequalities of wealth seem to be incompatible with marked decentralization of power. Extremely limited and centralized communication structures apparently are conducive to similarly concentrated power structures. Conversely, scattered communication patterns are generally incompatible with centralized, rapid, decisive power reactions. The reason for these agglutinative tendencies is obvious: prestige, wealth, and information are all resources that can contribute to an actor's power in most situations. Power patterns are formed in

part by the distribution of these other relations, just as they in turn are partly shaped by existing power patterns.

Communities. Power in various types of communities—villages, towns, cities, and metropolitan areas—has been extensively studied by researchers in two broad fields. Political scientists and sociologists have conducted dozens of studies, usually of fairly sizable communities located in the United States or, occasionally, in Europe; and anthropologists have made hundreds of case studies of peasant and primitive villages scattered around the world, especially in nontemperate-zone climates. The political science and sociological studies usually focus primarily and explicitly on power and stratification, while the anthropological literature is usually concerned with power peripherally and casually. Because both literatures suffer serious methodological difficulties, comparative conclusions are extremely doubtful.

The discussion that follows pertains almost entirely to studies conducted in the United States by political scientists and sociologists. Most of the literature has been concerned with prevailing power structures of communities, especially with the internal distribution of power. Of paramount interest have been questions of whether communities differ in their distributions of power, and if so, why. Somewhat less effort has also been directed toward understanding the consequences of differences in the distribution of community power for community policies.

Power structures of American communities

Fragmentation of formal power. Despite sharp methodological controversies, studies of power in American communities have revealed some surprising agreements in their findings. In contrast to the situation in many other countries, formal political power in most American communities is highly fragmented. The numerous boards, agencies, districts, councils, committees, associations, and offices share important blocks of community authority. In addition, there are federal, state, and local divisions of power. To get any single positive action through such a fragmented structure minimally requires agreement from many diverse governmental entities. The structure of formal authority thus seems to discourage major community initiatives and to provide an advantage to those favouring the status quo.

This fragmentation of formal power has been at least partly compensated for by informal power arrangements, such as the "machine," political parties, popular movements of various kinds, and informal leadership groups to "get things done." Community studies have noted, however, that the "reform movement" in urban America may have undermined these informal mechanisms to the point that establishing effective policy on basic problems has become structurally almost impossible to achieve in many communities. In any event, the fragmentation of formal power in municipal America has been widely observed.

Political–economic split. Many, but by no means all, studies have found some sort of "bifurcation of power" in American communities. Many investigations depict two main constellations of power in communities—political and economic. Sometimes one seems to be dominant and the other supporting, and sometimes the two appear as virtually independent realms. In the latter instance, economic interests remain largely aloof from politics, at least refraining from direct intervention; while politicians shun any major incursions into economic affairs. Several relatively sophisticated analyses suggest that important community initiatives are most likely to come from the staffs of governmental and civic organizations or their professional associates, while business leadership often plays a prestigious supporting role that gives it a marked veto power over many proposed projects or initiatives.

Power of elites. Very few investigations have found power within any issue area to be widely distributed. The bulk of the populace seems generally to have little influence on and little interest in most public policy. At best, the picture is one of competition among different small elites of power, with popular pressure being exerted only sporadically and very indirectly; perhaps most of the popular pressure comes largely through the reactions that power holders themselves, rightly or wrongly, anticipate from the electorate. The main controversy in the community-power literature has been over the degree of elite competition that typically exists. Little disagreement has occurred over the relative quiescence and ineffectiveness of the mass of the populace. At best, activated minorities are seen to predominate; at worst, a small power elite is perceived to rule.

Such studies frequently are based on the examination of issues that have arisen in the community. Critics contend, however, that an elite may be so powerful that it permits only the issues acceptable to it to surface in the community. In such instances, therefore, the elite does not have to display its power by intervening. The elite, in other words, is most effective when it can keep threatening items off the political agenda. One effective way to do this is through socialization—through spreading a political culture, much of it unrecognized by those who accept it, that supports and enhances the power of the dominant elite.

Factors shaping community power structures

If the essential correctness of each of the various studies of community power be assumed and the total literature then inspected for interesting empirical findings, certain conclusions emerge. Associations between the distribution of power and the following factors are suggested:

1. The relationship between community size and power does not seem to be linear, for there are many indications that the largest cities of the country tend to have relatively less concentrated power structures. Pluralistic, less concentrated patterns also seem to be found more often in communities that are growing less rapidly in size, while more concentrated patterns are more likely in rapidly growing communities.
2. It has frequently been asserted that economic diversity in a community is positively associated with a greater distribution of power. Certainly, several egregious examples of one-industry cities dominated by a single family have been presented. Other, more comparative, research, however, casts doubt on this assertion, so that any definitive conclusions must await better evidence.
3. At least one regional variation has been regularly reported: cities in the South seem to have more concentrated power structures than similar cities in other areas.
4. It has also been alleged, and is theoretically plausible, that the more heterogeneous the population of the community, the more pluralistic its power structure. This is especially true when cleavages have crystallized into established, competitive social groupings. Again, however, strong support for this contention is lacking.
5. Existing data seem to indicate that nonpartisan elections, city-manager forms of government, and other "reform" oriented arrangements are associated with more concentrated power patterns, while partisan elections, mayoral systems, and more institutionalized political conflict are linked with pluralistic patterns.
6. Finally, there seems to have been a movement in the direction of reduced concentration of power. Perhaps because of the increasing urbanization of the country, perhaps because of changes in its political culture, structures of community power seem to be somewhat more pluralistic than at the turn of the century. Some writers also note a tendency for power holders to be less "blatant," arrogant or obvious in their use of power.

BIBLIOGRAPHY. The literature on power is enormous. General treatments include: BERTRAND RUSSELL, *Power: A New Social Analysis* (1938); CHARLES E. MERRIAM, *Political Power: Its Composition and Incidence* (1934); HAROLD D. LASSWELL and ABRAHAM KAPLAN, *Power and Society* (1950); ROBERT M. MACIVER, *Power Transformed: The Age-Slow Deliverance of the Folk and Now the Potential Deliverance of the Nations from the Rule of Force* (1964); and ADOLF A. BERLE, *Power* (1969).

Many of the most valuable articles on the concept of power are assembled in RODERICK BELL, DAVID V. EDWARDS, and R. HARRISON WAGNER (comps.), *Political Power: A Reader in Theory and Research* (1969). One additional article that is essential is JAMES G. MARCH, "The Power of Power," in DAVID EASTON (ed.), *Varieties of Political Theory* (1966). An attempt at logical explication is INGMAR PORN, *The Logic of Power* (1970).

A few works offering explicit discussions of power are: FELIX E. OPPENHEIM, *Dimensions of Freedom* (1961); DORWIN CARTWRIGHT (ed.), *Studies in Social Power* (1959); MAX WEBER, *From Max Weber: Essays in Sociology*, ed. by H.H. GERTH and C.W. MILLS (1947); and FREDERICK FREY, "Developmental Aspects of Administration," in J.P. LEAGENS and C.P. LOOMIS (eds.), *Behavioral Change in Agriculture* (1971).

Basic works on power in small groups are: SIDNEY VERBA, *Small Groups and Political Behavior* (1961); TERENCE HOPKINS, *The Exercise of Influence in Small Groups* (1964); GEORGE C. HOMANS, *The Human Group* (1950); BARRY E. COLLINS and HAROLD S. GUETZKOW, *A Social Psychology of Group Processes for Decision-Making* (1964); ROBERT T. GOLEMBIEWSKI, *The Small Group: An Analysis of Research Concepts and Operations* (1962); JOHN W. THIBAUT and HAROLD H. KELLEY, *The Social Psychology of Groups* (1959); DORWIN CARTWRIGHT and ALVIN ZANDER (eds.), *Group Dynamics: Research and Theory*, 2nd ed. (1960); PAUL HARE *et al.* (eds.), *Small Groups* (1955); and JAMES D. BARBER, *Power in Committees: An Experiment in the Governmental Process* (1966).

Among the most significant works in community power studies are: NELSON W. POLSBY, *Community Power and Political Theory* (1963); ROBERT A. DAHL, *Who Governs? Democracy and Power in an American City* (1961); EDWARD BANFIELD, *Political Influence* (1960); ROBERT E. AGGER, DANIEL GOLDRICH, and BERT SWANSON, *The Rulers and the Ruled: Political Power and Impotence in American Communities* (1964); FLOYD HUNTER, *Community Power Structure* (1953); ANDREW MCFARLAND, *Power and Leadership in Pluralist Systems* (1969); ELIHU KATZ and PAUL F. LAZARSFELD, *Personal Influence: The Part Played by People in the Flow of Mass Communications* (1955); and TERRY CLARK (ed.), *Community Structure and Decision-Making: Comparative Analyses* (1968).

The literature on power in organizations is extremely large. A good starting point is the compendium by JAMES G. MARCH and HERBERT A. SIMON, *Organizations* (1958); or JAMES G. MARCH (ed.), *Handbook of Organizations* (1965). Other major titles are: CHESTER BARNARD, *The Functions of the Executive* (1938); HERBERT A. SIMON, *Administrative Behavior* (1957); ROBERT A. GORDON, *Business Leadership in the Large Corporation* (1961); WILBERT MOORE, *The Conduct of the Corporation* (1962); RICHARD S.F. EELLS, *The Government of Corporations* (1962); ROBERT L. KAHN and ELISE BOULDING (eds.), *Power and Conflict in Organizations* (1964); JAMES D. THOMPSON *et al.* (eds.), *Comparative Studies in Administration* (1960); HAROLD LEAVITT (ed.), *The Social Science of Organizations: Four Perspectives* (1963); AMITAI ETZIONI, *A Comparative Analysis of Complex Organizations* (1961); ROBERT L. PEABODY, *Organizational Authority* (1964); PETER M. BLAU and W. RICHARD SCOTT, *Formal Organizations: A Comparative Approach* (1962); and PHILIP SELZNICK, *Leadership in Administration: A Sociological Interpretation* (1957).

(F.W.F.)

Political Science

Political science is most generally understood to mean the systematic study of government processes by the application of scientific methods of analysis. More narrowly and more traditionally, it has been thought of as the study of the state and of the organs and institutions through which the state functions. In most countries, political science is thought to be a single discipline, but the plural form has been used in France, as in the name of the École Libre des Sciences Politiques (now Institut d'Études Politiques de l'Université de Paris), founded in 1871—although there is also an Association Française de Science Politique. Speculation about political subjects is not unknown in ancient non-Western cultures, but most students agree that the roots of political science are to be found in the earliest sources of Western thought, especially in the works of Aristotle, who is recognized by many as the founder of political science.

THE NATURE AND SCOPE OF POLITICAL SCIENCE

Although political science may be distinguished from political philosophy, the distinctions are unsatisfactory inasmuch as they lack categorical rigour. In the most usual distinction, political philosophy is thought to be concerned primarily with the study of political ideas, often within the context of their times. It is strongly normative in its thrust and disposition and rationalistic in its method. Political science, however, concerns itself with institutions and behaviour, eschews normative judgments as much as possible, and attempts to derive principles from objective facts with as much quantification as the evidence will allow. Political philosophy thus speculates about the place and order of values, the principles of political obligation (why men should or should not obey political authority), and the nature of such terms as right, justice, and freedom. Political science, on the other hand, seeks to establish by observation (and, if possible, by measurement) the existence of uniformities in political behaviour and to draw correct inferences from these data. The stated differences between political philosophy and political science are less than is sometimes supposed, for the most empirical scholar in both the social and natural sciences makes use of unproved postulates, hunches, and intuitions; and the most rationalistic philosopher employs conceptions that embody empirical statements.

Some theorists, however, who believe it possible to develop a completely value-free science of politics insist that the distinction between political philosophy and political science is not faint but vivid. It is their opinion that only a few hundred philosophers and political theorists have ever contributed to systematic speculation about and study of politics. It was said in 1966 by one of the exponents of this view that "probably two out of every three political scientists who have ever lived are alive and practicing today." In this view, political philosophy is believed to be addicted to obscurity and opacity of statement—an effort to bespeak the unspeakable—and it is thought that its task should be a more modest one, namely, to grope with the grammar of philosophical statements. This would require political philosophers to put their intelligence to the elucidation of the language of politics and to expose the difficulties placed by language in the consideration of matters of fact. One of those interested in this approach was the English political philosopher T.D. Weldon in *The Vocabulary of Politics* (1953), but few have followed his initiative.

Scientific status of the subject

The question as to whether political science is a science is largely inconsequential, because the problem is primarily one of definition. If the term science is to be applied to any body of systematically organized knowledge based on facts ascertained by empirical methods and described by as much measurement as the material allows, then political science is a science, just as are the other social disciplines. If, on the other hand, the term science is to be limited to those disciplines in which the scholar can control the materials to be studied and can perform experiments that others can reproduce under the same conditions and in which predictability is possible, then the label is less appropriate, although not entirely misapplied. The American political economist Thorstein Veblen denied that political science was anything more than a "taxonomy of credenda," and, more recently, a British writer, Bernard Crick, has said that the hope of creating an artificial science of politics on natural principles, although not originally and uniquely American, has been largely generated and sustained by two aspects of the American culture—an agreement on liberal doctrine that has made politics less a matter of serious doctrinal splits than of mere disagreement among partisans of the same creed, and a general national preoccupation with technology.

DEVELOPMENTS IN THE 19TH AND EARLY 20TH CENTURIES

Influence of early sociology. The origins of contemporary political science are to be found in the enthusiasm for the creation of social science that was widespread in the 19th century, an enthusiasm stimulated by the rapid growth of the natural sciences. It might be said that one starting point for the development of modern political science is the work of the Comte Henri de Saint-Simon, a notable Utopian Socialist, who in 1813 suggested that morals and politics could become "positive" sciences; that is, disciplines whose authority to command belief would rest not upon subjective preconceptions but upon objective evidence. With him worked the mathematician and philosopher Auguste Comte, the two collaborating in the publication in 1822 of the *Plan of the Scientific Operations Necessary for the Reorganization of Society*, which

argued, among much else, that politics would become social physics and that the purpose of social physics was to discover unchanging laws of progress. Out of this collaboration emerged the law of the three stages through which knowledge had to pass—the theological, the metaphysical, and the positive—that Comte was to establish as the theme of the science of social physics, a study he came to name sociology. An intellectual connection between political science and sociology was thus early established in schemes of political and social regeneration and reform, although political science was thought to be limited to only one form of association in society, namely, the state. Comte thought that the principal methods for the study of social phenomena were observation, experiment, and abstraction. Although one might have thought that politics could not be an experimental science, Comte was of the view that political experimentation did take place whenever there was a change in the life of the state, intended or not. It must be said, however, that even on this account there is no close similarity to experimentation in chemistry and physics, in which all the variables can be controlled.

In the search for more objective methods of inquiry into political and other social phenomena in the 19th century, contributions to the explanation of the state were supplied by several new intellectual disciplines. Because political science deals with some aspects of human behaviour, for example, it is closely allied to other social sciences that also deal with human behaviour. Long before the development of scientific inquiries in the 19th century, numerous theories of the state had drawn inspiration from the human being as model, as in the *Policraticus* of John of Salisbury (1159), in which the physiology of the body and that of the state are compared; or in *The Republic* of Plato, in which the elements of the human personality prefigure the class structure of the state; and in Rousseau's *Contrat Social*, in which the political order is animated by a general will (will being a human attribute). The positivism of the 19th century, however, brought new approaches to the study of the state, although the older ones continued to coexist with them.

Sociological analyses of the state

Among those following Comte was the Polish-born sociologist Ludwig Gumplowicz, who built a sociology on Comtean foundations but who owed much also to Darwin, to the social Darwinist Herbert Spencer, and to contemporary anthropology. In Gumplowicz' view, the earliest forms of group life were small hordes bound by consanguinity, which developed into matriarchies and patriarchies. He supposed the existence of a social-evolutionary process characterized by conflicts between autonomous groups and by conflicts of interest within those groups. The product of this process was the state, founded on force and maintained by power.

Gumplowicz and several other 19th-century political sociologists anticipated 20th-century concerns in political science with the significance of groups, the nature of interests, the role of parties as interest groups, and the social context within which political events occur.

Still another 19th-century writer with some precedental connection to the political science of the 20th was the Italian Vilfredo Pareto. Although he lived and wrote in both the 19th and 20th centuries, he may be counted in the earlier period because of his advocacy of the "logico-experimental" approach to sociology, which involved observation and logical inference. Pareto had no direct influence on the development of political science, but in two respects his sociology had implications for the developing discipline. First, his was a psychological sociology, and much of his concern was with the influence of beliefs, attitudes, opinions, and sentiments in shaping social life. This anticipates the 20th-century approach of many political scientists who regard psychology as the most important adjunct of the scientific study of politics. Second, Pareto thought of society as a system always tending toward equilibrium, and the conception of politics as a system was to mark much of academic political science after World War II (see below). Also to be mentioned in the context of important 19th-century sociological theories is the work of a Swedish political scientist, Rudolf Kjellen, whose systematic treatment of the state as a fusion of organic and intellectual moral elements in an ambience of geographical determinism led to a theory of politics that he termed geopolitics.

Juristic influences. In addition to sociology, another discipline with which the development of political science has been historically related is law. A close connection between the state and law was made in the 16th century in the French political philosopher Jean Bodin's theory of sovereignty, which supposed the necessary existence in each state of an authority to make the law. This theory gave rise to numerous juristic theories of the state, especially among German publicists of the 19th century who sought to define the nature of federation and empire. Although the doctrine of sovereignty made most sense as a statement of the power of monarchs to make the law in simple unitary (nonfederal) systems, earnest writers forced the facts of federation and empire to fit the theory and often ignored facts that did not. The Bodinian view invested sovereignty with attributes of singularity and omnipotence—that is, sovereignty was viewed as being indivisible and absolute—but theoretical efforts were made in Germany before 1871, notably by Georg Waitz, to establish federal theory on a division of sovereignty between the centre and the member states. After 1871, the theory of Max von Seydel, namely, that since sovereignty is indivisible, it cannot be divided and must rest in a single location—either in the constituent members of a federal system or in the centre—supplanted that of Waitz. Georg Jellinek, an Austrian, attempted to resolve the paradox that so-called sovereign states are in fact limited by constitutions and laws and by membership in the family of nations by arguing that the restrictions are autolimitations. That is to say, since by definition there is no power above the state, if in fact there are limitations it must be the state that created them. The state therefore continues to be omnipotent. In France, juristic theories of the state also persisted strongly because the teaching of political science was conducted in the law schools as "constitutional law." Efforts were made by some professors, however, to broaden the legal approach, notably by Léon Duguit, who attempted a sociological positivistic treatment of juridical rules for the limitation of the state, and Maurice Hauriou, who contributed a theory of institutions. In England the emergence of political science as a subject was recognized in the establishment of the London School of Economics and Political Science in 1895 and by the founding of a separate chair of politics at Oxford in 1912.

The doctrine of sovereignty

Developments in the United States. The enthusiastic development of social sciences in the 19th century, stimulated as it had been by the rapid growth of the natural sciences, reinforced an existing interest in politics in the United States and created a generation of distinguished American political scientists. There had, in fact, been much interest in the teaching of political subjects in American colleges and universities well before the 19th century. Political science in the United States, however, free of any connection with moral philosophy, fusion with history, or submergence in political economy, may be said to date from 1880, when John W. Burgess, after studying at the École Libre des Sciences Politiques, succeeded in establishing a separate school of political science at Columbia University. Although political-science faculties increased in numbers after 1900, the growth was uneven, and in some major institutions separate departments were not created until after World War I.

The development of American political science in the last quarter of the 19th century was influenced by the experience of numerous scholars who had done graduate work at German universities in which political science was taught as *Staatswissenschaft* ("science of the state") in an ordered, structured, and analytical organization of concepts, definitions, comparisons, and inferences. To modern readers the work of these men often seems somewhat formalistic and institutional in tone and focus. It did represent, however, an effort to establish an autonomous discipline, separate from history, moral philosophy, and political economy. Some of the new American political

scientists, such as Woodrow Wilson and Frank Goodnow, also showed in their writing an awareness of such new intellectual currents as theories of evolution and turned their attention to an examination of American institutions that, in the United States Constitution, had originally been based on the admiration of much of the 18th-century world for the harmonious perfections of mechanics. For Wilson, it was to be Darwin, not Newton, who would provide the inspiration for a transformation in American political science from the study of static institutions to the study of social facts, more truly in the positivist temper, less in the analytic tradition, and more oriented toward factual realism.

Bentley's early work on group processes

Little-noticed at the time he wrote *The Process of Government* (1908), Arthur F. Bentley was to have a celebrated influence on the development of American political science in the 1930s and the 1950s. Although his influence was not immediately felt, he sounded certain themes that became the orthodoxy of the new science of politics after World War II. First, he rejected all metaphysics and normative formulations as "spooks" and "mind-stuff" and insisted that the proper study of politics was observable fact, in imitation of the natural sciences. Second, his basic concept was the "group," rejecting thereby all previous formulations of the subject matter of political science that centred on the "state." Third, the "raw material of government," he thought, was the activity of men and the processes through which this activity flowed in legislation, administration, and adjudication. Behaviour and process were to become the focus of much of the interest in political science in the 1950s, after Bentley's single work on politics was given new currency just before the outbreak of World War II. He was considerably before his time in presaging the end of preoccupation with institutional and descriptive analysis. He acknowledged the leadership of Gumplowicz, who, in his view, had "taken the most important step toward bringing out clearly the nature of the group process," discarding the "individual as a causal factor in society," and insisting "that all social movements are brought about by group interaction."

Although the effort of Bentley to develop an objective, value-free analysis of politics had no initial consequence, other movements toward this goal were more immediately successful. The principal impetus was provided by what became known as the Chicago school in the mid-1920s and thereafter. The leading figure in this movement was Charles E. Merriam, who in 1925 published *New Aspects of Politics*, a book that argued for a reconstruction of method in political analysis, urged the greater use of statistics in the aid of empirical observation and measurement, and postulated that out of the converging interests of politics, medicine, psychiatry, and psychology might come "intelligent social control." The basic political datum for Merriam at this stage of his thinking was "attitude"; hence his reliance upon the insights of psychology for a better understanding of politics. These ideas were not entirely new, since Graham Wallas, an Englishman, had said in *Human Nature in Politics* (1908) that a new political science should be based upon quantitative methods and that serious attention should be given to the psychological elements ("human nature") in political activity, including nonrational acts and the exploitation in political life of subconscious nonrational inferences. The American political scientist and journalist Walter Lippmann had expressed much the same view in *Public Opinion* (1922). One of those in the Chicago group who carried the connection between politics and psychology quite far was Harold Lasswell, in his *Psychopathology and Politics* (1930). In *Power and Personality* (1948) he fused the Freudian categories of the earlier work with subsequent writings on power.

Influential works of Merriam and Lasswell

These two leading expositors of the Chicago school, Merriam and Lasswell, both published books at about the same time that gave a central place to the phenomenon of power in the empirical study of politics. Merriam published *Political Power* in 1934 and Lasswell *Politics: Who Gets What, When, How* in 1936. Merriam undertook to show how power came into being, to describe what he called the credenda, miranda, and agenda of authority (which he tended to equate with power), the techniques of power holders, the defenses available to those over whom power is wielded, and the dissipation of power. Lasswell's 1936 work was a naturalistic description of "influence and the influential." Although both were cast in the empirical mode, the second was more successful in this regard than the first, which tended to be abstract and rhetorical. A truly empirical work of the Chicago school that had considerable significance in the development of academic political science was Charles E. Merriam and Harold F. Gosnell's work, published in 1924, on *Non-Voting, Causes and Methods of Control*, which used sampling methods and survey data. Since then, certainly one of the most successful achievements in empirical political science has been the study of voter behaviour and election results. Although members of the Chicago school insistently professed an interest in value-free political science, they were characterized by two normative predilections—their acceptance of the values of the democratic system and their earnest attempts to improve it through their writings.

By 1945 political science in the United States was much more than the concern for institutions, law, formal structures of public government, procedures, and rules that it had earlier been. There was by then also a considerable body of writing on processes—on the dynamics as well as the statics of public governance. There were works on pressure groups and lobbies, on the "invisible government" operating behind public authority, on actual bureaucratic processes as distinguished from the rules of administrative procedure, on bosses and political parties, and on ethnic influences in the behaviour of the electorate. All of these works signified a turning away from formality and the development of a growing interest in the factual realities of political behaviour.

Developments in Europe. Outside the United States the development of political science was less quantitative and behavioural. In France the main tradition in the study of political institutions was still legal rather than sociological. Constitutional law and history were abundant, and politics in the main was viewed from legal perspectives, though not entirely so. As early as 1913 one writer, André Siegfried, had introduced the geographical and historical study of elections in *Tableau politique de la France de l'Ouest sous la troisième République*, and the development of French sociology in the works of Émile Durkheim and others had applications in political science.

In England, although there was little development of a quantitative science of politics, a substantial contribution was made toward the formulation of political philosophies that centred attention upon the group basis of politics. Particularly notable were the works of J.N. Figgis, G.D.H. Cole, Ernest Barker, and Harold Laski. In Sweden, Herbert Tingsten in his work *Political Behaviour: Studies in Election Statistics* (1937) gave currency in the title to what was to be the main development in political science after World War II.

CONTEMPORARY POLITICAL SCIENCE

Behavioralism. In American political science since the end of World War II, the behavioral persuasion has been the dominant one. A former president of the American Political Science Association has attributed the rapid development of the behavioral approach to six causes: the inspiration of the Chicago school; the immigration to the United States in the 1930s of large numbers of European scholars (particularly Germans) with backgrounds in European sociology, who stressed the relevance of sociology to politics; the movement of many political scientists into administrative and political positions during World War II; the influence of foundation support in the encouragement of research in political behaviour; the increasing development of the survey method in certain political studies, such as voter behaviour; and the missionary work of the Social Science Research Council under leadership sympathetic to behavioralism.

Etiology of the behavioral approach

Although the term behavioralism has been freely used in political-science writings, there is in fact confusion as to

whether it is a field of study, a method, or an approach. One American political scientist, Heinz Eulau, in *The Behavioral Persuasion in Politics* (1963), has said that the behavioral persuasion "is concerned with what man does politically and the meanings he attaches to his behavior," and he has suggested that researchers cannot afford to get tangled up in problems of definition. Another American, Robert Dahl, has said that it is a mood or even "the scientific outlook." The term behavioral, then, may be merely a term having distinctiveness, weight, and value for a certain time only, since it seems primarily to signify that phase in the quarter century after World War II during which there was a significant revival of interest in empirical studies in politics, a movement strong enough to establish at least a partnership with the traditional approaches, although some of its advocates have gone so far as to say that their science has made traditional approaches outdated.

Systems analysis. Contemporary political science does not display as much coherence as earlier modes of inquiry (coherence was one of their principal virtues), but it does exhibit a refreshing complexity, of both concept and method. Although much effort has been spent on the production of empirically derived evidence in a scatter of fields and a diffusion of subjects and although critics have scoffed at studies that they have said only prove the obvious, the product of 25 years of behavioralism has been voluminous and often stimulating in quality. Common in this output is the assumption that politics is process, the ceaseless interaction of individuals and groups on each other in a flow of activities in and around public governance. The most commanding concept devised to fit this flow with form has been the concept of the system. In this view the focus of political science is not the individual in solitude nor the multitude nor even the group. The American political scientist David Easton's *The Political System* (1953), a seminal work in empirical political theory, conceived of the political system as part of the total social system. For Easton the political system comprised all those activities having to do with the formulation and execution of social policy; that is, "policy-making process." The identifying criterion of political behaviour for Easton was the "authoritative allocation of values" for the society, by which he distinguished his sense of the subject matter of political science from that of Lasswell, who had argued that political science was concerned with the distribution and content of patterns of value throughout the society. In this conception of system, which is not unrelated to the conception of system in physics and biology, linkages are found between the system and its environment. Inputs (demands) flow into the system and are converted into the outputs (decisions and actions) that constitute the authoritative allocation of values for the society; that is, the distribution of rewards in wealth, power, and status that the system may provide.

Variants of systems theory

There are various versions of systems theory, although all suppose the existence of the system and more or less consciously pattern it after systems models in other disciplines. There has thus been developed a view of systems, based upon engineering models and ideas, that rejects the view of Easton that there can be a general theory of political systems. Another theorist, drawing on cybernetics, has viewed the political system as a communications net. Although expositors of systems concepts generally suppose they are working with scientific theory, critics have said that they are merely creating new taxonomies. What is certain is that systems theory has introduced new and—to more traditional scholars in the field—unusual terms into the vocabulary of politics. Thus, instead of such terms as the state and sovereignty, the new idiom speaks of systems, inputs and outputs, feedbacks, circular loops, networks, legitimacy symbols, information storage and retrieval, political socialization, interest articulation and aggregation, cluster blocs, zero-sum games, macropolitics and micropolitics, and much else drawn from the concepts and languages of other sciences and from statistics, with hopeful assertions about the possibility of making politics predictable.

Although decision making as a research field in political science may be analytically regarded as part of the process by which inputs are converted into outputs in systems theory, it also has an origin independent of systems theory. Interest in game theory provided a stimulant to studies of decision making, which already had an established place in the lore and lexicon of politics and administration. In decision theory the paradigm is the rational actor, and the research problem is the ascertainment of the most efficient means to effect given goals, which may or may not be rational. Investigators into decision making are generally less concerned with the system as a whole than with the activity that they regard as the most important part of it, namely, the way in which decisions are or should be made according to rational calculation. A body of writing on decision making by judges has earned a sub-classification as "jurimetrics."

Interest groups, elites, and political parties. Studies of interest groups, elites, and political parties also have their own independent origins, although they, too, have been brought within the framework of systems analysis. Interest groups and political parties, for example, have been described as agencies for the articulation and aggregation of interests, which in turn provide inputs (demands) for the political system to convert into outputs (decisions and actions). But interest-group analysis antedates the advent of behavioralism. The modern concern for the subject starts perhaps with studies of prohibition and other pressure groups during the 1920s. More generalized and theoretical treatments of interest groups and political parties resulted in part from a revived interest in the work of Bentley in the 1930s and 1950s. The study of elites was begun at least as early as 1936 (Lasswell's "influentials"), and it came to the forefront in the 1950s in community studies made by political scientists in Atlanta, Chicago, New York, New Haven, and elsewhere. Such studies had long been familiar in sociology, but they acquired special significance in political science, because democratic values seemed threatened by the possible existence of elites. Despite declarations of their concern to establish a value-free science, American political scientists have thus tended to cleave to the traditional democratic ethic, in which elites are presumed to have no place.

Analysis of political attitudes and voting behaviour. What some have called the behavioral revolution had its greatest successes in the analysis of public opinion, political attitudes, and electoral behaviour. Especially in the period after World War II, the refinement of statistical techniques in public-opinion polling, the analysis of voter behaviour, and the development of new research concepts have brought the study of opinions and attitudes closest to the goal of the scientific outlook and some considerable distance from the mark made by Merriam in the 1920s. The Survey Research Center at the University of Michigan has become an important national centre for the collection of data on elections and voter behaviour.

CURRENT TRENDS

The effort to establish a value-free, objective political science in the United States in the two decades after World War II has won what is doubtless a permanent place for the scientific study of politics, but it it has also bred a critical reaction. In the late 1960s opponents of "scientism" rejected what they felt was the increasing subjection of spontaneity and human values to determinisms in every aspect of life and argued that political science was an example of the pervasiveness of technology and of a search for rationality in a social complex that might be irrational and out of control. Although political science had developed skillful and sensitive techniques for the quantification of data termed political, there is no orthodoxy on the scope of political science nor on the delimitation of separate areas of research. Quite different outcomes emerge from the basic assumptions as to the focus of the discipline, whether it be power, government, system, process, decision making, or policy formulation. The failure of the discipline to settle the question of identity has made for a creative and inventive exploration of many avenues of research, but the achieve-

Reactions against "scientism"

ment of a unified general theory of political behaviour on which there is common consent still lies ahead.

Even outside the United States, non-normative political science is not extensive, although it is not unknown. England has made many creative contributions to political theory and law throughout its history, as have other European countries, but it has also produced substantial works that can be classified as positive (*i.e.*, non-normative) political science. Among these are the studies of R.T. McKenzie and D.E. Butler in the field of political parties, voter behaviour, and pressure groups, S.E. Finer on interest groups, and U.W. Kitzinger on German elections. Notable work has been done in France in the field of political parties by Maurice Duverger and François Goguel. Work has also been done on the political socialization of children in French schools by Charles Roig and François Billon-Grand. In Denmark, beginnings were made in the systematic study of political science in 1959 with the founding of the Institute of Governmental Studies at the University of Århus. In Finland the first extensive studies on voting behaviour appeared in 1956.

In Japan there was a flowering of social sciences after World War II, but political science at first did not grow at the same pace as other social sciences because of lack of agreement about both subject matter and method, a difficulty felt from the beginning by the man recognized to be the founder of Japanese academic political science, Onozuka Kiheiji, who published *Principles of Political Science* in 1903. With the opening of the behaviour of public officials and institutions to scientific scrutiny, however, there has been much political inquiry that would qualify as political science, including, for example, systems analysis and works on political culture, political development, and process and behaviour.

Political science in Communist countries

Although in the past the objective study of political subjects by researchers in Communist regimes has been difficult, if not impossible, a somewhat more permissive policy in some countries has led to what may be the beginnings of scholarly political science. The most advanced political science is to be found in Poland and Yugoslavia, and Romania and Czechoslovakia have come to recognize political science as a discipline. The Soviet Union does not yet sanction political science, but scholars do conduct empirical research, which was endorsed in 1962 by the U.S.S.R. Academy of Sciences under the term "concrete sociological investigations." The greatest movement has been in the conduct of public-opinion polls using advanced Western techniques. Interest in the development of political science was evidenced in the publication in 1969 of *Politicheskaya nauka v SShA: Kritika burzhuaznykh Kontseptsy vlasti* ("Political Science in the U.S.A.: A Critique of Bourgeois Conceptions of Power"), by V.G. Kalensky. Although there is no officially sanctioned political science, there is a Soviet Association of Political Sciences, which has sent delegates to the meeting of the International Political Science Association. Despite its title, the Soviet Association of Political Sciences is most heavily oriented toward the state and the law, and its members have been critical of what they regard as the anti-Marxist bias of bourgeois political science. One of its members, however, F.M. Burlatsky, published a major article in *Pravda* in 1965 calling for the establishment of a genuine political science in which the findings would emerge from the data.

In Yugoslavia a political-science association was established in 1951, and in 1962 a faculty of the political sciences was established at the University of Zagreb. In Czechoslovakia a political-science association was formed in 1965 and became a member of the International Political Science Association; and in 1968 a political-science association was formed in Romania. Political science in Yugoslavia has tended to centre on traditional divisions of the discipline, such as political theory, comparative government, and international relations. In Poland, political science has centred on the study of political behaviour, on community power structures, on voter behaviour, and on public opinion. Techniques of considerable sophistication have been employed.

Political science is one of the means by which people seek to understand the human condition and man's fate. Or, as Aristotle believed, politics is the most important of human activities, and the sovereign science. For 24 centuries, at least, the greatest intellects and scholars have striven to state the universal elements of just order in human affairs. None has succeeded in this, so far, hopeless ambition, although most have contributed some special insight and added to the common wisdom. The effort to achieve magisterial comprehension will doubtless continue; and the search will change direction as experience requires, with the aid that new perceptions, concepts, and methods will provide. Progress toward establishing general laws, however, may never be as steady or as swift in political science as it has been in laboratory sciences like physics; for, as Albert Einstein once said, politics is more difficult than physics.

BIBLIOGRAPHY. Although works of classical political philosophy are both venerable and extensive, few of them qualify as modern political science because they are neither quantitative nor, in most respects, even empirical in tone and temper. ARISTOTLE'S *Politics* and MACHIAVELLI'S *The Prince* come closest to meeting empirical standards because the first is based in part on the study of numerous constitutions in the Attic world and the second has the reputation of having divorced politics and ethics, although it was in fact written to achieve normative ends. AUGUSTE COMTE, *Cours de philosophie positive*, 6 vol. (1830–42; Eng. trans., *The Positive Philosophy of Auguste Comte*, 2 vol., 1853), and *Système de politique positive*, 4 vol. (1851–54; Eng. trans., *System of Positive Polity*, 4 vol., 1875–77), are seminal statements in the 19th century on a science of society. LUDWIG GUMPLOWICZ, *Grundriss der Sociologie* (1885; Eng. trans., *The Outlines of Sociology*, 1899; 2nd ed., 1963); and GUSTAV RATZENHOFER in *Wesen und Zweck der Politik*, 3 vol. (1893), argue the case for the primacy of groups in studies of the state. A useful summary statement of the sociologies of the 19th century is NICHOLAS S. TIMASHEFF, *Sociological Theory: Its Nature and Growth*, 3rd ed. (1967). A good general work on the efforts of German jurists in the 19th century to cope with the facts of federalism is RUPERT EMERSON, *State and Sovereignty in Modern Germany* (1928). Among Americans who either studied in Germany in the 19th century or showed the influence of new European thought in their work were THEODORE D. WOOLSEY, *Political Science; or, The State Theoretically and Practically Considered*, 2 vol. (1877); JOHN W. BURGESS, *Political Science and Comparative Constitutional Law* (1891); WOODROW WILSON, *The State: Elements of Historical and Practical Politics* (1889), and *Congressional Government* (1885, reprinted 1961); and FRANK J. GOODNOW, *Politics and Administration: A Study in Government* (1900, reprinted 1967). An Englishman of the same period who brought a realistic inspiration to the study of American institutions was JAMES BRYCE, *The American Commonwealth*, 3 vol. (1888; abridged ed., 1959). An excellent statement of the content of political-science teaching in American colleges and universities, and spanning almost three centuries, is ANNA HADDOW, *Political Science in American Colleges and Universities, 1636–1900* (1939, reprinted 1969). The most notable precursor of the behavioural approach in the 20th century was ARTHUR F. BENTLEY, *The Process of Government: A Study of Social Pressures* (1908, reprinted 1949). Others were GRAHAM WALLAS, *Human Nature in Politics*, 4th ed. (1962); and WALTER LIPPMANN, *Public Opinion* (1922; paperback edition, 1965). Besides works of the Chicago School mentioned in the article, the following may be noted: CHARLES E. MERRIAM, *Chicago: A More Intimate View of Urban Politics* (1929, reprinted 1970), an early contribution to the realistic study of urban government; LEONARD D. WHITE, *The Prestige Value of Public Employment in Chicago* (1929), a study in popular attitudes; and HAROLD D. LASSWELL and DANIEL LERNER (eds.), *The Policy Sciences: Recent Developments in Scope and Method* (1951), an effort to bring scientific method to the study of choices in public policy. Support for the establishment of a value-free non-normative science of politics was also provided by other writers such as STUART A. RICE, *Quantitative Methods in Politics* (1928, reprinted 1969), which may be considered the first general work on the application of statistical methods to the study of politics; GEORGE E.G. CATLIN, *The Science and Method of Politics* (1927), who thought it possible to state laws of politics; and WILLIAM BENNETT MUNRO, *Invisible Government* (1928), who also thought it possible to state laws of politics and urged disassociation from the sociologists and imitation of the natural scientists. A useful summary survey of political science around the world after the end of World War II is *Contemporary Political Science*, published

in 1950 by the UNITED NATIONS EDUCATIONAL, SCIENTIFIC, AND CULTURAL ORGANIZATION. The revival of an interest in Bentley that occurred in the 1930s and 1950s is exemplified by the restatement of his views in DAVID B. TRUMAN, *The Governmental Process: Political Interests and Public Opinion* (1951); EARL LATHAM, *The Group Basis of Politics: A Study in Basing-Point Legislation* (1952); and JACK W. PELTASON, *Federal Courts in the Political Process* (1955). A community study using reputational methods that seemed to validate the existence of local elites was FLOYD HUNTER, *Community Power Structure: A Study of Decision Makers* (1953). Community studies using decisional techniques that seemed to validate the existence of pluralized powers in local decision-making were ROBERT A. DAHL, *Who Governs? Democracy and Power in an American City* (1961); and WALLACE S. SAYRE, and HERBERT KAUFMAN, *Governing New York City: Politics in the Metropolis* (1960). In systems theory and its applications, besides the works of Easton and Deutsch, there is GABRIEL A. ALMOND and JAMES S. COLEMAN (eds.), *The Politics of the Developing Areas* (1960), in which the research technique is structural-functional analysis. The study of voting behaviour was advanced by the refinement of survey techniques in PAUL F. LAZARSFELD, BERNARD BERELSON, and HAZEL GAUDET, *The People's Choice: How the Voter Makes Up His Mind in a Presidential Campaign* (1944); and by ANGUS CAMPBELL, GERALD GURIN, and WARREN E. MILLER, *The Voter Decides* (1954). An exemplary work on the operation of political parties and factionalism in V.O. KEY and HEARD ALEXANDER, *Southern Politics in State and Nation* (1949). Trenchant criticisms of behavioralism are those of BERNARD CRICK, *The American Science of Politics* (1959); and HERBERT J. STORING (ed.), *Essays on the Scientific Study of Politics* (1962).

(Ea.L.)

Political Systems

The term political system may be used either narrowly or broadly. Narrowly defined, it is the set of formal legal institutions that comprise a "government" or a "state." This is the definition adopted by many studies of the legal or constitutional arrangements of advanced political orders. More broadly defined, it comprehends actual as well as prescribed forms of political behaviour, not only the legal organization of the state but also the realities of political life. Still more broadly defined, the political system is seen as a set of "processes of interaction" or as a subsystem of the social system interacting with other non-political subsystems, such as the economic system. This usage guides attention to the importance of informal sociopolitical processes and emphasizes the study of political development.

None of these approaches may be neglected. Traditional legal or constitutional analysis, using the first definition, has produced a huge body of literature on governmental structures, many of the specialized terms that are a part of the traditional vocabulary of political science, and several classifying schemes that are still instructive. Similarly, empirical analysis of political processes and the effort to identify the underlying realities of governmental forms have yielded a rich store of data and an important body of comparative theory. The third definition has inspired much recent scholarly work, particularly on non-Western states, that employs new kinds of data, new terms, and some new concepts and categories of analysis. The discussion that follows will draw upon all three approaches to the study of political systems.

The article is divided into the following sections:

I. Forms of government
  Supranational political systems
  National political systems
  Subnational political systems
  Types and models
  Development and change
II. The structure of government
  Contemporary forms of government
  The levels of government
  The divisions of government
III. The functions of government
  The indispensable functions of government
  The supervisory functions of government
  The regulatory functions of government
  The enterprising functions of government
  Public administration
IV. Development and change in political systems
  Stability and instability
  The problem of political change
V. The study of political systems
  Contemporary political science
  Future approaches to the study of political systems

I. Forms of government

The most important type of political system in the modern world is the nation-state. The world today is divided territorially into more than 100 states, in each of which a national government claims to exercise sovereignty—or the power of final authority—and seeks to compel obedience to its will by its citizens. This fact of the world's political organization suggests the distinction employed in the following section among supranational, national, and subnational political systems.

SUPRANATIONAL POLITICAL SYSTEMS

A principal result of the division of the world into a number of separate national entities, or states, that have contact with one another, share goals or needs, and face common threats is the formation of supranational relationships. In some cases, as in many alliances, these relationships are short-lived and fail to result in significant institutional development. In other cases, they lead to interstate organizations and supranational systems. The discussion below examines several types of supranational political systems, together with historical and contemporary examples of each.

Empires. All empires, since they are composed of peoples of different cultures and ethnic backgrounds, are ultimately held together by coercion and the threat of forcible reconquest. Imposing their rule on diverse political structures, they are characterized by the centralization of power and the absence of effective representation of their component parts. Although force is thus the primary instrument of imperial rule, it is also true that history records many cases of multi-ethnic empires that were governed peaceably for considerable periods and were often quite successful in maintaining order within their boundaries. The history of the ancient world is the history of great empires—Egypt, China, Persia, and imperial Rome—whose autocratic regimes provided relatively stable government for many subject peoples in immense territories over many centuries. Based on military force and religious belief, the ancient despotisms were legitimized also by their achievements in building great bureaucratic and legal structures, in developing vast irrigation and road systems, and in providing the conditions for the support of high civilizations. Enhancing and transcending all other political structures in their sphere, they could claim to function as effective schemes of universal order.

Ancient and modern empires

In contrast to the empires of the ancient world, the colonial empires of recent times fell far short of universal status. In part, these modern European empires were made up of "colonies" in the original Greek sense; peopled by immigrants from the mother country, the colonies usually established political structures similar to those of the metropolitan centre and were often able to exercise a substantial measure of self-government. In part, also, the European empires were composed of territories inhabited by native populations and administered by imperial bureaucracies. The government of these territories was generally more coercive than in the European colonies and more concerned with protection and supervision of the commercial, industrial, and other exploitative interests of the imperial power. The disintegration of these empires occurred with astonishing speed. The two world wars of the 20th century sapped the power of the metropolitan centres, while their own doctrines of democracy, equality, and self-determination undermined the principle of imperial rule. Powers such as Britain and France found it increasingly difficult to resist claims to independence couched in terms of the representative concepts on which their home governments were based, and they lacked the military and economic strength to continue their rule over restive native populations. In the two decades after 1945 nearly all the major colonial territo-

ries won their independence; the great colonial empires that had once ruled more than half the world were finally dismembered.

Leagues. One of the commonest forms of supranational organization in history is that of leagues, generally composed of states seeking to resist some common military or economic threat by combining their forces. This was the case with the early city leagues, such as the Achaean and Aetolian leagues in ancient Greece and the Hanseatic and the Swabian leagues in Europe; and to a great extent it was the case with the League of Nations. Other common features of leagues include the existence of some form of charter or agreement among the member states, an assembly of representatives of the constituent members, an executive organ for the implementation of the decisions of the assembly of representatives, and an arbitral or judicial body for adjudicating disputes.

The League of Nations

The League of Nations was one of the great experiments in supranational organization of the 20th century and the predecessor in several important respects of the United Nations. The Covenant of the League was drafted by a special commission of the Peace Conference after World War I, with Pres. Woodrow Wilson of the United States as its leading advocate, and approved by a plenary conference of the victorious powers in 1919. The initial membership of the League consisted of 20 states. The United States failed to take membership in the League, but by 1928 the organization had a total membership of 54. The machinery of the League consisted of an Assembly of all the member nations, acting through agents of their governments; a council on which the great powers were permanently represented and to which the other member powers were elected by the Assembly for three-year terms; a Secretariat to administer the internal affairs of the League; and a number of specialized agencies, such as the International Labour Organisation, that were responsible for implementing various economic and humanitarian programs on an international basis. The Covenant required that international disputes be submitted to peaceful settlement with a provision for adjudication or arbitration by the Permanent Court of International Justice or for intervention by the Council of the League. The Covenant also provided for the use of financial and economic penalties, such as embargoes, to enforce the decisions of the League and for joint military action against convicted aggressors. In practice, however, the League failed its most important tests and was unable to master the crises that led to World War II and its own collapse.

Confederations. Confederations are voluntary associations of independent states that, to secure some common purpose, agree to certain limitations on their freedom of action and establish some joint machinery of consultation or deliberation. The limitations on the freedom of action of the member states may be as trivial as an acknowledgement of their duty to consult with each other before taking some independent action or as significant as the obligation to be bound by majority decisions of the member states. Confederations usually fail to provide for an effective executive authority and lack viable central governments; their member states typically retain their separate military establishments and separate diplomatic representation; and members are generally accorded equal status with an acknowledged right of secession from the confederation. Historically, confederations have often proved to be a first or second step toward the establishment of a national state, usually as a federal union. Thus, the federal union of modern Switzerland was preceded by a confederation of the Swiss cantons; West Germany's modern federal arrangements may be traced to the German Confederation of the 19th century (the Deutsche Bund); and the federal constitution of the United States is the successor to the government of the Articles of Confederation. In some other cases confederations have replaced more centralized arrangements, as, for example, when empires disintegrate and are replaced by voluntary associations of their former colonies. The British Commonwealth, or Commonwealth of Nations, and the French Community are cases of this type.

The Articles of Confederation

An example of confederal arrangements that gave birth to a federal union is the Articles of Confederation (1781–89) that preceded the Constitution of the United States. The Articles established a Congress of the confederation as a unicameral assembly of ambassadors from the 13 states, each possessing a single vote. The Congress was authorized to appoint an executive committee of states

> to execute, in the recess of Congress, such of the powers of Congress as the United States, in Congress assembled, by the consent of nine States, shall from time to time think expedient to vest them with;

in turn, the committee of states could appoint a presiding officer or president for a term of one year. The Congress could also appoint such other committees and "civil officers as may be necessary for managing the general affairs of the United States," and was given the authority to serve as "the last resort or appeal in all disputes and differences, now subsisting or that hereafter may arise between two or more states." Although the Congress was given authority in important areas such as the regulation of foreign affairs, the establishment of coinage and weights and measures, the appointment of officers in the confederation's land and naval forces, and the issuance of bills of credit, all its powers were in fact dependent for their enforcement upon the states. The Congress lacked both an independent source of revenue and the executive machinery to enforce its will directly upon individuals. As the language of the Articles summarized the situation,

> each State retains its sovereignty, freedom and independence, and every power, jurisdiction and right, which is not by this Confederation expressly delegated to the United States in Congress assembled.

The Commonwealth of Nations

The Commonwealth of Nations is an example of a confederation born as the result of the decentralization and eventual disintegration of an empire. A number of former British colonies and dominions, together with the United Kingdom, composed the commonwealth in 1972: Australia, Barbados, Botswana, Canada, Cyprus, Fiji, Gambia, Ghana, Guyana, India, Jamaica, Kenya, Lesotho, Malawi, Malaysia, Malta, Mauritius, Nauru, New Zealand, Nigeria, Sierra Leone, Singapore, Sri Lanka (Ceylon), Swaziland, Tanzania, Tonga, Trinidad and Tobago, Uganda, Western Samoa, and Zambia. Ireland and South Africa had seceded from the commonwealth, and Rhodesia's status was unclear after a lengthy dispute with Britain and the other member nations. All Commonwealth states recognized the Queen as the head of the commonwealth. Barbados, Canada, Jamaica, Malta, and Trinidad and Tobago were monarchies in which the Queen was represented by a governor general appointed on the recommendation of the government of the country concerned and acting in accord with its own constitutional practice; Botswana, Cyprus, Ghana, India, Kenya, Nigeria, Sri Lanka, Tanzania, and Zambia were republics; Malaysia and Lesotho had their own sovereigns; and Uganda had a prime minister who was head of state. Commonwealth governments were represented in the capitals of other commonwealth countries by high commissioners equal in status to ambassadors. The nations of the commonwealth rarely acted in concert on the international scene, and, despite fairly regular meetings of the commonwealth prime ministers, there were at times severe strains in the relations among several of the member states. The fairly general use of the English language and of English common law, together with some common symbols and remaining cultural affinities, appeared to be the major ties binding together this loose assocation of former British imperial possessions.

Federations. The term federation is used to refer to groupings of states, often on a regional basis, that establish central executive machinery to implement policies or to supervise joint activities. In some cases such groupings are motivated primarily by political or economic concerns; in others, military objectives are paramount. Examples of the former include the association of Belgium, France, The Netherlands, Italy, Luxembourg, and West Germany in what is usually referred to as the Western European Community but is actually a combination of three main structures—the European Coal and Steel

The Western European Community

Community, established in 1952; the European Economic Community (Common Market), established in 1958; and the European Atomic Energy Community (Euratom), established in 1958. The Community quickly developed executive machinery exercising significant regulatory and directive authority over the governments and private business firms of the member countries. Although each of the member governments retains a substantial measure of sovereignty, and a systematic effort by one or more of the governments to resist the authority of the Community's agencies could endanger the whole fabric of cooperative effort, the Community has developed significant supranational features. These include the staffing of executive organs with persons other than governmental representatives, the making of binding decisions on important matters by majority vote, and the capability of the Community agencies to deal directly and authoritatively with individuals and companies within the member states. For example, the high authority of the Coal and Steel Community acts by majority vote of its members, without instruction from any of the governments, to "assure the achievement of the purposes stated in the Treaty"; and in pursuing this function it involves itself deeply in the economies of each of the member nations.

The North Atlantic Treaty Organization (NATO), established in April 1949, is an example of a modern military alliance endowed with complex and permanent executive machinery, employing multilateral procedures, and involving the continuous elaboration of plans for the conduct of joint military action by its member states (Belgium, Canada, Denmark, Greece, Iceland, Italy, Luxembourg, The Netherlands, Norway, Portugal, Turkey, the United Kingdom, the United States, and West Germany; France is associated with the NATO nations for some purposes). As stated in its treaty, the purpose of NATO is to maintain the security of the North Atlantic area by exercise of the right of collective security recognized in the Charter of the United Nations. An impressive array of institutional mechanisms was established, including a secretary general and a permanent staff, a council, a network of committees, a military command structure, various study groups, and liaison staffs; and an ongoing system of collaboration in planning and joint military exercises was brought into being. With the continued development of its organization, NATO gradually added a number of economic and cultural activities to its functions until it came to possess several of the features of multipurpose supranational organization.

The present world association

The United Nations organization. A supranational political system that does not fit precisely any of the conventional classifications of such systems is the United Nations, a voluntary association of most of the world's nation-states. Its membership had grown from an original 51 states to a total of 130 in 1971, when the government of the People's Republic of China was admitted in place of the government of the Republic of China (Taiwan). Founded at a conference in San Francisco in 1945 attended by representatives of all the nations that had declared war on Germany or Japan, the purposes of the organization are declared in its Charter to be the maintenance of international peace and security, the development of friendly relations among states, and international cooperation in solving the political, economic, social, cultural, and humanitarian problems of the world. Its organizational structure consists of a Security Council of five permanent members (China, France, the Soviet Union, the United Kingdom, and the United States) and ten nonpermanent members elected for two-year terms, a General Assembly, a Secretary General and a Secretariat, an Economic and Social Council, a Trusteeship Council, and the International Court of Justice. Attached to the United Nations are a number of specialized agencies, including the Food and Agriculture Organization, the International Atomic Energy Agency, the International Civil Aviation Organization, the International Labour Organisation, the International Monetary Fund, the International Telecommunications Union, the Universal Postal Union, the United Nations Educational, Scientific and Cultural Organization, the World Health Organization, and the International Bank for Reconstruction and Development (World Bank).

Aside from the rather generally stated and decidedly elusive aims of the Charter, the member states of the United Nations cannot be said to have any common goal; they lack even the unity that a common external threat to security brings to many supranational organizations. There is also difficulty in reaching and implementing decisions. Two different formulas are employed for voting in the two principal organs, the General Assembly and the Security Council. In the General Assembly a two-thirds majority decides on important matters; but, since the Assembly's decisions are not binding and are merely recommendations, this qualified majority principle must be viewed as of little significance. Although, on the other hand, the decisions of the Security Council may be binding, a unanimous vote of all five of the permanent members joined by the votes of at least four of the nonpermanent members is required; whenever important questions of peace and security are at stake, it is rarely possible to achieve agreement among the five great powers of the council. These difficulties, which might be fatal to the survival of many supranational organizations, are not in fact totally debilitating. The United Nations continues to serve as a very important forum for international debate and negotiation, and its specialized agencies play an important role in what is sometimes referred to as "the functional approach to peace."

NATIONAL POLITICAL SYSTEMS

The nation-state defined

The term nation-state is used so commonly but defined so variously that it will be well to indicate its usage in this article with some precision and to give historical and contemporary examples of nation-states. To begin with, there is no single basis upon which such systems are established. Many states were formed at a point in time when a people sharing a common history, culture, and language discovered a sense of identity. This was true in the cases of England and France, which were the first nation-states to emerge in the modern period, and of Italy and Germany, which were established as nation-states in the 19th century. In contrast, however, other states, such as India, the Soviet Union, and Switzerland, have come into existence without a common basis in race, culture, or language. It must also be emphasized that contemporary nation-states are creations of different historical periods and of very varied circumstances. Before the close of the 19th century the effective mobilization of governmental powers on a national basis had occurred only in Europe, the United States, and Japan. It was not until the 20th century and the collapse of the Ottoman, Habsburg, French, and British empires that the world could be fully organized on a national basis. In 1920 the League of Nations recognized seven nation-states as "Great Powers" (Britain, France, the United States, Germany, Italy, Japan, and Russia) and eventually admitted more than 40 other states to membership; in 1946 the United Nations admitted 51 states to membership, but the number had grown to 130 by 1971. The nation-states in today's world include the three "superpowers," the United States, the Soviet Union, and China; the established powers of second rank, Britain, France, Japan, and West Germany; emerging powers such as India and Indochina; and a host of old and new lesser states, such as Denmark, Gambia, Switzerland, Cyprus, Belgium, Malaysia, Norway, Chile, and others.

The characteristics that qualify these variously composed and historically differing entities as nation-states and distinguish them from other forms of social and political organization amount in sum to the independent power to compel obedience from the populations within their territories. The state is, in other words, a territorial association that may range in size from the Soviet Union to Singapore, in population from China to Luxembourg, and that claims supremacy over all other associations within its boundaries. As an association, the state is peculiar in several respects: membership is compulsory for its citizens; it claims a monopoly of the use of armed force within its borders; and its officers, who are the govern-

ment of the state, claim the right to act in the name of the land and its people.

A definition of the state in terms only of its powers over its members is not wholly satisfactory, however. Although all states make a claim to supremacy within their boundaries, they differ widely in their ability to make good their claims. States are, in fact, often challenged by competing associations within their boundaries; their supremacy is often more formal than real; and they are sometimes unable to maintain their existence. Moreover, a definition in terms of power alone ignores the fact that there are great differences among states in the structures they employ for the exercise of power, in the ways they use power, and in the ends to which they turn their power. Some of these differences are explored in the discussion that follows of two general categories of nation-states: the unitary state and the federal state. Partly from administrative necessity and partly because of the pressures of territorial interests, nearly all modern states provide for some distribution of governmental authority on a territorial basis. Systems in which power is delegated from the central government to subnational units and in which the grant of power may be rescinded at the will of the central government are termed unitary systems. Systems in which a balance is established between two autonomous sets of governments, one national and the other provincial, are termed federal. In federal systems, the provincial units are usually empowered to grant and take away the authority of their own subunits in the same manner as national governments in unitary systems. Thus, although the United States is federally organized at the national level, each of the 50 states is in a unitary relationship to the cities and local governments within its own territory.

Unitary nation-states. A majority of all the world's nation-states are unitary systems, including Belgium, Bulgaria, France, Great Britain, The Netherlands, Japan, Poland, Romania, the Scandinavian countries, Spain, and many of the Latin American and African countries. There are great differences among these unitary states, however, in the institutions and procedures through which their central governments interact with their territorial subunits.

Decentralization of power in unitary states

In one type of unitary system, decentralization of power among subnational governments goes so far that in practice, although not in constitutional principle, they resemble federal arrangements. In Britain, for example, there are important elements of regional autonomy in the relationship between Northern Ireland, Wales, and Scotland and the national government in London; and the complex system of elected local governments, although in constitutional theory subject to abrogation by Parliament, is in practice a fixed and fairly formidable part of the apparatus of British government. In other unitary systems of this type, decentralization on a territorial basis is actually provided for constitutionally, and the powers of locally elected officials are prescribed in detail. Thus, the Japanese constitution specifies certain autonomous functions to be performed by local administrative authorities.

A second type of unitary system makes substantially less provision for territorial decentralization of authority and employs rather strict procedures for the central supervision of locally elected governments. The classic example of this type is France. The French administrative system is built around 95 *départements*, each headed by a *préfet*, and 322 subdivisions of the *départements*, termed *arrondissements*, each headed by a *sous-préfet*. The *préfets* and *sous-préfets* are appointed by the government in Paris to serve as agents of the central government and also as the executives of the divisional governments or councils, which are composed of elected officials. The system thus combines central supervision of local affairs through appointed officers with territorial representation through locally elected governments.

A third type of unitary system provides for only token decentralization. In such cases, the officials responsible for managing the affairs of the territorial subdivisions are appointees of the central government, and the role of locally elected officers is either minimal or nonexistent. Examples of this kind of arrangement include Germany under Adolf Hitler and also several Communist countries. The Third Reich was divided into 42 *Gaue*, each headed by a gauleiter chosen for his personal loyalty to Hitler; in eastern Europe, the people's councils or people's committees are named by the centrally organized Communist parties; their appointment is confirmed by elections in which one slate of candidates is presented.

Federal systems. In federal systems, political authority is divided between two autonomous sets of governments, one national and the other subnational, both of which operate directly upon the people. Usually a constitutional division of power is established between the national government, which exercises authority over the whole national territory, and provincial governments that exercise independent authority within their own territories. Of the eight largest countries in the world, seven—Argentina, Australia, Brazil, Canada, India, the Soviet Union, and the United States—are organized on a federal basis. Federal states also include Austria, Cameroon, Czechoslovakia, Libya, Malaysia, Mexico, Nigeria, Switzerland, Tanzania, Venezuela, West Germany, and Yugoslavia.

The governmental structures and political processes found in these federal systems show great variety. One may distinguish, first, a number of systems in which federal arrangements reflect rather clear-cut cultural divisions. A classic case of this type is Switzerland, where the people speak four different languages—German, French, Italian, and Romansh—and the federal system unites 22 historically and culturally different entities, known as cantons. The Swiss constitution of 1848, as modified in 1874, converted a confederation originally formed in the 13th century by the three forest cantons of Uri, Schwyz, and Unterwalden into the modern federal state. The principal agencies of federal government are a bicameral legislature, composed of a National Council representing the people directly and a Council of States representing the constituent members as entities; an executive branch (Bundesrat) elected by both houses of the legislature in joint session; and a supreme court that renders decisions on matters affecting cantonal and federal relations. The Soviet Union's federal arrangements, although of a markedly different kind, also reflect underlying cultural and linguistic differences among the 15 union republics. The member republics of the Union of Soviet Socialist Republics are constitutionally endowed with territorial autonomy, a "right to secession," and equal representation in the Supreme Soviet. Ethnic subdivisions within the 15 union republics are also granted territorial autonomy and direct representation in the upper chamber of the Supreme Soviet. These arrangements, however, are rather more important in Soviet constitutional theory than in practice, since, in addition to the virtual monopoly of military, economic, and social controls vested in the central government, more than half the population and territory of the Soviet Union lies within one member republic, the Russian Socialist Federated Soviet Republic.

The Swiss and Soviet systems

In other systems, federal arrangements are found in conjunction with a large measure of cultural homogeneity. The Constitution of the United States delegates certain activities that concern the whole people, such as the conduct of foreign relations and war and the regulation of interstate commerce and foreign trade to the federal government; certain other functions are shared between the federal government and the states; and the remainder are reserved to the states. Although these arrangements require two separate bodies of political officers, two judicial systems, and two systems of taxation, they also allow extensive interaction between the federal government and the states. Thus, the election of Congress and the President, the process of amending the Constitution, the levying of taxes, and innumerable other functions necessitate cooperation between the two levels of government and bring them into a tightly interlocking relationship.

SUBNATIONAL POLITICAL SYSTEMS

Although national government is the dominant form of political organization in the modern world, an extraordi-

Basic political communities

nary range of political forms exists below the national level—tribal communities, the intimate political associations of villages and towns, the governments of regions and provinces, the complex array of urban and suburban governments, and the great political and administrative systems of the cities and the metropolises. These subnational entities are, in a sense, the basic political communities—the foundation on which all national political systems are built.

Tribal communities. The typical organization of mankind in its early history was the tribe. Today, in many parts of the world, the tribal community is still a major form of human political organization. Even in advanced systems, traces can still be found of its influence. Some of the *Länder* of modern Germany, such as Bavaria, Saxony, or Westphalia, have maintained their identity since the days of the Germanic tribal settlements. In England, too, many county boundaries can be explained only by reference to the territorial divisions in the period after the end of the Roman occupation.

In many of the new states of Africa, the tribe is still the effective community and a principal vehicle of political consciousness. Most of these states are the successors to the administrative units established by colonial regimes and owe their present boundaries to the often arbitrary decisions of imperial bureaucracies or to the territorial accommodations of rival colonial powers. The result was often the splintering of the tribal communities or their aggregation in largely artificial entities. That the force of tribalism is far from exhausted is suggested by the experience of Nigeria and other new states where a resurgence of tribal rivalries has presented great obstacles to the process of nation building.

Importance of kinship in tribal societies

In its primary sense, the tribe is a community organized in terms of kinship, and its subdivisions are the intimate kindred groupings of moieties, gentes, and totem groups. Its territorial basis is rarely defined with any precision, and its institutions are typically the undifferentiated and intermittent structures of an omnifunctional social system. The leadership of the tribe is provided by the group of adult males, the lineage elders acting as tribal chiefs, the village headmen, or the shamans, or tribal magicians. These groups and individuals are the guardians of the tribal customs and of an oral tradition of law. Law is thus not made but rather invoked; its repository is the collective memory of the tribal council or chief men. This kind of customary law, sanctioned and hallowed by religious belief, nevertheless changes and develops, for each time it is declared something may be added or omitted to meet the needs of the occasion.

Rural communities. The village has traditionally been contrasted with the city: the village is the home of rural occupations and tied to the cycles of agricultural life, while the inhabitants of the city practice many trades, and its economy is founded on commerce and industry; the village is an intimate association of families, while the city is the locus of a mass population; the culture of the village is simple and traditional, while the city is the centre of the arts and sciences and of a complex cultural development. The village and the city offer even sharper contrasts as political communities. Historically, the village has been ruled by the primitive democracy of face-to-face discussion in the village council or by a headman whose decisions are supported by village elders or by other cooperative modes of government; urban government has never been such a simple matter, and monarchical, tyrannical, aristocratic, and oligarchic forms of rule have all flourished in the city. In the village, the boundaries among political, economic, religious, and other forms of action have not been as clearly drawn as in cities.

The origins and development of the apparatus of government can be seen most clearly in the simple political society of the rural community. The transformation of kin-bound societies with their informal, folk-sustained systems of sociopolitical organization into differentiated, hierarchical societies with complex political structures began with the enlargement of the rural community —an increase in its population, the diversification of its economy, or its interaction with other communities. The rudimentary organs of communal government were then elaborated, the communal functions received more specialized direction, and leadership roles were institutionalized. This was sometimes a process that led by gradual stages to the growth of cities. Elsewhere, however, as in the case of ancient Attica, the city was established as the result of a process of *synoikismos,* or the uniting of a number of tribal or village communities. This was undoubtedly the origin of Athens, and, according to its legendary history, Rome also was established as a result of the forcible unification of the tribes that dwelt on the hills surrounding the Palatine Hill.

Even in the nation-states of today's world, the contrasts between the village or the town and the city as centres of human activity are readily apparent. In the country, life is more intimate, the human contacts more informal, the structure of society more stable. In the city, the individual becomes anonymous, the contacts between people are mainly formal, and the standing of the individual or the family in society is subject to rapid change. In many contemporary systems, however, the differences in the forms of government of rural and urban communities appear to be growing less pronounced. In the United States, for example, rural institutions have been seriously weakened by the movement of large numbers of people to the city. The township meeting of New England and other forms of direct citizen participation in the affairs of the community have declined in importance and have often been displaced by more formal structures and the growth of local governmental bureaucracies.

Cities. Cities first emerged as complex forms of social and political organization in the valleys of the Euphrates and the Tigris, the Nile, the Yellow River, and the Yangtze. These early cities broke dramatically with the patterns of primitive life and the rural societies from which they sprang. Kinship as the basis of society was replaced with status determined by class and occupation; the primitive magical leaders of the tribe were displaced by temple priesthoods presiding over highly developed religious institutions and functioning as important agencies of social control; earlier systems of rule by the tribal chieftains and the simple forms of communal leadership gave way to kingships endowed with magical powers and important religious functions; and specialized functionaries in the royal courts became responsible for supervising new kinds of governmental activity. Many other developments contributed to the growing centralization of power in these city civilizations. Barter was replaced by more effective systems of exchange, and the wealth generated in commerce and the specialized city trades became both an object of taxation and an instrument of power. Class distinctions emerged as the result of a division of labour and advances in technical development. A military order and a professional soldiery were created and trained in new techniques of warfare, and a slave class provided the work force for large-scale projects of irrigation, fortification, and royal architecture. As these developments proceeded, the city was able to project its power even further into the surrounding countryside, to establish its rule over villages and other cities in its sphere, and finally to become the centre of such early empires as those of Sumeria, Egypt, China, Babylonia, Assyria, and Persia.

Organization of ancient cities

A very different form of city life emerged among the Greeks. The Greek polis also broke with the folkways of primitive society, but its political development was in striking contrast to the despotism of the Oriental city empires and their massive concentrations of power in the hands of king and priest. As the polis transcended its origins in village life, the powers of the tribal chief dwindled and passed into the hands of aristocratic families. The kingship of Homeric tradition vanished, the "kings" who remained became mere dignitaries in the religious and ceremonial life of the city, and new magistracies and other civic offices were founded. These offices became the focus of factional struggle among the aristocratic families and, later, with the weakening of aristocratic rule, the chief prizes in a contest of power between the nobility

The Greek polis

and the common citizens. Eventually, these developments issued in the characteristic form of Greek city government. A citizen body, always a much narrower group than the total population but often as numerous as the population of freeborn males, acquired power in the direction of the city government through the election of its officers and direct participation in the city councils. Although often interrupted by episodes of oligarchic or tyrannical rule and by periods of civic dissension and class rivalry, the main theme of governmental development in the Greek city was the elaboration of structures that permitted the control of political affairs by its citizens.

The medieval city

Autonomous cities also sprang up in Europe in the later Middle Ages. Medieval city life, although it differed from that of the polis and was coloured by the forms of feudal society, also emphasized the principle of cooperative association. Indeed, for the first time in the history of city civilization, the majority of the inhabitants of the city were free. The development of trades, the growth of commerce, and the mobilization of wealth emancipated the city from its feudal environment, and the merchant and craft guilds became the matrices of a new kind of city democracy. In time, the guilds were transformed into closed corporations and became a basis for oligarchic control; and the city's independence was threatened by the rise of the new nation-states. Tempting targets for the ambition of kings, Venice, Genoa, Florence, Milan, Cologne, Amsterdam, Hamburg, and other free cities of Europe eventually succumbed to monarchical control. Theirs was an important legacy, however, for the political order of the medieval city was a powerful influence in the development of the constitutional structures of the modern democratic state.

Modern cities

Although cities are no longer independent, the almost universal increase in urban population has made them more important than ever before as centres of human activity. The political organization of modern cities differs from country to country. Even within the same nation-state, there are often important contrasts in the structures of city government. In the United States, for example, three principal types of city government are usually distinguished: the council–manager form, the mayor–council form, and the commission form.

More than half of all American cities with populations of between 25,000 and 250,000 operate under council–manager governments. In council–manager systems the council is generally small, elected at large on a nonpartisan ballot for overlapping four-year terms; no other offices are directly elected, and the mayor, who presides at council meetings and performs mainly ceremonial functions, is chosen by the council from among its members. The manager, a professional city administrator, is selected by the council, serves at the council's pleasure, and is responsible for supervising the city departments and municipal programs, preparing the budget, and controlling expenditures.

Mayor–council governments are found in two basic forms, the "weak" mayor and the "strong" mayor. The former was typical of the 19th-century municipal organization and is now mainly confined to cities of less than 25,000 population; the latter is a common arrangement in cities with populations of more than 5,000,000. In weak-mayor–council governments, a number of officials, elected or appointed for lengthy terms, wield important administrative powers; the council, typically elected by divisions of the city called wards, is responsible for the direction of the major city agencies; and the mayor's powers of appointment and removal and his control over the city budget are severely limited. In many cases, strong-mayor–council governments evolved from weak-mayor–council systems as an independently elected mayor won the power of veto over council ordinances, strengthened his control over appointment and removal, and established himself as the city's chief budgetary officer; at the same time, also, the elective administrative officers and the semi-autonomous appointive boards and commissions were often eliminated and the number of councilmen reduced.

The commission plan, which is now found in fewer than 200 cities of more than 10,000 population, concentrates legislative and executive powers in the hands of a small group of commissioners. The commissioners serve individually as the heads of administrative departments and choose one of their number to act as a ceremonial mayor without executive authority.

The variety in the governmental structures of American cities is paralleled in many other countries, for everywhere in the modern world the government of the city continues to challenge man's political invention. Although no longer sovereign, cities are the centres of modern civilization and, both in terms of the services demanded of them and the range and importance of the functions they exercise, the most important of contemporary subnational political systems. Moreover, it is in the cities that most of the problems of modern industrial society seem to have their focus. These problems are not only governmental but also technological, cultural, and economic. They are found in their most acute form in the great metropolitan centres and in that vast urban agglomeration known as the megalopolis. In political terms, the issue that is posed appears to be whether these huge centres of population can continue as effective communities with democratically manageable governments.

Regions. In many contemporary national political systems the forces of history and administrative necessity have joined to produce regional communities at an intermediate level between the local and the national community. In some cases—the Swiss canton, the English county, the German *Land*, and the American state—these regional communities possess their own political institutions and exercise governmental functions. In other cases, however, the territorial community is a product of ethnic, cultural, linguistic, physiographic, or economic factors and maintains its identity without the support of political structures.

Regional communities

As subnational political systems, regional communities are sometimes based in tradition, even tracing their origin to a period prior to the founding of the nation; in other cases, they are modern administrative units created by national governments for their own purposes. Examples of both types may be found in the history of regionalism in France and its complex pattern of internal territorial divisions. Before the French Revolution, France was divided into ancient provinces—Burgundy, Gascony, Brittany, Normandy, Provence, Anjou, Poitou, and others. After the Revolution, in what seems to have been an effort to discourage regional patriotism and threats of separatism, the Napoleonic government superimposed a new regional structure of *départements* on the old provincial map. More than a century and a half later, in the era of rapid communications and national economic planning, the French national government announced a regrouping of the Napoleonic *départements* into much larger Gaullist *régions*. Recognizing, perhaps, the continuing strength of the provincial attachments of Gascon, Breton, Normand, and Provençal and the survival of old regional folk cultures with their distinctive patterns of speech, the new *régions* were given boundaries similar in many cases to the traditional provincial boundaries of pre-republican France.

The history of the French regional communities is not a special case, for political, administrative, economic, and technical forces have led many other national governments to replace traditional territorial divisions with new regional units. In England, for example, the traditional structure of county governments (52 in number) was replaced by a system of administrative counties (61 plus London); and, in 1969, a royal commission proposed a further reform that would abolish 39 counties. Attempts have also been made to use older regional communities as the infrastructure for new systems of regional government. Thus, the Italian constitution provides for semi-autonomous government in five special regions—Valle d'Aosta, Sardinia, Sicily, Trentino-Alto Adige, and Friuli-Venezia Giulia—which, in different ways, are historically distinct from the rest of Italy. In yet other cases the fear of competition from regional governments or of sep-

aratist movements has led national governments to make various efforts to resist the development of regional political structures. Again, Italy provides a convenient example, for its constitution requires the establishment of 14 other autonomous regions, but Italian governments refused to implement this provision of the 1947 constitution until recently. It should be noted that the Italian republic of 1870–1922 and its Fascist successor state also made similar efforts to combat regional political development, the former by the creation of a large number of administrative provinces and the latter by establishing *corporazione* to represent occupations regardless of geographic location.

In several modern states the growth of vast conurbations and the rise of the megalopolis have prompted the development of new kinds of regional governmental structures. The Port of London Authority, the Port of New York Authority, and the San Francisco Bay Area Transit Authority are examples of regional systems designed to serve the needs of urban communities that have outgrown the boundaries of existing city governments. New regional structures have also resulted from the increased responsibility of national governments for the administration of comprehensive social and economic programs. The Tennessee Valley Authority, for example, is both a national agency and a regional government whose decisions affect the lives of the inhabitants of all the states and cities in its sphere. Other examples of new regional administrative structures include the zonal councils established in India for social and economic planning purposes, the districts of the Interstate Commerce Commission in the United States, and the governmental and economic units established in Britain to deal with the problems of industrially depressed areas.

TYPES AND MODELS

The almost infinite range of political systems has been barely suggested in this brief review. Confronted by the vast array of political forms, political scientists have attempted to classify and categorize, to develop typologies and models, or in some other way to bring analytic order to the bewildering variety of data. Many different schemes have been developed. There is, for example, the classical distinction between governments in terms of the number of rulers—government by one man (monarchy or tyranny), government by the few (aristocracy or oligarchy), and government by the many (democracy). There are schemes classifying governments in terms of their key institutions (for example, parliamentarism, cabinet government, presidentialism). There are classifications that group systems according to basic principles of political authority or the forms of legitimacy (charismatic, traditional, rational–legal, and others). Other schemes distinguish between different kinds of economic organization in the system (the laissez-faire state, the corporate state, and Socialist and Communist forms of state economic organization) or between the rule of different economic classes (feudal, bourgeois, and capitalist). And there are modern efforts to compare the functions of political systems (capabilities, conversion functions, and system maintenance and adaptation functions) and to classify them in terms of structure, function, and political culture.

Approaches to the analysis of political systems

Although none is comprehensive, each of these principles of analysis has some validity, and the classifying schemes that are based on them, although in some cases no longer relevant to modern forms of political organization, have often been a major influence on the course of political development. The most influential of such classifying schemes is undoubtedly the attempt of Plato and Aristotle to define the basic forms of government in terms of the number of power holders and their use or abuse of power. Plato held that there was a natural succession of the forms of government: an aristocracy (the ideal form of government by the few) that abuses its power develops into a timocracy (in which the rule of the best men, who value wisdom as the highest political good, is succeeded by the rule of men who are primarily concerned with honour and martial virtue), which through greed develops into an oligarchy (the perverted form of government by the few), which in turn is succeeded by a democracy (rule by the many); through excess, the democracy becomes an anarchy (a lawless government), to which a tyrant is inevitably the successor. Abuse of power in the Platonic typology is defined by the rulers' neglect or rejection of the prevailing law or custom (*nomos*); the ideal forms are thus *nomos* observing (*ennomon*), and the perverted forms are *nomos* neglecting (*paranomon*). Although disputing the character of this implacable succession of the forms of government, Aristotle also based his classification on the number of rulers and distinguished between good and bad forms of government. In his typology it was the rulers' concern for the common good that distinguished the ideal from perverted forms of government. The ideal forms in the Aristotelian scheme are monarchy, aristocracy, and polity (a term conveying some of the meaning of the modern concept of "constitutional democracy"); when perverted by the selfish abuse of power, they are transformed respectively into tyranny, oligarchy, and ochlocracy (or the mob rule of lawless democracy). The concept of the polity, a "mixed" or blended constitutional order, fascinated political theorists for another millennium. To achieve its advantages, innumerable writers from Polybius to St. Thomas Aquinas experimented with the construction of models giving to each social class the control of appropriate institutions of government.

Another very influential classifying scheme was the distinction between monarchies and republics. In the writings of Machiavelli and others, the tripartism of classical typologies was replaced by the dichotomy of princely and republican rule. Sovereignty in the monarchy or the principality is in the hands of a single ruler; in republics, sovereignty is vested in a plurality or collectivity of power holders. Reducing aristocracy and democracy to the single category of republican rule, Machiavelli also laid the basis in his analysis of the exercise of princely power for a further distinction between despotic and nondespotic forms of government. In the work of Montesquieu, for example, despotism, or the lawless exercise of power by the single ruler, is contrasted with the constitutional forms of government of the monarchy and the republic. As a result of the decline of monarchies and the rise of new totalitarian states terming themselves republics, this traditional classification is now, of course, of little more than historical interest.

The usefulness of all the traditional classifications has been undermined by the momentous changes in the political organization of the modern world. Typologies based on the number of power holders or the formal structures of the state are rendered almost meaningless by the standardization of "democratic" forms, the deceptive similarities in the constitutional claims and governmental institutions of regimes that actually differ markedly in their political practices, and the rise of new political orders in the non-Western world. A number of modern writers have attempted to overcome this difficulty by constructing classifying schemes that give primary importance to social, cultural, economic, or psychological factors. The most influential of such schemes is the Marxist typology, which classifies types of rule on the basis of economic class divisions and defines the ruling class as that which controls the means of production in the state. A monistic typology that also emphasized the importance of a ruling class was developed by an Italian theorist of the early 20th century, Gaetano Mosca. In Mosca's writings all forms of government appear as mere facades for oligarchy or the rule of a political "elite" that centres power in its own hands. Another classification, which distinguishes between "legitimate" and "revolutionary" governments, was suggested by Mosca's contemporary Guglielmo Ferrero. Using a sociopsychological approach to the relations between rulers and ruled, Ferrero held that a legitimate government is one whose citizens voluntarily accept its rule and freely give it their loyalty; in revolutionary systems, the government fears the people and is feared by them. Legitimacy and leadership are also the basis of a typology developed by the German sociologist Max We-

Modern classifying systems

ber. In Weber's scheme there are three basic types of rule: charismatic, in which the authority or legitimacy of the ruler rests upon some genuine sense of calling and in which the followers submit because of their faith or conviction in the ruler's exemplary character; traditional, in which, as in hereditary monarchy, leadership authority is historically or traditionally accepted; and rational–legal, in which leadership authority is the outgrowth of a legal order that has been effectively rationalized and where there is a prevailing belief in the legality of normative rules or commands. The Weberian typology has been elaborated by a number of recent writers who have found it particularly useful for comparing and classifying the emergent political orders of the non-Western world.

A serviceable classification of political systems must penetrate beneath formal appearances to underlying realities; these realities, however, do not consist only of the facts of social and economic organization. Important differences often exist between political systems having very similar socioeconomic structures. That is why some recent sociological classifications and schemes of analysis fail as tools of political inquiry: they cannot effectively distinguish between certain societies whose political orders are full of contrasts. The political system itself must be the primary focus of inquiry and the phenomena of politics the principal facts of investigation. Such an approach may involve many different kinds of analysis, but it must begin with an examination of the ways in which power is acquired and transferred, exercised, and controlled. This is important for comparing advanced political orders and also for drawing important distinctions between regimes in the underdeveloped areas of the world.

The acquisition and transfer of power. A key problem of all political orders is that of succession. "The king is dead; long live the king" was the answer, not always uncontested, of European hereditary monarchy to the question of who should rule after the death of the king. A second, closely related problem is in what manner and by whom a present ruler may be replaced or deprived of power. To this second question hereditary monarchy gave no definite answer, although the concept of *diffidatio,* or the severance of the bond of allegiance between king and feudal lord, was invoked more than once in the medieval period. Political systems, even those of primitive tribal societies, have approached both problems in a variety of ways. Anthropological records show that tribal chiefs or kings were sometimes selected as a result of ritual tests or the display of magical signs and proofs of divine origin, usually as determined by the tribal elders or magical leaders; in other cases, a principle of heredity, often diluted by a choice among heirs in terms of physique or warrior ability, was applied; in still other cases, the chief was elected, often from among the adult males of a select group of families. Techniques for the removal of tribal rulers were equally varied. Sometimes the ruler would be killed after a specified period or when his magical powers weakened or when his physical prowess or health failed; in other cases the chief was exposed to periodic tests of his magical powers or required to accept challenges to combat from other qualified candidates for rule; and in some cases the elders could remove him from office.

Techniques for assuring the succession are also varied in the modern world. Succession procedures range from the complex hieratic process of identifying a reincarnated Dalai Lama, which was practiced until quite recently in Tibet, to the subtle, informal procedures by which parliamentary majorities choose a successor to the office of prime minister in Britain. In fact, however, the succession practices of modern political systems appear to be of four main types: (1) heredity, (2) constitutional prescription, (3) election, and (4) force.

Hereditary succession

Although dictators still occasionally seek to establish their sons as their heirs, they usually rely on force rather than the claims of heredity to achieve their object. Apart from a few states, mostly in the Arab world, where the dynastic ruler is the effective head of the government, the hereditary principle of succession is now almost exclusively confined to the constitutional monarchies of western Europe. There is some irony in the fact that the line of succession is more securely established in these monarchies now than at any point in their earlier history: intradynastic struggle, it appears, is much less likely when kingship is mainly ceremonial. Heredity may be reinforced or modified by constitutional prescription: this was the case, for example, of the famous Act of Settlement that secured the Hanoverian succession in Britain.

Succession by constitutional prescription. A leading example of succession by constitutional prescription is the United States. Article II, Section 1, of the Constitution of the U.S. provides:

> In case of the removal of the President from office, or of his death, resignation, or inability to discharge the powers and duties of the said office, the same shall devolve on the Vice President, and the Congress may by law provide for the case of removal, death, resignation, or inability, both of the President and Vice President, declaring what officer shall then act as President, and such officer shall act accordingly, until the disability be removed, or a President shall be elected.

A constitutional amendment was ratified in 1967 elaborating these procedures to include further arrangements for dealing with the problem of presidential disability. The original language of the Constitution has been the basis for the peaceful succession of Vice Presidents John Tyler, Millard Fillmore, Andrew Johnson, Chester Arthur, Theodore Roosevelt, Calvin Coolidge, Harry S. Truman, and Lyndon Johnson. Constitutionally prescribed arrangements for assuring the succession are not always so successful, and many states whose constitutions contain very similar provisions have experienced succession crises that were resolved only by violence.

Succession by election. Election is a principle of succession also frequently combined with force. In cases of closely contested elections or where there is doubt as to the validity or proper form of the election, the result is often a disputed succession. The Great Schism in the papacy in the 14th century and the disputed succession to the elective kingship of Hungary in the 16th century are instructive examples of the failure of elective systems to assure an orderly succession. Force is also the effective basis of succession in several contemporary states in which *pro forma* confirmation by electoral majorities is given to the ruler who seizes power.

The problem of succession imposes great strains on any political order: the continuity of rule is broken, established patterns of action are interrupted, and the future suddenly becomes uncertain. This political crisis tests the character of regimes in ways that are of some importance for comparative political analysis. A number of interesting comparisons may be drawn from the study of succession practices, but perhaps the most important is the distinction between those systems in which the problem is resolved primarily by force and those systems in which heredity, constitutional prescription, or election assure a peaceful and orderly succession.

The transfer of power

Political orders are subjected to another kind of strain when the rule of their present power holders is challenged and the question arises of depriving them of authority. This is the problem of the transfer of power: whether, in what way, and by whom a present ruler may be displaced. Like succession, it is a recurrent problem in all political systems, and, as in the case of succession practices, the ways in which political systems respond to the strains involved offer important clues to their character. It is, in a sense, the fundamental political crisis, for all systems are in some way shaken, often violently, sometimes to the point of destruction, by the struggles between established rulers and their rivals.

Revolutions, which are the result of the crisis in its most extreme form, involve the overthrow not merely of the government but of the political order itself. Typically, a revolution is preceded by a series of strains within the system: challenges to the authority of the government mount, and its legitimacy is increasingly questioned; the exercise of power becomes coercive, and the challenge to rule assumes ever more violent forms; eventually, the

struggle comes to a dramatic climax in the destruction of the old order. The coup d'etat is another form of violent response to the crisis of rule, but it is distinguished from the revolution in that it involves the overthrow only of the government: the political order is not immediately affected, for the coup is managed by an individual or group within the government or within the ruling class. In some cases, however, the coup d'etat is merely a preliminary stage to revolution. Sometimes this happens when the new ruler leads a governmentally imposed revolution: this was the role played by Napoleon I, Napoleon III, Mussolini, and Hitler. At other times, coups are actually prompted by fear of revolution but succeed only in further weakening the claims to legitimacy of the existing order: this has recently been the case in some countries in the non-Western world where conservative-led coups were quickly overthrown by revolutionary movements. In addition to revolutions and coups d'etat, the crisis of rule may prompt other forms of violent political reaction, including civil war and secession, resistance movements and rebellions, guerrilla warfare and terrorism, class warfare, and peasant revolts.

Causes of the overthrow of governments

The causes of internal conflict leading to the forcible overthrow of governments are extremely varied. They include tensions created by rapid social and economic development; the rise of new social classes and the refusal of established elites to share their power; problems of the distribution of wealth and the grievances of different economic groups and interests; the rise of corrosive social and political philosophies and the estrangement of intellectuals; conflict of opinions over the ends of government; factional struggles among power holders or within the ruling class; the rise of a charismatic leader; oppressive rule that alienates powerful groups; weak rule that tolerates antigovernmental or revolutionary movements; and many different combinations of these and other social, economic, and political factors. All political systems experience some of these conditions with some frequency. Yet there are a number of modern states that have avoided internal wars and the forcible overthrow of their governments for considerable periods.

It appears that rulers in the contemporary world are generally safe from violent challenges if they possess an effective monopoly of military, economic, and political power, linked with certain important social controls; or, alternatively, if they are obliged to exercise limited powers for specified periods and are required to yield office to rivals who meet certain qualifications. The first is the definition of a modern totalitarian regime, fully and efficiently organized; the second describes the governments of several contemporary constitutional democracies. In the first case, the government secures itself by force combined with social and psychological means of preventing the formation of opposition. In the second case, alternatives to internal war are provided by the opportunities for oppositions to influence the exercise of power and ultimately to replace the government. The great achievement of constitutional democracy has been to give reasonable security to governments from forcible overthrow by compelling them to accept limitations on their power, by requiring them to forgo the use of force against rivals who agree to accept the same limitations, and by establishing well-known legal procedures through which these rivals may themselves constitute the government.

The exercise and control of power. The foregoing discussion has suggested a distinction among political systems in terms of the role played by force in the acquisition and transfer of power. The role of force is vital, also, in distinguishing among political systems in terms of the exercise and control of power. Here the contrast is essentially between "autocratic" and "nonautocratic" governments, for totalitarianism is only a recent, although very successful, species of autocracy, to which constitutionalism is the principal contemporary antithesis. Autocracy is characterized by the concentration of power in a single centre, be it an individual dictator or a group of power holders such as a committee or a party leadership. This centre relies on force to suppress opposition and to limit social developments that might eventuate in opposition. The power of the centre is not subject to effective controls or limited by genuine sanctions: it is absolute power. In contrast, nonautocratic government is characterized by the existence of several centres, each of which shares in the exercise of power. Nonautocratic rule allows the development of social forces that generate a variety of interests and opinions. It also subjects the power holders to reciprocal controls and to effective sanctions of law.

Autocracy

In appearance, autocracy may sometimes be difficult to distinguish from nonautocratic rule. Often, autocracies attempt to borrow legitimacy by adopting the language of the constitutions of nonautocratic regimes or by establishing similar institutions. It is a common practice, for example, in many modern totalitarian states to establish institutions—parliaments or assemblies, elections and parties, courts and legal codes—that differ little in appearance from the institutional structures of constitutional democracies. Similarly, the language of totalitarian constitutions is often couched in terms of the doctrines of popular rule or democracy. The difference is that in totalitarian regimes neither the institutions nor the constitutional provisions act as effective checks on the power of the single centre: they are essentially facades for the exercise of power through hierarchical procedures that subject all the officials of the state to the commands of the ruling individual or group. The underlying realities of autocratic rule are always the concentration of power in a single centre and the mobilization of force to prevent the emergence of opposition.

Totalitarianism, as already noted, is the most successful of contemporary forms of autocratic rule; it is distinguished from previous forms in its use of state power to impose an official ideology on its citizens. Nonconformity of opinion is treated as the equivalent of resistance or opposition to the government, and a formidable apparatus of compulsion, including various kinds of state police or secret police, is kept in being to enforce the orthodoxy of the proclaimed doctrines of the state. A single party, centrally directed and composed exclusively of loyal supporters of the regime, is the other typical feature of totalitarianism. The party is at once an instrument of social control, a vehicle for ideological indoctrination, and the body from which the ruling group recruits its members.

Constitutional democracy

In the modern world, constitutional democracy is the chief type of nonautocratic government. The minimal definition in institutional terms of a constitutional democracy is that it should provide for a regularized system of periodic elections with a free choice of candidates, the opportunity to organize competing political parties, adult suffrage, decisions by majority vote with protection of minority rights, an independent judiciary, constitutional safeguards for basic civil liberties, and the opportunity to change any aspect of the governmental system through agreed procedures. Two features of constitutional democracy require emphasis in contrasting it with modern totalitarian government: the constitution, or basic law, and the political party. A constitution, as the example of British constitutional democracy suggests, need not be a single written instrument; indeed, the essence of a constitution is that it formalizes a set of fundamental norms governing the political community and determining the relations between the rulers and the people and the interaction among the centres of power. In most modern constitutional democracies, however, there is a constitutional document providing for fixed limitations on the exercise of power. These provisions usually include three major elements: an assignment of certain specified state functions to different state organs or offices, the delimitation of the powers of each organ or office, and the establishment of arrangements for their cooperative interaction; a list of individual rights or liberties that are protected against the exercise of state power; and a statement of the methods by which the constitution may be amended. With these provisions a concentration of power in the hands of a single ruler is prevented, certain areas of political and social life are made immune to governmental intervention, and peaceable change in the political

order is made possible. The political party is the other chief instrument of constitutional democracy, for it is the agency through which the electorate is involved in both the exercise and transfer of power. In contrast with the centralized, autocratic direction of the totalitarian single-party organization, with its emphasis on ideological conformity and restricted membership, the political parties of constitutional democracy are decentralized, concerned with the integration of many interests and beliefs, and open to public participation. In constitutional democracies there is usually some measure of competition among two or more parties, each of which, if it cannot hope to form a future government, has some ability to influence the course of state action. The party in a constitutional democracy is at once a means of representing a mass electorate in the exercise of power and also a device for allowing the peaceful replacement of one set of power holders with another.

The distinction between autocratic and nonautocratic rule should not conceal the existence of a number of intermediate types of government that combine elements of both. In these cases, also, the best procedure for comparative purposes is to investigate the power configurations underlying the formal structures and to examine the extent to which power is concentrated in a single centre or the role that is played by force in the maintenance of the regime. It is a type of analysis that, by guiding attention to the relative weight of coercive and consensual power and the scope of individual freedom in the political order, allows comparisons between systems in terms of their most important attributes.

DEVELOPMENT AND CHANGE

The difficulties of analyzing political change

Political life is shaped by a wide variety of factors, including social and cultural conditions, economic organization, intellectual and philosophical influences, geography or climate, and historical circumstance. Recurrent attempts have been made to reduce this range of variables to analytically manageable dimensions. This is partly the motive, for example, of Marxist and other efforts to relate specific types of political systems to stages of economic development or particular kinds of socioeconomic organization. Although interesting interrelations between political and economic development have been discovered, such monistic, or single-factor, approaches are inadequate to the task of explaining political change. The problem is not only that there are many factors that should be examined but also that they are found in different combinations from one society to another. All political orders are unique as products of history and creations of the peculiar forces and conditions of their environment. A second problem that confronts comparative analysis is the difficulty of devising measures of political development. The definition of what is modern or what constitutes an advanced or developed political system has troubled many recent writers. Clearly, the older notions of development toward the goals of constitutionalism or democracy must now be seriously questioned, and to judge the maturity of a political system in terms of the extent to which it adopts any particular set of institutions or techniques of rule is an equally doubtful procedure. Another difficulty is that political change is not simply a reaction to "objective" factors such as economic forces but also the product of conscious manipulation. In explaining the growth and development of political systems it is impossible to ignore the fact that men, having considered the advantages and disadvantages of different forms of government, often decide to adopt one form rather than another. A similar problem arises from the fact that the nature of the interaction between political systems and their environment is extremely complex. For example, to treat the political system as merely the outgrowth of particular patterns of social or economic organization is to ignore the fact that changes in social and economic structures are often the product, sometimes the intended product, of governmental action.

These difficulties of analysis have prevented the emergence of any satisfactory theory to explain the processes of political change or growth. In the absence of such a theory, however, several writers have recently attempted to identify certain basic phases in the development of national political systems. For example, five major steps in the emergence of the advanced nation-states of the modern world are often distinguished: (1) unification and independence or autonomy; (2) development and differentiation of political institutions and political roles; (3) transfer of power from traditional elites; (4) further institutional and political role differentiation accompanied by the development of a number of organized social interests and growth in governmental functions; and (5) use of state power in attempts to guide or control social and economic activity, extensive exploitation of resources as the result of technological development, and full participation in the international political system.

Steps in the emergence of advanced nation-states

Other writers distinguish among "traditional," "transitional," and "modern" societies in an effort to identify differences and regularities in social, economic, cultural, and political development. The social structure of the traditional society is described as hierarchical, class bound, based on kinship, and divided into relatively few effectively organized social groupings; its economic basis is primarily agricultural, and industry and commerce are relatively undeveloped; its political institutions are those of sacred monarchy, rule by a nobility, and various forms of particularism. The social system of the transitional society is typified by the formation of new classes, especially a middle class and a proletariat, and conflict among ethnic, religious, and cultural groupings; its economic system experiences major tensions as the result of technological development, the growth of industry, urbanization, and the use of rapid communications; its political institutions are typically authoritarian, although constitutional forms also make their appearance. Modernity is seen as the age of high social mobility, equality, universal education, mass communications, increasing secularism, and sociocultural integration; in its economic system, the modern society experiences a further technological revolution, massive urbanization, and the development of a fully diversified economy; its political institutions are those of democracy and modified totalitarianism, and, in either case, a specialized bureaucracy is used to carry on the expanding functions of government.

These efforts to identify stages of "modernization" are poor substitutes for a general theory of political change, but they serve to emphasize the increasing complexity of all the structures—social, economic, and political—of the modern state. The elaboration of the institutions and procedures of modern government appears to be partly a reflection of the social and economic forces at work in the contemporary world and partly the result of efforts to control these forces through governmental action. The complex structures of advanced political orders are treated in the discussion that follows.

II. The structure of government

The study of governmental structures must be approached with great caution, for political systems having the same kind of legal arrangements and using the same type of governmental machinery often function very differently. A parliament, for example, may be an important and effective part of a political system; or it may be no more than an institutional facade of little practical significance. A constitution may provide the framework within which the political life of a state is conducted; or it may be no more than a piece of paper, its provisions bearing almost no relationship to the facts of political life. Political systems must never be classified in terms of their legal structures alone: the fact that two states have similar constitutions with similar institutional provisions and legal requirements should never, by itself, lead to the conclusion that they represent the same type of political system.

To be useful, the study of governmental structures must always proceed hand in hand with an investigation of the actual facts of the political process: the analyst must exercise the greatest care in distinguishing between form and reality and between prescription and practice. Approached in this way, an examination of the organiza-

tional arrangements that governments use for making decisions and exercising power can be a valuable tool of political inquiry.

CONTEMPORARY FORMS OF GOVERNMENT

The rapidity of change

Few states in the modern world have constitutional arrangements that are more than a century old. Indeed, the vast majority of all the world's states have constitutions written in the 20th century. This is true of states, such as Germany, Italy, and Japan, that were defeated in World War II and of other states, such as the Soviet Union, Spain, and China that have experienced civil war and revolutions in the course of the century. Great Britain and the United States are almost alone among major contemporary nation-states in possessing constitutional arrangements that predate the 20th century.

Even in Britain and the United States, the 20th century has seen much change in the governmental system. In the United States, for example, the relationship of legislature and executive at both the national and the state levels has been significantly altered by the growth of bureaucracies and the enlargement of the executive's budgetary powers. In Britain, even more far-reaching changes have occurred in the relationship between the prime minister and Parliament and in Parliament's role in supervising the executive establishment. In both countries, the appearance of the welfare state, the impact of modern technology on the economy, and international crises have resulted in major alterations in the ways in which the institutions of government function and interact.

The modern student of constitutional forms and institutional arrangements confronts an endlessly changing world. In many parts of the world, in countries as different as France, Pakistan, Argentina, Tanzania, and South Vietnam, there are continuing experiments with new constitutions. All systems, moreover, even without formal constitutional change, undergo a continual process of adjustment and mutation as their institutional arrangements respond to and reflect changes in the social order and the balance of political forces.

Decline of traditional monarchy

Contemporary monarchy. The ancient distinction among monarchies, tyrannies, oligarchies, and constitutional governments, like other traditional classifications of political systems, is no longer very descriptive of political life. A king may be a ceremonial dignitary in one of the parliamentary democracies of western Europe, or he may be an absolute ruler in one of the emerging states of North Africa, the Middle East, or Asia. In the first case his duties may be little different from those of an elected president in many republican parliamentary regimes; in the second his role may be much the same as that of countless dictators and strong men in autocratic regimes throughout the underdeveloped areas of the world.

It may be said of the reigning dynasties of modern Europe that they have survived only because they failed to retain or to acquire effective powers of government. Royal lines have been preserved only in those countries of Europe in which royal rule was severely limited prior to the 20th century or in which royal absolutism had never firmly established itself. More successful dynasties, such as the Hohenzollerns in Germany, the Habsburgs in Austria-Hungary, and the Romanovs in Russia, which continued to rule as well as to reign at the opening of the present century, have paid with the loss of their thrones. Today, in countries such as Great Britain or The Netherlands or Denmark, the monarch is the ceremonial head of state, an indispensable figure in all great official occasions and a symbol of national unity and of the authority of the state; but he is almost entirely lacking in power. Monarchy in the parliamentary democracies of modern Europe has been reduced to the status of a dignified institutional facade behind which the functioning mechanisms of government—cabinet, parliament, ministries, and parties—go about the tasks of ruling.

The 20th century has also seen the demise of most of the hereditary monarchies of the non-Western world. Thrones have toppled in Turkey, in China, in most of the Arab countries, in the principates of India, in the tribal kingdoms of Africa, and in several countries of Southeast Asia. The kings who maintain their position do so less by the claim of legitimate blood descent than by their appeal as popular leaders responsible for well-publicized programs of national economic and social reform or as national military chieftains. In a sense, these kings are less monarchs than monocrats, and their regimes are little different from several other forms of one-man rule found in the modern world.

Contemporary dictatorship. While royal rule, as legitimized by blood descent, has almost vanished as an effective principle of government in the modern world, monocracy—a term that comprehends the rule of the remaining non-Western royal absolutists, of the generals and strong men of Latin America and Asia, of the messianic leaders of postcolonial Africa, and of the totalitarian heads of Communist and Fascist states—still flourishes. Indeed, the 20th century, which has witnessed the careers of Kemal Atatürk, Benito Mussolini, Adolf Hitler, Joseph Stalin, Francisco Franco, Mao Tse-tung, Juan Perón, Tito, Gamal Abdel Nasser, Sukarno, Kwame Nkrumah, and Charles de Gaulle, could appear in history as the age of plebiscitary dictatorship.

Monocratic rule

The contemporary world provides examples of several types of monocratic or dictatorial rule. In many of the new states of Africa and Asia, for example, dictators quickly established themselves on the ruins of constitutional arrangements inherited from Western colonial powers. In some of these countries, presidents and prime ministers captured personal power by banning opposition parties and building primitive replicas of the authoritarian one-party systems of the Communist world. In other new countries the armies seized power, and military dictatorships were established. Whether as presidential dictatorships or as military dictatorships, the regimes that came into being appear to have had common roots in the social and economic problems of the new state. The constitutional systems inherited from the colonial powers proved unworkable in the absence of a strong middle class; local traditions of autocratic rule retained a powerful influence; the army, one of the few organized forces in society, was also often the only force capable of maintaining order; and a tiny intellectual class was impatient for economic progress, frustrated by the lack of opportunity, and deeply influenced by the example of authoritarianism in other countries. The dictatorships that resulted proved highly unstable, and few of the individual dictators were able to satisfy for long the demands of the different groups that supported their bids for power.

Although similar in some respects to the dictatorships of the new nations, the caudillos of 19th- and 20th-century Latin America represent a very different type of monocratic rule. In its 19th-century form, *caudillismo* was the result of the breakdown of central authority. After a brief period of constitutional rule, each of the former Spanish colonies in the Americas experienced a collapse of effective national government. A self-proclaimed leader, usually an army officer, heading a private army typically formed from the peasantry with the support of provincial landowners, established his control over one or more provinces, and then marched upon the national capital. The famous 19th-century caudillos—Antonio López de Santa Anna of Mexico or Juan Manuel de Rosas of Argentina, for example—were thus essentially provincial leaders who seized control of the national government to maintain the social and economic power of provincial groups. The 20th-century dictatorships in Latin-American countries have had different aims. The modern caudillo is less a provincial than a national leader. The Perón regime, for example, was established by nationalistic army officers committed to a program of national reform and various ideological goals. Often, too, the dictators of contemporary Latin America have allied themselves with a particular social class, attempting either to maintain the interests of established economic groupings or to press far-reaching social reforms.

Dictatorship in the technologically advanced, totalitarian regimes of modern Communism or Fascism is distinctively different from the authoritarian regimes of either Latin America or the new states of Africa and Asia. Nazi

Germany under Hitler and the Soviet Union under Stalin are the leading examples of modern totalitarian dictatorships. The crucial elements of both were the identification of the state with the single mass party and of the party with its charismatic leader, the use of an official ideology to legitimize and maintain the regime, the employment of a terroristic police force and a controlled press, and the application of all the means of modern science and technology to control the economy and individual behaviour. The two systems of dictatorship, however, may be distinguished in several ways. Fascism, in its National Socialist form, was primarily a counterrevolutionary movement that mobilized middle and lower middle class groups to pursue nationalistic and militaristic goals and whose sole principle of organization was that of obedience to the Führer. By contrast, Soviet Communism grew out of a revolutionary theory of society, pursued the goal of revolutionary overthrow of capitalist systems internationally, and employed the complex bureaucratic structures of the Communist Party as mechanisms of governmental organization.

Western constitutional democracies have provided examples of another type of contemporary dictatorship. At various points in the 20th century, during periods of domestic or foreign crisis, most constitutional regimes have conferred emergency powers on the executive, suspending constitutional guarantees of individual rights or liberties, or declaring some form of martial law. Indeed, the constitutions of some Western democracies explicitly provide for the grant of emergency powers to the executive in a time of crisis in order to protect the constitutional order. In many cases, of course, such provisions have been the instruments by which dictators have overthrown the regime. Thus, the proclamation of emergency rule was the beginning of the dictatorships of Mussolini in Italy, of Kemal Atatürk in Turkey, of Józef Piłsudski in Poland, of António de Olveira Salazar in Portugal, of Franz von Papen and Hitler in Germany, and of Engelbert Dollfuss and Kurt von Schuschnigg in Austria. In other democracies, however, constitutional arrangements have survived quite lengthy periods of crisis government. After World War II, for example, in both the United States and Britain, the use of extraordinary powers by the executive came to a halt with the end of the wartime emergency. Similarly, although the 1958 constitution of the Fifth Republic of France contained far-reaching emergency powers conferred on the president —"when the institutions of the Republic, the independence of the nation, the integrity of its territory or the fulfillment of its international obligations are threatened with immediate and grave danger, and when the regular functioning of the constitutional authority is interrupted" —their implicit threat to the constitutional order has not been realized.

Many forces at work in the 20th century appear to lend impetus to the rise of monocratic forms of rule. In nearly all political systems, the powers of chief executives have increased in response to the demanding social, economic, and military crises of the age. The complex decisions required of governments in a technological era, the perfectionist impulses of the great bureaucratic structures that have developed in all industrialized societies, and the imperatives of national survival in a nuclear world continue to add to the process of executive aggrandizement. The question for many constitutional regimes is whether the limitation and balance of power that are at the heart of constitutional government can survive the growing enlargement of executive power.

Contemporary oligarchy. In the Aristotelian classification of government there were two forms of rule by the few: aristocracy and its debased form, oligarchy. Although the term oligarchy is rarely used to refer to contemporary political systems, the phenomenon of irresponsible rule by small groups has not vanished from the world.

Small leadership groups

Many of the classical conditions of oligarchic rule were found until recently in those parts of Asia in which governing elites were recruited exclusively from a ruling caste—a hereditary social grouping set apart from the rest of society by religion, kinship, economic status, prestige, and even language. In the contemporary world, in some countries that have not experienced the full impact of industrialization, governing elites are still often recruited from a ruling class—a stratum of society that monopolizes the chief social and economic functions in the system. Such elites exercise power in the interests of their class.

The simple forms of oligarchic rule associated with pre-industrial societies are, of course rapidly disappearing. Industrialization produces new, differentiated elites that replace the small leadership groupings that once controlled social, economic, and political power in the society. The demands of industrialization compel recruitment on the basis of skill, merit, and achievement, rather than on the basis of inherited social position and wealth. New forms of oligarchic rule have also made their appearance in many advanced industrial societies. Although governing elites in these societies are no longer recruited from a single class, they are often not subjected to effective restraints on the exercise of their power. Indeed, in some circumstances, the new elites may use their power to convert themselves into a governing class whose interests are protected by every agency of the state. This is the criticism that is made, for example, of the Communist Party bureaucracy in the Soviet Union and in some eastern European states.

Oligarchic tendencies of a lesser degree have been detected in all the great bureaucratic structures of advanced political systems. The growing complexity of modern society and its government thrusts ever greater power into the hands of administrators and committees of experts. Even in constitutional regimes, no fully satisfactory answer has been found to the question of how these bureaucratic decision makers can be held accountable and their powers effectively restrained without, at the same time, jeopardizing the efficiency and rationality of the policy-making process.

Contemporary constitutional government. Constitutional government is defined by the existence of a constitution—which may be a legal instrument or merely a set of fixed norms or principles generally accepted as the fundamental law of the polity—that effectively controls the exercise of political power. The essence of constitutionalism is the control of power by its distribution among several state organs or offices in such a way that they are each subjected to reciprocal controls and forced to cooperate in formulating the will of the state. Although constitutional government in this sense flourished in England and in some other historical systems for a considerable period, it is only recently that it has been associated with forms of mass participation in politics. In England, for example, constitutional government was not harnessed to political democracy until after the Reform Act of 1832 and subsequent 19th-century extensions of the suffrage. In the contemporary world, however, constitutional governments are also generally democracies, and they are usually referred to as constitutional democracies or constitutional–democratic systems.

The contemporary political systems that combine constitutionalism and democracy share a common basis in the primacy they accord to the will of the majority of the people as expressed in free elections. In all such systems, political parties are key institutions, for they are the agencies by which majority opinion in a modern mass electorate is mobilized and expressed. Indeed, the history of the political party in its modern form is coincidental with the development of contemporary constitutional–democratic systems. In each case, the transition from the older forms of constitutionalism to modern constitutional democracy was accompanied by the institutionalization of parties and the development of techniques of party competition. The essential functions of political parties in a constitutional democracy are the integration of a multitude of interests, beliefs, and values into one or more programs or proposals for change and the nomination of party members for elective office in the government. In both functions, the party serves as a link between the rulers and the ruled: in the first case by allowing the electorate

to register an opinion on policy and in the second by giving the people a chance to choose their rulers. Of course, the centralized, autocratically directed, and ideologically orthodox one-party systems of contemporary totalitarian regimes perform neither of these functions.

The British and U.S. systems compared

The two major types of constitutional democracy in the modern world are exemplified by the United States and Great Britain. The United States is the leading example of the presidential system of constitutional democracy; Britain, although its system is sometimes referred to as a cabinet system, in recognition of the role of the Cabinet in the government, is the classic example of the parliamentary system. The U.S. presidential system is based on the doctrine of separation of powers and distinguishes sharply between the personnel, although not between the functions, of the legislature and the executive; the British parliamentary system provides for the integration or fusion of legislature and executive. In the U.S. system the separation of legislature and executive is reinforced by their separate election and by the doctrine of checks and balances that provides constitutional support for routine disagreements between the branches; in the British system the integration of legislature and executive is reinforced by the necessity for their constant agreement, or for a condition of "confidence" between the two, if the normal processes of government are to continue. In the U.S. system, reciprocal controls are provided by such devices as the presidential veto of legislation (which may be overridden by a two-thirds majority in Congress), the Senate's role in ratifying treaties and confirming executive nominations, congressional appropriation of funds, and judicial review of legislation; in the British system, the major control device is the vote of "no confidence" or the rejection of legislation that is considered vital.

The prestige of constitutional democracy was once so great that many thought all the countries of the world would eventually accede to the examples of the United States or Britain and establish similar arrangements. Recent history, however, has confounded this expectation. The collapse of the Weimar Constitution in Germany in the 1930s and the recurrent political crises of the Fourth Republic in France after World War II suggested that constitutional democracy, even in advanced systems, carries no guarantee of stability. The failure of both presidential and parliamentary systems to work as expected in less advanced countries that modelled their constitutions on those of the United States and Britain resulted in a further diminution in the prestige of both systems. Successful examples of established constitutional democracies are now limited to a dozen or so northwest European and North American countries, together with New Zealand and Australia in the Pacific. Systems in which experiments are being made in the use of constitutional-democratic arrangements with some degree of success include Mexico, Uruguay, Chile, the Philippines, India, and Malaya. In all these countries, constitutionalism and democracy have combined to produce political change under conditions of relative stability.

THE LEVELS OF GOVERNMENT

Most national societies have passed through a stage in their social and political development, usually referred to as feudalism, in which a weak and ineffectively organized national government competes for territorial jurisdiction with local power holders. In medieval England and France, for example, the crown was perennially threatened by the power of the feudal nobles, and a protracted struggle was necessary before the national domain was subjected to full royal control. Elsewhere, innumerable societies continued to experience this kind of feudal conflict between local magnates and the central government well into the modern era. The warlords of 19th- and 20th-century China, for example, were just as much the products of feudal society as the warring barons of 13th-century England and presented the same kind of challenge to the central government's claim to exercise sovereign jurisdiction over the national territory. By the 1970s, feudalism was almost extinct. The social patterns that had formerly supported the power of local landowners were rapidly disappearing, and central governments had generally acquired a near monopoly of communications and military technology, enabling them to project their power into areas once controlled by local rulers.

Feudalism

In nearly all national political systems, central governments are better equipped than ever before to exercise effective jurisdiction over their territories. In much of the underdeveloped world, nationalist political movements and a variety of modern economic forces have swept away the traditional structures of local government, and the quasi-autonomous governments of village and tribe and province have been replaced by centrally directed systems of subnational administration. Even in the heavily industrialized states of the modern world, there has been an accelerating tendency toward greater centralization of power at the national level. In the United States, for example, the structure of relationships among the governments at the national, state, and local levels has changed in a number of ways to add to the power of the federal government in Washington. Even though the system of national grants-in-aid appears to have been designed as a means of decentralizing administration, the effect has been decidedly centralist, for the conditional character of the grants has allowed the federal government to exercise influence on state policies in fields that were once invulnerable to national intervention.

The nation-state

Contemporary national government. The nation-state is the dominant type of political system in the contemporary world, and nationalism, or the creed that centres the supreme loyalty of the people upon the nation-state, is the dominating force in international politics. The national ideal triumphed as a result of the wars of the 19th and 20th centuries. The Napoleonic Wars, which spread the doctrines of the French Revolution, unleashed nationalism as a force in Europe and led to the Risorgimento in Italy and the emergence of Bismarck's Germany. The two world wars of the 20th century carried the principles of national self-determination and liberal democracy around the world and gave birth to the independence movements that resulted in the foundation of new states in eastern Europe in 1919 and the emergence from colonial status of countries in Asia and Africa after 1945.

All the major forces of world politics—war and the threat of war, the development of national economies, the demand for social services, and many others—have reinforced the national state as the primary focus of men's loyalties. Wars have played the major part in strengthening national governments and weakening political regionalism and localism. The attachments that men have to subnational political communities are loosened when they must depend for their security on the national power. Even in the new age of total war—which few nations are capable of waging and even fewer of surviving—men look for their security to national governments rather than to international organizations. In nearly all contemporary states, the national budget is dominated by expenditures for defense, the military employs the largest fraction of the work force, and questions of national security pervade the discussion of politics.

The lesson of the last three decades is that national sovereignty remains the most important obstacle to the emergence of new forms of supranational government and to effective international cooperation. Almost everywhere, attempts to achieve federation and other forms of multinational communication have foundered on the rocks of nationalism. The collapse of the Federation of Rhodesia and Nyasaland and the Federation of Malaya are paralleled by the failure of the Organization of American States and the Arab League: in all cases, nationalism has been the divisive force. National sovereignty has been successfully limited in only two major areas of the contemporary world: in eastern Europe, where, as a result of Soviet occupation, a number of formerly independent states were subjected to a form of centralized control from Moscow; and in western Europe, where several nation-states joined in a loose confederation (the European Economic Community) to achieve certain economic goals. Even in these cases, nationalism has been a major threat to continued unity. Several of the countries of

eastern Europe have recently declared their independence of Moscow, and France under President de Gaulle made clear its hostility to any form of supranational union of the countries belonging to the European Economic Community.

At the international level, anarchy is the principal form of contemporary rule, for the nation-state's freedom of action is limited only by its power. Some forces are at work, however, that may eventually lead to a lessening of the role of the nation-state and to the emergence of effective supranational governments. The first of these is industrial and commercial development. The development of national industries in the 19th and early 20th centuries played a major part in strengthening national as against regional and local political entities, but the scale of economic activity has now outgrown national markets. Industrial combines and commercial groupings have emerged that cross national frontiers and require international markets. This integrative influence of economic development may be assisted by the threat of nuclear war. Many national frontiers can no longer be adequately defended in the era of the intercontinental missile, and many states, even some that were until recently great powers, are incompetent to preserve themselves. Together these forces may assist the progress of efforts to develop new kinds of cooperative union among nation-states.

Although the failure of efforts to achieve world government and to develop an effective system of international law may be regretted, it should perhaps be remembered that the nation-state continues to function as an extremely effective system for maintaining order within its boundaries. In some cases, this is achieved with remarkably little coercion and in such a way that the progress of civilization is encouraged. In the conditions of our age, world government might well involve much higher levels of coercion and much less civilization.

Decline of regional and state government

Contemporary regional and state government. The 18th-century political philosopher Montesquieu wrote that governments are likely to be tyrannical if they are responsible for administering large territories, for they must develop the organizational capacity characteristic of despotic states. It was partly this fear that led the American founding fathers to provide for a federal system and to divide governmental functions between the government in Washington and the state governments. Modern technology and mass communication are often said to have deprived Montesquieu's axiom of its force. Yet the technology that makes it possible for large areas to be governed democratically also holds out the spectre of an even greater tyranny than Montesquieu foresaw.

In all political systems the relationships between national and regional or state governments have been affected by technology and new means of communication. In the 18th century Thomas Jefferson, in arguing that local government, or the government closest to the people, was best, could claim that citizens knew most about their local governments, somewhat less about their state governments, and least about the national government. In the present-day United States, however, the concentration of the mass media on the issues and personalities of national government has made nonsense of this proposition. As several recent studies have demonstrated, people know much less about local government than national government and turn out to vote in much larger numbers in national elections. The necessity for employing systems for the devolution of political power is reduced when a central government can communicate directly with citizens in all parts of the national territory, and the vitality of subnational levels of government is sapped when public attention is focussed on national problems.

Another general development that has lessened the importance of regional or state government is the rise of efficient national bureaucracies. In nearly all political systems, there has been some tendency toward bureaucratic centralization, and in some cases national bureaucracies have almost completely replaced older systems of regional and provincial administration. In the United States, for example, complex programs of social security, veterans' benefits, income taxes, agricultural subsidies, and many others that bear directly on individuals are centrally administered; and great agencies of government, such as the Department of Health, Education, and Welfare, maintain regional and local offices for the supervision of other national activities.

Even in systems in which a division of functions between national and subnational governments is constitutionally prescribed, the prevailing trend in intergovernmental relations is toward increasing involvement of the national government in areas once dominated by regional or state governments. Thus, the original constitutional arrangements prescribed by the Allied powers for the West German republic in 1949 won general acclaim at the time because they provided for greater decentralization than had the Weimar Constitution; but, as soon as Germany was free to amend its own constitution, several state functions were reassigned to the national government. In the United States, also, the collapse of the doctrine of "dual federalism," according to which the powers of the national government were restricted by the powers reserved to the states, signalled the end of an era in which the states could claim exclusive jurisdiction over a wide range of functions. Today, forms of cooperative federalism involving joint action by national and state governments are increasingly common. Such cooperative relationships in the United States include programs of public assistance, the interstate-highway system, agricultural extension programs, and aid to education. In some areas, such as school desegregation, the national government has used broad powers to compel states to conform to national standards.

Efforts made to halt the trend toward centralization and to re-invigorate regional or state governments have met with little success. In the U.S. a Commission on Intergovernmental Relations established by President Eisenhower in 1953 concluded that it could recommend no major reversion of functions to state governments. Similarly, efforts in France and Italy to decentralize parts of the national administrations have had few practical results. Political regionalism appears to be in steep decline almost everywhere, whether in China or in the American South. The attachments that bind men to localities and allow the growth of genuine subnational political communities have weakened under the impact of technology and the growth of national economies. Only where political regionalism has always been a cloak for movements of national independence—for example, in Scotland, Wales, Northern Ireland, Quebec, and Brittany—are there popular attempts to reverse the trend toward national centralization.

The urban metropolis

Contemporary city and local government. Political scientists since Aristotle have recognized that the nature of political communities changes when their populations grow larger. One of the central problems of contemporary government is the vast increase in urban population and the progression from "polis to metro-polis to mega-polis." The catalog of ills that have resulted from urban growth includes political and administrative problems of extraordinary complexity.

The rise of great urban centres has had a major impact on the politics of all advanced industrial societies. In the United States, for example, the issues of metropolitan politics have become key political issues at the national level. Programs relating to urban renewal, mass-transit systems, school desegregation, and air and water pollution have become of pressing national importance, along with other social problems of the metropolis, such as urban crime, juvenile delinquency, the disorganization of the family, ghetto conditions, and unemployment. The growing involvement of the national government with such issues is in part a consequence of the impoverishment of the cities and the collapse of effective municipal government. The tax base of U.S. cities has dwindled with the flight of the middle classes to the suburbs and the relocation of industry; at the same time, although "bossism" and machine politics have almost vanished, newer forms of city governments have failed to establish effective systems of administration or to win support from

stable majorities of city voters. In part, too, the national government gives priority to such issues because of the political power of the urban areas: cities have become the focuses of national politics, for they are rich in the votes that decide national campaigns. Aside from such fiscal and political pressures, the national government is inevitably concerned with the threat posed by racial conflict, ghetto violence, and other kinds of social chaos in the city.

The metropolis suffers from several acute governmental and administrative failures. Responsibility for the issues that transcend the boundaries of local governments has not been defined, for representative institutions have failed to develop at the metropolitan level. In most cases, there are no effective governmental structures for administering area-wide services or for dealing comprehensively with the common problems of the metropolitan community. The result has been the appearance of a new class of problems created by government itself, including uneven levels of service for metropolitan residents, inequities in financing government services and functions, and variations in the democratic responsiveness of the governments scattered through the metropolitan area. The tangled pattern of local governments, each operating in some independent sphere, does not allow the comprehensive planning necessary to deal with the escalating problems of urban life.

Efforts to create new governing structures for metropolitan communities are among the most interesting developments in contemporary government. In the United States these efforts include the creation of special districts to handle specific functions, area-wide planning agencies, interstate compacts, consolidated school and library systems, and various informal intergovernmental arrangements. Although annexation of outlying areas by the central city and city–county consolidations have been attempted in many cases, the reluctance of urban areas to surrender their political independence or to pay for central-city services has been an obstacle. The Los Angeles plan, by which the county has assumed responsibility for many area-wide functions, leaving the local communities with substantial political autonomy, may represent a partial solution to the problem of urban–suburban tensions. In other cases, "metropolitan federation" has been attempted. One of the earliest and most influential examples of a federated system of metropolitan government is the Greater London Area in Britain, which encompasses 32 London boroughs and places effective governing powers in the hands of an elected city council. In Canada the city of Toronto and its suburbs adopted a metropolitan "constitution" in 1953 under which mass transit, highways, planning, and several other functions are controlled by a council composed of elected officials from the central city and surrounding governments. In 1957 Miami and Dade counties in Florida chose "metro" government: Miami and 27 suburban cities retained control of local functions, while area-wide functions such as fire and police protection and transportation were allocated to the new federal structure. In 1962 Nashville, Tennessee, combined with Davidson County to form a single metropolitan government; and in 1968 Jacksonville, Florida, joined with Duval County in a similar arrangement. Other examples of various degrees of area-wide consolidation in the United States include Baton Rouge, Louisiana; Seattle, Washington; Portland, Oregon; and Indianapolis, Indiana.

Most of the major problems of contemporary politics seem to have found their focus in the metropolis, and there is almost universal agreement that new governing systems must be devised for the metropolitan community if the problems are ever to be resolved.

THE DIVISIONS OF GOVERNMENT

Legislative, executive, and judicial functions

In his *Politics*, Aristotle differentiated three categories of state activity—deliberations concerning common affairs; decisions of executive magistrates, and judicial rulings—and indicated that the most significant differences among constitutions concerned the arrangements made for these activities. This threefold classification is not precisely the same as the modern distinction among legislature, executive, and judiciary. Aristotle intended to make only a theoretical distinction among certain state functions and stopped short of recommending that they be assigned as powers to separate organs of government. Indeed, since Aristotle held that all power should be wielded by one man, pre-eminent in virtue, he never considered the concept of separated powers. In the 17th century the English political philosopher John Locke also distinguished the legislative from the executive function but, like Aristotle, failed to assign these to separate organs or institutions. Montesquieu was the first to make the modern division among legislative, executive, and judiciary. Arguing that the purpose of political association is liberty, not virtue, and that the very definition of liberty's great antagonist, tyranny, is the accumulation of all power in the same hands, he urged the division of the three functions of government among three separate institutions. After Montesquieu, the concept of separation of powers became one of the principal doctrines of modern constitutionalism. Nearly all modern constitutions, from the document written at Philadelphia in 1787 through the French Declaration of the Rights of Man and of the Citizen of August 1789 up to the constitutions of the new states of Africa and Asia, provide for the separate establishment of legislative, executive, and judiciary. The functional division among the branches of government is never precise. In the American system, for example, the doctrine of checks and balances justifies several departures from the strict assignment of functions among the branches. Parliamentary forms of government depart even further from the concept of separation and integrate both the personnel and the functions of the legislature and the executive. Indeed, the principle of shared rather than separated powers is the true essence of constitutionalism. In the constitutional state, power is controlled because it is shared or distributed among the divisions of government in such a way that they are each subjected to reciprocal checks and forced to cooperate in the exercise of political power. In the nonconstitutional systems of totalitarianism or autocracy, although there may be separate institutions such as legislatures, executives, and judiciaries, power is not shared but rather concentrated in a single organ. Because this organ is not subjected to the checks of shared power, the exercise of political power is uncontrolled or absolute.

The legislature. The characteristic function of all legislatures is the making of law. In most systems, however, legislatures also have other tasks, such as selection and criticism of the government, supervision of administration, appropriation of funds, ratification of treaties, impeachment of executive and judicial officials, acceptance or refusal of executive nominations, determination of election procedures, and public hearings on petitions. Legislatures, then, are not simply lawmaking bodies. Neither do they monopolize the function of making law. In most systems the executive has a power of veto over legislation, and, even where this is lacking, the executive may exercise original or delegated powers of legislation. Judges, also, often share in the lawmaking process, through the interpretation and application of statutes or, as in the U.S. system, by means of judicial review of legislation. Similarly, administrative officials exercise quasi-legislative powers in making rules and deciding cases that come before administrative tribunals.

Varieties of legislatures

Legislatures differ strikingly in their size, the procedures they employ, the role of political parties in legislative action, and in their vitality as representative bodies. In size, the British House of Commons, with 630 members, is among the largest; the Icelandic lower house, with 40, the New Zealand House of Representatives, with 80, and the Senate of Nevada, with 17 members, are among the smallest. Most legislatures are bicameral, although New Zealand, Denmark, the state of Queensland, in Australia, and Nebraska, in the United States, have all abolished their second chambers. The procedures of the United States House of Representatives, which derive from a manual of procedure written by Thomas Jefferson, are among the most elaborate of parliamentary rules, requir-

ing study and careful observation over a considerable period before members become proficient in their manipulation. Voting procedures range from the formal procession of the division or teller vote in the British House of Commons to the electric voting methods employed in the California legislature and in some other American states. Another point of difference among legislatures concerns their presiding officers. These are sometimes officials who stand above party and, like the speaker of the British House of Commons, exercise a neutral function as parliamentary umpires; sometimes they are the leaders of the majority party and, like the speaker of the United States House of Representatives, major political figures; and sometimes they are officials who, like the vice president of the United States in his role as presiding officer of the Senate, exercise a vote to break ties and otherwise perform mainly ceremonial functions.

Legislative parties are of various types and play a number of roles or functions. In the United States House of Representatives, for example, the party is responsible for assigning members to all standing committees; the party leadership fills the major parliamentary offices, and the party membership on committees reflects the proportion of seats held by the party in the House as a whole. The congressional party, however, is not disciplined to the degree found in British and some other European legislative parties, and there are relatively few "party line" votes in which all the members of one party vote against all the members of the other party. In the House of Commons, party-line voting is general; indeed, it is very unusual to find members voting against their party leadership, and, when they do, they must reckon with the possibility of penalties such as the "withdrawal of the whip" or the loss of their official status as party members.

It is often said that the 20th century has dealt harshly with legislatures and that this is an age of executive aggrandizement. Certainly, executives in most countries have assumed an increasingly large role in the making of law, through the initiation of the legislation that comes before parliaments, assemblies, and congresses, through the exercise of various rule-making functions, and as a result of the growth of different types of delegated legislation. It is also true that executives have come to predominate in the sphere of foreign affairs and, by such devices as executive agreements, which are frequently used in place of treaties, have freed themselves from dependence upon legislative approval of important foreign-policy initiatives. Moreover, devices such as the executive budget and the rise of specialized budgetary agencies in the executive division have threatened the traditional fiscal controls of legislatures. This decline in legislative power, however, is not universal. The United States Congress, for example, has preserved a substantial measure of its power. Indeed, congressional oversight of the bureaucracy is an area in which it has added to its power and has developed new techniques for controlling the executive. The difficulties of recent presidents with legislative programs of foreign aid and the insistent congressional criticism of executive policies in Southeast Asia also suggest that Congress continues to play a vital role in the governing process.

The executive. Political executives are government officials who participate in the determination and direction of government policy. They include heads of state and government leaders—presidents, prime ministers, premiers, chancellors, and other chief executives—and many secondary figures, such as cabinet members and ministers, councillors, and agency heads. By this definition, there are several thousand political executives in the U.S. national government, including the president, dozens of political appointees in the Cabinet departments, in the agencies, in the commissions, and in the White House staff, and hundreds of senior civil servants. The same is true of most advanced political systems, for the making and implementation of government policy require very large executive and administrative establishments.

The crucial element in the organization of a national executive is the role assigned to the chief executive. In presidential systems, such as in the United States, the president is both the political head of the government and also the ceremonial head of state. In parliamentary systems, such as in Great Britain, the prime minister is the national political leader, but another figure, a monarch or elected president, serves as the head of state. In mixed presidential–parliamentary systems, such as that established in France under the constitution of 1958, the president serves as head of state but also wields important political powers, including the appointment of a prime minister and Cabinet to serve as the government.

Varieties of executives

The manner in which the chief executive is elected or selected is often decisive in shaping his role in the political system. Thus, although he receives his seals of office from the monarch, the effective election of a British prime minister usually occurs in a private conclave of the leading members of his party in Parliament. Elected to Parliament from only one of 630 constituencies, he is tied to the fortunes of the legislative majority that he leads. By contrast, the American president is elected by a nationwide electorate, and, although he leads his party's ticket, his fortunes are independent of his party. Even when the opposition party controls the Congress, his fixed term and his independent base of power allow him considerable freedom of manoeuvre. These contrasts explain many of the differences in the roles of the two chief executives. The British prime minister is invariably a man who has served for many years in Parliament and has developed skills in debate and in political negotiation. His major political tasks are the designation of the other members of the Cabinet, the direction of parliamentary strategy, and the retention of the loyalty of a substantial majority of his legislative party. The presidential chief executive, on the other hand, often lacks prior legislative and even national-governmental experience, and his main concern is with the cultivation of a majority in the electorate through the leadership of public opinion. Of course, since the president must have a legislative program and often cannot depend on the support of a congressional majority, he may also need the skills of a legislative strategist and negotiator.

Another important area of contrast between different national executives concerns their role in executing and administering the law. In the U.S. presidential system, the personnel of the executive branch are constitutionally separated from the personnel of Congress: no executive officeholder may seek election to either house of Congress, and no member of Congress may hold executive office. In parliamentary systems the political management of government ministries is placed in the hands of the party leadership in parliament. In the U.S. system the president often appoints men to Cabinet positions who have had little prior experience in politics, and he may even appoint members of the opposition party. In the British system, Cabinet appointments are made to consolidate the prime minister's personal ascendancy within the parliamentary party or to placate its different factions. These differences extend even further into the character of the two systems of administration and the role played by civil servants. In the U.S. system a change in administration is accompanied by the exodus of a very large number of top government executives—the political appointees who play the vital part in shaping day-to-day policy in all the departments and agencies of the national government. In Britain, when political control of the House of Commons changes, only the ministers, their parliamentary secretaries, and one or two other top political aids are replaced. For all practical purposes, the ministries remain intact and continue under the supervision of permanent civil servants.

In nearly all political systems, even in constitutional democracies where executive responsibility is enforced through free elections, the 20th century has seen an alarming increase in the powers of chief executives. The U.S. presidency, like the office of prime minister in Britain, has greatly enlarged the scope of its authority. One of the future tasks of representative government is to develop more constitutional restraints on the abuse of executive powers while retaining their advantages for effective rule.

The judiciary. Like legislators and executives, judges are major participants in the policy-making process; and courts, like legislatures and administrative agencies, promulgate rules of behaviour having the nature of law. The process of judicial decision making, or adjudication, is distinctive, however, for it is concerned with specific cases in which an individual has come into conflict with society by violating its norms or in which individuals have come into conflict with one another, and it employs formal procedures that contrast with those of parliamentary or administrative bodies.

Varieties of court systems

Established court systems are found in all advanced political systems. Usually there are two judicial hierarchies, one dealing with civil and the other with criminal cases, each with a large number of local courts, a lesser number at the level of the province or the region, and one or more courts at the national level. This is the pattern of judicial organization in Britain, for example. In some countries—for example, in France—although there is a double hierarchy, the distinction is not between courts dealing with criminal cases and other courts dealing with civil cases but rather between those that handle all civil and criminal cases and those that deal with administrative cases or challenges to the administrative authority of the state. Reflecting the federal organization of its government, the United States possesses two court systems: one set of national courts and 50 sets of state courts. By contrast, West Germany and the Soviet Union, both of which are federal in governmental organization, each possess only one, integrated court system.

Local courts are found in all systems and are usually of two types. The first type deals with petty offenses and may include a traffic court, a municipal court, a small-claims court, and a court presided over by a justice of the peace or a local magistrate. The second type, sometimes called trial courts, are courts of first instance in which most cases of major importance are begun. These are the state superior courts in the United States, the county courts and quarter sessions in Britain, the *tribunal de grande instance* in France, and the district courts, or *Landgerichte*, in Germany. In some systems there is a level above the local court, usually referred to as assize courts, in which exceptionally serious crimes, such as homicide, are tried. Courts of appeal review the procedures and the law in the lower court and either reverse or affirm its judgment or, in some cases, return the case for a new trial. In all systems there are national supreme courts that hear appeals and exercise original jurisdiction in cases of the greatest importance, such as those involving conflict between a state and a national government. Outside the regular court systems, there are sometimes found specialized judicial tribunals, such as administrative courts, or courts of claims that deal with special categories of cases.

III. The functions of government

In all modern states, governmental functions have greatly expanded with the emergence of government as an active force in guiding social and economic development. In Communist countries, government has a vast range of detailed controls over all types of social and economic behaviour. Even in the United States, where there remains a much greater attachment than in most societies to the idea that government should be only an umpire adjudicating the rules by which other forces in society compete, such governmental activities as the Tennessee Valley Authority or the use of credit controls to prevent economic fluctuations are now accepted with relatively little question. Government has thus become the major or even the dominant organizing power in all contemporary societies.

The historical stages by which governments have come to exercise their contemporary functions make an interesting study in themselves. The scope of government in the ancient polis involved the comprehensive regulation of the ends of human existence. As Aristotle expressed it, what was not commanded by government was forbidden. The extent of the functions of government in the ancient world was challenged by Christianity and its existence on a division of those things that belong separately to Caesar and to God. When the feudal world succeeded the Roman Empire, however, the enforcement of the sanctions of religion became one of the first objects of political authority. The tendencies that began in the 18th century separated church from state and state from society, and the modern concept of government came into being. The American Colonies' Declaration of Independence expresses the classic modern understanding of those ends that governmental functions exist to secure. The first aim of government is to secure the right to life; this comprehends the safety of fellow citizens as regards one another and the self-preservation of the nation as regards foreign powers. Life exists for the exercise of liberty, in terms of both natural and civil rights, and these, along with other specific functions of government, provide those conditions upon which men may pursue happiness, an end that is finally entirely private and beyond the competence of government.

With the advent of the Marxist conception of the state, the ends of human existence once again became the objects of comprehensive government regulation. Marxism sees the state as a product of class warfare that will pass out of existence in the future age of perfect freedom. Aristotle believed human perfection to be possible only within political society; Marx believed that the perfection of man would follow upon the abolition of political society. Before the final disposal of the state, however, many Marxists believe that forceful use of governmental power is justified in order to hasten mankind's progress toward the last stage of history.

THE INDISPENSABLE FUNCTIONS OF GOVERNMENT

The maintenance of authority

The first right of men and nations is self-preservation. The task of maintaining the nation, however, is more complex than the individual's duty of self-preservation, for the nation must seek to command the attachment of a community of citizens as well as to preserve itself from external violence. As Thomas Hobbes insisted, civil war constitutes the greatest threat to governments, for it represents the dissolution of the "sovereign power." In modern terms, civil war signifies that the government has lost one of the basic attributes of political authority: its monopoly of force and its control over the use of violence. In a fundamental sense, political authority may be preserved from the threat of civil war only when there exists in the political community an agreement on the basic principles of the regime. Such a consensus is the result, among other things, of a shared "ideology" that gives fellow citizens a sense of communal belonging and recognizes interlocking values, interests, and beliefs. Ideology, in this sense, may be the product of many different forces. Sometimes it is associated with ancient customs, sometimes with religion, sometimes with severe dislocations or the sort of common need that has led to the formation of many nation states, and sometimes with the fear of a common enemy. The ideological commitment that men call patriotism is typically the product of several of these forces.

Governments neglect at their peril the task of strengthening the ideological attachment of their citizens to the regime. In this sense, civic education should be counted among the essential functions of the state, for it is primarily through systems of education that citizens learn their duties. Indeed, as a number of recent sociological studies have shown, the process of political socialization that transforms men into citizens begins in kindergarten and grade school. Even more than this, education is the instrument by which governments further the cohesion of their societies and build the fundamental kinds of consensus that support their authority. It is not surprising, therefore, that national systems of education are often linked to central elements of the regimes. The educational system of the Soviet Union emphasizes political indoctrination; in France, public education is traditionally mixed with the teachings of the Roman Catholic Church; in Great Britain, until very recently, a private system of education supported the class divisions of society; and in the United States a primarily secular form of public edu-

cation has traditionally used constitutional documents as the starting point of children's training in patriotism.

The preservation of the authority of the state also requires a governmental organization capable of imposing its jurisdiction on every part of the national territory. This involves the maintenance of means of communication, the use of administrative systems, and the employment of police forces capable of controlling domestic violence. The police function, like education, is often a key to the character of a regime. In Nazi Germany, Hitler's Brownshirts took over the operation of local and regional police systems and often supervised the administration of law in the streets. In the Soviet Union, the security police acts to check any deviation from the policy of the party or state. In the United States the police powers are left in the hands of the 50 states and the local agencies of government. They serve to check civil and criminal offenses; with the exception of certain offenses created by the McCarran Act and some parallel statutes, political crimes as such are unknown. In addition, there are state militias that act, under the control of the governors of the various states, in moments of local emergency, such as riots or natural catastrophes. The Federal Bureau of Investigation (FBI), the only equivalent of a national police force, is an agency established to carry out specific assignments dealing with a limited but important class of crimes. Since there is no comprehensive federal criminal code, there is not, strictly speaking, a federal police.

Governments must preserve themselves against external as well as domestic threats. For this purpose they maintain armed forces and carry on intelligence activities. They also try to prevent the entry of aliens who may be spies or saboteurs, imprison or expel the agents of foreign powers, and embargo the export of materials that may aid a potential enemy. The ultimate means of preserving the state against external threats, of course, is war. In war, governments usually enlarge the scope of their domestic authority; they may raise conscript forces, imprison conscientious objectors, subject aliens to internment, sentence traitors to death, impose extraordinary controls on the economy, censor the press, compel settlement of labour disputes, impose internal-travel limitations, withhold passports, and provide for summary forms of arrest.

Many forces generate clashes between nations, including economic rivalry and disputes over trade, the desire to dominate strategic land or sea areas, religious or ideological conflict, and imperialistic ambition. All national governments develop organizations and policies to meet these and other situations. They have foreign ministries for the conduct of diplomatic relations with other states, for representing them in the United Nations and other international organizations, and for negotiating treaties. Some governments conduct programs such as foreign aid, cultural exchange, and other activities designed to win goodwill abroad.

In the 20th century, relationships among governments have been affected by a developing awareness that world peace depends upon multinational and international cooperation. The League of Nations and the United Nations, together with their associated agencies, represent major efforts to establish substitutes for traditional forms of diplomacy. Regional alliances and joint efforts, such as the Organization of American States, the North Atlantic Treaty Organization, the European Economic Community, and the Organization of African Unity, represent another type of cooperation among nations.

THE SUPERVISORY FUNCTIONS OF GOVERNMENT

Mediation of conflicts

The conflict of private interest is the leading characteristic of the political process in constitutional democracies, and the supervision, mediation, arbitration, and adjudication of such conflicts are among the key functions of their governments. Representative institutions are themselves a device for the resolution of conflict. Elections in constitutional democracies provide opportunities for mass participation in a process of open debate and public decision; assemblies, congresses, and other parliamentary institutions provide for public hearings on major issues of policy and require formal deliberative procedures at different stages of the legislative process; and political parties integrate a variety of interests and effect compromises on policy that win acceptance from many different groups.

If the interests that compete in the political process are too narrow or restricted, efforts may be made to control or change the rules of competition. Thus, laws have been enacted that seek to prevent discrimination from locking racial and other minorities out of the democratic process; the franchise has been extended so as to permit all groups, including minorities such as women, blacks, and 18-year-olds, to have a voice in elections; and government bodies such as courts and administrative agencies enforce legislation against groups considered to be too large or monopolistic.

Judicial processes offer a means by which some disputes in society are settled according to rule and legal authority, rather than by political struggle. In all advanced societies, law is elaborated in complex codes governing rights and duties and procedural methods; and court systems are employed that adjudicate disputes in terms of the law. In constitutional systems such as the United States, the judiciary is deeply involved in the process of public decision making; the courts actually produce much of the substantive law that bears on private individuals and economic groups in society.

THE REGULATORY FUNCTIONS OF GOVERNMENT

Regulation of the economy

Government regulation of economic life is not a new development. The national mercantilist systems of the 18th century provided for regulation of the production, distribution, and export of goods by government ministries; even during the 19th century, governments continued to intervene in the economy. The government of the United States, for example, from its inception in 1789, allotted funds or subsidies for the support of agriculture, maintained a system of tariffs for its own revenue and the support of domestic manufacturers, patronized the arts and sciences, and engaged in various kinds of public works to advance commerce and promote the general welfare. In France, even more elaborate governmental schemes of economic regulation were practiced throughout the 19th century, including a variety of Socialist experiments such as the Public Workshops that Louis Blanc established in Paris in 1848. In Britain, the various factory acts of the 19th century represented an effort by government to control working conditions in industry.

After World War II the ability of a government to regulate or control the economy became one of the chief tests of its success, and regulatory agencies multiplied to the point at which they are now often referred to as "the fourth branch of government." The extent of the controls imposed on the economy is one of the principal distinctions among capitalist, Socialist, and Communist systems. In Communist countries it is a matter of doctrine that the means of production should be owned and therefore controlled by the state; in the 1960s and 1970s, however, some Communist countries experimented with various ways of decentralizing economic decision making in an effort to increase flexibility and reduce the weight of the central bureaucracy. In Britain the Labour governments nationalized some major industries, including coal, steel, and the railroads, prompted partly by Socialist doctrine and partly by the failure of British industry to remain competitive in international markets. In the United States the government has involved itself in the economy primarily through its regulatory powers. In France the government has gone further and has engaged in national economic planning in cooperation with private business organizations.

The regulation of industrial conditions and of labour–management relations has been a major concern of most Western governments. In the United States the first regulatory efforts in this field were made during the Progressive era at the turn of the 20th century, when the wages, hours, and working conditions of women and children in industry became a matter of public scandal. A little later, the conditions, hours, food, and wages of merchant seamen were brought under government regulation; an eight-hour day was set for railway crews; and workmen's

compensation laws were instituted. With the Depression of the 1930s, minimum wages were introduced for workers in many industries, hours of work were set, and the right to collective bargaining was given legal sanction.

Regulation of transportation has been another major activity in most Western political systems, beginning with the railroads. In the United States their monopolistic practices attracted the criticism of agricultural interests and led eventually to the Interstate Commerce Act of 1887, which regulated railroad rates; subsequent legislation covered the hours, conditions, and wages of railroad employees, among other things. Other modes of land and air transportation have since been brought under regulatory controls implemented by government agencies.

In most European countries, facilities of communication—the telegraph, telephone, radio, and television—are owned and operated by the government. In the United States most of these facilities have remained in private ownership, although they are regulated by the Federal Communications Commission. The regulation by government of important instruments of public opinion such as radio, television, and newspapers has important implications for the freedoms of speech and press and other individual rights. In the United States and Great Britain, government censorship of the press and other media has been restricted to matters of national security. This is also generally true of other Western constitutional democracies, although the celebrated *Der Spiegel* affair in Germany in 1962 and some extraordinary controls imposed on the media in France have been widely criticized. In Communist countries and in many of the new states of Africa and Asia, very extensive controls are imposed on the press, and government-owned newspapers are often the principal sources of political news.

Other forms of government regulation of the economy involve the use of taxes and tariffs, the regulation of weights and measures, and the issuance of money.

Protection of political and social rights

To some extent, all modern governments assume responsibility for protecting the political and social rights of their citizens. The protection of individual rights has taken two principal forms: first, the protection of liberty in the face of governmental oppression; second, the protection of individual rights against hostile majorities and minorities. Even Communist governments recognize certain rights of individuals and minorities in the ordinary spheres of life, if not in matters touching the interests of the state. In the 1960s and 1970s there appeared to be a broadening of the sphere of private rights in the Soviet Union. Authors, artists, and scientists were able to engage in criticism of official policies, not with impunity but with much greater freedom than in the Stalin era; and there were some signs that the Soviet state had begun to recognize the rights of the Jewish minority and the claims of some other national groups. In the United States the Supreme Court expanded the rights of the criminally accused; and, after 1954, the national government acted to bar legal discrimination against ethnic minorities. Indeed, almost all the freedoms detailed in the first ten amendments to the Constitution have been extended since World War II.

Another type of government regulation bearing on the individual concerns the law of immigration and emigration. The great mass migrations of the 19th and early 20th centuries came to an abrupt halt after 1914 with the proliferation of government controls on the freedom of movement across national boundaries.

THE ENTERPRISING FUNCTIONS OF GOVERNMENT

Provision of goods and services

All modern governments participate directly in the economy, purchasing goods, operating industries, providing services, and promoting various economic activities. One of the indispensable functions of government—national defense—has made governments the most important consumers of goods, and they have not hesitated to use their resulting pricing, purchasing, and contracting powers to achieve various economic aims. In efforts to avoid dependence on private sources of strategic goods and defense materials, some governments have taken a further step and established their own military production plants. In wartime, governments have assumed control over entire industries and have subjected the work force to military direction.

In nearly all political systems, certain functions are recognized as public, or belonging to the government. In addition to national defense, these include the maintenance of domestic peace, public education, fire protection, traffic control, aid to the indigent, conservation of natural resources, flood control, and postal services. But governments have assumed responsibility for many other commercial operations, even in non-Socialist countries. The sale of electric power, for example, is one of the established enterprising functions of national, state, and local governments in the United States and Canada. Municipally owned power utilities exist in about 2,000 cities in North America; 14 states of the U.S. have public power districts; and the U.S. government markets power through the Tennessee Valley Authority, the Bureau of Reclamation, the Bonneville Power Administration, and the Southwestern and Southeastern Power administrations. Another range of functions is performed by other national agencies, including the Rural Electrification Administration, which loans money to rural cooperatives to finance local power projects; the Export–Import Bank of Washington, which makes loans to finance export and import trade; the Maritime Administration, which holds mortgages on ships; and the Veterans Administration, which makes loans for farm or home purchases to military veterans. The United States government, acting through agencies such as the Social Security Board, the Federal Deposit Insurance Corporation, and the Federal Housing Administration, is also the largest insurer in the nation. Through other agencies, such as the Housing and Home Finance Agency, the Urban Renewal Administration, and the Public Works Administration, the national government has also developed a major role in the construction and rental of residential housing for low-income persons.

Other miscellaneous enterprises in which governments are involved include the provision of health care, the operation of public transport facilities, the development of public works, airport and port maintenance, and water-supply systems. In Great Britain the government operates hospitals and provides medical care under the National Health Service. In the United States, many state and local governments operate hospitals on a commercial basis, although providing some charity care. At the local level in the United States, the Port of New York Authority constructs and operates bridges, terminals, and airports. The states in the Delaware Basin recently joined in a compact to establish an agency to control the use of water from the basin, institute programs to prevent pollution, provide recreation facilities, transmit and sell hydroelectric power, and provide watershed management. Cities in the United States and Canada operate more than 70 urban transit systems, 600 municipal gas utilities, and more than 4,000 water-supply systems. Cities are also generally responsible for garbage disposal and sometimes operate commercial slaughterhouses, coal yards, laundries, ice plants, and golf courses. Finally packaged liquor sales are often made by the state governments, at either wholesale or retail or both.

PUBLIC ADMINISTRATION

Civil service

While the functional objectives of government administration vary from system to system, all countries that are technologically developed have evolved systems of public administration. A number of common features may be detected in all such systems. The first is the hierarchical, or pyramidal, character of the organization by which a single chief executive oversees a few subordinates, who in turn oversee their chief subordinates, who are in turn responsible for overseeing other subordinates, and so on, until a great structure of personnel is integrated and focussed on the components of a particular program. A second common feature is the division of labour or specialization within the organization. Each individual in the hierarchy has specialized responsibilities and tasks. A third feature is the maintenance of detailed official re-

cords and the existence of precise paper procedures through which the personnel of the system communicate with each other and with the public. Finally, tenure of office is also characteristic of all public bureaucracies.

The various national civil services, despite their similarities, also show important differences, particularly in the way in which individuals are recruited and in the status accorded them in the political system. The British civil service, for example, has traditionally been composed of three classes, or grades—clerical, executive, and administrative. Administrative civil servants, the highest grade, are recruited by examination from among recent university graduates. The top managers of the different government ministries are drawn from this elite group. They remain in office despite changes in government and are accorded immense prestige in the British political system. The U.S. civil service is organized into 18 grades. Although promotion from the lower grades is the typical means by which positions in the top grades are filled, there is also a flow of individuals into senior positions from private business and the professions. The U.S. equivalent of the administrative civil servant in Britain is usually a political appointee recruited by each new administration from private life or from a position in politics.

IV. Development and change in political systems

The student of political systems grapples with a subject matter that is today in constant flux. He must deal not only with the major processes of growth, decay, and breakdown but also with a ceaseless ferment of adaptation and adjustment. The magnitude and variety of the changes that occurred in the world's political systems between the second and eighth decades of the 20th century suggest the dimensions of the problem. Great empires disintegrated; nation-states emerged, flourished briefly, and then vanished; world wars twice transformed the international system; new ideologies swept the world and shook established groups from power; all but a few nations experienced at least one revolution and many nations two or more; domestic politics in every system were contorted by social strife and economic crisis; and everywhere the nature of political life was changed by novel forms of political activity, new means of mass communication, the enlargement of popular participation in politics, the rise of new political issues, the extension of the scope of governmental activity, the threat of nuclear war, and innumerable other social, economic, and technical developments.

STABILITY AND INSTABILITY

Although it is possible to identify a number of factors that obviously have a great deal to do with contemporary development and change in the world's political systems —industrialization, population growth, the "revolution of rising expectations" in the less developed countries, and international tensions—there is no agreed theory to explain the causes of political change. Some social scientists have followed Aristotle's view that political instability is generally the result of a situation in which the distribution of wealth fails to correspond with the distribution of political power and have echoed his conclusion that the most stable type of political system is one based on a large middle class. Others have adopted Marxist theories of economic determinism that view all political change as the result of changes in the mode of production. Still others have focussed on governing elites and their composition and have seen in the alienation of the elite from the mass the prime cause of revolutions and other forms of violent political change.

In the discussion that follows, a distinction is drawn between unstable and stable political systems, and an attempt is made to suggest ways of understanding the processes of political development and change.

Crisis situations

Unstable political systems. In modern times the great majority of the world's political systems have experienced one form or another of internal warfare leading to violent collapse of the governments in power. Certain crisis situations seem to increase the likelihood of this kind of breakdown. Wars and, more particularly, national military defeats have been decisive in prompting many revolutions. The Paris Commune of 1871, the Russian revolutions of 1905 and 1917, Hitler's overthrow of the Weimar Constitution in Germany, and the revolutions in China all occurred in the aftermath of national military disasters. Many factors in such a situation, including the cheapening of human life, the dislocation of population, the ready availability of arms, the disintegration of authority, the discrediting of the national leadership, material scarcities, and a sense of wounded national pride, contribute to the creation of an atmosphere in which radical political change and violent mass action are acceptable to large numbers of people. Economic crises are another common stimulus to revolutionary outbreaks, for they produce not only the obvious pressures of material scarcity and deprivation but also a threat to the individual's social position, a sense of insecurity and uncertainty as to the future, and an aggravation of the relationships among social classes. A severe national economic crisis works, in much the same way as a military disaster, to discredit the existent leadership and the present regime. Another triggering factor is the outbreak of revolutions in other political systems. Revolutions have a tendency to spread: the Spanish Revolution of 1820 had repercussions in Naples, Portugal, and Piedmont; the French Revolution of July 1830 provoked similar outbreaks in Poland and Belgium; the Russian Revolution of 1917 was followed by a dozen other revolutions; and the colonial liberation movements after World War II appear to have involved a similar chain reaction.

Crisis situations test the stability of political systems in extremely revealing ways, for they place extraordinary demands on the political leadership and the structure and processes of the system. Since the quality of the political leadership is often decisive, those systems that provide methods of selecting able leaders and replacing them possess important advantages. Although leadership ability is not guaranteed by any method of selection, it is more likely to be found where there is free competition for leadership positions. The availability of established methods of replacing leaders is equally, if not more, important, for the result of crises is often to disgrace the leaders in power, and, if they cannot be replaced easily, their continued incumbency may discredit the whole regime. The stamina and resolve of the ruling elite are also important. It is often said that a united elite, firmly believing in the justice of its own cause and determined to employ every measure to maintain its power, will not be overthrown. Most revolutions have gotten under way not when the oppression was greatest but only after the government had lost confidence in its own cause.

Other conditions of the survival of political systems relate to the effectiveness of the structures and processes of government in meeting the demands placed on them. Political systems suffer violent breakdown when channels of communication fail to function effectively, when institutional structures and processes fail to resolve conflicts among demands and to implement acceptable policies, and when the system ceases to be viewed as responsive by the individual and groups making demands on it. Usually, a system has failed over a period of some time to satisfy persistent and widespread demands; then, exposed to the additional strains of a crisis situation, it is unable to maintain itself. Revolutions and other forms of violent collapse are thus rarely sudden catastrophes but rather the result of a process of considerable duration that comes to its climax when the system is most vulnerable.

Causes of the breakdown of political systems

Unstable political systems are those that prove vulnerable to crisis pressures and that break down into various forms of internal warfare. The fundamental causes of such failures appear to be the lack of a widespread sense of the legitimacy of state authority and the absence of some general agreement on appropriate forms of political action. Governments suffer their gravest handicap when they must govern without consent or when the legitimacy of the regime is widely questioned. This is often the case in systems that have experienced prolonged civil war, that are torn by tensions among different national or ethnic

groups, or in which there are divisions along sharply drawn ideological or class lines. The problem is often most acute where there is a pretender to the throne, a government in exile, a neighbouring state sympathetic to a rebel cause, or some other focus for the loyalty of dissidents. To some degree, also, the problem of legitimacy confronts all newly established regimes. Many of the new states of Africa and Asia, for example, have found it a source of great difficulty. Often they have emulated the form of Western institutions but failed to achieve their spirit: borrowing eclectically from Western political philosophies and systems of law, they have created constitutional frameworks and institutional structures that lack meaning to their citizens and that fail to generate loyalty or a sense that government exercises rightful powers.

Closely related to the problem of legitimacy as a cause of the breakdown of political systems is the absence of a fundamental consensus on what is appropriate political behaviour. A regime is fortunate if there are well-established, open channels of political action and settled procedures for resolving grievances. Although the importance of such "rules of the game" is that they allow change to occur in mainly peaceful ways, stable political systems often show surprising tolerance for potentially violent forms of political behaviour, such as strikes, boycotts, and mass demonstrations. Such forms of political behaviour are not permitted in systems where there are no agreed limits to the role of violence and where there is a high risk that violence may escalate to the point of actual warfare. If the government cannot count upon widespread support for peaceful political procedures, it must restrict many kinds of political action. Such restriction, of course, inhibits still more the development of open methods of citizen participation in politics and adds to tension between the government and the people.

Managed and evolutionary systems

Stable political systems. The simplest definition of a stable political system is one that survives through crises without internal warfare. Several types of political systems have done so, including despotic monarchies, militarist regimes, and other authoritarian and totalitarian systems. After 1868, in the period of the restoration regime under the Meiji emperor, Japan succeeded, without major political breakdowns, in building an industrial state and developing commercial structures that transformed traditional Japanese society. This achievement was based on the development of centralized patterns of political control and the growth of a type of authoritarianism involving the rule of a military elite. Similarly, some of the totalitarian regimes of the contemporary world have demonstrated an impressive capability for survival. The key to their success is their ability to control social development, to manage and prevent change, and to bring under governmental direction all the forces that may result in innovations that are threatening to the system.

In some systems, survival does not depend on the detailed management of the society or close governmental control over social processes but is the result of sensitive political response to the forces of change, of flexible adjustment of the structures of the system to meet the pressures of innovation, and of open political processes that allow gradual and orderly development. Much of the Western democratic world has achieved peaceful progress in this way, despite new political philosophies, population increases, industrial and technological innovations, and many other social and economic stresses.

Such evolutionary change is possible when representative institutions provide effective channels for the communication of demands and criticisms to governments that rely upon majority support. The election of legislators and executive officials, competition between political parties, constitutional guarantees of freedom of speech and press, the right of petition, and many other structures and procedures perform this function in contemporary constitutional democracies. In such systems, social and economic problems are quickly transformed into issues in the open arenas of politics; governments are obliged to shape policies that reflect a variety of pressures and effect compromises among many conflicting demands.

The representative mechanisms that have produced evolutionary change in Western constitutional democracies are themselves subject to a continuous process of adjustment and mutation. Indeed, representative institutions must develop in ways that reflect social and economic developments in the society or they will lose their legitimacy in the minds of the people. In political systems such as the United States, for example, subtle shifts in the function and relative power of different institutions are continuously being made and, over time, produce entirely new structures and very different patterns of institutional behaviour. It is as a result of this process that the presidency has accumulated a range of new powers that have given it primacy among the branches of American government. This process also explains the growth of administrative agencies that perform both legislative and judicial functions. This process of dynamic adjustment is crucial, for institutions that remain static in a changing society are unable to serve as agencies of evolutionary change.

THE PROBLEM OF POLITICAL CHANGE

Four types of political change

The study of political change is difficult, for change occurs in many different ways and at many different points in the political system. One may distinguish several major types of change. First are changes of the most fundamental type—transformations not only of the structure of government but of the whole polity. Such change is not limited to political life but transforms also the social order, the moral basis, and the values of the whole society. Drastic change of this kind occurred in the four great revolutions of the modern era—the English Revolution of the 17th century, the American Revolution, the French Revolution, and the Russian Revolution. These movements had the most profound effect on social and political life, permanently altering the beliefs by which men live. Their consequences were felt not only in the societies in which they occurred but also in many other political systems, in which, as a result of their example, revolutions of an equally fundamental character occurred.

Each of these major revolutions was something of a world revolution, for it resulted in a basic change in the ways in which men in all political systems viewed the nature of politics and the purpose of political life. The independence movements in the colonial empires after World War II, for example, were fuelled by those principles of individual liberty and representative government that were once the slogans of 18th-century American and French revolutionaries. Marxist revolutionary concepts emphasizing economic progress and radical social change have shaped the development of many of the new nations. The continuing impact of such ideas is an example of another way in which fundamental political change occurs. The nature of a political system may be transformed not suddenly or violently in the course of revolution but by the gradual, corrosive influence of ideas and by the accumulating impact of different political philosophies.

A second type of change involves alterations to the structure of the political system. Such change is not fundamental, in the sense of a basic transformation of the nature of the regime, but it may produce great shifts in policy and other political outcomes. Because the structure of a political system—that is, its formal and informal institutional arrangements—is a major determinant of policy outcomes, it is frequently the target of political action of various kinds. The political activist, the reformer, and the revolutionary share the recognition that the policies of a government may be effectively changed by adjusting the institutional forms through which the government acts. In some systems, structural change has been accomplished by legal means. In the United States, for example, such major institutional reforms as the direct election of the Senate and the limitation on presidential terms were made by constitutional amendment; and in Britain the various reforms of Parliament were accomplished by statute. In other systems, structural changes are often achieved by revolution and other violence.

A third type of political change involves the replacement of leaders. Again, the recognition that to change the personnel of a government may be an effective way of

changing government policy prompts many kinds of political action, ranging from election contests to political assassination and various forms of coup d'etat. In some systems the existence of established means of changing political leaderships works to prevent violent types of political action. In the United States the quadrennial contests for the presidency afford a constitutional opportunity to throw the whole executive leadership out of office. At the other extreme, the coup d'etat leads to the abrupt, often violent replacement of national executives. Although it is a type of revolution, the coup d'etat usually does not involve prolonged struggle or popular participation; after seizing office, the principal aim of the leaders of the coup is usually the restoration of public order. The coup d'etat occasionally develops into much more than the replacement of one set of governmental leaders by another and may prove to be the initial stage of a truly revolutionary process; *e.g.*, the coups d'etat that initiated Communist rule in Czechoslovakia in 1948 and ended King Farouk I's regime in Egypt in 1952.

Government policy itself may be an important agency of political change. The social and economic policies of Franklin D. Roosevelt's New Deal and the Socialist programs implemented by the British Labour Party after 1945 are examples. In both cases, government policies resulted in far-reaching modifications to the functioning of the political system: a vast expansion in the role of government in the economy, the use of taxes to redistribute wealth, an increase in the political influence of organized labour, and the implementation of national programs of social welfare. Major policy change of this type, of course, is often a response to widespread pressures and demands that, if not satisfied by the system, may intensify and lead to various forms of violent political action. At other times, however, policy changes are imposed by a government to achieve the political, social, and economic goals of a single class, of an elite, or of the political leadership itself.

Many important questions remain as to the reasons for change, the ways in which change occurs, and the effects of change. Political scientists are still not completely certain, for example, why some systems have managed to avoid violent political change for considerable periods, while in other systems change is typically accomplished through coups d'etat, revolutions, and other forms of internal warfare. As suggested above, the explanation may have much to do with the existence in countries such as the United States and Great Britain of well-established political institutions that permit peaceful change, the presence in the population of widely shared attitudes toward the government, and the existence of basic agreement on the legitimacy of state authority. Clearly, however, other factors are also involved. Perhaps one of the chief goals of the study of political systems should be to determine as exactly as possible the conditions and prerequisites of those forms of change that permit the peaceful and evolutionary development of human society.

V. The study of political systems

CONTEMPORARY POLITICAL SCIENCE

The academic discipline of political science underwent a profound transformation in the four decades after 1930. The study of politics, particularly in the United States, gradually developed into a behavioral science. First, the social sciences generally experienced a technological revolution—a radical change in the equipment, techniques, and procedures used in research. Second, there was also a revolution in the philosophical posture and theoretical orientation of students of politics: interest gradually shifted from the traditional concerns of speculative philosophy to the theoretical problems of empirical analysis; increasingly, political scientists became concerned with "systematic theory," turning for guidance to the work of logicians and philosophers of science rather than to the classics of political theory. A third development was the rise of prestigious new social-science disciplines. Political scientists displayed mounting enthusiasm for interdisciplinary cooperation and borrowed increasingly from the theories, methods, conceptual schemes, and research results of other behavioral sciences. The effect of these three developments was to bring into question many of the approaches traditionally used in political inquiry.

New techniques and methods of analysis. The revolution in social-science technology has placed many novel research tools at the disposal of political scientists. Today many scholars use the interview techniques of the mass survey and the "panel" method; metric techniques, such as the scalogram, scale analysis, and factor analysis are frequently employed; and increasing interest has been shown in the use of specialized computer routines for purposes such as "pattern searches," "multiple regression analysis," and "simulation." Some of these technical innovations have already had a dramatic impact in more than one field of political science. The probability sample survey, for example, although it began with voting and public-opinion studies, has been extended to the investigation of specialized elites and institutionalized groups such as legislators and bureaucratic organizations. Similarly, metric techniques such as scalogram and factor analysis have been applied not only to voting and public-opinion research but also to the treatment of legislative roll-call votes and judicial decisions. Observational and sociometric techniques have been increasingly used in several areas for the study of small and middle-sized groups and for the analysis of group properties such as authority, communication, morale, cohesion, and consensus. Other techniques have been shown to have potential usefulness. For example, "experimental" or "prototype" studies and techniques—planned and deliberate "interferences" in real-life situations—may eventually be brought to bear upon the study of decision-making processes. Similarly, computer simulation—already a fruitful device when applied to problems of strategy in conjunction with game-theoretic analysis—may prove to be useful. The effect has been a revolutionary expansion in the data resources available to political scientists.

The empirical approach

New theoretical approaches. Increasingly, political scientists are committed to the belief that theory and research are mutually interrelated activities. Theoretical questions, it is said, must be stated in operational terms —in the form of testable hypotheses—for purposes of empirical research. And, in turn, empirical findings must be brought to bear upon theoretical formulations. Some students seek to develop general theoretical frameworks designed merely to orient the observer and to serve as "research guides" or "heuristic devices." At another extreme, there are attempts to build logically consistent, deductive models of the political process and to utilize theory as a tool of explanation and prediction.

The ultimate goal of much modern political inquiry is explanation, not description. A majority of contemporary political scientists are no longer content to describe the universe of politics. They seek, instead, to explain political behaviour—why people behave politically as they do and why, as a result, political processes and systems function as they do. With this emphasis, there is a new interest in the logic of scientific explanation. Much self-conscious attention is now paid to the problems of logical inference and to the use of different kinds of proof or techniques of validation in empirical analysis.

The interdisciplinary orientation. A leading development in modern political science is the willingness of students to borrow from the concepts, theories, and data of other social sciences. For example, the concept of role has been taken from psychology and sociology to construct a "role-theory model of the legislative actor." Similarly, structural–functional analysis has been borrowed from anthropology and sociology by students of both comparative politics and public administration. Systems analysis, which has many disciples in other behavioral sciences, has been utilized in fields of political inquiry.

Borrowings from other fields

Recent developments in the study of political leadership have owed a great deal to the pioneering efforts of sociologists and psychologists. In their studies of elites and social mobility, sociologists developed techniques that political scientists could use, with little modification, to determine political mobility and the representativeness of political elites. The results of primary- and middle-size-

group research in psychology and sociology had an obvious interest to students of cabinets, legislative and executive committees, administrative bodies, and executive staff organizations. The conception of the relational nature of leadership was a valuable corrective for political scientists who had vainly sought to isolate stable characteristics and personality traits in political elites. The application of sociometric techniques that could elicit interindividual choices among group members was important in identifying informal leadership structures in middle-sized political groups. And the distinction between formal and effective authority, a result of early sociological studies, found rapid application by students of politics.

Criticisms of traditional approaches. The older political science was characterized by the use of historical, legal, and prescriptive approaches that have increasingly come to be questioned.

Criticisms of the historical approach. Many modern political scientists do not consider history to be a science. The logic of historical explanation, the use of theory in historical research, and the procedures, sources, and goals of historical analysis have all been criticized. To begin with, historical explanations of events are viewed dubiously. The mere statement of a historical sequence, it is said, does not amount to causal explanation. The historian may describe the genesis of a particular event, but his premises do not suffice to establish the event deductively. Historians' attitudes to theory are also suspect. On the one hand, philosophers have united to discredit historicism—the construction of grand, overarching theories of the first causes and final ends of history viewed as a deterministic process. On the other hand, social scientists have condemned the specialized, "scientific" history in which concern with detailed facts is at the expense of hypotheses, generalizations, and theory of all kinds. On a less abstract level, the historian's procedures have also been criticized. Historical analysis, it is claimed, consists merely of an impressionistic linking of variables and an intuitive treatment of complex phenomena. Historical sources are said to be inadequate, since historians rely upon materials that come to them by the haphazard process of documentary survival. And, finally, the historian's chief goals of realistic description and accurate reconstruction of historical events are also questioned. Mere description, it is said, is not the aim of science.

The modern tendency among social scientists, therefore, is to deny that history has an autonomous status as a social science and to insist that it is a mere auxiliary, a reservoir of data, for other disciplines. Among political scientists, modern behavioralist writers have most sharply expressed their discontent with historical-descriptive approaches to political subjects. They believe that, where historians are principally concerned with the uniqueness of the phenomena investigated, the political scientist should be interested in the search for hypotheses, generalizations, and even universal laws. In nearly all fields of political science, moreover, the goal of realistic description has been replaced by the effort to evolve analytical schemes that will relate one event to another causally rather than chronologically and systematically rather than impressionistically.

Criticisms of legal approaches. Legal approaches to political subjects have also met with considerable criticism. Even among early political scientists there were some who contrasted "real" with "legal" forms and functions of government and who preferred realistic to legal methods of analysis. But it was the development of new areas of inquiry—political parties, pressure groups, and public opinion—that finally brought legalism in political science into disrepute. Students had now to deal with a new and broader universe of politics, in which extralegal groups and processes were a primary focus of attention. Legal sources—constitutional clauses, statutory provisions, judicial dicta, and the like—had little relevance in these new areas. Increasingly, political scientists contrasted formal, legal materials with the data thrown up by the new methods of empirical analysis. A belief gradually developed that the perspectives of constitutional law were false and artificial and that only the distinctively political approaches that had been developed in the new areas of inquiry could capture the realities of the political process. Today, a diminishing minority of political scientists continue to employ legal approaches.

Even the traditional subjects of the public law syllabus have been affected by the new, nonlegal approaches. The court system, for example, is now represented as an arena for the play of political pressures; and the traditional simplistic model of a neutral judiciary whose only function was to interpret or apply laws made by the representative body has been replaced with a view of the courts as an integral part of the political system and of judges as policy makers. More recently, legal studies have been further revolutionized by the application of methods of modern social science to the analysis of judicial opinions.

Criticisms of prescriptive approaches. Political scientists' attitudes to the use of prescriptive and reform-oriented approaches also have changed. One position, modelled on the procedures and aims of the physical sciences, holds that the student of political subjects should not evaluate, criticize, or advocate the reform of the phenomena with which he deals. A less rigorous position concludes that, although prescriptive or meliorative activities and the attempt to advise policy makers should have their place in the discipline, the chief purpose of inquiry should not be policy advice but the pursuit of knowledge. A third position insists that, though political scientists can never choose the goals of politics, their skills can be used in problem solving, and political science as a policy science may have a legitimate function in clarifying (without evaluating) policy alternatives and estimating (without judging) their consequences. All these positions are a considerable distance from the crusading, curative, and reformist attitudes of earlier political scientists and from the ethical inquiries into the nature of the good state once typical of political theory.

Even among those political scientists who continue to hold that it is proper and laudable to search for means to improve the working of the political system, there is evident a new caution and hesitancy. Reform is understood to be a very difficult and complex undertaking, while proposals for wholesale change, involving major constitutional revision, are considered unrealistic. Adjustments to governmental mechanisms, it is agreed, must match existent developments. Governmental institutions, moreover, are no longer regarded as separate and isolable from the remainder of the government and the society; they are viewed as components of a system, affecting and affected by needs and changes in the society and the government as a whole. It is recognized that the features of a governmental system that one may wish to change are often the product of deeper social and political forces that are irreversible and beyond human control. It is likewise recognized that the attempt to modify some apparently minor but awkward piece of institutional machinery may lead to major, unforeseen, and unwanted changes in other parts of the system. The effort to transfer bits and pieces of one political system to another is seen to be impossible for the very reason that it is right to use the word system. The stress on formal and structural changes to accomplish reorganization or institutional reform has been largely replaced with a recognition of the importance of the fluid, dynamic, and behavioral forces that affect institutional decision making. And, finally, the development of the modern, more complex view of institutions as patterns of anticipated behaviour has been accompanied by the growth of an understanding that institutional change does not come easily and that there is great toughness and resilience in the established forms of behaviour. All these insights have worked to sharpen an awareness of the limitations of political analysis and of the difficulties and dangers of governmental reform.

Weaknesses of contemporary political science

Although these innovations have been accompanied by a vast expansion in the number of professional political scientists and in the financial resources available for research, there are many troubling features of the contemporary discipline. In the view of many critics, the promise of a more realistic political science is still unfulfilled. In many cases, the new theoretical approaches have yielded

not the promised additions to our knowledge but sterile controversies among a new generation of schoolmen. In many cases, also, the new techniques and methods of analysis have led to investigation of trivial questions or to an obsessive concern with methodological problems for their own sake. The interdisciplinary orientation, too, has often resulted in a dependence on the conceptual apparatus of sociology, psychology, and other modern social science disciplines that is at least as dangerous as the older emphasis on legal and historical approaches. Finally, the reaction to prescription has made the discipline vulnerable to charges that it is incapable of confronting the important problems of the modern world.

FUTURE APPROACHES TO THE STUDY OF POLITICAL SYSTEMS

The study of advanced systems

Although it is hazardous to speculate on the future development of political science as a discipline, it seems clear that one must not expect any general reaction to the major trends of recent decades. All the main features of the behavioral revolution are now deeply entrenched in the discipline, and they will certainly continue to shape most of the writing and research on political systems for a long time to come. In a few areas, however, one may hope for adjustments that will correct some of the obvious weaknesses of recent scholarship. Much of the literature on comparative politics of the last four decades has dealt with non-Western political systems. This emphasis yielded much information on the process of political development and change, and many of the new concepts that are now employed to explain the role of social forces in shaping political life are the product of work on the new nations of Africa and Asia.

This progress in the understanding of non-Western systems has no parallel in the study of the political institutions of advanced systems. Scholarly work on the politics of western European countries is still largely dominated by legal and historical approaches. Research on the nonlegal political institutions and processes—parties, interest groups, public opinion, leadership recruitment, and the like—of many European constitutional democracies is still in its infancy. The advanced political systems of the Communist world have also been given much less attention than they merit.

One of the trends of the future may be a renewal of interest in the politics of advanced political systems. Many of the tools of inquiry and the theoretical concepts that are needed for such an enterprise have been made available in studies of the politics of the United States and Britain. The developing role of the European Common Market, the re-emergence of Germany and Japan as great powers, and the changes that are occurring in the relationships among the Communist states of eastern Europe may provide a new focus for research.

The limits of analysis

The contemporary behavioral political scientist is no longer able to confine his research to formal political institutions. He must treat the whole social environment of the political system. Indeed, every social relationship that involves the exercise of authority or the allocation of social values has been brought within his professional purview. Thus, the field of comparative politics has become unmanageably broad and almost hopelessly complex.

One way of lightening the burden of the political scientist might be to break down the field of comparative politics into more manageable segments of specialization. Another, perhaps more fruitful development might be to redefine the limits of analysis. This would involve not returning to the narrow legalism of earlier political science but placing more emphasis on the political system itself and on the structures and processes of politics.

A recent tendency among political scientists, particularly those who have sought to escape from the normative emphasis of traditional political science, has been to avoid dealing with issues of public policy. They study the processes by which policies are made rather than the policies themselves. Research on other political systems is even less concerned with policy.

Widespread controversy in the United States over national policy issues has made the subject matter of much "scientific" research on politics appear trivial and irrelevant. Some American political scientists, reacting to what they perceive as the dehumanizing tendency of behavioral research, have begun to insist that policy evaluation should be a principal concern of the discipline. If this movement gathers impetus, it may have important consequences for research on other political systems. Techniques that have proved useful in studying the processes of public decision making in the United States might be applied with great profit to other political systems. Eventually, there may develop a school of comparative politics that focusses on policy processes and that is concerned with comparing and evaluating the policy outputs of different political systems.

Perhaps the future will ultimately bring many more fundamental changes in the study of political systems. More realistic ways of comparing political systems may be discovered or rediscovered, and a discipline may emerge that is appropriate to modern conditions. Such a discipline would be sensitive to differences in the character of regimes, attuned to revealing contrasts in policy, and concerned with the protection of freedom.

BIBLIOGRAPHY

General works: Perhaps the best single introduction to the subjects covered in this article is CARL J. FRIEDRICH, *Man and His Government: An Empirical Theory of Politics* (1963). Other excellent general works include KARL LOEWENSTEIN, *Political Power and the Governmental Process*, 2nd ed. (1965); and R.M. MACIVER, *The Modern State* (1926) and *The Web of Government* (1947). A good introductory text is JOHN C. WAHLKE and ALEX N. DRAGNICH (eds.), *Government and Politics* (1966); and some carefully selected readings are available in HARRY ECKSTEIN and DAVID E. APTER (eds.), *Comparative Politics* (1963). For many subjects, *The International Encyclopedia of the Social Sciences*, 17 vol. (1968), is an excellent reference.

Supranational political systems: The history of the empires of the ancient world may be studied in a number of monumental works, including ARNOLD J. TOYNBEE, *A Study of History*, 1st–2nd ed., 12 vol. (1948–61); OSWALD SPENGLER, *Der Untergang des Abendländes*, 2 vol. (1918–23; Eng. trans., *The Decline of the West*, 2 vol., 1926–28); and EDUARD MEYER, *Geschichte des Altertums*, 5 vol. (1884–1902, reprinted 1910–39). Among other general works, S.N. EISENSTADT, *The Political Systems of Empires* (1963), compares the ancient empires in terms of bureaucracy; and KARL WITTFOGEL, *Oriental Despotism: A Comparative Study of Total Power* (1957), traces the origins of their political orders. Treatments of the major empires of the ancient world include JAMES H. BREASTED, *Development of Religion and Thought in Ancient Egypt* (1912); A.T. OLMSTEAD, *History of Assyria* (1923, reprinted 1960); JOHN A. WILSON, *The Culture of Ancient Egypt* (1956); WILLIAM C. HAYES, *The Scepter of Egypt* (1953); R.E.M. WHEELER, *The Indus Civilization* (1953); OTTO FRANKE, *Geschichte des chinesischen Reiches*, 5 vol. (1930–52); WOLFRAM EBERHARD, *Chinas Geschichte* (1948; Eng. trans., *A History of China*, 3rd ed. rev., 1969); ETIENNE BALAZS, *Chinese Civilization and Bureaucracy* (1964); MIKHAIL ROSTOVTSEV, *The Social and Economic History of the Roman Empire* (1963); A.E.R. BOAK, *History of Rome to 565 A.D.* (1921); GEORGE OSTROGORSKI, *Geschichte des byzantinischen Staates* (1965; Eng. trans., *History of the Byzantine State*, 2nd ed., 1968). Histories of modern colonial empires are found in J. HOLLAND ROSE *et al.* (eds.), *The Cambridge History of the British Empire*, 9 vol. (1929–59; 2nd ed., 1963–); RICHARD KOEBNER and HELMUT D. SCHMIDT, *Imperialism: The Story and Significance of a Political World, 1840–1960* (1964); CHARLES DE LANNOY and HERMAN V. LINDEN, *Histoire de l'expansion coloniale des peuples européens*, 3 vol. (1907–21); STEPHEN H. ROBERTS, *The History of French Colonial Policy, 1870–1925* (1963); ROBERT L. SCHUYLER, *The Fall of the Old Colonial System* (1945); MARY E. TOWNSEND, *The Rise and Fall of Germany's Colonial Empire, 1884–1918* (1930); CLARENCE H. HARING, *The Spanish Empire in America* (1947). A discussion of the post-imperial era in Asia and Africa is provided by RUPERT EMERSON in *From Empire to Nation* (1960). An excellent discussion of modern supranational political institutions is available in INIS L. CLAUDE, *Swords into Ploughshares*, 4th ed. (1971); the same author discusses the conditions for the development of different types of international organization in his *Power and International Relations* (1962). GERARD J. MANGONE, *A Short History of International Organization* (1954), is a convenient reference for the development of most contemporary supranational political institutions. Standard treatments of the League of Nations and the United Nations

are available in FRANCIS P. WALTERS, *A History of the League of Nations* (1960); ALFRED E. ZIMMERN, *The League of Nations and the Rule of Law, 1918–1935* (1938); and HERBERT G. NICHOLAS, *The United Nations As a Political Institution*, 2nd ed. (1962). More specialized works that may be consulted include THOMAS HOVET, *Bloc Politics in the United Nations* (1958); STEPHEN M. SCHWEBEL, *The Secretary-General of the United Nations* (1952); and ALEXANDER DALLIN, *The Soviet Union at the United Nations* (1962). The development of supranational institutions in Europe is discussed in ERNST B. HAAS, *The Uniting of Europe* (1958); MICHAEL CURTIS, *Western European Integration* (1965); WALTER HALLSTEIN, *United Europe: Challenge and Opportunity* (1962); and UWE W. KITZINGER, *The Politics and Economics of European Integration* (1963). Good discussions of the political and constitutional organization of the British Commonwealth are found in WILLIAM S. LIVINGSTON (ed.), *Federalism in the Commonwealth* (1963); J.D.B. MILLER, *The Commonwealth in the World* (1958); and K.C. WHEARE, *The Constitutional Structure of the Commonwealth* (1960). An extremely useful commentary on various forms of supranational political organization is provided in IVO D. DUCHACEK, *Comparative Federalism: The Territorial Dimension of Politics* (1970). A journal published since 1947 by the World Peace Foundation, *International Organization* (quarterly), contains informative articles on current developments in international organization and also provides selective bibliographies.

National political systems: The phenomenon of nationalism is treated in HANS KOHN, *The Idea of Nationalism* (1961); and EUGEN LEMBERG, *Nationalismus*, 2 vol. (1964); and a historical sketch of the emergence of the idea and its reality is provided in CARLTON J.H. HAYES, *The Historical Evolution of Modern Nationalism* (1931, reprinted 1968). Among the many works on federal and unitary systems that the student should consult are ARTHUR W. MACMAHON (ed.), *Federalism, Mature and Emergent* (1955); WILLIAM S. LIVINGSTON, *Federalism and Constitutional Change* (1956); VALERIE EARLE (ed.), *Federalism* (1968); CARL J. FRIEDRICH, *Trends of Federalism in Theory and Practice* (1968); PETER HAY, *Federalism, and Supranational Organizations* (1966); K.C. WHEARE, *Federal Government*, 4th ed. (1963); and GEORGE C.S. BENSON *et al.*, *Essays in Federalism* (1961). IVO D. DUCHACEK (*op. cit.*) should also be consulted. Works on individual nation-states are so numerous that the student may wish to consult some standard texts that include selected bibliographies: HAROLD ZINK, *Modern Governments*, 2nd ed. (1962); HERMAN FINER, *The Major Governments of Modern Europe* (1960); and GWENDOLEN M. CARTER and JOHN H. HERZ, *Major Foreign Powers*, 5th ed. (1967). Comparative studies of different aspects of contemporary national government are also numerous. The bureaucracies and administrative procedures of different modern governments are treated in BRIAN CHAPMAN, *The Profession of Government: The Public Service in Europe* (1959); JOSEPH G. LA PALOMBARA (ed.), *Bureaucracy and Political Development* (1963); FRITZ MORSTEIN MARX, *The Administrative State* (1957); WILLIAM J. SIFFIN (ed.), *Toward the Comparative Study of Public Administration* (1957); ERICH STRAUSS, *The Ruling Servants: Bureaucracy in Russia, France and—Britain?* (1960); and J.D. THOMPSON *et al.* (eds.), *Comparative Studies in Administration* (1959). Constitutions, courts, and other judicial institutions are comparatively treated in LESLIE WOLF-PHILLIPS (ed.), *Constitutions of Modern States* (1968); K.C. WHEARE, *Modern Constitutions*, 2nd ed. (1966); WILLIAM GEORGE ANDREWS (ed.), *Constitutions and Constitutionalism*, 3rd ed. (1968); HENRY J. ABRAHAM, *Courts and Judges* (1959) and *The Judicial Process: An Introductory Analysis of the Courts of the United States, England, and France*, 2nd ed. rev. (1968); FREDA CASTBERG, *Freedom of Speech in the West: A Comparative Study of Public Law in France, the United States, and Germany* (1960); RUSSELL F. MOORE (ed.), *Modern Constitutions* (1957); DOROTHY PEASLEE XYDIS, *Constitutions of Nations*, rev. 3rd ed., 4 vol. (1965–70); and CHARLES F. STRONG, *A History of Modern Political Constitutions* (1964). National legislatures are discussed in LORD CAMPION and D.W.S. LIDDERDALE, *European Parliamentary Procedure* (1953); PAUL EINZIG, *The Control of the Purse* (1959); JOHN E. KERSELL, *Parliamentary Supervision of Delegated Legislation* (1960); and K.C. WHEARE, *Legislatures* (1963). Political parties, elections, and interest groups are comparatively treated in ROBERT R. ALFORD, *Party and Society: The Anglo-American Democracies* (1963); DAVID E. BUTLER (ed.), *Elections Abroad* (1959); ROBERT A. DAHL (ed.), *Political Oppositions in Western Democracies* (1966); MAURICE DUVERGER, *Les Partis politiques*, 5th ed. (1964; Eng. trans., *Political Parties*, 2nd ed. rev., 1959); HENRY W. EHRMANN (ed.), *Interest Groups on Four Continents* (1958); JOSEPH G. LA PALOMBARA and MYRON WEINER (eds.), *Political Parties and Political Development* (1966); W.J.M. MACKENZIE, *Free Elections* (1958); SIGMUND NEUMANN (ed.), *Modern Political Parties* (1956); and T.E. SMITH, *Elections in Developing Countries* (1960). General comparative studies of national political systems include GABRIEL ALMOND and SIDNEY VERBA, *The Civic Culture: Political Attitudes and Democracy in Five Nations* (1965); GABRIEL ALMOND and JAMES S. COLEMAN (eds.), *The Politics of the Developing Areas* (1960); GABRIEL ALMOND and G. BINGHAM POWELL, JR., *Comparative Politics: A Developmental Approach* (1966); ZBIGNIEW BRZEZINSKI and SAMUEL P. HUNTINGTON, *Political Power: USA/USSR* (1964); JAMES S. COLEMAN (ed.), *Education and Political Development* (1965); ROBERT C. FRIED, *Comparative Political Institutions* (1966); LUCIAN W. PYE (ed.), *Communications and Political Development* (1963); and LUCIAN W. PYE and SIDNEY VERBA (eds.), *Political Culture and Political Development* (1965).

Subnational political systems: Excellent general treatments of local and city government are found in WILLIAM A. ROBSON, *The Development of Local Government*, 3rd rev. ed. (1954); and (ed.), *Great Cities of the World: Their Government, Politics, and Planning*, 2nd ed. rev. (1957); and in LEWIS MUMFORD, *The City in History* (1961). On early forms of city government, the student should consult HENRI PIRENNE, *Les Villes du moyen âge* (1927; Eng. trans., *Medieval Cities*, 1956); and FUSTEL DE COULANGES, *La Cité antique* (1864; Eng. trans., *The Ancient City*, 1873, many reprints). A useful comparative study of local government is found in G.M. HARRIS, *Comparative Local Government* (1949). City and local governments in contemporary Western systems are treated in D.N. CHESTER, *Central and Local Government* (1951); HERMAN FINER, *English Local Government*, 4th ed. rev. (1950); and BRIAN CHAPMAN, *Introduction to French Local Government* (1953). Political and sociological analyses of the local community include ROBERT A. DAHL, *Who Governs?* (1961); DONALD J. BOGUE, *The Structure of the Metropolitan Community* (1949); FLOYD HUNTER, *Community Power Structure* (1953); ROBERT S. and HELEN M. LYND, *Middletown: A Study in Contemporary American Culture* (1929); and H.D. MALAVIYA, *Village Panchayats in India* (1966). For tribal forms of government, see J.A. NOON, *Law and Government of the Grand River Iroquois* (1949); and ISAAC SCHAPERA, *The Khoisan Peoples of South Africa* (1930) and *Government and Politics in Tribal Societies* (1956).

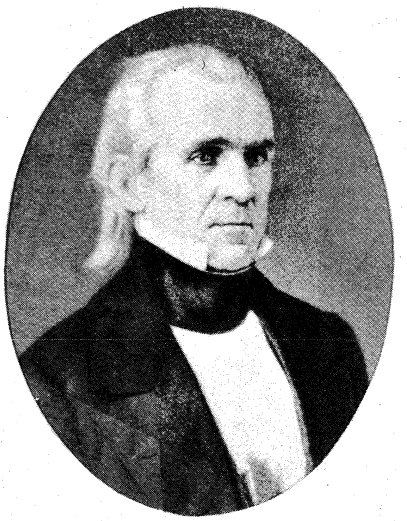
Types and models: The student of classical typologies of political systems will first refer to Book IV of Aristotle's *Politics* and then perhaps consult Book VIII of Plato's *Republic* together with a number of passages in *The Laws*. Leading modern efforts to develop types and models of political systems may be found in GAETANO MOSCA, *Elementi di scienza politica*, 2nd ed. (1923; Eng. trans., *The Ruling Class*, rev. ed., 1939); GUGLIELMO FERRERO, *Pouvoir* (1942; Eng. trans., *The Principles of Power*, 1942); and MAX WEBER, *Wirtschaft und Gesellschaft* (1922; Eng. trans. of pt. 1, *The Theory of Social and Economic Organization*, 1947). The Marxist typology, of course, is set forth in the writings of KARL MARX, FRIEDRICH ENGELS, LENIN, and their disciples. Contemporary efforts to develop typologies may be studied in DAVID E. APTER, "A Comparative Method for the Study of Politics," *American Journal of Sociology*, 64:221–237 (1958); DAVID EASTON, *A Systems Analysis of Political Life* (1965); GABRIEL ALMOND and G. BINGHAM POWELL, JR. (*op. cit.*); and ALEXANDER J. GROTH, *Comparative Politics: A Distributive Approach* (1971).

Development and change: There is a large contemporary literature centring on the question of modernization and political development. In addition to works by Gabriel Almond noted above, the student should consult PETER H. MERKL, *Modern Comparative Politics* (1970), which includes an excellent bibliography; and DAVID E. APTER, *The Politics of Modernization* (1965). Other works are CYRIL E. BLACK, *The Dynamics of Modernization* (1966) and (ed.), *The Transformation of Russian Society: Aspects of Social Change Since 1861* (1960); S.N. EISENSTADT, *Modernization: Protest and Change* (1966); JASON FINKLE and RICHARD W. GABLE (eds.), *Political Development and Social Change* (1966); EVERETT E. HAGEN, *On the Theory of Social Change* (1962); ROBERT T. HOLT and JOHN E. TURNER, *The Political Basis of Economic Development* (1966); SAMUEL P. HUNTINGTON, *Political Order in Changing Societies* (1968); JOHN H. KAUTSKY (ed.), *Political Change in Underdeveloped Countries* (1962); DANIEL LERNER, *The Passing of Traditional Society* (1958); MAX F. MILLIKAN and DONALD L.M. BLACKMER (eds.), *The Emerging Nations* (1961); DANKWART RUSTOW, *A World of Nations: Problems of Political Modernization* (1967); EDWARD A. SHILS, *Political Development in the New States* (1962); I. ROBERT SINAI, *The Challenge of Modernisation* (1964); FRED VON DER

MEHDEN, *Politics of the Developing Nations* (1964); IMMANUEL WALLERSTEIN, *Social Change: The Colonial Situation* (1966); BARBARA WARD, *The Rich Nations and the Poor Nations* (1961); and ARISTIDE R. ZOLBERG, *Creating Political Order: The Party-States of West Africa* (1966).

Forms, levels, and divisions of government: One of the best introductions to the study of different forms of government and an excellent review of the differences between constitutionalism and autocracy, democracy and totalitarianism, is KARL LOEWENSTEIN, *Political Power and the Governmental Process*, 2nd ed. (1965). Also excellent are CARL J. FRIEDRICH, *Constitutional Government and Politics* (1937); and with ZBIGNIEW BRZEZINSKI, *Totalitarian Dictatorship and Autocracy*, 2nd rev. ed. (1965). On totalitarianism, other books that should be consulted are ZBIGNIEW BRZEZINSKI, *The Soviet Bloc*, rev. ed. (1967), and *Ideology and Power in Soviet Politics*, rev. ed. (1967); MILOVAN DJILAS, *The New Class* (1957); MERLE FAINSOD, *How Russia Is Ruled*, rev. ed. (1963); ALEX INKELES and R.A. BAUER, *The Soviet Citizen: Daily Life in a Totalitarian Society* (1959); ERNST NOLTE, *Der Faschismus in seiner Epoche* (1963; Eng. trans., *The Three Faces of Fascism*, 1966); J.L. TALMON, *The Rise of Totalitarian Democracy* (1952); ALEXANDER DALLIN and ALAN F. WESTIN (eds.), *Politics in the Soviet Union* (1966); and HERBERT MCCLOSKY and JOHN E. TURNER, *The Soviet Dictatorship* (1960). On constitutional forms, the student should refer to WALTER BAGEHOT, *The English Constitution*, rev. ed. (1911, reprinted 1966); JAMES BRYCE, *The American Commonwealth*, rev. ed., 2 vol. (1931–33)); D.L. KEIR, *The Constitutional History of Modern Britain, 1485–1951*, 9th ed. (1969); IVOR JENNINGS, *Cabinet Government*, 3rd ed. (1969), and *Parliament*, 2nd ed. (1957); C.W. CASSINELLI, *The Politics of Freedom* (1961); V.O. KEY, *Politics, Parties, and Pressure Groups*, 5th ed. (1964), and *Public Opinion and American Democracy* (1961); A.D. LINDSAY, *The Modern Democratic State* (1943); C.H. MCILWAIN, *Constitutionalism, Ancient and Modern*, rev. ed. (1947); HERBERT MORRISON, *Government and Parliament*, 3rd ed. (1964); CLINTON ROSSITER, *Constitutional Dictatorship* (1948); and HERBERT J. SPIRO, *Government by Constitution: The Political Systems of Democracy* (1959). A good general introduction to the major European forms of constitutional and totalitarian governments is available in SAMUEL H. BEER and ADAM B. ULAM (eds.), *Patterns of Government: The Major Political Systems of Europe*, 2nd ed. rev. (1962). CARL J. FRIEDRICH offers an excellent introduction to the problem of the relationship between different levels of government in *Man and His Government* (1963)—see especially pt. 5, "Ranges and Levels of Government." Other books to consult on this subject are CLAUDE AKE, *A Theory of Political Integration* (1967); HAROLD ALDERFER, *Local Government in Developing Countries* (1964); REINHARD BENDIX, *Nation-Building and Citizenship* (1964); BRIAN CHAPMAN, *Introduction to French Local Government* (1953); L.G. COWAN, *Local Government in West Africa* (1958); RICHARD COX, *Pan-Africanism in Practice* (1964); KARL W. DEUTSCH, *Nationalism and Social Communication* (1953) and *The Nerves of Government* (1963; with new introd., 1966); RUPERT EMERSON, *From Empire to Nation* (1960); RICHARD R. FAGEN, *Politics and Communication* (1966); JAMES FESLER, *Area and Administration* (1949); HERMAN FINER, *English Local Government* (1933); J.A.G. GRIFFITH, *Central Departments and Local Authorities* (1966); LUCIAN W. PYE (ed.), *Communications and Political Development* (1963); WILLIAM A. ROBSON, *Local Government in Crisis* (1966); and MARC J. SWARTZ (ed.), *Local-Level Politics* (1968). Short introductions to the divisions of government, suitable for the beginning student, are available in ROBERT C. FRIED, *Comparative Political Institutions* (1966); and JOHN C. WAHLKE and ALEX N. DRAGNICH (*op. cit.*). On the legislative division of government, in addition to the books listed in an earlier section of this bibliography, the student should consult BERTRAM GROSS, *The Legislative Struggle* (1953); WILLIAM J. KEEFE and MORRIS S. OGUL, *The American Legislative Process*, 2nd ed. (1968); D.W.S. LIDDERDALE, *The Parliament of France* (1951); STEPHEN KING-HALL and R.K. ULLMANN, *German Parliaments* (1954); JOHN C. WAHLKE and HEINZ EULAU (eds.), *Legislative Behaviour* (1959); and JOHN C. WAHLKE *et al.*, *The Legislative System* (1962). Additional reading on executives should include C.G. BROWNE and T.S. COHN (eds.), *The Study of Leadership* (1958); EDWARD S. CORWIN, *The President: Office and Powers, 1787–1957*, 4th rev. ed. (1957); ALVIN W. GOULDNER (ed.), *Studies in Leadership* (1950); HOOVER INSTITUTE STUDIES, *Elites*, 5 vol. (1951–55); RICHARD E. NEUSTADT, *Presidential Power* (1960); and ERIC STRAUSS (*op. cit.*). Further reading on courts and systems of law is available in HAROLD J. BERMAN, *Justice in the U.S.S.R.* (1963); FELIX S. COHEN, *Ethical Systems and Legal Ideals* (1933); RENE DAVID and HENRY DE VRIES, *The French Legal System* (1957); JEROME FRANK, *Courts on Trial* (1949); RICHARD M. JACKSON, *The Machinery of Justice in England*, 3rd ed. (1960); HANS KELSEN, *The Communist Theory of Law* (1955); W.F. MURPHY and C.H. PRITCHETT, *Courts, Judges, and Politics* (1961); J.W. PELTASON, *Federal Courts in the Political Process* (1955); J.R. SCHMIDHAUSER, *The Supreme Court: Its Politics, Personalities, and Procedures* (1960); GLENDON SCHUBERT (ed.), *Judicial Decision-Making* (1963); and BERNARD SCHWARTZ, *French Administrative Law and the Common-Law World* (1954).

The functions of government: The functions of government may be studied in many works dealing with each of the world's advanced political systems. For the United States, the student should consult JAMES E. ANDERSON, *The Emergence of the Modern Regulatory State* (1962); MELVIN ANSHEN and FRANCIS D. WORMUTH, *Private Enterprise and Public Policy* (1954); MORROE BERGER, *Equality by Statute* (1952); RICHARD E. CAVES, *Air Transport and Its Regulators* (1962); ROBERT A. DAHL and CHARLES E. LINDBLOM, *Politics, Economics, and Welfare* (1953); KENNETH CULP DAVIS, *Administrative Law* (1951); ERNST FREUND, *Administrative Powers over Persons and Property* (1928); D.E. HATHAWAY, *Government and Agriculture: Public Policy in a Democratic Society* (1963); CARL KAYSEN and DONALD F. TURNER, *Antitrust Policy* (1959); JAMES M. LANDIS, *The Administrative Process* (1938); AVERY LEISERSON, *Administrative Regulation* (1942); JOHN H. LEEK, *Government and Labor in the United States* (1952); MICHAEL D. REAGAN, *The Managed Economy* (1963); EMMETTE S. REDFORD, *American Government and the Economy* (1965) and *Administration of National Economic Control* (1952); GEORGE A. STEINER, *Government's Role in Economic Life* (1953); GEORGE W. TAYLOR, *Government Regulation of Industrial Relations* (1948); and DONALD S. WATSON, *Economic Policy: Business and Government* (1960). For Great Britain, the student should consult PATRICK ABERCROMBIE, *Town and Country Planning*, 3rd ed. (1959); W.P. ALEXANDER, *Education in England: The National System—How It Works*, 2nd ed. (1964); MAX BELOFF, *New Dimensions in Foreign Policy* (1961); A.M. CARTTER, *The Redistribution of Income in Postwar Britain* (1955); HARRY ECKSTEIN, *The English Health Service* (1958); PETER GOLDMAN, *The Welfare State* (1964); F.A. JOHNSON, *Defense by Committee* (1960); T.H. MARSHALL, *Social Policy* (1965); and HAROLD E. RAYNES, *Social Security in Britain*, 2nd ed. (1960). On France there are WARREN C. BAUM, *The French Economy and the State* (1958); JOHN S. HARLOW, *French Economic Planning* (1966); MARIO EINAUDI, MAURICE BYE, and ERNESTO ROSSI, *Nationalization in France and Italy* (1955); W.R. FRASER, *Education and Society in Modern France* (1963); JOHN and ANNE-MARIE HACKETT, *Economic Planning in France* (1963); WALLACE C. PETERSON, *The Welfare State in France* (1960); and JOHN B. SHEAHAN, *Promotion and Control of Industry in Postwar France* (1963).



The changing of government: Further reading on the politics of change should include DAVID E. APTER (ed.), *Ideology and Discontent* (1964); ROBERT N. BELLAH, *Religion and Progress in Modern Asia* (1965); CRANE BRINTON, *The Anatomy of Revolution*, rev. ed. (1952); HARRY ECKSTEIN (ed.), *Internal War* (1964); SAMUEL E. FINER, *The Man on Horseback: The Role of the Military in Politics* (1962); CLIFFORD GEERTZ (ed.), *Old Societies and New States* (1963); MANFRED HALPERN, *The Politics of Social Change in the Middle East and North Africa* (1963); CHALMERS JOHNSON, *Revolutionary Change* (1966); JOSEPH LOPREATO, *Peasants No More* (1967); PAUL E. SIGMUND (ed.), *The Ideologies of the Developing Nations* (1962); KALMAN H. SILVERT (ed.), *Churches and States: The Religious Institution and Modernization* (1967); and ROBERT E. WARD and DANKWART RUSTOW (eds.), *Political Modernization in Japan and Turkey* (1964).

The analysis of political systems: An excellent brief review of contemporary trends in the discipline of political science is available in W.J. MACKENZIE, *Politics and Social Science* (1967). Other works that should be consulted include ROBERT R. BROWN, *Explanation in Social Science* (1963); MAURICE DUVERGER, *Méthodes des sciences sociales* (1959); Eng. trans., *An Introduction to the Social Sciences*, 1965); DAVID EASTON, *A Systems Analysis of Political Life* (1965); HEINZ EULAU, *The Behavioral Persuasion in Politics* (1963); HARRY V. JAFFA, *Equality and Liberty* (1965); ABRAHAM KAPLAN, *The Conduct of Inquiry* (1964); EUGENE J. MEEHAN, *The Theory and Method of Political Analysis* (1965); W.G. RUNCIMAN, *Social Science and Political Theory* (1963); EDWARD A. SHILS and HENRY A. FINCH (eds.), *Max Weber on the Methodology of the Social Sciences* (1949); FRANCIS J. SORAUF, *Political Science: An Informal Overview* (1965); and T.D. WELDON, *The Vocabulary of Politics* (1953).

(D.A.He.)

Polk, James K.

A friend of Pres. Andrew Jackson and a loyal proponent of his political principles, James Knox Polk, the 11th president of the United States, distinguished himself by the skill, equalled by few presidents, with which he won legislative approval for the large majority of his goals in foreign and domestic policy. The most important legacy of his presidency was the acquisition of the territories that today comprise the states of Texas, New Mexico, California, and Oregon.

Polk, daguerreotype by Mathew Brady, 1849.
By courtesy of the Library of Congress, Washington, D.C.

Polk was born in Mecklenburg County, North Carolina, on November 2, 1795. At the age of 11 he accompanied his family to Tennessee, where his father operated a prosperous farm in Maury County. Though ill health made formal schooling impossible during his childhood, at the age of 20 he successfully passed the entrance requirements for the second-year class of the University of North Carolina. He was "correct, punctual, and industrious," and as a graduating senior in 1818 he was the Latin salutatorian of his class—the pre-eminent scholar in both the classics and mathematics.

Early career

After graduation he returned to Tennessee and began to practice law in Nashville. His interest in politics, which had fascinated him even as a young boy, was encouraged by his association with leading public figures in the state. In 1820 he was admitted to the bar. Because he was a confirmed Democrat and an unfailing supporter of Andrew Jackson and because his style of political oratory became so popular that he was characterized as the "Napoleon of the stump," his political career was assured. His rapid rise to political power was furthered by his wife, Sara Childress Polk (1803–91), whom he married January 1, 1824, while serving in the state house of representatives (1823–25). The social prominence of her family and her personal charm were distinct assets for a politically ambitious lawyer. As an official hostess she won the admiration and esteem of the leading figures of the day, and for 25 years she was her husband's close companion in state and national politics.

James K. Polk was by nature a student of government, by experience a legislator, and by force of circumstance an administrator. He was not an easy man to know or to like. Even close companions did not relish his austerity, and associates tolerated but did not approve his inflexible living standards. Among his few close friends was Andrew Jackson, who encouraged and advanced Polk and whose influence carried him from the Tennessee House of Representatives to the United States House of Representatives, where he served from 1825 to 1839. As speaker of the House from 1835 to 1839, Polk acquired a reputation as an undeviating supporter of Jacksonian principles. In 1839 he left the House to become governor of Tennessee. Two defeats for a second term (1841, 1843) by small majorities convinced him that to strengthen his party he should return to Washington in some capacity.

Polk's nomination as the Democratic candidate for president in 1844 was unsought by him, for the party had more prominent sons in Martin Van Buren, Lewis Cass, and James Buchanan. But the Democrats could not reconcile their differences, and a compromise candidate had to be found because the campaign was to be run on issues and not on personalities; it was decided that Polk would do. He is regarded as the first "dark horse" nominee in the history of the presidency. As a party man from what was then the West, and a former member of the House of Representatives, it was thought that Polk would bring about legislative and executive cooperation and understanding in the functioning of the national government. While speaker of the House he had decided many procedural questions and had usually been sustained by majorities composed of the leaders of both parties. His party feeling was intense, but his integrity was unquestioned; he knew the rights and privileges of the House, and he also knew its responsibilities.

During his campaign Polk surprised the country by taking a positive stand on two burning issues of the day. Whereas other candidates hedged on the question of whether to annex Texas, which had been independent of Mexico since 1836, he demanded annexation. Whereas other candidates evaded the problem of joint occupancy of Oregon with England, he openly laid claim to the whole territory that extended as far north as 54°40′ with the campaign slogan "Fifty-four Forty or Fight." His election was close, but it was decisive—a popular plurality of about 38,000 and 170 electoral votes against 105 for Henry Clay.

Presidency

Not yet 50 years of age, Polk was the youngest successful presidential candidate up to that time. He entered the presidency full of vigour and with an expressed zeal to serve his country to the best of his ability. He left it four years later exhausted and enfeebled by his efforts. In office he demonstrated remarkable skill in the selection and control of his official advisors, and in his formal relations with Congress his legislative experience served him well. When his party was firmly united behind a policy he himself opposed, he yielded to the wishes of Congress. When he disagreed strongly with congressional policy and decided to make an issue of it, he fortified his position with recognized executive precedent and practice. His formal disapprovals (in the form of two message vetoes and one pocket veto by which legislation is killed by the failure of the president to sign a bill before the adjournment of Congress) were questioned, but the two returned measures failed to command the necessary two-thirds majority in order to override his vetoes.

The Polk administration was marked by large territorial gains. The annexation of Texas as a state was concluded and resulted in a two-year war with Mexico. As a consequence of that war the Southwest and far West (California), partly by conquest and partly by purchase, became part of the United States domain. During this period the northwest boundary became fixed by treaty, and the continental United States emerged a recognized reality. Additional achievements included a treaty with New Granada (Colombia) resolving the problem of right-of-way for U.S. citizens across the Isthmus of Panama; establishment of a warehouse system that provided for the temporary retention of undistributed imports; and the passage of the Walker Tariff Act of 1846, which lowered import duties and did much to pacify British public opinion that had been inflamed over the Oregon compromise of 1846 that established the international frontier at the 49th parallel. As these measures helped foreign trade, so the reenactment of the independent treasury system in 1846 helped in the solution of domestic financial problems.

The expansion of the country westward led to the creation of a new agency, the Department of the Interior. The Polk administration should also be credited with the establishment of the United States Naval Academy at Annapolis and the authorization of the Smithsonian Institution, a national foundation for all areas of science.

Polk's influence over his congresses may be gauged from

Assessment

the results of the recommendations of four annual messages and ten significant special messages to one or both houses. His control of legislative policy in bitterly partisan congresses must be judged in terms of results, not oratory or parliamentary delay. He recommended with a high degree of success settlement of a trade dispute with Great Britain; an increase in U.S. armed forces; war with Mexico, peace with Great Britain over Oregon, making available finances to expedite peace conclusions; organization of the Oregon Territory; peace with Mexico providing for limited conquest; and a revised treasury system. He refused information desired by Congress (on the ground that it was incompatible with the public interest), recognized a new French revolutionary government, and proclaimed the validity of the Monroe Doctrine. Succeeding presidents recognized these pronouncements.

A diary kept by Polk during his term of office stressed the presidential burden. Day after day, week after week, he recounted in his diary his experiences with the hosts of office seekers who infested Washington and who occupied so much of his public time. Again and again there is evident in his writings a note of despair. He knew from experience what an evil an unlimited executive patronage can become, but he felt powerless to change its obligations and too conscientious to avoid its duties. At the close of his term, March 4, 1849, Polk retired to his Nashville home, where he died on June 15, 1849.

The office of chief executive under Polk was well filled. He maintained it with dignity, with integrity, and with an extraordinary sense of duty. His great influence over Congress was due to the justness of his policies and the persistence of his efforts in having the members see the questions not as interests of district or section but as matters of national welfare. His sturdy character and unblemished reputation gave weight to his counsels and strengthened his pleas. History may not rate James K. Polk as one of the greatest U.S. presidents, but his successes in office made his influence considerable.

BIBLIOGRAPHY. No published definitive work on the life and times of James K. Polk is known; however, attention is called to the biographical sketch preceding the published papers of President Polk found in JAMES D. RICHARDSON, *Messages and Papers of the Presidents*, vol. 4 (1897). The restricted accounts on aspects of his life before the presidency, E.I. MCCORMAC, *James K. Polk: A Political Biography* (1922, reprinted 1965); and C.G. SELLERS, *James K. Polk, Jacksonian, 1795–1843* (1957), are highly selective. M.M. QUAIFE (ed.), *The Diary of James K. Polk During His Presidency, 1845 to 1849*, 4 vol. (1910), is a reliable, almost complete printing of the manuscript and a revelation of a president's mind.

(G.C.R.)

Pollen Stratigraphy

Pollen stratigraphy is the record of the chronologic and geographic distribution of fossil pollen and spores in the earth's strata. This distribution provides a basis for the time-stratigraphic subdivision of rock sequences and, hence, for the correlation of strata, or geological events, from one region to another. Pollen stratigraphy is one aspect of palynology (Greek *palynein*, "to strew or sprinkle"; *cf. palē*, "fine meal"; cognate with Latin *pollen*, "flour, dust"), a term coined in 1944 to embrace all aspects of the study of pollen and spores, ranging from examination of pollen morphology by the electron microscope, to a determination of the source or adulteration of honey by analysis of its pollen content, and to a study of fossil spores extracted from ancient coals.

Pollen stratigraphy has primarily geological overtones because it is concerned with the time-space relations of fossils, but it is of great importance in such disparate fields as biology, archaeology, climatology, and anthropology, among others. Most changes in pollen profiles of the Pleistocene Epoch (10,000 to 2,500,000 years ago) reflect the impact of climatic fluctuations on the natural vegetation. But the innovation of primitive agriculture in the late Stone Age introduced a nonclimatic factor into vegetational distribution and development that is conspicuous in many pollen profiles of northern and central Europe. This change is marked by the appearance of cultivated cereal pollen and by the first appearance or greatly increased frequency of pollen of agricultural weeds that are commonly associated with human settlement. Changes in the pollen profiles give clear evidence that Neolithic man cleared the virgin forest by ax felling and burning and then began cultivation of grains. Occasional finds of corn (*Zea mays*) pollen in the southwestern United States and Mexico confirm that corn was used by prehistoric peoples of the New World and was treated as a cultivated or semi-cultivated species.

Because pollen passes through the digestive tracts of vertebrate animals and may be recovered undamaged, the examination of coprolites (fossilized fecal material) can provide precise information concerning the diet of prehistoric peoples and their animal husbandry and cultural practices. In Europe, for example, many plants have been used and valued in historic times as fodder plants, among them ivy (*Hedera*), mistletoe (*Viscum*), and elm (*Ulmus*). Study of the pollen record at Danish and Swiss sites suggests that Neolithic farmers may also have used them as fodder for their domestic animals. The pollen of all three genera showed a simultaneous decline that coincided with the occurrence of farmer cultures and the introduction of agriculture in the immediate vicinity. Climatic change was ruled out as a cause because other pollen in the assemblage indicated that this was unlikely. Direct evidence in support of ivy as fodder was found from examination of the pollen content of cultural layers. Despite the general decline of ivy pollen in the natural pollen rain, it was very abundant (*i.e.*, reaching 40 to 80 percent) in samples from the site of a stable and in feces of goats or sheep. Evidently, Neolithic farmers helped to reduce the population of ivy (and of elm and mistletoe) by feeding the flowering plants to their cattle.

This article treats the properties, transportation, distribution, and deposition of organic microfossils—principally pollen and spores—and their evolution and stratigraphic occurrence. Coverage of the paleoecology and paleogeography implied by the pollen record also is presented. For further information on the general principles of stratigraphic analysis, see STRATIGRAPHIC BOUNDARIES. See also PLEISTOCENE EPOCH; HOLOCENE EPOCH; and CLIMATIC CHANGE for relevant data on the deposits and environmental conditions of the last 2,500,000 years, which are related to the pollen record; COALS, which indicates the existence of a Carboniferous (280,000,000 to 345,000,000 years ago) pollen record; and FOSSIL RECORD for general paleontological information, including the geological occurrence and evolution of plants.

CHARACTERISTICS OF ORGANIC MICROFOSSILS

Nature and diversity of microfossils

Organic microfossils, sometimes called palynomorphs, are microfossils of generally similar size with organic walls composed of carbon, hydrogen, oxygen, and nitrogen compounds. They include pollen and spores, dinoflagellates, acritarchs, chitinozoans, bacteria, fungal spores and fruiting bodies, and fossils such as scolecodonts (jaws of certain worms). Varied plant parts and tissue fragments, such as epidermis, tracheids, trichomes, fern sporangia, and moss leaves, as well as a variety of dispersed organic matter also may be present. Some organic microfossils are whole organisms, whereas others are, or appear to be, some part of the life cycle of a larger organism. Pollen is the male reproductive structure of higher vascular plants (gymnosperms and angiosperms); spores are the asexual reproductive bodies produced by lower vascular plants (ferns, psilopsids, lycopsids, sphenopsids). The reproductive structures of nonvascular plants (bryophytes, algae, fungi) are also called spores, but only those of the bryophytes morphologically resemble spores of the so-called lower vascular plants with which they may be confused in the fossil record.

Many organic microfossils are among the group of "primitive" one-celled organisms that zoologists call animals and botanists call plants. These borderline organisms are sometimes grouped into a separate kingdom called the Protista, which includes the bacteria, algae, and fungi of some botanical classifications and the protozoa of some zoological classifications. Other organic microfossils are of problematical or unknown affinity.

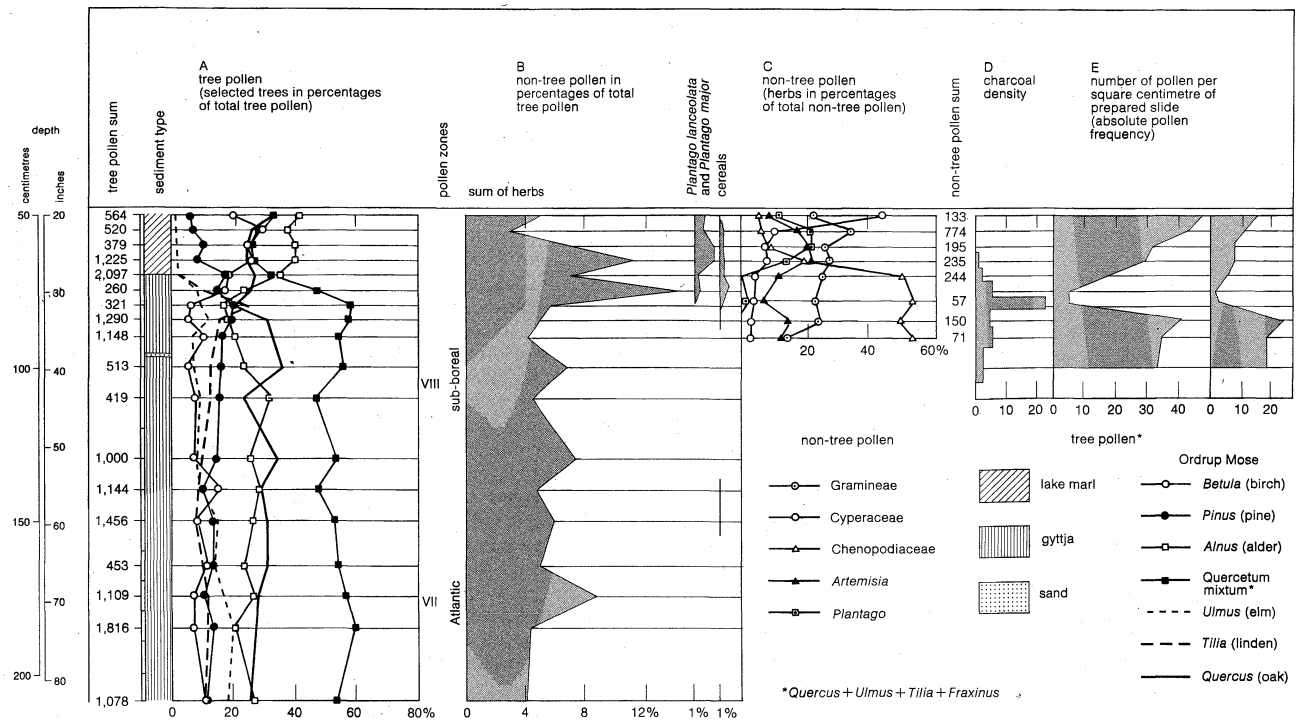


Figure 1: Pollen diagrams used to depict palynological data obtained from a vertical sequence of sediments or sedimentary rocks. They illustrate the vegetational history of an area and, in the case of the Ordrup Mose (Ordrup Bog, Denmark) diagram (E), the kinds of data that bear upon interpretations of Neolithic farming (see text).
After Geological Survey of Denmark, II. Series No. 66. Author Johannes Iversen, painter Ingeborg Frederiksen

Physical and chemical properties. As a group, palynomorphs are nonmineralized, although individuals within some of the groups, for example certain of the dinoflagellates, have mineralized (siliceous or calcareous) tests (hard parts). The chemical composition of organic microfossils does not appear to be the same for all groups and, in general, remains poorly known because the substances involved are relatively inert.

Pollen and spores are complex chemical structures of which only the outer wall, the exine, is preserved in the fossil state. The specific resistant substance in spore-pollen walls has been called sporopollenin. It appears to consist of organic substances the nature and structure of which are still not clear. Other palynomorphs may be composed of a substance similar to sporopollenin; some are described as chitinous or pseudochitinous. Chitin is a complex carbohydrate, a polysaccharide that may be regarded as a derivative of cellulose, which it resembles in many of its properties. Among living plants, chitin is confined to the green algae and the fungi, but it is found in a wide group of invertebrates within which it forms the major organic skeletal substance. Pseudochitin (composed of nitrogen, carbon, hydrogen, and oxygen) is chemically distinct from chitin. As used to describe the tests of chitinozoans, for example, the term indicates primarily that the chemical properties of these microfossils are distinct from those that characterize chitin of modern organisms. This may be the result, in part, of postdepositional modification of the original organic substance of the organism.

Organic microfossils are characteristically measured in microns (one micron equals 0.001 millimetre). Size ranges for representative groups are as follows: pollen and spores, five to 200 microns; dinoflagellates, 20 to 350 microns; acritarchs, seven to 500 microns; chitinozoans, 30 to 1,500 microns. Typical sizes in each group fall between these extremes; most dinoflagellates, for example, are about 60 to 150 microns, and most pollen about 20 to 60 microns. Large spores (megaspores) derived from heterosporous plants such as *Selaginella* may vastly exceed the size limits of most pollen and spores, and some megaspores, including fossil specimens, may be between one and seven millimetres (1,000 and 7,000 microns). The largest organic microfossils can be observed directly without the microscope, or with the use of only minimum magnification (50 ×).

General shape and appearance

Organic microfossils are (as their diverse biological affinities would suggest), varied in their appearance. There are four principal groups.

Chitinozoans are typically rod-, club-, and flask- or trumpet-shaped with a terminal opening. The tests are smooth or partially or entirely covered with short spinelike protrusions. Tests are commonly black and opaque but may be amber and translucent. Chitinozoans occur singly or in chains of as many as six individuals.

Dinoflagellates are commonly spherical, ellipsoidal, or polygonal; the basic shape is sometimes modified by outgrowths. The test is often divided into a system of smooth or variously ornamented plates whose junction is clearly marked or, in the case of cysts of the type generally called hystrichospheres, the plate pattern is indistinct or absent. Hystrichospheres often have long, sometimes bifurcating, spinelike processes radiating from the surface.

Acritarchs are varied, and may be spherical, ellipsoidal, discoidal, elongate or polygonal. Some acritarchs lack ornamentation; others possess spines or raised ridges. Ornamentation, if present, is random or confined to certain parts of the test. Some acritarchs resemble some dinoflagellate cysts.

Spores and pollen—though treated as a group—differ in appearance. Spores are typically bilateral-monolete (kidney-bean shaped) or radial-trilete (rounded triangular). They are smooth or variously ornamented. Pollen are morphologically the most complex organic microfossils. They typically have one to many apertures that are commonly round or ellipsoidal (pores), or elongate (furrows or colpi), or a combination of the two. Pollen grains are symmetrical and possess complex surface patterns.

Extraction of samples from rocks

The extraction of microfossil samples from sediments and sedimentary rocks is accomplished by chemical and mechanical techniques. The chemical techniques are based on the use of acids and bases which dissolve or disaggregate mineral and certain organic fractions of the rock, but to which the microfossils are resistant. Silicates and carbonates are removed by hydrochloric and hydrofluoric acid. Organic materials, other than microfossils, are destroyed by oxidation using, for example, nitric acid, hydrogen peroxide, Schulze's solution (nitric acid plus

potassium chlorate), or by acetylation (sulfuric acid plus acetic anhydride). Oxidation, which attacks the lignin fraction of organic residues, and acetylation, which attacks the cellulose fraction, may be used on the same sample. Various mechanical techniques are effective in removing material that survives chemical processing. The most successful of these involve heavy liquid flotation that will float the organic microfossils but permit heavier, organic or inorganic fractions to sink. Commonly used heavy liquids include zinc chloride and bromoform. The extraction procedure must be done with considerable care to avoid contaminating the sample with airborne modern pollen or with fossils of a different age; selective destruction of some of the microfossils also must be avoided. The occurrence of any of these errors will bias the fossil assemblage and will lead to errors of interpretation of the assemblage.

Environments of accumulation. The principal environments of accumulation of organic microfossils are continental, continental-marine, and marine, which correspond to the depositional environments of sedimentary rocks. Continental environments are terrestrial, such as soils, glacial ice, freshwater lakes, and swamps and bogs. The marine-nonmarine environments include near-shore littoral, deltaic, and estuarine sites. Marine environments extend from immediately below the tidal limits to the deepest oceanic zone.

Organic microfossils are found in each principal environment and in many specialized sub-environments. Pollen and spores, the most widespread palynomorphs, are found in soils, fluviatile deposits, and glacial ice, as well as in transitional and marine environments; their occurrence is by no means uniform in these environments, however. Terrestrial bogs, lake sediments, soils, and cave deposits are important in pollen stratigraphy of Pleistocene deposits and archaeological sites. Transitional marine-nonmarine environments with interbedded continental and marine deposits are abundant sites of pollen accumulation, although the littoral zone is not generally favourable to pollen preservation because of its instability and frequent accumulation of coarse sediments. Richly fossiliferous coal deposits near sea level, with interbedded terrestrial bog and marine shales, accumulated in transitional enviroments. Marine environments, especially those of the continental shelf, are extremely favourable to pollen preservation but pollen-spore density in ocean sediments drops off at the continental slope and into the abyssal (deep sea) zone.

The other principal groups of palynomorphs, the chitinozoans, acritarchs, and dinoflagellates, are entirely or largely confined to marine environments. A few acritarchs have been recovered from nonmarine rocks and some fossil freshwater dinoflagellates are known, but such finds are exceptional.

Problems of interpretation can arise because the contamination potential of a fossil assemblage is high. Organic microfossils are so indestructible that they may survive several generations of deposition and erosion and, thus, migrate from one environment to another. Under some circumstances redeposited specimens are abundant and, depending on the age differential, redeposited and younger microfossils may be indistinguishable. Contamination may also occur when percolating groundwater picks up pollen from the rocks it transgresses and redeposits these alien grains elsewhere. Drilling muds containing pollen and spores foreign to the host rock provide still another possibility for contamination.

STRATIGRAPHY AND SEDIMENTATION

Influence of life habits on occurrence

Transportation and deposition of microfossils. Most organic microfossils, exclusive of pollen and spores, appear to be the remains of planktonic (free-floating) marine organisms. Living dinoflagellates primarily inhabit near-surface layers of the oceans; presumably this was true of the fossil forms when they were living. They are found in marine, brackish-water, and freshwater environments, though they are most abundant in marine environments. Hystrichospheres (encysted dinoflagellates with radiating structures) seem to manifest decreased diversity and abundance in areas of reduced salinity adjacent to shorelines, and a general increase in absolute abundance seaward. Acritarchs, to a large extent extinct, also appear to have been planktonic because their remains are common in a variety of sedimentary rocks of marine origin. A few nonmarine acritarchs occur in Pleistocene and younger strata. Chitinozoans, wholly extinct, are also found in rocks of many lithologies. They too are presumably marine plankton, although some may have been benthonic (bottom dwellers) and attached to the substratum. The frequent association of chitinozoans with corals and crinoids has led to the speculation that these problematical micro-organisms lived in maximum concentration in warm, shallow, well-aerated waters, although the association of chitinozoans with the mineral glauconite suggests that some also lived in oxygen-poor environments. Pollen and spores are derived largely from land-based vegetation; the habitats of individual plants may include freshwater lakes and streams and some few monocotyledons, such as ditch grass (*Ruppia*), grow submerged in salt and brackish water. Pollen and spores dispersed by wind and water transgress widely into marine environments, as well as into terrigenous environments that are alien to their immediate source vegetation. Lacustrine and fluviatile micro-organisms, such as the green alga *Pediastrum*, are also found in marine deposits as a result of transportation. Marine-based micro-organisms, however, seldom transgress into continental environments.

Occurrence in sedimentary rocks

Because they are the remains of free-floating organisms, or wind- and water-dispersed structures, organic microfossils are not necessarily restricted to environments primarily suited to the living organisms. Organic microfossils, thus, occur in sedimentary rocks representing many environmental types. The usefulness of organic microfossils for determining the ecology of depositional environments therefore varies. Some empirical generalizations are obvious. The presence of dinoflagellates and acritarchs, for example, generally indicates deposition in marine environments. The presence of pollen and spores without an admixture of marine microfossils is indicative of continental conditions. Generalizations based on empirical observations such as the ratio of marine to nonmarine microfossils and the association of distinct microfossil assemblages with distinctive rock types may also be useful in determining the ecology of depositional environments. In a vertical sequence of essentially homogeneous rock strata, for example, a mixed assemblage of marine- and land-derived microfossils in one part of the section, compared with an entirely land-derived assemblage in another part of the section, probably indicates a change in depositional environments from open marine conditions distant from shore, to shallow-water, near-shore, or continental environments. When distinctive microfossil assemblages are confined to distinctive rock types, the combined sedimentological-microfossil data may be necessary to determine the relation between the microfossil assemblage and the depositional environment if the affinities of the specimens are unknown. This is true of certain interbedded Carboniferous coals and marine shales of England; the sequence of coals contains similar pollen-spore floras that are distinct from those that occur in the sequence of marine shales. The coal plant assemblage represents a recurring swamp flora that is obliterated by marine transgressions and then re-established following sea regression. The swamp flora is independent of the stratigraphy and will reoccur, at least locally (in restricted areas) in this particular part of the Carboniferous, wherever swamp conditions are re-established. The environmental significance of the different microfossil assemblages would not have been apparent without knowledge that they were restricted to particular and distinctive rock types and sequences.

When botanical relationships of fossils are determinable, they may provide sensitive indicators of depositional environments without resorting to empirical observations. In coals and lignites, for example, a pronounced representation of swamp vegetation is expected. Sometimes vegetation that is environmentally suggestive may

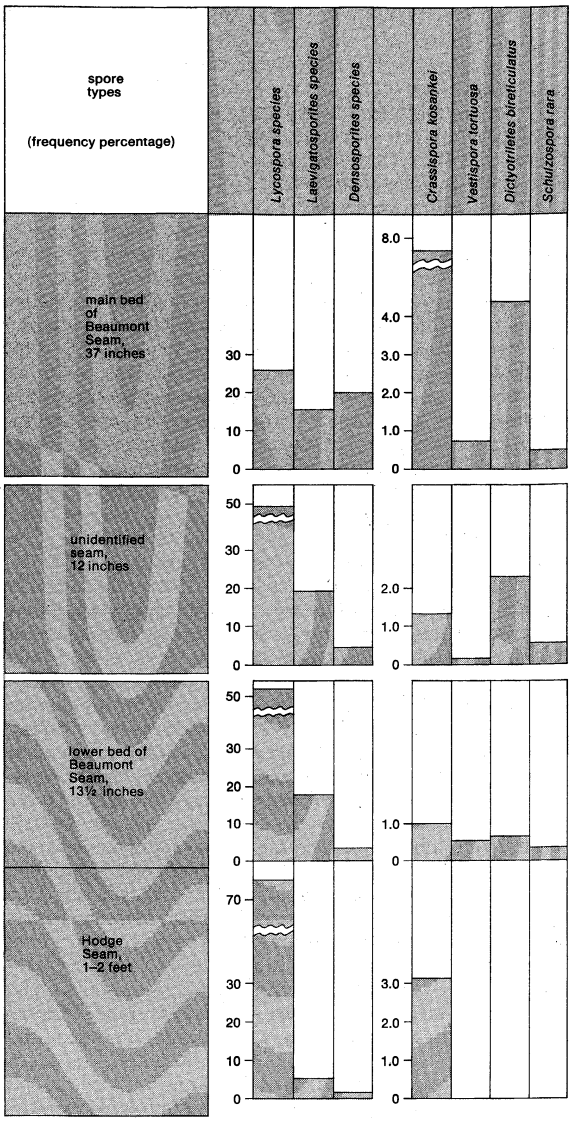

Figure 2: Miospore frequencies in coal seams at Montagu Colliery, Great Britain.

Reprinted with the permission of the Palaeontological Association from the original figure used in *Palaeontology*

occur in situations in which the environment in question is not immediately obvious from the lithology. Some types of coastal vegetation may thus show pronounced quantitative fluctuations dependent on local conditions. This is the case beginning in the Oligocene, in such remote regions as Venezuela, Nigeria, New Guinea, and Borneo, where large quantities of pollen of the *Rhizophora* type point to the introduction and perpetuation of mangrove-swamp vegetation in the tidal zone along these coasts.

Dispersal of pollen by wind and water

Palynomorphs are transported by wind and by water. Agents such as insects and birds also play a part in pollen dispersal, and the long distance transport of pollen may involve hundreds or thousands of miles. Pollen of the Southern Hemisphere beech (*Nothofagus*) has been found in the South Atlantic island of Tristan da Cunha, to which it apparently was borne from South America at least 4,500 kilometres (2,800 miles) to the west. Pollen of the conifers *Podocarpus* and *Dacrydium* have been found in Pacific island peats at least 700 kilometres (435 miles) from their apparent New Zealand source. Pollen from North America is found over the mid-Atlantic and alder (*Alnus*) pollen occurs on the continental shelf near Trinidad; the latter was waterborne from an Andean source 800 kilometres (500 miles) to the west at elevations of 2,000 to 3,000 metres (6,550 to 9,850 feet). Few instances of long-distance pollen transport are quantitatively important.

The distribution of planktonic aquatic palynomorphs largely reflects water currents and turbulence but the restriction of pollen-spore studies to terrestrial environments for many years has emphasized their aerial distribution by the wind as of prime importance. Though it has long been known that buoyant conifer pollen floats on water for extended periods, the potential of rivers and ocean currents as avenues of pollen travel are still poorly explored.

The amounts of pollen suspended in estuarine and open ocean water and contained in surface sediments from deltas, the continental shelf, and the ocean basins have demonstrated that pollen is abundant in marine and transitional marine-continental environments, and that water transport in noncontinental environments may well exceed wind as the primary agent. For example, 2,000 grains of pine (*Pinus*) pollen was concentrated from 100 litres (26 gallons) of water on the Great Bahama Banks as much as five months after pine had flowered. Delaware Bay water contained 200 pollen grains per gallon in June. Pollen density in the open ocean during June was far less, although at a depth of 2,240 fathoms, 100 gallons of water still contained 68 pollen grains, a richer concentration than in surface layers where approximately one to 18 grains per 100 gallons were recovered.

In surface sediments from the Orinoco River Delta and the Gulf of Paria, the abundance of pollen and spores per gram of sediment decreases seaward, with heaviest concentrations opposite the larger delta tributaries. Because the wind direction is predominantly easterly, marine currents must be the main transport medium. Studies on the Great Bahama Bank also demonstrate that wind is not accountable for the distribution of pollen in surface sediments. The distribution of pine pollen, which remains suspended in water for long periods, was related neither to proximity of pine trees nor to wind direction during flowering, but was explained by water turbulence and sedimentation patterns. Studies of surface sediments adjacent to the coast of Israel also demonstrate the effectiveness of the Nile and the currents of the Mediterranean in pollen and spore transport.

It is clear that spores and pollen that settle directly into moving water, or that do so after some wind transport, may be transported great distances from their source areas. Water turbulence keeps pollen and spores in suspension because of their natural buoyancy. The lighter fraction is winnowed from the heavier and is carried with the lighter sedimentary particles an increasing distance from vegetation and sediment sources. Selectivity of pollen on the basis of size occurs with increasing distance seaward; the highest concentrations of small, light pollen are preferentially associated with silt-size particles with which waterborne pollen compares in settling velocity (rate of fall of particles in still water). Size selection and concentrations of pollen where water turbulence is minimal and sediments are uniformly fine-grained emphasize that the transportational and depositional characteristics of pollen are similar to those of sedimentary particles of similar size and density.

Limits of dispersal

The normal limits of effective pollen and spore dispersal by water are still unknown, but they appear to be tens of miles. Pollen and spores are found in workable quantities both on the continental shelf and in some ocean basins, although the abundance and the diversity both drop off with increasing distance from shoreline. In the Gulf of Mexico the absolute abundance of pollen and spores per gram of surface sediment drops off rapidly up to a distance of about 30 miles offshore, after which it tends to become constant. At 80 miles from shore, surface sediments still contain between 2,000 and 3,000 spores and pollen grains per gram. Off the Atlantic Coast of North America the concentration per gram of sample increases eastward from about 20 miles to a maximum of about 185 miles offshore, and then it decreases toward the ocean basins. The greatest diversity of types is found on the continental shelf. In the Pacific Ocean pollen and spores are recovered from all bottom sediments of marginal seas (Sea of Japan, Sea of Okhotsk, Bering Sea), but along meridional profiles from Hawaii to New Zea-

land only surface sediments from comparatively nearby islands contain pollen and spores in any quantity. Surface sediments from the South Pacific 100 to 150 kilometres (60 to 90 miles) east of New Zealand have conifer pollen and spores but almost no angiosperm pollen, whereas sediments 300 to 400 kilometres east of New Caldeonia have mainly spores and almost no pollen.

Palynomorphs behave like sedimentary particles in another way. They may survive the erosion of sedimentary rocks and retransportation and redeposition. Recycled organic microfossils may involve several generations of rocks.

Pollen and spores travel at least a short distance in air before settling on land and water surfaces. As in water, pollen is suspended in air according to turbulence and natural buoyancy. Pollen from vegetation at any one locality, therefore, is not necessarily deposited at the same time within a limited geographic region. Experiments show that great quantities of the most buoyant pollen may be updrafted in warm, dry, high-velocity air currents beneath cumulus clouds or along mountain fronts to be transported horizontally for great distances at high altitudes. Pollen fallout from the upper air masses occurs during periods of relative calm. The heavy pollen drops first—the light pollen may remain continuously suspended for varying times. Transport distance and suspension time are largely determined by pollen density and by meteorological conditions such as wind strength and direction and relative humidity. Rain, especially of small droplets, will collect and eliminate airborne spores and pollen almost immediately. In areas of daily rains the effectiveness of aerial transport of pollen and spores is greatly restricted. Fifty to 100 kilometres (30 to 60 miles) is generally accepted as the effective limit of aerial pollen dispersal. The aerial pollen density drops off rapidly away from vegetation-clothed landmasses although both tree and herb pollen have been trapped across the Atlantic from Göteborg to New York during the early summer.

Eh–pH conditions favouring preservation

Preservation and alteration of pollen and spores. The best natural environments for pollen-spore preservation are said to be those in which the potential oxidation of substances (Eh) is low or negative (reducing, anaerobic environments) and the hydrogen ion concentration (pH) is low (acidic environments). Anaerobic, acidic environments are common in bogs and in the deepwater layers of some lake and ocean bottoms. Some alkaline (high pH), anaerobic Pleistocene lake deposits yield well-preserved, abundant pollen except where the Eh rises; then the pollen is scarce or absent. Alkaline evaporite deposits such as salt and gypsum also contain well-preserved pollen and spores as their only significant fossil. High pH carbonate deposits (limestones) are also said to be unfavourable for pollen-spore preservation, but plant microfossils are found in modern carbonate sediments from the Grand Bahama Banks and the Persian Gulf, and dinoflagellates, acritarchs, chitinozoans, and others are common and well-preserved in calcareous rocks. In some Upper Cretaceous limestones it has been found that laboratory oxidation destroys the available pollen. This has given rise to the postulate that the resistance to oxidation of pollen depends on the pH of environments in which the pollen are preserved. Pollen and spores have low concentration in both limestones and saline rocks, and neither is found in dolomites (calcium magnesium carbonate), although chitinozoa occur in this rock type.

The highest concentrations of well-preserved palynomorphs are found in unaltered, slowly deposited, fine-grained sedimentary rocks where: (1) distortion due to sediment compaction and sedimentary overburden is minimum, and (2) post-depositional weathering (oxidation) also is minimum. Excessive overburden of several thousand or more feet of rock produces a low-grade metamorphism (rock alteration) with the gradual carbonization of plant fragments and pollen and spores. With the increasing weight of overburden these microfossils lose their structure and eventually are converted to amorphous carbon. Some low-grade metamorphic coals do yield pollen and spores, but in the highest rank coals (*e.g.*, anthracites), they may be difficult to isolate from the coal matrix without chemically attacking the pollen and spores. In such floras only durable, resistant types of microfossils are preserved and liberated. Porous rocks long exposed to atmospheric oxygen or groundwater may be weathered to great depths and their original pollen and spore content partially or entirely destroyed. Red beds, for example, whether deposited in an already oxidized state or whether subjected to *in situ* oxidation following deposition, are commonly free of pollen and spores and other organic material, although interbedded nonred shales may contain plant microfossils.

Stratigraphic correlation. The application of pollen and spores to the solution of stratigraphic and other geologic problems has been extensively explored in some parts of the geological column; in problems involving Carboniferous coals, German Tertiary brown coals, and Quaternary history, for example, their use has become essentially routine. The use of pollen and spores and other organic microfossils for stratigraphic correlation of a variety of sedimentary rocks of all ages has gained increasing popularity among petroleum companies in recent years.

Utility of organic microfossils

Organic microfossils are stratigraphically useful because of their extensive geographic distribution, limited stratigraphic ranges of genera and species, great abundance of some groups throughout much of the geological column (the rock record of all geological time), independence from local environmental conditions, and their distinctive and diverse morphology that permits characterization of individual genera and species. Accordingly, many organic microfossils are useful for local, regional, interregional, and long distance correlation.

Because of their general resistance to biochemical degradation and their easy dispersal, organic microfossils occur in certain types of sediments and sedimentary rocks that lack other fossils. Black shales deposited in reducing (anaerobic) environments, or saline deposits that are generally unsuitable for the preservation of other fossils, are good repositories for palynomorphs, for example. Because of their small size, thousands of specimens may occur in a few grams of rock; this is a special advantage in studying drill core samples. Organic microfossils may be especially valuable if fossils traditionally used for correlation and age determinations are absent. Organic microfossils are among the only Precambrian (older than 570,000,000 years) fossils with stratigraphic promise, although they are still imperfectly known and do not yet provide an independent basis for stratigraphic correlation and dating of strata. Organic microfossils may complement information from other fossil groups when these are present, as in the case of many marine and brackish water environments. In particular, pollen and spores, either alone or in conjunction with other fossils, are especially useful in predominantly continental stratigraphic sequences such as bogs, lake deposits, and archeological sites, or where marine and continental rocks alternate within a single depositional environment as in many Carboniferous (280,000,000 to 345,000,000 years ago) coal deposits. In mixed or transitional environments pollen and spores are the most useful microfossils, for they are widely and simultaneously deposited and thus provide a means of correlating sedimentary rocks across marine, brackish water, and continental environments. Most of the traditional stratigraphic fossils are restricted to one of these environments or have only limited stratigraphic use when they occur in others.

Chronology of floral changes

Pollen stratigraphy has become the cornerstone of Pleistocene stratigraphy by providing a chronological scale against which to measure events of the Quaternary Period (the last 2,500,000 years). In Quaternary deposits, pollen zones are established by significant changes in the character of the vegetation, such as the appearance and disappearance of some forest type, or changes in dominance of some of the principal pollen types. Quaternary vegetational changes are primarily the result of regional climatic fluctuations; sometimes they are the result of some factor not climatically predicated, such as the introduction of agriculture by Neolithic man in Europe. The

initiation of purely local environmental changes may result in the introduction of local plant communities. Changes of the latter type have local stratigraphic significance of potential paleogeographic and paleoecologic interest. When the botanical affinities of most of the specimens are determinable, as in the Quaternary, it is possible to recognize what vegetational changes are due to nonclimatic or local factors. For most of pre-Cenozoic time (prior to 65,000,000 years ago), pollen and spores are arbitrarily designated without regard to their taxonomic and phylogenetic relationships. Under these circumstances, the ability to recognize purely local environmental changes and their specific vegetational assemblages is limited.

The correlation and age determination of pre-Quaternary strata by pollen and spores also depends on major differentiation of floras through time on a regional basis. But in comparison with the Quaternary, the order of magnitude differs as do some of the mechanisms that initiate floral changes. The Quaternary zonation (subdivisions) involves rock units that represent only a few thousand years; pre-Quaternary studies may involve rock units that span several million years. Climatic fluctuations that are by and large the "normal" determinant of floral change in the Quaternary in practice occur at a reduced magnitude and pace during much of the rest of geologic time. Most traceable pre-Quaternary floral changes are determined principally by organic evolution and secondarily by major topographic or climatic changes.

Vegetational changes that are determined by evolution involve the morphological modification of specific types or the replacement of one floral assemblage by another because of the introduction of new plant groups and the extinction of old groups. Floral changes useful in stratigraphic work thus involve changes in taxonomic composition (qualitative) and in relative abundance (quantitative) of members of plant assemblages. Similar floral successions of a regional nature provide the basis for correlation of sedimentary rocks from area to area by their pollen and spore content. In a later section of this article (*Stratigraphic distribution and evolution*), some floral changes useful in stratigraphic work are traced.

Correlation of coals and coal seams

One of the first applications of plant microfossils in stratigraphic work was to Carboniferous coals in the United States and Great Britain in the 1920s and 1930s. Within the Carboniferous coals, variation in spore content in individual coals was found to differ. Once individual coals were characterized, it was possible to correlate coal beds by means of their spores. Many of the changes from coal to coal, depend on: (1) striking changes in generic and specific content, with some genera and species having long stratigraphic ranges and some having very restricted ranges; (2) characteristic assemblages of spore types; and (3) pronounced changes in the abundance of genera and species. One bed is correlated with another if assemblages in the two are the same and the abundance or frequencies of types is at least roughly similar. The precision of correlations made by this means is improved if the ecology of the coal swamp flora and the environmental conditions relating to the deposition are also utilized as fully as possible.

In favourable instances individual, adjacent coal seams can be identified and correlated by their spore assemblages. During mining operations at a colliery in England, for example, the question arose whether a 12-inch coal seam was the lower bed of the Beaumont Seam, which overlay it or whether it was a part of the upfaulted Hodge Seam, which occurred stratigraphically beneath the Beaumont Coal. Comparisons of the relative frequencies of certain spores in composite samples of each of the coals showed that the Lower Beaumont and the unidentified seam were correlative.

Stratigraphic distribution and evolution. *Pollen and spores.* The evolution and stratigraphic distribution of pollen and spores are traced primarily from morphological types. It is possible, however, to relate morphological types of pollen and spores to major plant groups whose times of appearance, dominance, and extinction are known from paleobotanical data, and sometimes to determine the relationship of microfossils to megafossil groups. The major evolutionary events of the palynological record generally parallel those of the plant kingdom traced from megafossil remains.

Plant microfossils called spores may be functionally different. Spores of one size, sexually undifferentiated, and produced by homosporous plants are homospores or isospores. Spores produced by heterosporous plants are commonly of different sizes and are called microspores (male) and megaspores (female). Isolated spores the affinities of which are unknown can seldom be distinguished as homospores or microspores and not always as microspores or megaspores. Pollen are the microspores of seed plants, living and fossil. The microspores of some primitive Paleozoic gymnosperms appearing to have the germinal aperture in the proximal rather than the distal position of modern pollen are sometimes referred to as prepollen.

Spores commonly have one or two principal aperture types and symmetries—monolete bilateral (kidney-bean shaped) or radial-trilete (rounded triangular). Some are inaperturate (alete). Gymnosperm pollen, including primitive types, are broadly saccate (with wings, bladders, or sacci) or nonsaccate. Primitive types may possess a trilete aperture. Saccate types have the general configuration of modern conifer pollen: they are monosaccate, bisaccate, or polysaccate (three or more sacci). Gymnosperm pollen of nonsaccate type may have one to many furrows or no apertures. Angiosperm pollen are classified primarily on the number and distribution of pores and furrows.

The Paleozoic record

Sporelike fossils found by Soviet workers in pre-Silurian strata (older than 430,000,000 years) are not accepted as constituting proof of the existence of terrestrial vascular plants of such antiquity, nor have they been substantiated by comparable records elsewhere. No land plants that could have borne these spores are known.

Trilete spores assigned to genus *Ambitisporites*, which probably represent vascular land plants, first occur in Silurian rocks of Libya, Spain, and Great Britain. Silurian spores are of limited numbers and variability—only 24 small, comparatively simple types, representing at most eight genera—are known by the end of the period (Lower Downtonian). The relationship of dispersed Silurian spores to Silurian plants is unknown.

By the end of the Lower Devonian (the Devonian Period began 395,000,000 years ago and extended over 50,000,000 years in time), however, abundant, diverse trilete spores represent most of the genera that characterize the rest of the period. Because of their small and essentially uniform size, Silurian and earliest Devonian spores are judged to be homospores. An increase in spore size accompanied the introduction of new spore types during the Devonian. Some large Lower Devonian spores, in excess of 200 microns (one micron equals 0.001 millimetre), may be megaspores and indicate the condition of heterospory, although plant megafossils clearly demonstrated to be heterosporous are unknown prior to the Middle to Late Devonian, when the spore evidence is also more convincing. Rapid diversification of spore types during the uppermost Upper Devonian and the Lower Carboniferous again introduced many new types. Uppermost Devonian spores are more similar to those of the Lower Carboniferous than to spores of the rest of the Devonian or of the Silurian. Several genera of dispersed small spores and one dispersed megaspore genus can be related to Devonian plant genera.

Microfloras of Carboniferous age (from 280,000,000 to 345,000,000 years ago) include homospores, megaspores, and microspores, and the first specimens classified as pollen. Carboniferous spores and pollen provide many significant guide fossils (fossils with restricted stratigraphic ranges) that are useful in correlation and age determination. Carboniferous assemblages are commonly dominated by spores and pollen of radial-trilete configuration. Monolete spores (a morphologic type rarely recorded in the Devonian) are first prominent in the Pennsylvanian (approximately correlative with the Upper Carboniferous). Monolete spores with coarsely ornamented surfaces are an innovation of the Middle to Late Pennsyl-

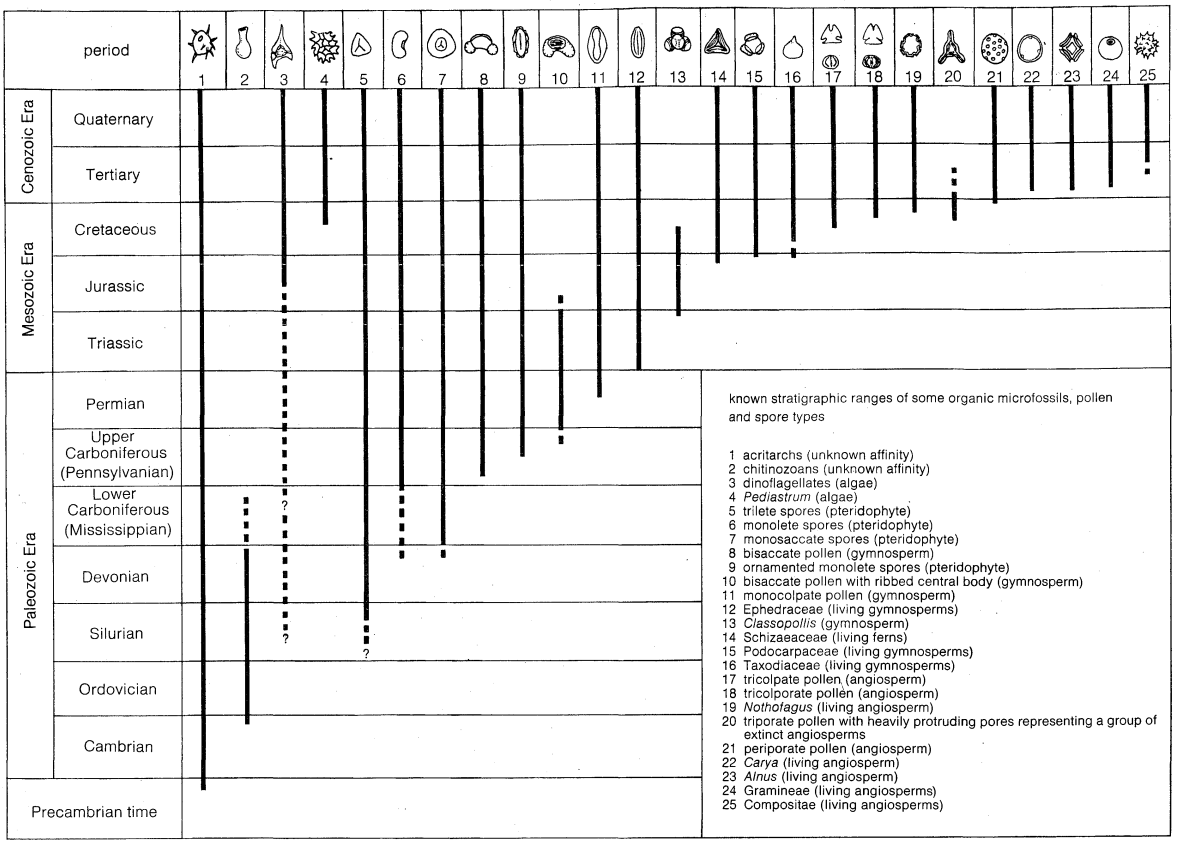

Figure 3: Known stratigraphic ranges of some organic microfossils, pollen, and spore types.

vanian. A few Carboniferous spores and pollen are alete. Carboniferous spores greatly exceed those of the Silurian and the Devonian in the diversity and complexity of their surface ornamentation. Many possess a variety of equatorial structures. Characteristic sacci or wings appear for the first time on spores and on pollen. Carboniferous saccate genera are predominantly monosaccates, some having a lycopsid source, others a gymnosperm source. Bisaccate genera proliferate in the Late Pennsylvanian and are common to dominant by the Early Permian, largely replacing monolete and trilete spores. Bisaccates are considered gymnosperm pollen or prepollen even when their provenance is unknown. One trilete, multisaccate spore genus is known. Three to 16 (depending on classification) Carboniferous trilete megaspore genera are recognized and are among the largest found; *Cystosporites*, for example, may reach a diameter exceeding one centimetre.

Spore-pollen floras of Permian age (from 225,000,000 to 280,000,000 years ago) are dominated by bisaccate pollen. Some prominent Permian bisaccate genera bore thickened longitudinal ribs on the central body. This type, the parent source of which is unknown, became extinct or essentially so in the early part of the Mesozoic Era (from 65,000,000 to 225,000,000 years ago). Bisaccates without ribs and types with a proximal monolete mark are also characteristic of Permian spore-pollen floras. Monosaccates are less diverse and abundant than bisaccates. Nonsaccate, single-furrowed and multifurrowed gymnosperm pollen are forerunners of these abundant types in the Mesozoic. The single-furrowed *Cycadopites* is the most common; it may have been produced by a variety of plants allied to the cycadophytes, the ginkgoes, or the pteridosperms (seed ferns). Permian trilete and monolete spores differ from Carboniferous genera mainly at the species level; trilete types are more abundant than monoletes.

Permian pollen floras are gymnospermous and they are dominated by prominent Mesozoic groups (conifers, cycadophytes, ginkgoes, and pteridsperms) in Upper Permian strata. Lycopsids, sphenopsids, and the ferns declined from their Carboniferous maximum occurrence, judged by diminished numbers of trilete spores, especially in the Late Permian. The prominence of Mesozoic groups and the decreased importance of significant Paleozoic groups give the Permian a Mesozoic rather than a Paleozoic stamp.

The Mesozoic record

Palynological changes between the Late Permian and the Early Triassic (the Triassic Period began 225,000,000 years ago and lasted 35,000,000 years in time) are less pronounced than those that occurred during the Permian. Many Triassic spore and pollen genera occur either in the Permian or in the Jurassic (from 136,000,000 to 190,000,000 years ago), although some are restricted to the Triassic. Bisaccate gymnosperm pollen are prominent, and nonribbed forms are more abundant and diverse than ribbed types; only three Permian genera with ribbed bodies survive into the Triassic and only one into the Lower Jurassic. Also occurring in the Triassic, but gaining prominence in Jurassic and Cretaceous floras, are nonsaccate, single-furrowed gymnosperm pollen of the type first recorded in the Permian and multifurrowed specimens possibly representing the living Ephedraceae. One such furrowed type, *Eucommiidites*, first appearing in the Middle Triassic, was originally regarded as angiosperm pollen. Trilete spores rival or outnumber bisaccate pollen in prominence only in the Late Triassic. Most of these types are thought (on megafossil evidence) to represent ferns, whereas trilete spores of the Late Paleozoic had lycopsid, sphenopsid, and fern affinities. A number of Triassic spores are assigned to living fern families (Osmundaceae, Gleicheniaceae, and others), and some are attributed to the bryophytes.

Major plant groups of the Triassic continue into the Jurassic and Cretaceous (the Cretaceous Period began 136,000,000 years ago and lasted 71,000,000 years). Bisaccate gymnosperm pollen are important and sometimes dominant in Jurassic microfloras but decline in diversity and size during the period. The abundance of *Parvisaccites*, a bisaccate genus characterized by small sacci, in the Early Cretaceous temporarily reverses the general Jurassic decline in bisaccates. Some Cretaceous bisaccates are morphologically inseparable from pollen of modern conifers. Monosaccate gymnosperm pollen

decline after the Triassic, although one such type, *Tsugaepollenites*, is a conspicuous element in some European Middle and Late Jurassic floras. Trisaccate gymnosperm pollen are important in the Early Cretaceous of the Southern Hemisphere. Such types are allied to the Podocarpaceae, a prominent Southern Hemisphere family. Nonsaccate, multifurrowed pollen, first recorded in the Triassic and similar to pollen of the living genus *Ephedra*, are prominent in Cretaceous strata from equatorial regions such as Venezuela, Colombia, and Nigeria, where bisaccate conifer pollen are absent. Single-furrowed nonsaccates with ginkgoalean and cycadophyte affinities are present in both Jurassic and Cretaceous pollen-spore floras, though seldom abundant. Spores of the Jurassic and Cretaceous commonly resemble those of a variety of modern fern and fern-allied families. The abundant trilete spores often display elaborate and diversified sculpture patterns and equatorial structures. Widespread and common, especially during the Early Cretaceous, were types with heavy ribs, fine to coarse warts, and radial equatorial appendages. Many of these have affinities with the living fern family Schizaeaceae. Jurassic and Early Cretaceous megaspores are more diversified than the known heterosporous land plants that could have been their source. Some of them appear comparable to megaspores of some living members of the Selaginellaceae; others may have been related to the water ferns, Salviniaceae and Marsileaceae. Spores of bryophyte types are also found during the Jurassic but reach greater diversity in the Early Cretaceous.

Toward the end of the Early Cretaceous, rare angiosperm pollen appear in the fossil record. No evidence suggests an earlier occurrence in either the tropical regions or the Southern Hemisphere, both among the postulated sites of initial angiosperm evolution, although some limited palynological evidence suggests that angiosperm pollen may be relatively more abundant in Upper Cretaceous strata of tropical and subtropical regions. The first simple tricolpate (three-furrowed) types are harbingers of the enormous elaboration of angiosperm pollen to follow in the Late Cretaceous and Early Tertiary (the Tertiary Period began 65,000,000 years ago and lasted 62,500,000 years) during the palynological transition from archaic pteridophyte-gymnosperm floras of the Mesozoic to angiosperm floras of the Cenozoic. In early Upper Cretaceous floras angiosperm pollen are limited in diversity and abundance or absent entirely; they are seldom assignable to living families or genera, including those identified from leaf remains. By contrast, megafossil floras of similar age have a large number of angiosperms attributed to living families. This discrepancy has not been satisfactorily explained; it may hinge on ecological factors or on the forced assignment of many fossil leaf genera to extant genera and families on superficial similarities in their leaf characters. The gradual increase in the abundance of angiosperm pollen during the Late Cretaceous is accompanied by increase in their diversity. Many of the types elaborated became extinct in a relatively short time during the Late Cretaceous and the Early Tertiary. Certain of them are thus ideal for stratigraphic correlation and zonation. In some Southern Hemisphere pollen-spore floras—as, for example, those from New Zealand—Podocarpacean pollen continue to dominate microfloras into the latest Cretaceous and earliest Tertiary. In South America (Colombia), an influx of palm pollen and dicotyledonous types, foreshadowing the modern flora, replaced the predominantly fern floras of older and more primitive stamp by the latest Upper Cretaceous. Some latest Cretaceous floras from western North America are markedly different from European and Australian floras of the same age, indicating definite provincialism (geographic restriction).

The Cenozoic record

The transition from the Mesozoic to the Cenozoic Era (the last 65,000,000 years) is not without floral change, but the dramatic change in the world's vegetation marked by the onset of angiosperms occurred within the Cretaceous Period. Angiosperms, primarily dicotyledons, dominate Tertiary floras, but palm pollen was common in some strata of Early Tertiary age, and gymnosperm pollen of *Taxodium* and *Sequoia* types were locally abundant.

Pollen floras of the Paleocene, Eocene, and Oligocene (the first three epochs of Tertiary time) gradually assume a more modern aspect, and the major morphological classes of angiosperm pollen are recognized. Because the elaboration of new forms and the rate of extinction among angiosperms appear to have been high during this interval, Early Tertiary pollen commonly are unassignable to modern taxa. Nevertheless pollen of a number of living genera including alder (*Alnus*), hickory (*Carya*), linden (*Tilia*), maple (*Acer*), sweet gum (*Liquidambar*), and holly (*Ilex*) can be recognized at least by the Eocene (38,000,000 to 54,000,000 years ago). By the end of the Oligocene (26,000,000 to 38,000,000 years ago), major evolution and dispersal within most angiosperm families appears to have been completed.

Miocene and Pliocene pollen floras are progressively modernized as related to modern plant communities. Most Late Tertiary and all Quaternary (the last 2,500,000 years) pollen and spores are related to living genera and species of plants. With decreasing age, pollen floras take on the cast of the local vegetation—a decreasing proportion of the flora is exotic. Increasing provincialism makes it more difficult to make generalizations about the stratigraphic distribution of specific pollen-spore types. Few evidences of organic evolution have been recognized in Late Tertiary and Quaternary vegetation. Changes mainly involve plant redistribution related to environmental factors, but a significant mid-Tertiary evolutionary event is the introduction of the sunflower family (Compositae). This predominantly herbaceous group is the largest angiosperm family and has global distribution. Most taxonomists agree that composites are the most advanced dicotyledonous plants. The family lacks authentic megafossil remains, possibly because of its largely herbaceous nature; its pollen first appears in the Miocene or the latest Oligocene. Pollen attributable to other herbaceous plants also assumes increasing importance in the Late Tertiary pollen floras, although a number of herbs have Early Tertiary records. Pollen assigned to the Chenopodiaceae, for example, is recorded in the Paleocene and grass pollen in the Eocene. Corn (*Zea mays*) is a member of the grass family that apparently evolved sometime during the Late Pleistocene.

Dinoflagellates, acritarchs, and chitinozoans

Other organic microfossils. Dinoflagellate fossils consist mainly of resistant encysted specimens. Dinoflagellates are known from Silurian deposits, but they are uncommon Paleozoic and early Mesozoic fossils with limited stratigraphic usefulness. Dinoflagellates become abundant in Middle Jurassic time when a variety of cyst types appeared. During the rest of the Mesozoic and Tertiary, the group appears to have evolved rapidly and many species have worldwide distribution. The dinoflagellates are an important stratigraphic group from mid-Mesozoic onward because of the occurrence of many cosmopolitan (widespread) species, the progressive introduction of new types that gain dominance, and the decline and disappearance of early types.

The acritarchs were rapidly evolving, abundant forms during the early Paleozoic, when most other organic microfossils have no fossil records or are too scarce to have any stratigraphic impact. Acritarchs are at least locally abundant in Precambrian strata and may prove useful for stratigraphic subdivision during that interval. From middle Paleozoic onward, most acritarchs are too long-ranging to be stratigraphically useful. In Upper Jurassic and younger deposits, acritarchs are scarce fossils, although Cretaceous, Tertiary, and nonmarine Quaternary forms are known. *Tasmanites*, a genus locally abundant in Paleozoic marine black shales, is sometimes included in the acritarchs, although some workers regard *Tasmanites* and its possible allies as closely similar to certain living planktonic green algae. *Tasmanites* and related Paleozoic forms are too long-ranging to have stratigraphic potential.

Chitinozoans appear to be ideally suited both for intercontinental and local stratigraphic work because of restricted stratigraphic ranges, rapid evolution, and commonness in a wide variety of sedimentary rocks of ap-

propriate age. Chitinozoans first appeared in the Late Cambrian or Early Ordovician and apparently had become largely extinct by Late Devonian. A single specimen has been reported from Mississippian strata of North America.

PALEOECOLOGY AND PALEOGEOGRAPHY

Fossil palynomorphs were once living organisms or parts of living organisms that influenced their environments and were influenced by them. Among organic microfossils, Cenozoic pollen and spores provide the most significant source of paleoecological inferences. Whether concerned with pollen and spores or with other fossils, paleoecology suffers from a variety of limitations of evidence. The principal of these for pollen and spores are: (1) the incompleteness of the fossil record, either as preserved or as known; (2) the limited geologic time during which spores and pollen can be related to living species; (3) the assumption that fossil plants represented by spores and pollen and their living relatives have maintained similar ecological requirements through geologic time; (4) the difficulty of deducing the environments of organisms with no living relatives; and (5) the presence of pollen and spores in assemblages and environments quite different from those in which their source plants lived, due to long-distance transport or reworking from older deposits.

Environmental change. The reliability of paleoecological inferences deduced from pollen and spores drops off rapidly as their geologic age increases. Only during the Cenozoic and the latest Mesozoic are pollen and spores assignable to living genera and not always then. The most valid inferences are based on fossils or subfossils of the Pleistocene where pollen may be assigned to living species of plants. Since pioneering work in Scandinavia in the early 1900s, pollen studies (pollen analysis) have served as the principal guide to climatic and environmental change of the Quaternary, particularly the late Quaternary. Thousands of pollen studies throughout the world have traced the sequence of former vegetation types and deduced from them fluctuations of Quaternary climate. On the basis of significant geographic change in vegetation it is possible to divide much of Pleistocene time into pollen zones each with a climatic basis. Because the concern is with existing plant communities and with familiar species or genera whose ecology is determinable, Pleistocene pollen analysis is a highly sensitive paleoclimatological technique.

The fact that Pleistocene as well as late Tertiary pollen floras seldom contain disharmonious mixtures of genera lends an air of reliability to the ecological conclusions drawn from them. The reconstruction of plant communities and their environments even from subfossil pollen assemblages is hampered, however, by the difficulty of relating pollen fallout to vegetation in some quantitative way. Part of this difficulty is overcome by seeking "good matches" between fossil pollen fallouts and those of modern communities of plants. By such direct comparisons it may be possible to determine the significance of pollen frequencies in fossil assemblages.

Paleoecological inferences from single fossils or small groups of fossils are strengthened by data from other fossil groups and from sedimentology. Thus, the presence of the freshwater alga *Pediastrum* is no proof of terrestrial environments because *Pediastrum* is found in bottom sediments of the continental shelf off the Pacific Coast and in marine Cretaceous rocks. Pollen and spores from land-based plants including those restricted to fresh water, such as cattail (*Typha*) and water lily (*Nymphaea*), also occur in ocean sediments where they have been borne by wind and water. Dinoflagellates, acritarchs, chitinozoans, and other marine or brackish-water microorganisms seldom transgress into terrestrial environments.

Pollen as a climatic indicator

A classic example of the use of pollen as a climatic indicator is provided by a study of holly (*Ilex aquifolium*), whose pollen is identified in interglacial and postglacial deposits of northern Europe. The presence of holly pollen has enhanced significance; the low pollen productivity related to insect pollination virtually guarantees nearby occurrence of the plant. When a detailed study of the climatic requirements of holly in northern Europe was made, using the mean temperatures of the warmest and coldest months at meteorological stations near holly sites to establish a thermal correlation curve, the curve suggested that holly is intolerant of winter frost, but not especially demanding of high summer temperatures. During hard winters in Denmark, holly was badly damaged and a large proportion was killed. For the intervals when holly pollen is recorded, mild, oceanic winters based on the previously established climatic index were deduced. A German interglacial site of holly pollen now lies beyond the winter temperature limits of *Ilex aquifolium*; winter climate at that site was clearly milder than it is today. Companion studies of ivy (*Hedera helix*) and mistletoe (*Viscum album*), also recorded as pollen, amplify and reinforce this climatic interpretation. Ivy is only slightly more tolerant of winter cold than holly. Mistletoe can tolerate lower winter temperatures than either holly or ivy, but its present northern range is restricted by higher summer temperature requirements than now obtain in northern Europe. The parameters controlling the distribution of these species probably operated in the past. Together holly and ivy are regarded as the best indicators of winter temperatures and mistletoe of summer temperatures in northern Europe. When found together during postglacial periods they indicate higher winter and summer temperatures than those of today.

Plants of the more remote geologic past, including those assigned to living genera, provide a greater challenge to interpretation, for habitat requirements may have changed through time. Commonly, this seems the best explanation for disharmonious palynological assemblages, barring misidentification of some of the members. Some fossils, by their morphology, provide clues to changing environmental adaptations. Thus some Tertiary leaves gradually reduce in size through time with increasing drought. Pollen and spores show no such changes. Fossil pollen that are virtually identical to pollen of living plants with specific habitat requirements can be traced for millions of years. In the absence of supporting evidence, the assumption that these plants always occupied the same ecological niche is questionable. The gymnosperm *Ephedra*, for example, is presently an arid land shrub of deserts and dry woodlands; as dispersed fossil pollen, named *Gnetaceaepollenites* and *Ephedripites*, it has a pollen record that extends into the early Mesozoic. *Ephedra* pollen is frequent in some Tertiary floras where the rest of the assemblage provides little indication of conditions favourable to the genus. Pollen of *Ephedra* is distinctive and not readily confused with that of other plants. Local conditions of dryness of the soil in highly insolated sites may have favoured the occurrence of *Ephedra* for millions of years in habitats virtually identical to those it now occupies. But the ecological requirements of some of the fossil species may have been quite different from those of the living species.

Location of ancient shorelines. The potential usefulness of pollen distribution for locating shoreline position was noted in a patent issued to an oil company palynologist in 1954, in which it was claimed that nearshore sediments might contain as many as 7,500 pollen grains per gram of sediment and that the ratio of large to small pollen was about 1:4. At increasing distances from the shoreline, small pollen was more common and grains per gram of sediment progressively decreased. Studies of the Orinoco River Delta and continental shelf in the vicinity of Trinidad generally support the offshore decrease in pollen and spores, but locally the nature of the shoreline, wind direction, river supply, presence of coarse-textured sediments, mineral sedimentation rates, and current patterns upset the picture so that the position of the coastline is not invariably reflected by the palynology of the sediments. In environments of carbonate rock deposition such as the Great Bahama Bank, pollen was finally sedimented largely as a result of fluctuations in turbulence and other hydrographic factors not clearly related to land proximity.

Considerable work is needed to substantiate the reliabil-

ity of pollen and spores alone to define shoreline position, although in marine Silurian rocks from England, it was noted that rocks coming from sites consistent with proximity to the supposed shoreline yielded among their components 90 percent spores (of presumed land plants) whereas more offshore samples contained only about 1 percent spores.

The potential of redeposited palynomorphs as shoreline indexes is suggested by study of the Eocene London Clay of southern England. There, 17 percent derived Jurassic and Cretaceous acritarchs, dinoflagellates, and pollen and spores were found nearest the reconstructed Eocene shoreline, but dropped off to about 6 percent at the locality most distant from the shoreline. A Silurian assemblage of acritarchs that consists almost entirely of redeposited pre-Silurian specimens was also found in close proximity to the position of the postulated Silurian shoreline. Redeposited Eocene pollen was similarly found in greatest abundance in the Orinoco Delta, close to its source, but decreased rapidly toward the sea.

Evidence of water depth fluctuation

Some evidence suggests that morphology, taxonomic diversity, and population density are environmentally controlled in dinoflagellates and acritarchs, and that these microfossils are therefore useful as indexes to depositional environments and to shoreline position and water depths. Rich varied assemblages of Jurassic acritarchs from Great Britain, for example, are found in strata indicative of open sea conditions, whereas inshore, basin environments are marked by a reduction in diversity and abundance; a group of small acritarchs that belong primarily to a single genus is dominant. Changes in the diversity and morphology of the acritarch assemblages appeared to trace cycles of sedimentation corresponding to transgression and regression of the sea. Oligocene dinoflagellates from the southeastern United States also appear to show distinctive morphology related to shoreline position and water depth.

In general, dinoflagellate frequency drops off from the open ocean toward land, suggesting the usefulness of the ratio of these microplankton to pollen and spores. Such a ratio was used to interpret water-depth fluctuations and, hence, periods of sea transgression and regression during deposition of the Upper Cretaceous Mancos Group of Utah. In the Upper Cretaceous Frontier Formation of Wyoming, the ratio of pollen and spores to marine microplankton appeared to delineate marine and nonmarine sedimentation based on other information.

The geographic distribution of fossil assemblages may suggest major changes in landmass distribution, some of which is of global significance. The areal distribution of Permian spore assemblages on a worldwide basis delimits distinct paleobotanical provinces that conform to the classical concept of the landmasses of Gondwanaland and Laurasia. These distinct assemblages seldom transgress the limits of the paleobotanical provinces originally defined by leaf genera in establishing Permian biogeography. Typical Gondwanian pollen-spore assemblages are found in Australia, Africa, India, South America, and Antarctica. They are palynologically distinct from Laurasian pollen-spore assemblages known from Europe, North America, the Soviet Union, Iraq, Turkey, and southern China. Not all authorities agree that continental drift is the only possible mechanism by which to explain such striking geographic differentiation of floral assemblages. Other hypotheses, however, must postulate the existence of major geographic barriers to account for the varied and disparate Permian floras.

(J.Gr.)

Pollination

Pollination is the transference of pollen grains from the stamens, the flower parts that produce them, to the ovule-bearing organs or to the ovules (seed precursors) themselves. In conifers and cycads, in which the ovules are exposed, the pollen is simply caught in a drop of fluid secreted by the ovule. In flowering plants, however, the ovules are contained within a hollow organ called the pistil, and the pollen is deposited on the pistil's receptive surface, the stigma. There the pollen germinates and gives rise to a pollen tube, which grows down through the pistil toward one of the ovules in its base. In an act of double fertilization, one of the two sperm cells within the pollen tube fuses with the egg cell of the ovule, making possible the development of an embryo, and the other cell combines with the two subsidiary sexual nuclei of the ovule, which initiates formation of a reserve food tissue, the endosperm. The growing ovule then transforms itself into a seed. As a prerequisite for fertilization, pollination is essential to the production of fruit and seed crops and plays an important part in programs designed to improve plants by breeding. Furthermore, studies of pollination are invaluable for understanding the evolution of flowering plants and their distribution in the world today. As sedentary organisms, plants usually must enlist the services of external agents for pollen transport. In flowering plants, these are (roughly in order of diminishing importance): insects, wind, birds, mammals, and water.

Importance to agriculture

Pollination by insects probably occurred in primitive seed plants, reliance on other means being a relatively recent evolutionary development. Reasonable evidence indi-

cates that flowering plants first appeared in tropical rain forests during the Mesozoic Era (about 65,000,000 to 225,000,000 years ago). The most prevalent insect forms of the period were primitive beetles; no bees and butterflies were present. Some Mesozoic beetles, already adapted to a diet of spores from primitive plants, apparently became pollen eaters, capable of effecting chance pollination with grains accidentally spared. The visits of such beetles to primitive flowering plants may have been encouraged by insect attractants, such as odours of carrion, dung, or fruit, or by sex attractants. In addition, visits of the insects to the plants could be made to last longer and thus potentially be more valuable to the plant as far as fertilization was concerned, if the flower had a functional, traplike structure. Nowadays, such flowers are found predominantly, although not exclusively, in tropical families regarded as ancient; *e.g.*, the water lily (Nymphaeaceae) and the arum lily (Araceae) families. At the same time, other plants apparently began to exploit the fact that primitive gall-forming insects visited the flowers to deposit eggs. In the ancient genus *Ficus* (figs and banyan trees), pollination still depends on gall wasps. In general, Mesozoic flowering plants could not fully rely on their pollinators, whose presence also depended on the existence of a complete, well-functioning ecological web with dung, cadavers, and food plants always available. More advanced flowers escaped from such dependence on chance by no longer relying on deceit, trapping, and tasty pollen alone; nectar became increasingly important as a reward for the pollinators. Essentially a concentrated, aqueous sugar solution, nectar existed in certain ancestors of the flowering plants. In bracken fern even nowadays, nectar glands (nectaries) are found at the base of young leaves. In the course of evolutionary change, certain nectaries were incorporated into the modern flower (floral nectaries), although extrafloral nectaries also persist. Flower colours thus seem to have been introduced as "advertisements" of the presence of nectar, and more specific nectar guides (such as patterns of dots or lines, contrasting colour patches, or special odour patterns) were introduced near the entrance to the flower, pointing the way to the nectar hidden within. At the same time, in a complex pattern of parallel evolution, groups of insects appeared with sucking mouthparts capable of feeding on nectar. In extreme cases, there arose a complete mutual dependence. For example, a Madagascar orchid, *Angraecum sesquipedale*, with a nectar receptacle 20 to 35 centimetres (eight to 14 inches) long, depends for its pollination exclusively on the local race of a hawkmoth, *Xanthopan morganii*, which has a proboscis of 22½ centimetres (nine inches). Interestingly enough, the existence of the hawkmoth was predicted by Charles Darwin and Alfred Russel Wallace, codiscoverers of evolution, about 40 years before its actual discovery.

Development of nectar

TYPES OF POLLINATION

An egg cell in an ovule of a flower may be fertilized by a sperm cell derived from a pollen grain produced by that same flower or by another flower on the same plant, in either of which two cases fertilization is said to be due to self-pollination (autogamy); or, the sperm may be derived from pollen originating on a different plant individual, in which case the process is called cross-pollination (heterogamy). Both processes are common, but cross-pollination clearly has certain evolutionary advantages for the species: the seeds formed may combine the hereditary traits of both parents, and the resulting offspring generally are more varied than would be the case after self-pollination. In a changing environment, some of the individuals resulting from cross-pollination still may be found capable of coping with their new situation, ensuring survival of the species, whereas the individuals resulting from self-pollination might all be unable to adjust. Self-pollination, or selfing, although foolproof in a stable environment, thus is an evolutionary cul-de-sac. There also is a more direct, visible difference between selfing and outbreeding (cross-pollination): in those species where both methods work, cross-pollination usually produces more, and better quality, seeds. A dramatic demonstration of this effect is found with hybrid corn (maize), a superior product that results from cross-breeding of several especially bred lines.

Self-pollination and cross-pollination

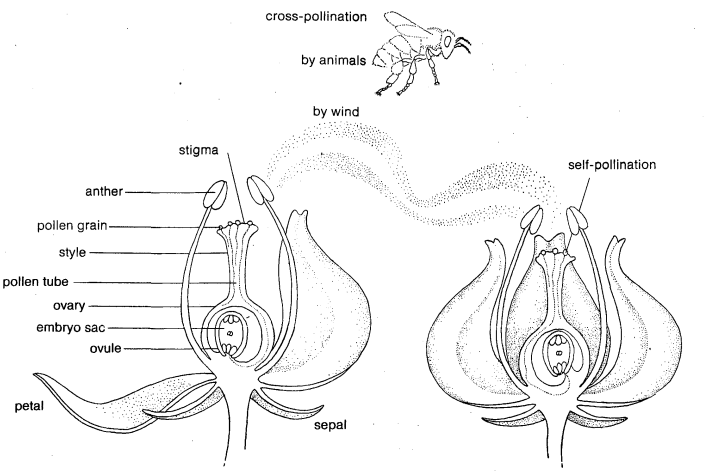

Figure 1: Types of pollination.
Drawing by M. Moran based on B.J.D. Meeuse, *The Story of Pollination*

Mechanisms that prevent self-pollination. *Structural.* Not surprisingly, many species of plants have developed mechanisms that prevent self-pollination. Some—*e.g.*, date palms (*Phoenix dactylifera*) and willows (*Salix* species)—have become dioecious; that is, some plants produce only "male" (staminate) flowers, with the rest producing only "female" (pistillate or ovule-producing) ones. In species in which staminate and pistillate flowers are found on the same individual (monoecious plants) and in those with hermaphroditic flowers (flowers possessing both stamens and pistils), a common way of preventing self-fertilization is to have the pollen shed either before or after the period during which the stigmas on the same plant are receptive, a situation known as dichogamy. The more usual form of dichogamy, which is found especially in such insect-pollinated flowers as fireweed (*Epilobium angustifolium*) and salvias (*Salvia* species), is proterandry, in which the stamens ripen before the pistils. Proterogyny, the situation in which the pistils mature first, occurs in arum lilies and many wind-pollinated plants, such as grasses—although several grasses are self-pollinated, including common varieties of wheat, barley, and oats. Avocado has both proterogynous and proterandrous varieties, and these often are grown together to encourage cross-fertilization. A structural feature of flowers that discourages selfing is heterostyly, or variation in the length of the style (neck of the pistil). This occurs in the common primrose (*Primula vulgaris*) and species of wood sorrel (*Oxalis*) and flax. In most British primrose populations, for example, approximately half the individuals have so-called "pin" flowers, which possess short stamens and a long style, giving the stigma a position at the flower's mouth, whereas the other half have "thrum" flowers, in which the style is short and the stamens are long, forming a "thrumhead" at the opening of the flower. Bees can hardly fail to deposit the pollen they receive from one type of flower onto the stigmas of the other type. The genetic system that regulates flower structure in these primroses is so constituted that cross-pollination automatically maintains a 50:50 ratio between pins and thrums. In the flowers of purple loosestrife (*Lythrum salicaria*), the stamens and styles are of three different lengths to limit self-fertilization.

Chemical. Chemical self-incompatibility is another device for preventing self-fertilization. In this phenomenon, which depends on chemical substances within the plant, the pollen may fail to grow on a stigma of the same flower that produced it or, after germination, the pollen-tube may not grow normally down the style to effect fertilization. The process is controlled genetically; it need not be absolute and can change in degree during the flowering season. Not surprisingly, chemical incompatibility usually is not found in those plants that have strong structural or temporal barriers against self-pollination.

Wind pollination: pollen of the lodgepole pine *(Pinus contorta)* and mountain hemlock *(Tsuga mertensiana)* on the surface of Crater Lake, Oregon.

Beetle pollination: pollen-eating longhorn beetle (family Corambycidae) in a thimbleberry (*Rubus parviflorus*).

Butterfly pollination: the extended proboscis of the heliconian butterfly *(Heliconius)* carries pollen between flowers of *Lantana camara*.

Bee pollination: pollen-laden honeybee *(Apis mellifera)* on a wall flower *(Erysimum)*.

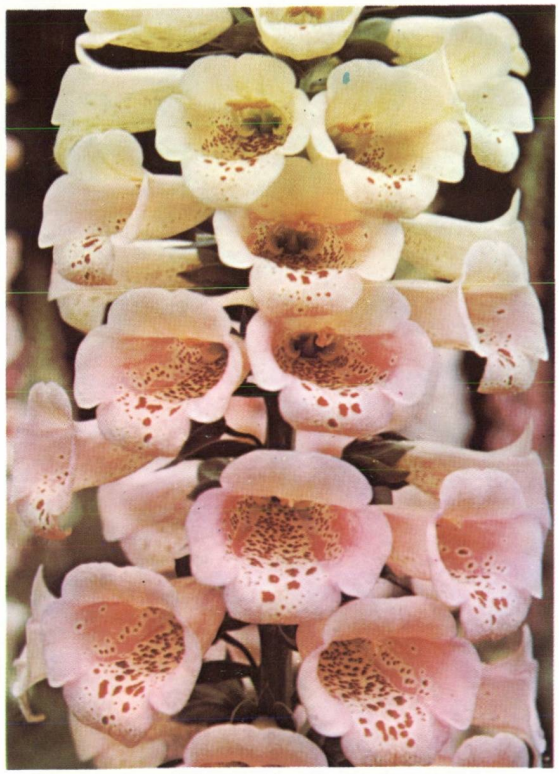
Wind pollination in grasses: yellow free-hanging anthers (pollen producers) and white feathery stigmas (pollen collectors) of meadow fescue *(Festuca pratensis)* provide maximum wind exposure.

Bird pollination: Anna's hummingbird (*Calypte anna*) feeding on nectar of a fuchsia.

Hawkmoth pollination: hawkmoth (Sphingidae) hovering near a honeysuckle *(Lonicera caprifolium)*.

Agents of pollen dispersal

Plate 1: (Top right, centre) E.S. Ross, (top left) Joe Van Wormer—Bruce Coleman Inc., (centre left) Rudolf Schmid, (centre right) Mary W. Ferguson, F.P.S.A., (bottom left) Walter E. Harvey—National Audubon Society, (bottom right) Ingmar Holmasen



Trap flower: pollinating psychodid flies trapped in the floral chamber of cuckoopint (*Arum maculatum*; vertical section with spathe cut away).

Deception flower: carrion flower *(Stapelia)* has the appearance and odour of decayed meat. Flies laying eggs crawl over flower's surface and come into contact with stigmas and stamens.

Trap flower: when certain bees land on the hairy, upright petal of the flower of grass-pink orchid (*Calopogon pulchellus*), the petal topples forward, and a visiting bee falls on its back onto the sticky surface of the column.

Nectar guides: spots in throat of foxglove *(Digitalis purpurea* variety *gloxiniaeflora)* provide insects with a visual pathway to nectar glands.

Explosive flower: (top) flower of Scotch broom *(Cytisus scoparius)*. (Bottom left) The bumblebee *(Bombus vosnesenskii)* triggers release of the stamens (bottom right) which forcibly strike underside of bee and dust it with pollen.

Flower adaptations related to pollination

Plate 2: (Top left, top right) B.J.D. Meeuse, (centre) Rudolf Schmid, (centre left, bottom left, bottom right) E.S. Ross, (centre right) Derek Fell

Formation of one such mechanism during evolution apparently was enough for most plant species.

Circumstances favouring self-pollination

Mechanisms that permit self-pollination. In many instances, successful self-pollination takes place at the end of a flower's life-span if cross-pollination has not occurred. Such self-pollination may be achieved by curving of stamens or style as occurs, for example, in fireweed. It can be an evolutionary advantage when animal pollinators are temporarily scarce or when the plants in a population are widely scattered. Under such circumstances, selfing may tide the species over until better circumstances for outbreeding arrive. For this reason, selfing is common among annual plants; these often must produce an abundance of seed for the rapid and massive colonization of any bare ground that becomes available. If, in a given year, an annual plant were to produce no seed at all, survival of the species might be endangered. A persistent habit of self-pollination apparently has been adopted successfully by some plant species whose natural pollinators have died out. Continued selfing also is practiced by many food-crop plants. Some of these plants are cleistogamous, meaning that the flowers fail to open, an extreme way of ensuring self-pollination. A similar process is apomixis, the development of an ovule into a seed without fertilization. Apomixis is easily demonstrated in lawn dandelions, which produce seeds even when stamens and styles are cut off just before the flowers open. Consistent apomixis has the same pros and cons as continued selfing. The offspring show very little genetic variability, but there is good survival if the species is well adapted to its habitat and if the environment does not change.

AGENTS OF POLLEN DISPERSAL

Insects. *Beetles and flies.* The ancient principle of trapping insects as a means of ensuring pollination was readopted by some advanced families (*e.g.*, orchids and milkweeds), and further elaboration perfected the flower traps of primitive families. The cuckoo pint (*Arum maculatum*), for example, attracts minute flies, which normally breed in cow dung, by means of a fetid smell. This smell is generated in early evening, along with considerable heat, which helps to volatilize the odour ingredients. The flies visiting the plant, many of which carry *Arum* pollen, enter the floral trap through a zone of bristles and then fall into a smooth-walled floral chamber from which escape is impossible. Gorging themselves on a nutritious stigmatic secretion produced by the female flowers at the base of the chamber, the flies effect cross-pollination. Late at night, when the stigmas no longer function, the male flowers, situated much higher on the floral column, proceed to bombard the flies with a rain of pollen. The next day, when smell, heat, and food are gone, the prisoners, "tarred" with stigmatic secretion and "feathered" with pollen, are allowed to escape by a wilting of the inflorescence (flower cluster). Usually the escaped flies are soon recaught by another inflorescence, which is still in the smelly, receptive stage, and cross-pollination again ensues. Superb timing mechanisms underlie these events. The heat-generating metabolic process in the inflorescence is triggered by a hormone, calorigen, originating in the male flower buds only under the right conditions. The giant inflorescences of the tropical plant *Amorphophallus titanum* similarly trap large carrion beetles.

Trap flowers

In general, trap flowers victimize beetles or flies of a primitive type. Although beetles most likely were involved as pollinators when flowering plants as a group were born, their later performance in pollination has been disappointing. Some modern beetles do visit smelly flowers of an open type, such as elderberry and hawthorn, but with few exceptions they are still mainly pollen eaters. Flies as a group have become much more diversified in their habits than beetles have. Female short-tongued flies may be deceived by open-type flowers with carrion smells; *e.g.*, the flowers of *Stapelia* and *Rafflesia*. Mosquitoes with their long tongues are effective pollinators of certain orchids (*Habenaria* species) in North American swamps. In Europe, the bee fly (*Bombylius*) is an important long-tongued pollinator. Extremely specialized as nectar drinkers are certain South African flies; for example, *Megistorhynchus longirostris*, which has a tongue that is 60 to 70 millimetres (2.3 to 2.7 inches) long.

Pollen flowers

The voraciousness of flower beetles demonstrates the futility of enticing insect pollinators solely with such an indispensable material as pollen. As a defensive strategy, certain nectar-free flowers that cater to beetles and bees —such as wild roses, peonies, and poppies—produce a superabundance of pollen. Other plants—*e.g.*, *Cassia*—have two types of stamens, one producing a special sterile pollen used by insects as food, the other yielding normal pollen for fertilizing the ovules. Other flowers contain hairs or food bodies that are attractive to insects.

Bees. In the modern world, bees are probably the most important insect pollinators. Living almost exclusively on nectar, they feed their larvae pollen and honey (a modified nectar). To obtain their foods, they possess striking physical and behavioral adaptations, such as tongues as long as 2½ centimetres (1 inch), hairy bodies, and (in honeybees and bumblebees) special pollen baskets. The Austrian naturalist Karl von Frisch has demonstrated that honeybees, although blind to red light, distinguish at least four different colour regions, namely, yellow (in-

cluding orange and yellow green), blue green, blue (including purple and violet), and ultraviolet. Their sensitivity to ultraviolet enables bees to follow nectar-guide patterns not apparent to the human eye. They are able to taste several different sugars and also can be trained to differentiate between aromatic, sweet, or minty odours but not foul smells. Fragrance may be the decisive factor in establishing the honeybee's habit of staying with one species of flower as long as it is abundantly available. Also important is that honeybee workers can communicate to one another both the distance and the direction of an abundant food source by means of special dances.

Bee flowers

Bee flowers, open in the daytime, attract their insect visitors primarily by bright colours; at close range, special patterns and fragrances come into play. Many bee flowers provide their visitors with a landing platform in the form of a broad lower lip on which the bee sits down before pushing its way into the flower's interior, which usually contains both stamens and pistils. The hermaphroditism of most bee flowers makes for efficiency, because the flower both delivers and receives a load of pollen during a single visit of the pollinator, and the pollinator never travels from one flower to another without a full load of pollen. Indeed, the floral mechanism of many bee flowers permits only one pollination visit. The pollen grains of most bee flowers are sticky, spiny, or highly sculptured, ensuring their adherence to the bodies of the bees. Since one load of pollen contains enough pollen grains to initiate fertilization of many ovules, most individual bee flowers produce many seeds.

Examples of flowers that depend heavily on bees are larkspur, monkshood, bleeding heart, and Scotch broom. Alkali bees (*Nomia*) and leaf-cutter bees (*Megachile*) are both efficient pollinators of alfalfa; unlike honeybees, they are not afraid to trigger the explosive mechanism that liberates a cloud of pollen in alfalfa flowers. Certain Ecuadorian orchids (*Oncidium*) are pollinated by male bees of the genus *Centris*; vibrating in the breeze, the beelike flowers are attacked headlong by the strongly territorial males, who mistake them for competitors. Other South American orchids, nectarless but very fragrant, are visited by male bees (*Euglossa* species) who, for reasons not yet understood, collect from the surface of the flowers an odour substance, which they store in the inflated parts of their hindlegs.

Wasp flowers

Wasps. Few wasps feed their young pollen or nectar. Yellow jackets, however, occurring occasionally in large numbers and visiting flowers for nectar for their own consumption, may assume local importance as pollinators. These insects prefer brownish-purple flowers with easily accessible nectar, such as those of figwort. The flowers of some Mediterranean and Australian orchids mimic the females of certain wasps (of the families Scoliidae and Ichneumonidae) so successfully that the males of these species attempt copulation and receive the pollen masses on their bodies. In figs, it is not the pollinator's sexual drive that is harnessed by the plant but the instinct to take care of the young; tiny gall wasps (*Blastophaga*) use the diminutive flowers (within their fleshy receptacles) as incubators.

Butterflies and moths. The evolution of moths and butterflies (Lepidoptera) was made possible only by the development of the modern flower, which provides their food. Nearly all species of Lepidoptera have a tongue, or proboscis, especially adapted for sucking. The proboscis is coiled at rest and extended in feeding. Hawkmoths hover while they feed, whereas butterflies alight on the flower. Significantly, some butterflies can taste sugar solutions with their feet. Although moths, in general, are nocturnal and butterflies are diurnal, a colour sense has been demonstrated in representatives of both. Generally, the colour sense in Lepidoptera is similar to that of bees, but swallowtails and certain other butterflies also respond to red colours. Typically, colour and fragrance cooperate in guiding Lepidoptera to flowers, but in some cases there is a strong emphasis on just one attractant; for example, certain hawkmoths can find fragrant honeysuckles hidden from sight.

Moth flowers and butterfly flowers

Typical moth flowers—*e.g.*, jimsonweed, stephanotis, and honeysuckle—are light-coloured, often long and narrow, without landing platforms. The petals are sometimes fringed; the copious nectar is often in a spur. They are open and overwhelmingly fragrant at night. Butterfly flowers—*e.g.*, those of butterfly bush, milkweed, and verbena—are conspicuously coloured, often red, generally smaller than moth flowers, but grouped together in erect, flat-topped inflorescences that provide landing space for the butterflies.

Important pollinating moths are the various species of the genus *Plusia*, sometimes occurring in enormous numbers, and the hummingbird hawkmoth (*Macroglossa*), which is active in daylight. A small moth, *Tegeticula maculata*, presents an interesting case. It is totally dependent on yucca flowers, in whose ovules its larvae develop. Before depositing their eggs, the females pollinate the flowers, following an almost unbelievable pattern of specialized behaviour, which includes preparing a ball of pollen grains and carrying it to the stigma of the plant they are about to use for egg laying.

Wind. Although prevalent in the primitive cycads and in conifers, such as pine and fir, wind pollination (anemophily) in the flowering plants must be considered as a secondary development. It most likely arose when such plants left the tropical rain forest where they originated and faced a more hostile environment, in which the wind weakened the effectiveness of smell as an insect attractant and the lack of pollinating flies and beetles also made itself felt. Lacking in precision, wind pollination is a wasteful process. For example, one male plant of *Mercurialis annua*, a common weed, produces 1,250,000,000 grains of pollen to be dispersed by the wind; a male sorrel plant produces 400,000,000. Although, in general, the concentration of such pollen becomes very low about one-fourth mile from its source, nonetheless in windy areas it can cover considerable distances. Pine pollen, for example, which is naturally equipped with air sacs, can travel up to 500 miles (although the grains may lose their viability in the process). Statistically, this still gives only a slim chance that an individual stigma will be hit by more than one or two pollen grains. Also relevant to the number of pollen grains per stigma is the fact that the dry, glueless, and smooth-surfaced grains are shed singly. Since the number of fertilizing pollen grains is low, the number of ovules in a single flower is low and, as a consequence, so is the number of seeds in each fruit. In hazel, walnut, beech, and oak, for example, there are only two ovules per flower, and, in stinging nettle, elm, birch, sweet gale, and grasses, there is only one. Wind-pollinated flowers are inconspicuous, being devoid of insect attractants and rewards, such as fragrance, showy petals, and nectar. To facilitate exposure of the flowers to the wind, blooming often takes place before the leaves are out in spring, or the flowers may be placed very high on the plant. Inflorescences, flowers, or the stamens themselves move easily in the breeze, shaking out the pollen, or the pollen containers (anthers) burst open in an explosive fashion when the sun hits them, scattering the pollen widely into the air. The stigmas often are long and divided into arms or lobes, so that a large area is available for catching pollen grains. Moreover, in open areas wind-pollinated plants of one species often grow together in dense populations. The chance of self-pollination, high by the very nature of wind pollination, is minimized by the fact that many species are dioecious or (like hazel) have separate male and female flowers on each plant. Familiar flowering plants relying on wind pollination are grasses, rushes, sedges, cattail, sorrel, lamb's quarters, hemp, nettle, plantain, alder, hazel, birch, poplar, and oak. (Tropical oaks, however, may be insect-pollinated.)

Wind flowers

Birds. Because the study of mechanisms of pollination began in Europe, where pollinating birds are rare, their importance is often underestimated. In fact, in the tropics and the southern temperate zones, birds are at least as important as pollinators as insects are, perhaps more so. About a third of the 300 families of flowering plants have at least some members with ornithophilous flowers; *i.e.*, flowers attractive to birds. Conversely, about 2,000 species of birds, belonging to 50 families, visit flowers more

or less regularly to feed on nectar, pollen, and flower-inhabiting insects or spiders. Special adaptations to this way of life, in the form of slender, sometimes curved, beaks and tongues provided with brushes or shaped into tubes, are found in 1,615 species of eight families: hummingbirds, sunbirds, honey eaters, brush-tongued parrots, white-eyes, flower-peckers, honeycreepers (or sugarbirds), and Hawaiian honeycreepers. Generally, the sense of smell in birds is poorly developed and not used in their quest for food; instead, they rely on their powerful vision and their colour sense, which resembles that of man (ultraviolet not being seen as a colour, whereas red is). Furthermore, the sensitivity of the bird's eye is greatest in the middle and red part of the spectrum. This is sometimes ascribed to the presence in the retina of orange-red drops of oil, which together may act as a light filter.

Bird flowers

Although other explanations have been forwarded, the special red sensitivity of the bird eye is usually thought to be the reason why so many bird-pollinated flowers are of a uniform, pure red colour. Combinations of complementary colors, such as orange and blue, or green and red, also are found, as are white flowers. As might be expected, bird flowers generally lack smell and are open in the daytime; they are bigger than most insect flowers and have a wider floral tube. Bird flowers also are sturdily constructed as a protection against the probing bill of the visitors, with the ovules kept out of harm's way in an inferior ovary beneath the floral chamber or placed at the end of a special stalk or behind a screen formed by the fused bases of the stamens. The latter, often so strong as to resemble metal wire, are usually numerous, brightly coloured, and protruding, so that they touch a visiting bird on the breast or head as it feeds. The pollen grains often stick together in clumps or chains, with the result that a single visit may result in the fertilization of hundreds of ovules. In America, where hummingbirds usually suck the nectar of flowers on the wing, ornithophilous flowers (*e.g.*, fuchsias) are often pendant and radially symmetrical, lacking the landing platform of the typical bee flower. In Africa and Asia, bird flowers often are erect and do offer their visitors, which do not hover, either a landing platform or special perches in the form of small twigs near the flower. Pollinating birds are bigger than insects and have a very high rate of metabolism. Although some hummingbirds go into a state resembling hibernation every night, curtailing their metabolism drastically, others keep late hours. Thus, in general, birds need much more nectar per individual than insects do. Accordingly, bird flowers produce nectar copiously—a thimbleful in each flower of the coral tree, for example, and as much as a liqueur glassful in flowers of the spear lily (*Doryanthus*). Plants bearing typical bird flowers are: cardinal flower, fuchsia, red columbine, trumpet vine, hibiscus, strelitzia, and eucalyptus, and many members of the pea, orchid, cactus, and pineapple families.

Mammals. In Madagascar, the mouse lemurs (*Microcebus*), which are only ten centimetres (four inches) long, obtain food from flowers, and in Australia the diminutive marsupial honey possums and pygmy possums also are flower specialists. Certain highly specialized tropical bats, particularly *Macroglossus* and *Glossophaga*, also obtain most or all of their food from flowers. The *Macroglossus* (big-tongued) species of southern Asia and the Pacific are small bats with sharp snouts and long, extensible tongues, which carry special projections (papillae) and sometimes a brushlike tip for picking up a sticky mixture of nectar and pollen. Significantly, they are almost toothless. Colour sense and that sonar sense so prominent in other bats, seem to be lacking. Their eyesight is keen but, since they feed at night, they are probably guided to the flowers principally by their highly developed sense of smell. The bats hook themselves into the petals with their thumb claws and stick their slender heads into the flowers, extracting viscid nectar and protein-rich pollen with their tongues. The plants involved have, in the process of evolution, responded to the bats by producing large (sometimes huge) amounts of these foods. One balsa-tree flower, for example, may contain a full ten grams of nectar, and one flower from a baobab tree has about 2,000 pollen-producing stamens. Some bat flowers also provide succulent petals or special food bodies to their visitors. Another striking adaptation is that the flowers are often placed on the main trunk or the big limbs of a tree (cauliflory); or, borne on thin, ropelike branches, they dangle beneath the crown (flagelliflory). The pagoda shape of the kapok tree serves the same purpose: facilitation of the bat's approach. Characteristics of the flowers themselves include drab colour, large size, sturdiness, bell-shape with wide mouth and, frequently, a powerful rancid or urinelike smell. The giant saguaro cactus and the century plant (*Agave*) are pollinated by bats, although not exclusively, and cup-and-saucer vine (*Cobaea scandens*) is the direct descendant of a bat-pollinated American plant. Calabash, candle tree, and areca palm are other examples of plants with bat-pollinated flowers.

Bat flowers

Water. Although pollen grains can be made to germinate in aqueous sugar solutions, water alone in most cases has a disastrous effect on them. Accordingly, only a very few terrestrial plants, such as the bog asphodel of the Faroes, use rainwater as a means of pollen transport. Even in aquatic plants, water is seldom the true medium of pollen dispersal. Thus, the famous Podostemonaceae, plants that grow only on rocks in rushing water, flower in the dry season when the plants are exposed; pollination occurs with the aid of wind or insects or by selfing. Another aquatic plant, ribbon weed, sends its male and female flowers to the surface separately. There, the former transform themselves into minute sailboats, which are driven by the wind until they collide with the female flowers. In the Canadian waterweed, and also in pondweed (*Potamogeton*) and ditch grass (*Ruppia*), the pollen itself is dispersed on the water's surface; it is, however, still water-repellent. True water dispersal (hydrophily), in which the pollen grains are wet by water, is found only in the freshwater hornworts and the marine eelgrasses.

Pollock, Jackson

Jackson Pollock was the leading painter of Abstract Expressionism, an American art movement characterized by free-associative gestures in paint sometimes referred to as action painting. During his lifetime he received widespread publicity and some serious recognition for the radical "drip" or pouring technique he used to create his major works. Among his contemporaries, he was respected for his deeply personal and totally uncompromising commitment to the art of painting. His work and example had enormous influence on them and on most subsequent art movements in America. He is also one of the few American painters to be recognized during his lifetime and after as a peer of 20th-century European masters of modern art.

Paul Jackson Pollock, the fifth and youngest son of Stella May McClure and LeRoy Pollock, was born on January 28, 1912, at Cody, Wyoming. Both parents were of Scottish-Irish extraction (the father's original surname was McCoy before his adoption about 1890 by a family named Pollock), and both were born and raised in Iowa. Jackson dropped his first name, Paul, about the time he went to New York in 1930. The family left Cody 11 months after Jackson's birth. He would know Cody only through family photographs. Over the next 16 years the

Pollock painting in his studio on Long Island, New York, 1950.
Hans Namuth

family lived in California and Arizona, moving nine times during the period. In 1928 it moved to Los Angeles where Pollock enrolled at Manual Arts High School. There he came under the influence of Frederick John de St. Vrain Schwankovsky, a painter and illustrator who was also a member of the Theosophical Society, a mystical religious sect. Schwankovsky gave Pollock some rudimentary training in drawing and painting, introduced him to advanced currents of European modern art, and encouraged an interest in Theosophical literature. At this time Pollock also attended the camp meetings of the former messiah of the Theosophists, Jiddu Krishnamurti, who was a personal friend of Schwankovsky. This experience of occult religion prepared Pollock, who had been raised an agnostic, to later accept the theories of the Swiss psychologist Carl Gustav Jung and the concept of the exploration of unconscious imagery espoused by adherents to Surrealism, a modern literary and artistic movement.

Early influences

In the fall of 1930 he followed his brother Charles, who left home to study art in 1922, to New York, where he enrolled at the Art Students League under his brother's teacher, the regionalist painter Thomas Hart Benton. He studied life drawing, painting, and composition with Benton for the next two and one-half years, leaving the League in the early months of 1933. For the next two years he lived in poverty, first with his brother Charles and, by the fall of 1934, with his brother Sanford. He shared an apartment in Greenwich Village with Sanford and his wife until 1942. In the fall of 1935 he was employed on the WPA Federal Art Project as an easel painter. This provided economic security during the years of the Great Depression and the opportunity to develop his art through early 1943. In 1937 he began psychiatric treatment for alcoholism, and he suffered a nervous breakdown in 1938, during which he was institutionalized for about four months. From 1939 through 1941 he was in treatment with two successive Jungian psychoanalysts, who used Pollock's own drawings in the therapy sessions. In 1943 after the liquidation of the Federal Art Project, he was given a contract by Peggy Guggenheim at her Art of This Century Gallery in New York City, and his first one-man show was held there in November. Thereafter he had one-man shows of new work nearly every year in New York, his work being handled by Peggy Guggenheim through 1947, the Betty Parsons Gallery from 1947 to 1952, and finally by the Sidney Janis Gallery. In 1945 he married the painter Lee Krasner (1908–) and moved to East Hampton on Long Island in New York where he lived until his death in an automobile accident on August 11, 1956.

Pollock's artistic development can be divided into six periods. From his years with Benton to 1938, his work was strongly influenced by the compositional methods and regionalist subject matter of his teacher and by the poetically expressionist vision of the American painter Albert Pinkham Ryder. It consisted mostly of small landscapes and figurative scenes such as "Going West" in which Pollock also utilized motifs derived from photographs of his birthplace at Cody. After his breakdown and hospitalization in 1938 until the time of his first one-man show in 1943, his work was semiabstract and shows the assimilation of motifs from the modern Spanish artists Pablo Picasso and Joan Miró, as well as the Mexican muralist José Clemente Orozco. Jungian symbolism and Surrealist theory also influenced the works of this period. Paintings such as "Bird," "Male and Female," and "Guardians of the Secret" reflect these influences. Very late in 1943, possibly in the early weeks of 1944, Pollock painted his first wall-size work, called "Mural." This painting is his breakthrough into a totally personal style in which Benton's compositional methods and energetic linear invention are fused with Surrealist free-association of motifs or unconscious imagery. His evolution from this point through the 1940s shows a struggle to find a process by which he could translate his entire personality into painting. The figurative character of works such as "The Totem, Lesson I" and "The Blue Unconscious" contrasts with the heavily painted allover design of "Shimmering Substance" and "Eyes in the Heat," indicating the range of imagery and technique he employed during this period. In 1947 he first used the process of pouring or dripping paint onto a flat canvas in stages, often taking weeks of alternating periods of painting and contemplating to finish a canvas. This process permitted him to record the force and scope of his gestures in trajectories of enamel or aluminum paint that he said "veiled the image" that often appeared in his earlier work. The results, in effect, were huge areas covered with complex linear patterns that fused image and form to engulf the vision of the spectator in their scale and intricacy. A whole series of paintings, beginning with "Full Fathom Five" and proceeding through "Summertime" and "Number Ten, 1949" to the mural-size canvasses of 1950 such as "One," "Autumn Rhythm," "Lavender Mist," and the black and white "Number Thirty-two," display the infinite variety of effect and expression this method—poured painting—permitted him. In 1951 and 1952 he painted almost exclusively in black and white, creating works in which his earlier imagery can be seen. The configuration in "Number Twenty-three, 1951" ("Frogman"), for example, relates to "Bird" and also to drawings Pollock did for his second Jungian analyst. Other important paintings of this phase, painted in black enamel on unsized canvas, are "Echo" and "Number Seven, 1952." In 1952 he returned to colour and mural-scale in "Convergence" and "Blue Poles." In 1953 he created his last series of major works. "Portrait and a Dream," "Easter and the Totem," "Ocean Greyness," and "The Deep," among other works, recapitulate many aspects of his former styles and images. Though his production waned and his health deteriorated after 1953, he did produce important paintings such as "White Light" and "Scent" in his last years.

Poured painting or the "drip" technique

From the early 1940s on, Pollock created numerous works on paper, ranging from drawings to mixed-media paintings that parallel the development of his work on canvas. He created very few prints and only experimental sculpture.

As a man Pollock was described by his contemporaries as gentle and contemplative when sober, violent when drunk. These extremes found equilibrium in his art. He was highly intelligent, widely read and, when he chose, incisively articulate. He believed that art derived from the unconscious, saw himself as the essential subject of his painting, and judged his work and that of others on its inherent authenticity of personal expression.

Personality and painting

His critical reception ranged from the discerning art criticism of Clement Greenberg (1909–) in *The Nation* during the 1940s to *Time* magazine's reference to him as "Jack the Dripper" a few months before his death in 1956. Despite occasional attempts in the art press to understand his work seriously, his name became synonymous with extreme artistic caprice, since the novelty of

his "drip" technique overshadowed his obsession with the deeply personal expression that technique permitted. Ironically, he did not profit financially from his fame. He never sold a painting for more than $10,000 in his life and often was hard-pressed for cash. His work was more appreciated abroad. It was seen in Europe, for example, at the Venice Biennales of 1948, 1950, and 1956 and in a one-man show at Paris in 1952. In 1949, the French Abstractionist Georges Mathieu (1921–) stated that he considered Pollock the "greatest living American painter," a judgment still shared by many foreign and American critics.

Art movements following Abstract Expressionism in America, such as Pop art, Op art, and Color-field art, have looked back, with more or less cause, to Pollock's work or the example of his personality as fundamental to their departures. Critical opinion has tended largely to emphasize the formal elements of his art and affinities with such artists as the French Impressionist Claude Monet and Piet Mondrian, the Dutch painter of the de Stijl movement, as well as with modern European art movements, notably Expressionism, Cubism, and Surrealism. The psychologically orientated iconography, so important to Pollock and to a balanced understanding of his contribution to human culture, has generally been ignored.

MAJOR WORKS

Jackson Pollock's works are, for the most part, scattered throughout the United States and abroad in museum and private collections. Major concentrations of his creations are to be found in the collection of the artist's widow, Lee Krasner Pollock and at the Museum of Modern Art, New York. The following are his major paintings. In general, all are painted on canvas except "Number Twenty-nine, 1950," which is on glass.

"Going West" (*c.* 1935; Thomas Hart Benton Collection, Kansas City, Missouri); "The Flame" (1937; Lee Krasner Pollock Collection, New York); "Bird" (*c.* 1941; Lee Krasner Pollock Collection, New York); "Male and Female" (1942; Mrs. H. Gates Lloyd Collection, Haverford, Pennsylvania); "The She-Wolf" (1943; Museum of Modern Art, New York); "Pasiphaë" (1943; Lee Krasner Pollock Collection, New York); "Guardians of the Secret" (1943; San Francisco Museum of Art, San Francisco); "Mural" (dated on canvas 1943, 1944?; The University of Iowa Museum of Art, Iowa City); "The Totem, Lesson I" (1944; Mrs. Emily Walker Collection, West Redding, Connecticut); "The Blue Unconscious" (1946; Mrs. Cecil Blaffer Hudson Collection, Houston, Texas); "Shimmering Substance" (1946; Museum of Modern Art, New York); "Eyes in the Heat" (1946; Peggy Guggenheim Collection, Venice, Italy); "Full Fathom Five" (1947; Museum of Modern Art, New York); "Lucifer" (1947; Mr. and Mrs. Harry B. Anderson Collection, Atherton, California); "Summertime" ("Number Nine, 1948"; American Broadcasting Company Collection, New York); "Number Ten, 1949" (Alfonso A. Ossorio Collection, East Hampton, New York); "One" ("Number Thirty-one, 1950"; Museum of Modern Art, New York); "Autumn Rhythm" ("Number Thirty, 1950"; The Metropolitan Museum of Art, New York); "Lavender Mist" ("Number One, 1950"; Alfonso A. Ossorio and Edward F. Dragon Collection, East Hampton, New York); "Number Twenty-nine, 1950" (National Gallery of Canada, Ottawa); "Number Thirty-two, 1950" (Kunstsammlung Nordrhein-Westfalen, Düsseldorf, Germany); "Mural" (1950; William Rubin Collection, New York); "Number Twenty-three, 1951" ("Frogman"; Martha Jackson Gallery, New York); "Echo" (1951, Museum of Modern Art, New York); "Number Seven, 1952" (Lee Krasner Pollock Collection, New York); "Convergence" ("Number Ten, 1952"; Albright-Knox Art Gallery, Buffalo, New York); "Blue Poles" ("Number Eleven, 1952"; dated on canvas 1953; Ben Heller Collection, New York); "Portrait and a Dream" (1953; Dallas Museum of Fine Arts, Dallas, Texas); "Easter and the Totem" (1953; Lee Krasner Pollock Collection, New York); "Ocean Greyness" (1953; Solomon R. Guggenheim Museum, New York); "Sleeping Effort" (1953; Washington University Gallery of Art, St. Louis, Missouri); "The Deep" (1953; Lee Krasner Pollock Collection, New York); "White Light" (1954; Sidney Janis Collection, New York); "Scent" (1955; Mr. and Mrs. Frederick R. Weisman Collection, Beverly Hills, California).

BIBLIOGRAPHY. The definitive biography to date, along with all known statements by the artist, a detailed history of his exhibitions and their critical reception, and a comprehensive bibliography, is FRANCIS V. O'CONNOR, *Jackson Pollock* (1967). Interpretative monographs have been written by FRANK O'HARA, *Jackson Pollock* (1959); and BRYAN ROBERTSON, *Jackson Pollock* (1960). BERNICE ROSE has written a study of Pollock's drawings and small paintings in *Jackson Pollock: Works on Paper* (1969); C.L. WYSUPH has published the drawings Pollock gave to his first Jungian analyst in *Jackson Pollock: Psychoanalytic Drawings* (1970). All the works cited are heavily illustrated.

Two important articles are: ROBERT GOODNOUGH, "Pollock Paints a Picture," *Art News*, 50:38–41 (1951); and FRANCIS V. O'CONNOR, "The Genesis of Jackson Pollock: 1912 to 1943," *Artforum*, 5:16–23 (1967).

An excellent short colour film of Pollock painting was produced by HANS NAMUTH and PAUL FALKENBERG, with music by MORTON FELDMAN and narration by JACKSON POLLOCK in 1951. It is distributed by Film Images, New York.

(F.V.O'C.)

Pollution Control

Pollution is caused when a change in physical, chemical, or biological conditions in the environment harmfully affects the quality of human life, including effects on other animals and plants, industries, and cultural and aesthetic assets. Most pollution may be characterized as a production excess resulting from manufacturing or growing more than is to be consumed or as a result of discarding products after use. Though pollution is generally attributed to material substances (gases and particulate matter from smokestacks, chemicals in water or solid wastes, paper, glass, used automobiles), pollution may also be nonmaterial, such as an excess of noise and light. Pollution in all its forms is a more serious problem in the heavily industrialized areas of the world than it is in predominantly agricultural regions. Thus, this article is primarily concerned with the control of pollution in North America, Europe, and Japan.

Pollution control consists of the legal, institutional, scientific, and technological arrangements established to avoid or mitigate such excesses in the environment. It can be accomplished by containing pollutants at the source, by devising new technologies of manufacture that eliminate or reduce pollutants, and by reusing (recycling) materials and commodities through reprocessing and resource recovery.

Except for highly toxic substances or for substances concentrated by nature (accumulation in groundwater or concentration in the food chain), pollution control does not mean the elimination of all substances put into air, water, or onto the land. It is notable that, even in the proper uses of water and air, impurities are added, though only in amounts that permit renewal of purity.

Even before man, nature put great quantities of material into the environment and still does (volcanoes, dust storms). Solid material in air, such as salt particles or dust, are essential as the nuclei for raindrops. Yet, when cities add massively to the amount of these nuclei, the excess may diminish rainfall because the drops that form are too small to fall as rain. Because of the multiple uses of air, water, and land, the tolerable amount or level of pollution varies. A ship canal may be allowed a higher level of pollution than recreational water.

Some kinds of pollution, notably radioactive fallout and certain toxic substances from smokestacks, may be widespread and even global. But pollution usually occurs where people and their activities are concentrated. Generally, if all pollutants were distributed equally over the Earth, they would not exceed tolerable limits. Because of his tendency to congregate in huge cities, man himself may be considered a pollutant inasmuch as an excess of people in one place is often the cause of deteriorating human conditions. Thus, one effective way of pollution control is dispersal of its sources.

Interaction of three major types of pollution

Although pollution and pollution control are usually treated in three natural categories—air pollution, water pollution, and land pollution—these three elements of the environment also interact. Many failures in pollution control have resulted from inappropriate division of control responsibilities. Junk piles and dumps pollute the land, but municipalities that burn their solid wastes using incomplete combustion also contribute to air pollution. Pollutants in air or on land, washed or leached out by rain, contribute to water pollution; and substances in wa-

ter settle out in sediments and end up as pollution of the land. What is tolerable depends on when and where the pollution occurs and involves a careful assessment of risks and benefits. DDT, for example, may well be banned or used most sparingly in much of the world, but in Ceylon a worse pollutant is an excess of malaria-carrying mosquitoes; there, DDT may be a proper pollution-control technique.

History of pollution-control problems. Pollution problems had their beginnings with the growth of cities and the massing of people and their related water, industrial, and disposal needs. There are numerous references in ancient history to pollution. Excavations at the site of Troy indicated that inhabitants dropped their refuse on the floor and let it accumulate until the level rose so high that doors would not open, whereupon the doors were repositioned. Ancient Athenians improved somewhat on these sanitation habits, disposing of refuse in dumps at the borders of the city. The Romans, too, left masses of refuse, garbage, and even human corpses in open trenches on the city's outskirts, which historians say contributed to the typhoid, typhus, cholera, and malaria outbreaks that plagued the city.

As urbanization increased, so did pollution. Medieval cities passed many ordinances against refuse dumping in streets and canals, though without much effect. The first smoke abatement law was passed in England in 1273, and by 1306 a man was executed for burning coal in London. In 1388 Parliament forbade disposition of filth and garbage in ditches, rivers, and waters, but the act was no more effective than the edict against burning coal. Pollution problems continued through the Middle Ages, compounded by the practice of throwing waste out of windows onto the streets below.

But it was in the early years of the Industrial Revolution, with the massing of industries in urban areas, that pollution began to produce its staggering environmental effects. A single factory chimney or a single blast furnace might easily have its effluents absorbed by the surrounding landscape, but 20 in a narrow area polluted the air or water beyond technological remedies of the time. Noise levels began rising, and a contemporary account of mid-19th-century Birmingham tells of "hammerings incessantly on the anvil" and of "unending clangs of engines, flame rustles, water hisses, steam roars." More dangerous were the air pollutants, such as chlorine, ammonia, carbon monoxide, and methane, that increased the incidence of bronchitis and pneumonia. Among adults and children living in high-density, highly polluted urban areas in England in the 19th century, the disease and death rates were considerably higher than among those living in low-density and rural areas.

Industrialization contributed to stream deterioration, with wastes thrown into the water. At about the same time, the water-carriage system of sewage disposal was introduced. Large amounts of untreated municipal and industrial wastes began to find their way into streams. By the mid-19th century, water pollution was a serious health problem, particularly in densely populated areas. Odours arising from the Thames River in the late 1850s are reported to have made life in London almost intolerable. In cities elsewhere, conditions were not much better; the Chicago Sanitary and Ship Canal, known as Bubbly Creek, was said to have had in places a scum so thick people could walk on it. Contaminated water supplies led to repeated cholera and typhoid epidemics: one of the most famous was London's Broad Street Pump epidemic in 1854, caused by direct leakage from privies into the hand-pumped well that provided the neighbourhood water supply.

Problems of pollution became steadily more widespread in the 20th century. The automobile, a fledgling in transportation at the turn of the century, became the major air polluter, first in the United States, then in Europe and Japan. Technological advances in industry and agriculture produced thousands of new chemicals, including fertilizers, insecticides, and herbicides, many of which are thrown back or naturally run off into rivers causing eutrophication, a process by which an excess of nutrients stimulates the growth of algae and other plant life to such an extent that they choke waterways.

Air-pollution episodes began to occur. The first recorded disaster was in the heavily industrialized section of the Meuse Valley in Belgium, where, in December 1930, hundreds of people became ill and 60 died during a four-day fog. In the United States during a four-day period in October 1948, the small mill town of Donora, Pennsylvania, was fog-filled with pollutants that made almost half of its 14,000 inhabitants sick. In the 1950s and 1960s both London and New York had air-pollution episodes that resulted in excess deaths and illnesses, chiefly among persons with known heart and respiratory diseases.

Air-pollution disasters

AIR POLLUTION

Pollutants and their sources. Five major classes of pollutants are discharged into the air: carbon monoxide, particulates, sulfur oxides, hydrocarbons, and nitrogen oxides. In addition to the automobile, other major sources are from combustion of fuel in electric-power plants, industrial processes, and space heating, from the combustion in solid-waste disposal, coal-waste fires, and agricultural burning.

Carbon monoxide (CO) is a colourless, odourless, poisonous gas, slightly lighter than air. The only significant source of carbon monoxide is the combustion process when the carbon in fuel is burned incompletely, with the carbon partly oxidized to carbon monoxide instead of fully to carbon dioxide. The largest single source of carbon monoxide is the internal-combustion engine.

Particulates include particles of solid or liquid substances in a number of sizes ranging from those that are visible as soot and smoke to particles too small to detect except under an electron microscope. Particulates are produced primarily by stationary fuel combustion and industrial processes; forest fires account for a small percentage.

Sulfur oxides are acrid, corrosive, poisonous gases produced when fuel containing sulfur is burned. Most of the sulfur oxides come from utility and industrial plants that burn coal and oil, both of which contain sulfur as an impurity. The burning of coal produces about 60 percent of the sulfur oxides annually emitted. Oil burning and industrial processes that use sulfur also are major producers of sulfur oxides, usually concentrated in urban areas.

Hydrocarbons, like carbon monoxide, represent unburned and wasted fuel. Unlike carbon monoxide, gaseous hydrocarbons at concentrations normally found in the atmosphere are not toxic; they are a major pollutant, however, because of their role in forming photochemical smog (see below). Sources of airborne hydrocarbons include incineration, evaporation of industrial solvents, and combustion of coal and wood, but the leading contributor is gasoline, emitted by evaporation and by the internal-combustion engine. Other hydrocarbon emission comes from miscellaneous burning and industrial processes. About 60 percent is produced in urban areas, with their high concentrations of automobiles.

Nitrogen oxides are produced when fuel is burned at very high temperatures. The major sources of this pollutant are transportation vehicles and the combustion process as used in electric-power plants and industrial boilers (which account for about half of the nitrogen oxide emissions). In combustion, the ordinarily inert nitrogen in the air combines with oxygen at high temperatures and tends to stay combined if the exhaust gases are cooled too quickly. Nitrogen oxides combine with hydrocarbons to form a complex variety of secondary pollutants called photochemical oxidants. These oxidants, together with solid and liquid particles in the air, make up what is commonly known as smog. Photochemical-oxidant pollutants include ozone, nitrogen dioxide, peroxyacyl, aldehydes, and acrolein.

Another common air pollutant in urban areas is lead, which comes from manufacturing sources, pesticides, combustion of coal, refuse incineration, and leaded gasoline, which, when burned in automotive engines, is the major source of airborne lead in urban areas. Apart from

the pollutants themselves, certain natural factors affect air pollution. The ultraviolet rays in sunlight combine with hydrocarbons and nitrogen oxides to form photochemical smog, which can result in conditions of atmosphere stagnation during temperature inversions. Such phenomena occur when temperature increases from ground level up to several hundred feet within the troposphere (lower atmosphere); they are called inversions because temperature usually decreases with altitude. Inversions can impede the rise of the air from below, and, if the lower air contains pollutants, the inversion acts as a lid to seal them below. If no significant lateral movement of air occurs, the stage is set for an acute air-pollution episode.

Effect of temperature inversions

Effects on man, plants, and materials. Effects of air pollutants on man are varied. When carbon monoxide is inhaled, it displaces the oxygen in the blood and reduces the amount of oxygen carried to the body tissues. At levels commonly found in city air, mental performances can be dulled and reactions of even the healthiest persons can be slowed, making them more prone to accidents. The gas is believed to impose an extra burden on those already suffering from anemia, diseases of the heart and blood vessels, chronic lung conditions, and overactive thyroid.

Sulfur oxides can cause temporary and permanent injury to the respiratory system, irritating the upper respiratory tract and lung tissue. Photochemical oxidants result in eye irritations, and studies indicate that nitrogen oxides are harmful to human health, specifically increasing children's susceptibility to flu.

Many other pollutants are a growing public health worry even though they may not constitute immediate and direct threats. Studies suggest that lead levels found in the bodies of urban people may interfere with their ability to produce blood. It is being debated whether the lead levels in the environment are of themselves dangerous to health or whether the major danger from them is an increased likelihood of further concentrating lead in some food chains, leading ultimately to toxic doses for man or other organisms.
