There is another possible and—in its factual consequences—very real disadvantage; the other animals, tightly enclosed within the limits set by nature, are crippled almost exclusively by external factors; but man, in consequence of the freedom of choice granted to him through the variety of his gifts, can and very often does cripple and harm himself. All human activities are directed toward the end of a good and satisfactory life. But there are many subordinate aims that are sensible ends only as far as they serve a superior end. There is no sense in producing or acquiring more shoes than can possibly be worn. This is self-evident. With regard to money, however, which has become exchangeable against everything, the illusion arises that it is good to accumulate it without limit. By doing so, however, man harms both the community and himself because, concentrating on such a narrow aim, he deprives his soul and spirit of larger and more rewarding experiences. Similarly, an individual especially gifted for large-scale planning needs power to give orders to those capable of executing his plans. Used for such purposes, power is good. But coveted for its own sake it becomes oppressive to those subdued by it and harmful to the oppressor because he thus incurs the hatred of the oppressed. Because of his imperfection, man is not able to engage in serious and fruitful activities without interruption. He needs relaxation and play, or amusement. Because the necessities of life frequently force man to work beyond the limit within which working is pleasant the illusion arises that a life of constant amusement would be the most pleasant and joyful. In reality, nothing is more tedious. This is the true meaning of Aristotle's teleology. It seems to be based entirely on empirical observation. It has nothing to do with a belief in divine providence and is not, as some modern critics believe, at variance with the law of causality. It forms the foundation, however, of Aristotle's ethics and political theory. Aristotle was an avid collector of empirical evidences. He induced his students, for instance, to make collections of the laws and political institutions (and their historical developments) of all known cities and nations in order to find out how they worked and at what points their initiators had been mistaken regarding the way in which they would work. In later times, Aristotle came to be considered (and by many is still considered) a dogmatic philosopher because the results of his inquiries were accepted as absolutely authoritative. In reality, however, he was one of the greatest Empiricists of all times.

Disciples and commentators. After Aristotle's death his immediate disciples carried on the same kind of work, especially in the historical field: Theophrastus wrote a history of philosophy and works on botany and on mineralogy, Eudemus of Rhodes wrote histories of mathematics and of astronomy, Meno a history of medicine, and Dicaearchus of Messene a history of civilization and a book on types of political constitutions. The next two generations of Peripatetics spread out in two different directions: literary history, in the form of histories of types of poetry, epic, tragedy, and comedy, and of biographies of famous writers, and physical science, Straton of Lampsacus creating a new kind of physics based on experiments, and the great astronomer Aristarchus of Samos inventing the heliocentric system. The school then went for some time into eclipse until, in the 1st century AD, after the rediscovery of Aristotle's lecture manuscripts, there arose a great school of commentators on his works, which had an enormous influence on medieval philosophy.

HELLENISTIC AND ROMAN PHILOSOPHY

The period after the death of Aristotle was characterized by the decay of the Greek city-states, which then became pawns in the power game of the Hellenistic kings who succeeded Alexander. Life became troubled and insecure. It was in this environment that two dogmatic philosophical systems came into being, the Stoic and the Epicurean, which were destined to give their adherents something to hold onto and to make them independent of the external world.

Stoics. The Stoic system was created by a Syrian, Zeno of Citium (flourished around the turn of the 3rd century BC), who went to Athens as a merchant but lost his fortune at sea. Zeno was consoled by the Cynic philosopher Crates, who taught him that material possessions were of no importance whatsoever for a man's happiness. He therefore stayed at Athens, heard the lectures of various philosophers, and—after he had elaborated his own philosophy—began to teach in a public hall, the Stoa Poikile (hence the name Stoicism). Zeno of Citium

Zeno's thought comprised, essentially, a dogmatized Socratic philosophy, with added ingredients derived from Heracleitus. The basis of human happiness, he said, is to live "in agreement" (with oneself), a statement which was later replaced by the formula "to live in agreement with nature." The only real good for man is the possession of virtue; everything else (wealth or poverty, health or illness, life or death) is completely indifferent. All virtues are based exclusively on right knowledge—self-control (*sōphrosynē*) being the knowledge of the right choice, fortitude the knowledge of what must be endured and what must not, and justice the right knowledge "in distribution." The passions, which are the cause of all evil, are the result of error in judging what is a real good and what is not. Because it is difficult to see, however, why murder, fraud, and theft should be considered evil if life and possessions are of no value, the doctrine was later modified by making among the "indifferent things" distinctions between "preferable" things, such as having the necessities of life and health; completely indifferent things; and "anti-preferable things," such as lacking the necessities of life or being ill—while insisting still that the happiness of the truly wise man could not be impaired by illness, pain, hunger, or any deprivation of external goods. In the beginning, Zeno also insisted that a man is either completely wise, in which case he would never do anything wrong and would be completely happy, or he is a fool. Later he made the concession, however, that there are men not completely wise but who are progressing toward wisdom. Though the latter might even have true insight, they are not certain that they have it, whereas the truly wise man is also certain of having true insight. The world is governed by divine *logos*—a word originally meaning "word" or "speech," then (with Heracleitus) also a speech that expresses the laws of the universe, and, finally, "reason." This *logos* keeps the world in perfect order. Man can deviate from or rebel against this order, but by doing so he cannot disturb it but can only do harm to himself.

Development of Zeno's philosophy

Zeno's philosophy was further developed by Cleanthes, the second head of the school, and by Chrysippus, its third head. Chrysippus elaborated a new kind of logic, which did not receive much attention, however, outside the Stoic school, until, in recent times (under the name of the "propositional logic"), it has been hailed by some logicians as superior to the "conceptual logic" of Aristotle. In the mid-2nd century BC, Panaetius of Rhodes adapted Stoic philosophy to the needs of the Roman aristocracy (whose members were then governing the known world) and made a great impression on some of the leading men of the time, who tried to follow his moral precepts. In the following century, in the time of the decay of the Roman republic, of civil war, and of slave rebellions, Poseidonius of Apamea, who was also one of the most brilliant historians of all times, taught that the Stoic takes a position above the rest of mankind, looking down on their struggles as on a spectacle. In the periods of the rising monarchy and of its established rule, Stoicism became the religion of the republican opposition, the most famous example of which was the younger Cato, who committed suicide after the victory of Julius Caesar. It was also the religion of Seneca, the educator and (for a long time) the adviser of Nero, who tried to keep Nero

on the path of virtue but failed and finally had to commit suicide on the orders of the Emperor. In spite of the oddities of Zeno's original doctrine, Stoicism gave consolation, composure, and fortitude in times of trouble to many proud men to the end of antiquity and beyond.

Epicurus and Lucretius Carus

Epicureans. The thought of Zeno's contemporary Epicurus also comprised a philosophy of defense in a troubled world. It has been (and still is) considered—in many respects justly—the opposite of Zeno's. Whereas Zeno had proclaimed that the wise man would try to learn from everybody and would always acknowledge his debt to earlier philosophers, Epicurus insisted that everything he taught was the result of his own thinking, though it is obvious that his physical explanation of the universe is a simplification of Democritus' Atomism. And whereas the Stoics had taught that pleasure and pain are of no importance for a man's happiness, Epicurus made pleasure the very essence of a happy life. Moreover, the Stoics from the beginning had acted as advisers of kings and statesmen. Epicurus, on the other hand, lived in the retirement of his famous Garden, cultivating intimate friendships with his adherents but warning against participation in public life. The Stoics believed in divine providence; Epicurus taught that the gods pay no attention whatsoever to human beings. Yet in spite of these contrasts, the two philosophies had some essential factors in common. Though Epicurus made pleasure the criterion of a good life, he was far from advocating a dissolute life and debauchery; he insisted that it was the simple pleasures that made life happy. When in his old age he suffered terrible pains from kidney trouble (or prostatitis?) he asserted that philosophizing and the memory and love of his distant friends made pleasure prevail even in the grips of such pain. Nor was Epicurus an atheist. His Roman admirer, the poet Lucretius Carus (*c.* 95–55 BC), in his poem *De rerum natura* ("On the Nature of Things") praised Epicurus enthusiastically as the liberator of mankind from all religious fears; and Epicurus himself had affirmed that this had been one of the aims of his philosophy. But although he taught that the gods are much too superior to trouble themselves with paying attention to mortals, he said—and, as his language clearly shows, sincerely believed—that it is important for human beings to look at the gods as perfect beings, since only in this way could they approach perfection. It was only in Roman times that people began to misunderstand Epicureanism, holding it to be an atheistic philosophy justifying a dissolute life, so that a man could be called "a swine from the herd of Epicurus." Seneca recognized the true nature of Epicureanism, however, and in his *Epistulae morales* ("Moral Letters") deliberately interspersed through his Stoic exhortations maxims from Epicurus.

Pyrrho of Elis and Sextus Empiricus

Skeptics. There was still another Hellenistic school of philosophy, the Skeptic school initiated by another of Zeno's contemporaries—Pyrrho of Elis—a school that was destined to become of great importance for the preservation of a detailed knowledge of Hellenistic philosophy in general. Pyrrho had come to the conviction that no man can know anything for certain nor ever be certain that the things he perceives with his senses are real and not illusory. He is said to have carried the practical consequences of his conviction so far that, when walking in the streets, he paid no attention to the vehicles and other obstacles, so that his faithful disciples always had to accompany him to see that he came to no harm. Pyrrho's importance for the history of philosophy lies in the fact that one of the later adherents of his doctrine, Sextus Empiricus (2nd–3rd century AD), wrote a large work *Pros dogmatikous* ("Against the Dogmatists"), in which he tried to refute all of the philosophers who had a more positive philosophy and that in so doing he quoted extensively from their works, thus preserving much that would otherwise have been lost. It is a noteworthy fact that the British sensualists of the 18th century and also Immanuel Kant derived most of their knowledge of ancient philosophy from Sextus.

Neo-Pythagoreans and Neoplatonists. All of the philosophical schools and sects of Athens that originated in the 4th century BC continued into late antiquity, most of them until the emperor Justinian I, in AD 529, ordered all of them closed because of their pagan character. Within that whole period of nearly 1,000 years only two new schools were added; even these, however—the Neo-Pythagorean and the Neoplatonic schools—drew their inspiration from early Greek philosophy, though only the latter was of greater importance for the history of philosophy. Neoplatonism began with Ammonius Saccas (first half of the 3rd century AD), who had been brought up as a Christian but had abandoned his religion for the study of Plato and developed his own kind of Platonic philosophy. Because he wrote nothing, his philosophy is known only through his famous disciple, Plotinus. Plotinus, however, did not publish anything either. But his philosophy is known through the publication of notes, discussions, and explanations following his lectures made by his disciple Porphyry, who also wrote a biography of Plotinus.

Plotinus and Iamblichus

The philosophy of Plotinus (and Ammonius) was derived from a study of Plato. Moreover, it used many philosophical terms first coined by Aristotle, and adopted some elements of Stoic philosophy as well. Yet it is essentially a new philosophy, agreeing with the religious and mystical tendencies of its time. Plotinus assumed the existence of several levels of Being, the highest being that of the One, or the Good, which are identical but indescribable and indefinable in human language. The next lower level is that of the *nous*, or pure intellect or reason; the third is that of the soul or souls. There then follows the world perceivable by the senses and, finally, at the lowest level there is matter, which is the cause of all evil. The highest bliss for man is union with the One, or Good, attained by contemplation and purification. That this is not a lasting state attained once for all—like the status of the Stoic wise man, who was supposed never to lose his wisdom again—is shown by the fact that Porphyry, in his *Vita Plotini*, said that Plotinus had experienced this supreme bliss seven times in his life, whereas he, Porphyry, had experienced it only once.

The further history of Neoplatonism is extremely complicated. While Porphyry had emphasized the ethical element in Plotinus' philosophy, his disciple Iamblichus of Chalcis in Syria (died *c.* AD 325), founder of a Syrian branch of the sect, mingled Neoplatonism with Neo-Pythagoreanism, writing on the Pythagorean way of life and on number theory. Above all, he multiplied the levels of being or the emanations from the One, which enabled him to incorporate the traditional Greek gods into his system. Another branch of the school was founded in Pergamum, in western Asia Minor, by his disciple Aedesius. He and his disciple Maximus tried to revive the ancient Greek mystery religions, such as Orphism. All of these developments became of great importance for the attempt made in the 4th century by the emperor Julian to revive paganism. In the following century the Athenian school reached a new high point when Proclus combined ideas of his predecessors into one comprehensive system. When in 529 Justinian closed all of the philosophical schools in Athens, however, a branch continued to exist in Alexandria. The Athenian Neoplatonists found refuge at the court of the Persian king Khosrow, and in 535 they were permitted to return to Athens. But gradually pagan philosophy as such died out, though it continued to exist as an influence in the development of Christian philosophy and theology. (K.v.Fr.)

III. Medieval philosophy

Medieval philosophy designates the philosophical speculation that occurred in western Europe during the Middle Ages; *i.e.*, from the fall of the Roman Empire in the 4th and 5th centuries AD to the Renaissance of the 15th century. Greek philosophy ceased to be creative after Plotinus in the 3rd century AD. A century later, Christian thinkers, such as Ambrose, Victorinus, and Augustine, began to assimilate Neoplatonism into Christian doctrine in order to give a rational interpretation of Christian faith. Thus, medieval philosophy was born of the confluence of Greek (and to a lesser extent of Roman) philosophy and Christianity. Plotinus' philosophy was already deeply religious,

having come under the influence of Near Eastern religion. Medieval philosophy continued this religious orientation, for it remained in close conjunction with Christian faith. Its methods were philosophical and rational, at first those of Plotinus and later those of Aristotle. But it developed within faith as a means of throwing light on the truths and mysteries of faith. Thus, religion and philosophy fruitfully cooperated in the Middle Ages. Philosophy, as the handmaid of theology, made possible a rational understanding of faith. Faith, for its part, inspired Christian thinkers to develop new philosophical ideas, some of which became part of the philosophical heritage of the West.

Confluence of Greek philosophy and Christian faith

Toward the end of the Middle Ages, this helpful interplay of faith and reason started to break down. Philosophy began to be cultivated for its own sake, apart from, and even in contradiction to, Christian religion. This divorce of reason from faith, made definitive by Francis Bacon and René Descartes, marked the birth of modern philosophy.

EARLY MEDIEVAL PHILOSOPHY

The early medieval period, which extended to the 12th century, saw the barbarian invasions of the Roman Empire, the collapse of its civilization, and the gradual building of a new, Christian culture in western Europe. Philosophy in these troubled and darkened times was cultivated by late Roman thinkers, such as Augustine (354–430) and Boethius (*c.* 480–*c.* 525), then by monks such as Anselm (1033–1109). The monasteries became the main centres of learning and education and retained their preeminence until the founding of the cathedral schools and universities.

Augustine. During these centuries philosophy was heavily influenced by Neoplatonism; Stoicism and Aristotelianism played only a minor role. Augustine was awakened to the philosophical life by reading Cicero, but the Neoplatonists most decisively shaped his philosophical methods and ideas. To them he owed his conviction that beyond the world of the senses there is a spiritual, eternal realm of truth that is the object of the human mind and the goal of all man's striving. This truth he identified with the God of Christianity. Man encounters this divine world of truth and beauty not through his senses but by turning inward to his mind, and above his mind to the intelligible light, in which he sees the truth. The Augustinian demonstration of the existence of God coincides with the proof of the existence of necessary, immutable Truth. Augustine considered the truths of both mathematics and ethics to be necessary, immutable, and eternal. These truths cannot come from the world of contingent, changing, and temporal things, nor from the mind itself, which is also contingent, mutable, and temporal. They are due to the illumining presence in man's mind of eternal and immutable Truth, or God. Any doubt that man knows the truth with certainty was dispelled for Augustine by the certitude that even if he is deceived in many cases, man cannot doubt that he exists and knows and loves.

Augustine conceived of man as a composite of two substances, body and soul, of which the soul is by far the superior. Nevertheless, the body is not to be excluded from human nature, and its eventual resurrection from the dead is assured by Christian faith. The soul's immortality is proved by its possession of eternal and unchangeable Truth.

Augustine's *Confessions* (*c.* 400) and *De Trinitate* (400–416; *On the Trinity*) abound with penetrating psychological analyses of knowledge, perception, memory, and love. His *De civitate Dei* (413–426; *The City of God*) presents the whole drama of human history as a progressive movement of humanity, redeemed by God, to its final repose in its Creator.

Boethius. One of the most important channels by which Greek philosophy was transmitted to the Middle Ages was Boethius. He began to translate into Latin all the philosophical works of the Greeks, but his imprisonment and death by order of Theodoric, king of the Ostrogoths, cut short this project. He translated only the logical writings of Porphyry (a 3rd-century Neoplatonist) and Aristotle. These translations and his commentaries on them brought to the thinkers of the Middle Ages the rudiments of Aristotelian logic. They also raised important philosophical questions, such as the nature of universals (terms that can be applied to more than one particular thing). Are universals real or only mental concepts? If real, are they corporeal or incorporeal; if incorporeal, do they exist in the sensible world or apart from it? Medieval philosophers debated at length these and other problems relating to universals. In his logical works Boethius presents the Aristotelian doctrine of universals, that they are only mental abstractions. In his *De consolatione philosophiae* (*c.* 525; *Concerning the Consolation of Philosophy*), however, he adopts the Platonic notion that they are innate ideas and their origin is in the remembering of knowledge in a previous existence. This book was extremely popular and influential in the Middle Ages. It contains not only a Platonic view of knowledge and reality but also a lively treatment of providence, divine foreknowledge, chance, fate, and human happiness.

The question of the nature of universals

Greek Fathers of the Church and Erigena. Another stream from which Greek philosophy, especially Neoplatonic thought, flowed into the Middle Ages was the Greek Fathers of the Church, notably Origen (*c.* 185–*c.* 254), Gregory of Nyssa (*c.* 335–*c.* 394), Nemesius (*c.* 400), Pseudo-Dionysius the Areopagite (*c.* 500), and Maximus the Confessor (*c.* 580–662). In the 9th century, John Scotus, called Erigena ("belonging to the people of Erin") because he was born in Ireland, a master at the Carolingian court of Charles the Bald, translated into Latin some of the writings of these Greek theologians, and his own major work, *De divisione naturae* (862–866; "On the Division of Nature"), is a vast synthesis of Christian thought organized along Neoplatonic lines. For him, God is the primal unity, unknowable and unnameable in himself, from which the multiplicity of creatures flows. He so far transcends his creatures that he is most appropriately called super-real and super-good. Creation is the process of division whereby the many derives from the One. The One descends into the manifold of creation and reveals himself in it. By the reverse process of analysis the multiplicity of creatures will return to its unitary source at the end of time, when everything will be absorbed in God.

Anselm. After the breakdown of the Carolingian Empire in the 10th century, intellectual speculation was at a low ebb in western Europe. In the next century some political stability was achieved by Otto I, who re-established the empire, and Benedictine monasteries were revitalized by reformers, such as Peter Damian. Like Tertullian, a Christian writer of the 2nd and 3rd centuries, Damian mistrusted secular learning and philosophy as harmful to the faith. Other monks showed a keen interest in dialectics and philosophy. Among the latter was Anselm, an Italian who became abbot of the French monastery of Bec and, later, archbishop of Canterbury.

Like Augustine, Anselm used both faith and reason in his search for truth. Faith comes first, in his view, but reason should follow, giving reasons for what men believe. Anselm's monks asked him to write a model meditation on God in which everything would be proved by reason and nothing on the authority of Scripture. He replied with his *Monologium* (1077; "Soliloquy"), the original title of which was "A Meditation on the Reasonableness of Faith." It contains three proofs of the existence of God, all of which are based on Neoplatonic thought. The first proof moves from the awareness of a multiplicity of good things to the recognition that they all share or participate more or less in one and the same Good, who is supremely Good in itself, and this is God. The second and third proofs are similar: beginning with their awareness of a multiplicity of beings that have more or less of being, and more or less of perfection, men recognize that they share in One who is supremely Being and perfect.

Anselm's proofs of the existence of God

Anselm's later work, the *Proslogium* (1077/78; "Allocution" or "Address"), also entitled "Faith Seeking Understanding," contains his most famous proof of the exis-

tence of God. This begins with a datum of faith: men believe God to be the being than which none greater can be thought. Some, like the fool in the Psalms, say there is no God; but even the fool, on hearing these words, understands them, and what he understands exists in his intellect, even though he does not grant that such a being exists in reality. But it is greater to exist in reality and in the understanding than to exist in the understanding alone. Therefore, it is contradictory to hold that God exists only in the intellect, for then the being than which none greater can be thought is one than which a greater can be thought, namely, one that exists both in reality and in the understanding. Philosophers still debate the meaning and value of this so-called ontological argument for God's existence.

Bernard of Clairvaux and Abelard. Anselm's inquiry into the existence and nature of God, as also his discussion of truth, love, and human liberty, aimed at fostering monastic contemplation. Other monks, such as the Cistercian Bernard of Clairvaux, were suspicious of the use of secular learning and philosophy in matters of faith. Bernard complained of the excessive indulgence in dialectic displayed by contemporaries, such as Peter Abelard and Gilbert de la Porrée. He himself developed a doctrine of mystical love, the influence of which lasted through the centuries. The monks of the Parisian Abbey of St. Victor were no less intent on fostering mystical contemplation, but they cultivated the liberal arts and philosophy as an aid to it. In this spirit, Hugh of Saint-Victor wrote his *Didascalion* (*c.* 1127; "Teaching"), a monumental treatise on the theoretical and practical sciences and the *trivium* (grammar, rhetoric, dialectic) and the *quadrivium* (arithmetic, music, geometry, astromony). During this same period the School of Chartres, attached to the famous cathedral near Paris, was the focus of Christian Platonism and Humanism.

Urban development in the 12th century shifted the centre of learning and education from the monasteries to the towns. Abelard founded several urban schools near Paris and taught in them. A passionate logician, he pioneered a method in theology that contributed to the later Scholastic method. His *Sic et non* (1115–17; *Yes and No*) cites the best authorities on both sides of theological questions in order to reach their correct solution. In philosophy his main interest was logic. On the question of universals he agreed with neither the Nominalists nor the Realists of his day. His Nominalist teacher Roscelin held that universals, such as "man" and "animal," are nothing but words or names (*flatus vocis*). Abelard argued that this does not take into account the fact that names have meaning. His Realist teacher William of Champeaux taught that universals are realities apart from the mind. For Abelard, only individuals are real; universals are indeed names or mental concepts, but they have meaning because they refer to individuals. They do not signify an essence common to individuals, as the Realists maintained (*e.g.*, the essence "humanity" shared by all men), but the individuals in their common condition or status of being in a certain species, which results from God's creating them according to the same divine idea.

TRANSITION TO SCHOLASTICISM

In the 12th century a cultural revolution took place that influenced the whole subsequent history of Western philosophy. The old style of education, based on the liberal arts and emphasizing grammar and the reading of the Latin classics, was replaced by new methods stressing logic, dialectic, and all the scientific disciplines known at the time. John of Salisbury, of the School of Chartres, witnessed this radical change:

> Behold, everything was being renovated: grammar was being made over, logic was being remodeled, rhetoric was being despised. Discarding the rules of their predecessors, [the masters] were teaching the *quadrivium* with new methods taken from the very depths of philosophy.

Growing interest in Aristotelianism

In philosophy itself, there was a decline in Platonism and a growing interest in Aristotelianism. This change was occasioned by the translation into Latin of the works of Aristotle in the late 12th and early 13th centuries. Until then, only a few of his minor logical treatises were known. Now his *Topics, Analytica priora,* and *Analytica posteriora* were rendered into Latin, giving the schoolmen (the teachers of Western Christian philosophy in the 13th and 14th centuries) access to the Aristotelian methods of disputation and science, which became their own techniques of discussion and inquiry. Many other philosophical and scientific works of Greek and Arabian origin were translated at this time, creating a "knowledge explosion" in western Europe.

Arabic thought. Among the translations from Arabic were some of the writings of Avicenna (980–1037). This Islāmic philosopher had an extraordinary impact on the medieval schoolmen. His interpretation of Aristotle's notion of metaphysics as the science of *ens qua ens* ("being as being"), his analysis of many metaphysical terms, such as "being," "essence," "existence," and his metaphysical proof of the existence of God were often quoted, with approval or disapproval, in Christian circles. Also influential were his psychology, logic, and natural philosophy. His *al-Qānūn fī aṭ-ṭibb* ("Canon of Medicine") was an authority on the subject until modern times. The *Maqāṣid al-Falāsifah* (1094; "The Aims of the Philosophers") of the Arabian theologian al-Ghazālī, known in Latin as Algazel (d. *c.* 1111), an exposition of Avicenna's philosophy written in order to criticize it, was read as a complement of Avicenna's works. The anonymous *Liber de causis* ("Book of Causes") was also translated into Latin from Arabic. This work, excerpted from Proclus' *Stiocheiōsis theologikē* (*Elements of Theology*), was often ascribed to Aristotle, and it gave a Neoplatonic cast to his philosophy until its true origin was discovered by Thomas Aquinas.

The commentaries of the Arabian philosopher Averroës were translated along with Aristotle's works. As Aristotle was called "the Philosopher" by the medieval philosophers, Averroës was dubbed "the Commentator." These two, more than any others, taught the Scholastics philosophy as a purely rational discipline, divorced from revealed religion. The Christian schoolmen often attacked Averroës as the archenemy of Christianity for his rationalism and for his doctrines of the eternity of the world and the unity of the intellect for all men.

Jewish thought. Of considerably less influence on the Scholastics was medieval Jewish thought. Ibn Gabirol, known to the Scholastics as Avicebron or Avencebrol, was thought to be an Arab or Christian, though in fact he was a Spanish Jew. His chief philosophical work, written in Arabic and preserved only in a Latin translation, entitled *Fons vitae* (*Fountain of Life*), stresses the unity and simplicity of God. All creatures are composed of form and matter, either the gross corporeal matter of the sensible world or the spiritual matter of angels and human souls. Some of the schoolmen were attracted to the notion of spiritual matter and also to Gabirol's analysis of a plurality of forms in creatures, according to which every corporeal being receives a variety of forms by which it is given its place in the hierarchy of being—*e.g.*, a dog has the forms of a corporeal thing, a living thing, an animal, a dog.

Maimonides, or Moses ben Maimon, was known to Christians of the Middle Ages as Rabbi Moses. His *Dalālat al-hā'irīn* (*c.* 1190; *Guide of the Perplexed*) helped them to reconcile Greek philosophy with revealed religion. For Maimonides, there can be no conflict between reason and faith because both come from God; an apparent contradiction is due to a misinterpretation of either the Bible or the philosophers. Thus, he showed that creation is reconcilable with philosophical principles and that the Aristotelian arguments for an eternal world are not conclusive because they ignore the omnipotence of God, who can create a world of either finite or infinite duration.

The universities and Scholasticism

While Western scholars were assimilating the new treasures of Greek, Islāmic, and Jewish thought, universities were being founded, which became the centres of Scholasticism. Of these the most important were Paris and Oxford. Scholasticism is the name given to the theological and philosophical teachings of the schoolmen in the

universities. There was no one Scholastic doctrine; each of the Scholastics developed his own, which was often in disagreement with that of his fellow teachers. They had in common a respect for the great writers of old, such as the Fathers of the Church, Aristotle, Plato, Boethius, the Pseudo-Dionysius, and Avicenna. These they called "authorities." Their interpretation and evaluation of the authorities, however, frequently differed. They also shared a common style and method that developed out of the teaching practices in the universities. Teaching was done by lecture and disputation (a formal debate). A lecture consisted of the reading of a prescribed text followed by the teacher's commentary on it. Masters also held disputations in which the affirmative and negative sides of a question were thoroughly argued by students and teacher, before the latter resolved the problem.

THE AGE OF THE SCHOOLMEN

Robert Grosseteste and Roger Bacon. The newly translated Greek and Arabian treatises had an immediate effect on Oxford University. Its first chancellor, Robert Grosseteste (*c.* 1168–1253), commented on some of Aristotle's works and translated the *Nicomachean Ethics* from Greek to Latin. He was deeply interested in scientific method, which he described as both inductive and deductive. By the observation of individual events in nature, man advances to a general law, called a "universal experimental principle," that accounts for these events. Experimentation either verifies or falsifies a theory by testing its empirical consequences. For Grosseteste, the study of nature is impossible without mathematics. He cultivated the science of optics (*perspectiva*), which measures the behaviour of light by mathematical means. His studies of the rainbow and comets employ both observation and mathematics. His treatise *De luce* (1215–1220; "On Light") embodies a metaphysics of light, presenting light as the basic form of all things and God as the primal uncreated light.

Grosseteste's pupil, Roger Bacon (*c.* 1220–*c.* 1292), made the mathematical and experimental methods the key to natural science. The term experimental science was popularized in the West through his writings. For him, man acquires knowledge through reasoning and experience, but without the latter he can have no certitude. Man gains experience through the senses and also through an interior divine illumination that culminates in mystical experience. Bacon was critical of the methods of the Parisian theologians, such as Albertus Magnus and Thomas Aquinas. He strove to create a universal wisdom embracing all the sciences and organized by theology. He also proposed the formation of a single worldwide society or "Christian republic" that would unite all men under the leadership of the pope.

William of Auvergne. At the University of Paris, William of Auvergne was one of the first to feel the impact of the philosophies of Aristotle and Avicenna. As a teacher, and then as bishop of Paris, he was concerned with the threat of pagan and Islāmic thought to the Christian faith. He opposed the Aristotelian doctrine of the eternity of the world as contrary to the Christian notion of creation. His critique of Avicenna centred around the latter's conception of God and creation. The God of Avicenna, who creates the universe eternally and necessarily, through the mediation of ten Intelligences, was opposed by William of Auvergne with the Christian notion of a God who creates the world freely and directly. Creatures are radically contingent and dependent on God's creative will. Unlike God, they do not exist necessarily; indeed, their existence is distinct from their essence and accidental to it. God has no essence distinct from his existence; he is pure existence. In stressing the essential instability and noneternity of the world, he attributed true existence and causality to God alone. William of Auvergne was a follower of Augustine, but, like others at the time, he was compelled to rethink the older Augustinian notions in terms of the newer Aristotelian and Avicennian philosophies.

Opposition to Aristotelianism

Bonaventure. The Franciscan friar Bonaventure reacted similarly to the growing popularity of Aristotle and his Arabian commentators. He admired Aristotle as a natural scientist, but he preferred Plato and Plotinus, and, above all, Augustine, as metaphysicians. His main criticism of Aristotle and his followers was that they denied the existence of divine ideas. As a result, Aristotle was ignorant of exemplarism (that is, God's creation of the world according to ideas in his mind) and also of divine providence and government of the world. This involved Aristotle in a threefold blindness: he taught that the world is eternal, that all men share one agent intellect (the active principle of understanding in man), and that there are no rewards or punishments after death. Plato and Plotinus avoided these mistakes, but, because they lacked Christian faith, they could not see the whole truth. For Bonaventure, faith alone enables men to avoid error in these important matters.

Bonaventure did not confuse philosophy with theology. Philosophy is the knowledge of the things of nature and the soul innate in man or acquired by his own efforts, whereas theology is the knowledge of heavenly things based on faith and divine revelation. Bonaventure, however, rejects the practical separation of philosophy from theology. Philosophy needs the guidance of faith; far from being self-sufficient, it is but a stage toward the higher knowledge that culminates in the vision of God.

For Bonaventure, every creature to some degree bears the mark of its Creator. The soul has been made in the very image of God. Thus, the universe is like a book in which the triune God is revealed. His *Itinerarium mentis in Deum* (1259; "Journey of the Mind to God") follows Augustine's path to God, from the external world to the interior world of the mind, and then above the mind from the temporal to the eternal. Throughout this journey, men are aided by a moral and intellectual divine illumination. The mind has been created with an innate idea of God, so that, as Anselm pointed out, man cannot think that God does not exist. In a terse reformulation of the Anselmian argument for God's existence, Bonaventure states that if God is God, he exists.

Albertus Magnus. The achievement of the Dominican friar Albertus Magnus was of vital importance for the development of medieval philosophy. A man of immense erudition and intellectual curiosity, he was one of the first to recognize the true value of the newly translated Greco-Arabian scientific and philosophic literature. Everything he considered valuable in it, he included in his encyclopaedic writings. He set out to teach this literature to his contemporaries and in particular to make the philosophy of Aristotle, whom he considered to be the greatest philosopher, understandable to them. He also proposed to write original works in order to complete what was lacking in the Aristotelian system. In no small measure, the triumph of Aristotelianism in the 13th century can be attributed to him.

Triumph of Aristotelianism

Albertus' observations and discoveries in the natural sciences advanced botany, zoology, and mineralogy. In philosophy he was less original and creative than his famous pupil Thomas Aquinas. He produced a synthesis of Aristotelianism and Neoplatonism, blending together the philosophies of Aristotle, Avicenna, and Gabirol, and, among Christians, Augustine and Pseudo-Dionysius.

Thomas Aquinas. Albertus Magnus' Dominican confrere and pupil Thomas Aquinas shared his master's great esteem for the ancient philosophers, especially Aristotle, and also for the more recent Arabian and Jewish thinkers. He welcomed truth wherever he found it and used it for the enrichment of Christian thought. For him, reason and faith cannot contradict each other because they come from the same divine source. In his day conservative theologians and philosophers regarded Aristotle with suspicion and leaned toward the more traditional Christian Platonism. Aquinas realized that their suspicion was due, in part, to the fact that Aristotle's philosophy had been distorted by his Arabian commentators; so he wrote his own commentaries on Aristotle to show the essential soundness of his system and to convince contemporaries of its value for Christian theology.

Aquinas' own philosophical views are best expressed in his theological works, especially his *Summa theologiae*

(1265/66–1273) and *Summa contra gentiles* (1258–1264). In these works he clearly distinguishes between the domains and methods of philosophy and theology. The philosopher seeks the first causes of things, beginning with data furnished by the senses; the subject of the theologian's inquiry is God as revealed in sacred Scripture. In theology, appeal to authority carries most weight; in philosophy, it carries least.

Aquinas found Aristotelianism and, to a lesser extent, Platonism useful instruments for Christian thought and communication; but he transformed and deepened everything he borrowed from them. For example, he took over Aristotle's proof of the existence of a primary unmoved mover, but the primary mover at which Aquinas arrives is very different from that of Aristotle; it is in fact the God of Judaism and Christianity. He also adopted Aristotle's teaching that the soul is man's form and the body is his matter, but for Aquinas this does not entail, as it does for the Aristotelians, the denial of the immortality of the soul or the ultimate value of the human person. Aquinas never compromised Christian doctrine by bringing it into line with the current Aristotelianism; rather, he modified and corrected the latter whenever it clashed with Christian belief. The harmony he established between Aristotelianism and Christianity was not forced but achieved by a new understanding of philosophical principles, especially the notion of being, which he conceived as the act of existing (*esse*). For him, God is pure being, or the act of existing. Creatures participate in being according to their essence; for example, man participates in being, or the act of existing, to the extent that his humanity, or essence, permits. The fundamental distinction between God and creatures is that creatures have a real composition of essence and existence, whereas God's essence is his existence.

Averroists. A group of masters in the Faculty of Arts at Paris welcomed Aristotle's philosophy and taught it in disregard of its possible opposition to the Christian faith. They wanted to be philosophers, not theologians, and to them this meant following the Aristotelian system. Because Averroës was the recognized commentator on Aristotle, they generally interpreted his thought in an Averroistic way. Hence, in their own day they were known as "Averroists"; today they are often called "Latin Averroists" because they taught in Latin. Their leader, Siger of Brabant, taught as rationally demonstrated certain Aristotelian doctrines that contradicted the faith, such as the eternity of the world and the oneness of the intellect for all men. They were accused of holding a "double truth" —of maintaining the existence of two contradictory truths: one commanded by faith, the other taught by reason. Although Siger never proposed as true philosophical conclusions contrary to faith, other members of this group upheld the right and duty of the philosopher to follow human reason to its natural conclusions, even when they contradicted the truths of faith.

This growing rationalism confirmed the belief of theologians of a traditionalist cast that the pagan and Muslim philosophies would destroy the Christian faith. They attacked these philosophies in treatises such as Giles of Rome's *Errores philosophorum* (1270; Eng. trans., *The Errors of the Philosophers*). In 1277 the bishop of Paris condemned 219 propositions based on the new trend toward rationalism and naturalism. These included even some of Aquinas' Aristotelian doctrines. The same year, the archbishop of Canterbury made a similar condemnation at Oxford. These reactions to the novel trends in philosophy did not prevent the Averroists from treating philosophical questions apart from religious considerations. Theologians, on their part, were increasingly suspicious of the philosophers and less optimistic about the ultimate reconciliation of philosophy and theology.

Condemnation of Aristotelian doctrines

PHILOSOPHY IN THE LATE MIDDLE AGES

In the late Middle Ages, earlier ways of philosophizing were continued and formalized into definite schools of thought. In the Dominican order, Thomism (theology and philosophy of Thomas Aquinas) was made the official teaching, though the Dominicans did not always adhere to it rigorously. Averroism, cultivated by philosophers such as John of Jandun (d. *c.* 1328), remained a live, though sterile, movement into the Renaissance. In the Franciscan order, the Englishmen John Duns Scotus and William of Ockham developed new styles of theology and philosophy that vied with Thomism throughout the late Middle Ages.

Scotus. John Duns Scotus (*c.* 1265–1308) opposed the rationalists' contention that philosophy is self-sufficient and adequate to satisfy man's desire for knowledge. In fact, he claimed, a pure philosopher such as Aristotle could not truly understand the human condition because he was ignorant of the Fall of man and his need for grace and redemption. Unenlightened by Christian revelation, Aristotle mistook man's present fallen state, in which all his knowledge comes through the senses, for his natural condition, in which the object of his knowledge would be coextensive with all being, including the being of God. The limitation of Aristotle's philosophy is apparent to Scotus in the Aristotelian proof of the existence of God as the primary mover of the universe. More adequate than this physical proof, he contended, is his own very intricate metaphysical demonstration of the existence of God as the absolutely primary, unique, and infinite being. He incorporated the Anselmian argument into this demonstration. For Scotus, the notion of infinite being, not that of primary mover or being itself, is man's most perfect concept of God.

In opposition to the Greco-Arabian view of the government of the universe from above by necessary causes, Scotus stressed the contingency of the universe and its total dependence on God's infinite creative will. He adopted the traditional Franciscan voluntarism, elevating the will above the intellect in man.

Defense of the doctrine of God's will

Scotus' doctrine of universals justly earned him the title "Doctor subtilis." Universals, in his view, exist only as abstract concepts, but they are based on common natures, such as humanity, which exist, or can exist, in many individuals. Common natures are real, and they have a real unity of their own distinct from the unity of the individuals in which they exist. The individuality of each individual is due to an added positive reality that makes the common nature to be *this* individual; for example, humanity to be Socrates. Scotus calls this reality an "individual difference," or "thisness" (haecceitas). This is an original development of the earlier medieval realism of universals.

William of Ockham. In the late 14th century, Thomism and Scotism were called the "old way" (*via antiqua*) of philosophizing in contrast to the "modern way" (*via moderna*) begun by such men as William of Ockham (*c.* 1285–1349). Ockham, no less than Scotus, wanted to defend the Christian doctrine of the freedom and omnipotence of God and the contingency of creatures against the necessitarianism of Greco-Arabian philosophy. But for him the freedom of God is incompatible with the existence of divine ideas as positive models of creation. God does not use preconceived ideas when he creates, as Scotus maintained, but he fashions the universe as he wishes. As a result, creatures have no natures or essences in common. There are no realities but individual things, and these have nothing in common. They are more or less like each other, however, and on this basis men can form universal concepts of them and talk about them in general terms.

The absolute freedom of God was often used by Ockham as a principle of philosophical and theological explanation. Because the order of nature has been freely created by God, it could have been different: fire, for example, could cool, as it now heats. If he wishes, he can give us the sight, or "intuitive knowledge," of a star without the reality of the star. The moral order could also have been different. God could have made hating him meritorious instead of loving him. It was typical of Ockham not to put too much trust in the power of human reason to reach the truth. For him, philosophy must often be content with probable arguments, for example, in establishing the existence of the Christian God. Faith alone gives certitude in this and in other vital matters. Another

principle invoked by Ockham is that a plurality is not to be posited without necessity. This principle of the economy of thought, later stated as Beings are not to be multiplied without necessity, is called "Ockham's razor."

Ockhamism was censured by a papal commission at Avignon, France, in 1326, and in 1474 it was forbidden to be taught at Paris: nevertheless, it spread widely in the late Middle Ages and rivalled Thomism and Scotism in popularity. Other Scholastics in the 14th century shared Ockham's basic principles and contributed with him to skepticism and probabilism in philosophy. John of Mirecourt (fl. *c.* 1345) stressed the absolute power of God and the divine will to the point of making him the cause of man's sin. Nicholas of Autrecourt (fl. *c.* 1347) adopted a skeptical attitude regarding such matters as man's ability to prove the existence of God and the reality of substance and causality. Rejecting Aristotelianism as inimical to the Christian faith, he advocated a return to the Atomism of the ancient Greeks as a more adequate explanation of the universe.

Trend away from Aristotelianism

Meister Eckehart. The trend away from Aristotelianism was accentuated by the German Dominican Meister Eckehart, who developed a speculative mysticism of both Christian and Neoplatonic inspiration. Eckehart depicts the ascent of the soul to God in Neoplatonic terms: by gradually purifying itself from the body, the soul transcends being and knowledge until it is absorbed in the One. The soul is then united with God at its highest point or "citadel." God himself transcends being and knowledge. Sometimes Eckehart describes God as the being of all things. This language, which was also used by Erigena and other Christian Neoplatonists, leaves him open to the charge of pantheism (the doctrine that the being of creatures is identical with that of God); but for Eckehart there is an infinite gulf between creatures and God. Eckehart means that creatures have no existence of their own but are given existence by God, as the body is made to exist and is contained by the soul. Eckehart's profound influence can be seen in the flowering of mysticism in the German Rhineland in the late Middle Ages.

Nicholas of Cusa. Nicholas of Cusa also preferred the Neoplatonists to the Aristotelians. To him, the philosophy of Aristotle is an obstacle to the mind in its ascent to God because its primary rule is the principle of contradiction, which denies the compatibility of contradictories. But God is the "coincidence of opposites." Because he is infinite, he embraces all things in perfect unity; he is at once the maximum and the minimum. Nicholas uses mathematical symbols to illustrate how, in infinity, contradictories coincide. If a circle is enlarged, the curve of its circumference becomes less; if a circle is infinite, its circumference is a straight line. As for man's knowledge of the infinite God, he must be content with conjecture or approximation to the truth. The absolute truth escapes man; his proper attitude is "learned ignorance."

For Nicholas, God alone is absolutely infinite. The universe reflects this divine perfection and is relatively infinite. It has no circumference, for it is limited by nothing outside of itself. Neither has it a centre; the earth is neither at the centre of the universe nor is it completely at rest. Place and motion are not absolute but relative to the observer. This new, non-Aristotelian conception of the universe anticipated some of the features of modern theories of the universe.

Thus, at the end of the Middle Ages, some of the most creative minds were abandoning Aristotelianism and turning to newer ways of thought. The philosophy of Aristotle, in its various interpretations, continued to be taught in the universities, but it had lost its vitality and creativity. Christian philosophers were once again finding inspiration in Neoplatonism. The Platonism of the Renaissance was in direct continuity with the Platonism of the Middle Ages. (A.A.Ma.)

IV. Modern philosophy

THE RENAISSANCE AND EARLY-MODERN PERIOD

The philosophy of a period arises as a response to social need, and the development of philosophy in the history of Western civilization since the Renaissance has, thus, reflected the process in which creative philosophers have responded to the unique challenge of each stage in the development of Western culture itself.

The career of philosophy—how it views its tasks and functions, how it defines itself, the special methods it invents for the achievement of philosophic knowledge, the literary forms it adopts and utilizes, its conception of the scope of its subject matter, and its changing criteria of meaning and truth—hinges on the mode of its successive responses to the challenges of the social structure within which it arises. Thus, Western philosophy in the Middle Ages was primarily a Christian philosophy, clarifying the divine revelation, reflecting the feudal order in its cosmology, devoting itself in no small measure to the institutional tasks of the Roman Catholic Church. It was no accident that the major philosophical achievements of the 13th and 14th centuries were the work of churchmen who also happened to be professors of theology at the universities of Oxford and Paris.

Cultural impact of new inventions and nations

The Renaissance of the late 15th and 16th centuries presented a different set of problems and therefore suggested different lines of philosophical endeavour. What is called the European Renaissance followed upon the introduction of three novel mechanical inventions from the East: gunpowder, block printing from movable types, and the compass. The first was used to explode the massive fortifications of the feudal order and thus became an agent of the new spirit of nationalism that threatened the rule of churchmen—and, indeed, the universalist emphasis of the church itself—with a competing secular power. The second, printing, made the propagation of knowledge widespread, secularized learning, reduced the intellectual monopoly of an ecclesiastical elite, and restored the literary and philosophical classics of Greece and Rome. The third, the compass, increased the safety and scope of navigation, produced the voyages of discovery that opened up the Western Hemisphere, and symbolized a new spirit of physical adventure and a new scientific interest in the structure of the natural world.

Each of these inventions with its wider cultural consequences presented new intellectual problems and novel philosophical tasks within a changed political and social environment. For, as the power of a single religious authority was slowly eroded under the influence of the Protestant Reformation, and as the prestige of the universal Latin language gave way to vernacular tongues, philosophers became less and less identified with their positions in the ecclesiastical hierarchy and more and more identified with their national origins. The works of Albertus Magnus, St. Thomas Aquinas, St. Bonaventure, and John Duns Scotus had been basically unrelated to the countries of their birth; but the philosophy of Machiavelli was directly related to Italian experience, that of Sir Francis Bacon and Thomas Hobbes was English to the core, and that of René Descartes set the standard and tone of French intellectual life for 200 years.

Dominant strands of Renaissance philosophy. The conventional division of pure knowledge in the contemporary world is drawn between the natural sciences, the social sciences, and the humanities. In the Renaissance, however, fields of learning had not yet become so sharply departmentalized: thus each of these divisions arose in the comprehensive and broadly inclusive area of Renaissance philosophy. For, as the Renaissance mounted its revolt against the reign of religion and therefore reacted against the church, against authority, against Scholasticism, and against Aristotle, there was a sudden blossoming of interest in problems centring about man, about nature, and about civil society. These three interests found exact representation in the three dominant strands of Renaissance philosophy: (1) political theory, (2) Humanism, and (3) the philosophy of nature.

Political theory. As secular authority replaced ecclesiastical, and as the dominant interest of the age shifted from religion to politics, it was natural that the rivalries of the national states and their persistent crises of internal order should raise with renewed urgency philosophical problems about the nature and the moral status of politi-

cal power, which had been practically dormant since pre-Christian times. And this new preoccupation with national unity, internal security, state power, and international justice stimulated the growth of political philosophy in Italy, in France, in England, and in Holland.

Machiavelli and power

In early-16th-century Italy, Niccolò Machiavelli, sometime state secretary of the Florentine republic, explored in *Il Principe* (written 1512–13; Eng. trans., *The Prince*, 1955) and in his *Discorsi sopra la prima deca di Tito Livio* (completed by 1517; Eng. trans., *Discourses*, 1950) the techniques for the seizure and retention of power in ways that seemed to exalt "reasons of state" above morality and codified the actual practices of Renaissance diplomacy for the next 100 years. In fact, Machiavelli was motivated by the most patriotic hopes for the ultimate unification of Italy and by the conviction that the low estate of Italian Renaissance morality needed to be elevated by restoring the ancient Roman virtues. Over half a century later in France, Jean Bodin, magistrate of Laon and a member of the States General, insisted that the state must possess a single, unified, and absolute power; he thus developed in detail the doctrine of national sovereignty in all of its administrative consequences and in its role as the source of all legal legitimacy.

In the 17th century in England, Thomas Hobbes, who was to become tutor to the future Charles II, elaborated the fiction that, in the "state of nature" that preceded civilization, life was "nasty, brutish, and short" with "every man's hand raised against every other," and that a "social contract" was thus agreed upon to convey all private rights to a single sovereign in return for general protection and for the institution of a reign of law. Because law is simply "the command of the sovereign," Hobbes at once turned justice into a by-product of power and denied any right of rebellion except when the sovereign becomes too weak to protect the commonwealth and hold it united.

In Holland, a prosperous and tolerant commercial republic in the 17th century, the issues of political philosophy took a different form. Thus, when the Dutch East India Company commissioned a great jurist, Grotius, to provide a defense of their trade rights and of their free access to the seas, the resulting two treatises, *Mare Liberum* (1609; "Freedom of the Seas") and *De Jure Belli ac Pacis* (1625; Eng. trans., *On the Law of War and Peace*, 1925), were the first significant codifications of international law. Their philosophical originality lay, however, in the fact that, in defending the rights of a small, militarily weak nation against the powerful absolutisms of England, France, and Spain, Grotius was led to a preliminary investigation of the sources and validity of the concept of "natural law"—the notion that inherent in human reason and immutable even against the willfulness of sovereign states are imperative considerations of natural justice and moral responsibility, which must serve as a check against the arbitrary exercise of vast political power.

Ambivalence of political philosophers

In general, the political philosophy of the Renaissance was dualistic: it was haunted, even confused, by the conflict between political necessity and general moral responsibility. Machiavelli, Bodin, and Hobbes asserted claims that justified the actions of Italian despotism and the absolutisms of the Bourbon and Stuart dynasties. Yet Machiavelli was obsessed with the problem of human virtue; Bodin insisted that even the sovereign ought to obey the law of nature—that is, to govern in accordance with the dictates of natural justice; and Hobbes himself found in natural law the rational motivation that causes a man to seek for security and peace. In the end, though Renaissance political necessity required that the philosophical doctrines of Thrasymachus (who held that right is what is in the interest of the strong) be implemented, it could never finally escape a twinge of Socratic conscience.

Humanism. The Renaissance was characterized by the renewed study of mathematics, medicine, and classical literature. The first two sparked the scientific revolution of the 16th and 17th centuries; the last became the foundation of the philosophy of Renaissance Humanism. From its origin, Humanism—suspicious of science and generally indifferent to religion—emphasized anew the centrality of man in the universe, his supreme value and importance. Characteristic of this emphasis was the famous *Oratio de hominis dignitate* (written 1486; Eng. trans., *Oration on the Dignity of Man*, 1956) of a late-15th-century Platonist, Pico della Mirandola, a leading member of Lorenzo de' Medici's Florentine Academy. But the new emphasis upon man's personal responsibility and on the possibility of his self-creation as a work of art was in no small part a consequence of the rediscovery of a series of crucial classical texts, which served to reverse the trends of medieval learning. Renaissance Humanism was predicated upon the victory of rhetoric over dialectic and of Plato over Aristotle, as Quintilian and Cicero had triumphed over Abelard (see above *Early medieval philosophy: Bernard of Clairvaux* and *Abelard*) and as the cramped format of Scholastic philosophic method gave way to a Platonic discursiveness.

Much of this had been prepared by Italian scholarly initiative in the early 15th century. The recently discovered manuscript of Quintilian was used by Lorenzo Valla, an anti-authoritarian Humanist, for the creation of modern rhetoric and the principles of textual criticism. But even more important was the rebirth of an enthusiasm for the philosophy of Plato in Medicean Florence and at the cultivated court of Urbino, a dukedom southeast of Florence. Precisely to service this enthusiasm, Marsilio Ficino, head of the Florentine Academy, had translated the entire Platonic corpus into Latin by the end of the century.

Enthusiasm for Plato

Except for Pico and Giordano Bruno, a late-16th-century Italian philosopher, the direct influence of Platonism upon Renaissance metaphysics is difficult to trace. The Platonic account of the moral virtues, however, was admirably adapted to the requirements of Renaissance education and gave new support to the Renaissance ideal of the courtier and the gentleman. But Plato also represented the philosophical importance of mathematics and the Pythagorean attempt to discover the secrets of the heavens, the earth, and the world of nature in terms of number and exact calculation; and this aspect of Platonism spilled over from Humanism into the domain of Renaissance science. The scientists Nicolaus Copernicus, Johannes Kepler, and Galileo owe more to the general climate of Pythagorean confidence in the explanatory power of number than does Renaissance metaphysics.

But Platonism also had the effect of influencing the literary form in which Renaissance philosophy was written. Although the very early medieval Platonists St. Augustine and John Scotus Erigena occasionally had used the dialogue form, later Scholasticism had abandoned it in favour of the formal treatise, of which the great "Summas" of Alexander of Hales and St. Thomas Aquinas are pristine examples. The Renaissance rediscovery of the Platonic dialogues suggested the literary charm of this conversational method to Humanists, scientists, and political theorists alike. The Humanist philosopher Bruno put forth his central insights in a dialogue, *De la causa, principio e uno* (1584); Galileo presented his novel mechanics in his *Dialogo sopra i due massimi sistemi del mondo* (1632); and even the politician Machiavelli wrote *Dell'arte della guerra* (1521; "On the Art of War") as a genteel conversation taking place in a quiet Florentine garden.

Of course, Renaissance Humanism was primarily a moral and a literary, rather than a narrowly philosophical, movement. And it flowered in figures with broadly philosophical interests such as Erasmus of Rotterdam, erudite citizen of the world; Sir Thomas More, the learned but unfortunate chancellor of Henry VIII; and, in the next generation, in the great French essayist and mayor of Bordeaux, Michel de Montaigne. But the recovery of the Greek and Latin classics, which was the work of Humanism, had profound effects upon the entire field of Renaissance philosophy and science through the ancient schools of philosophy to which it once more directed attention. In addition to Platonism, the most notable of these were Greek atomistic Materialism, Greek Skepti-

Revival of other ancient Greek schools

cism, and Roman Stoicism. The discovery of the manuscript of Lucretius (and the atomistic doctrines of Democritus) finally came to influence Galileo, Bruno, and, later, Pierre Gassendi, a modern Epicurean, through the insights into nature reflected in this work. The recovery of the manuscript of Sextus Empiricus, with its carefully argued Skepticism presented in a printed text in 1562, produced "a skeptical crisis" in French philosophy, which dominated the period from Montaigne to René Descartes. And the Stoicism of Seneca and Epictetus became almost the official ethics of the Renaissance—to appear prominently in the *Essais* (1580–88) of Montaigne, in the letters that Descartes wrote to the princess Elizabeth of Bohemia and to Queen Christina of Sweden, and in the later sections of the *Ethics* (first published 1675) of the Rationalist Benedict de Spinoza.

Philosophy of nature. Philosophy in the modern world is a self-conscious discipline. It has managed to define itself narrowly, so as to differentiate itself on the one hand from religion and on the other from exact science. But this narrowing of focus came about very late in its history—certainly not before the 18th century. The earliest philosophers of Greece were theorists of the physical world; Pythagoras and Plato were at once philosophers and mathematicians; and in Aristotle no clear distinction between philosophy and natural science can be maintained. The Renaissance continued this breadth of conception characteristic of the Greeks. Galileo and Descartes were mathematicians, physicists, and philosophers at once; and physics retained the name of "natural philosophy" at least until the death of Sir Isaac Newton (1727).

Had the Renaissance been painstakingly self-aware in the matter of definition (which it was not), it might have defined philosophy, on the basis of its actual practice, as "the rational, methodical, and systematic consideration of man, civil society, and the natural world." The areas of its interests would in no case have been in doubt. But exactly what constitutes "rational, methodical, and systematic consideration" would have been extremely controversial. For knowledge advances through the discovery and advocacy of new philosophic methods; and, because the diverse methods advocated depend for their validity upon the acceptance of different philosophic criteria of truth, meaning, and importance, the crucial philosophic quarrels of the 16th and 17th centuries were at bottom quarrels in the advocacy of methods. It is this issue, rather than any disagreement over subject matter or areas of attention, that separated the greatest Renaissance philosophers—such as Francis Bacon, René Descartes, and Thomas Hobbes.

The great new fact that confronted the Renaissance was the immediacy, the immensity, and the uniformity of the natural world. But what was of primary importance was the new perspective in which this fact was interpreted. To the Middle Ages the universe was hierarchical, organic, and God-ordained. To the Renaissance it was pluralistic, machinelike, and mathematically ordered. In the Middle Ages scholars thought in terms of purposes, of ends, of divine intentions; in the Renaissance they thought in terms of forces, mechanical agencies, and physical causes.

Leonardo's three theses

All of this had become clear by the end of the 15th century. Within the early pages of the *Notebooks* of Leonardo da Vinci, the great Florentine artist, scientist, Humanist, and mechanical genius, occur the following three propositions:

> (1) Since experience has been the mistress of whoever has written well, I take her as my mistress, and to her on all points make my appeal.
> (2) Instrumental or mechanical science is the noblest and above all others the most useful, seeing that by means of it all animated bodies which have movement perform all their actions.
> (3) There is no certainty where one can neither apply any of the mathematical sciences, nor any of those which are based upon the mathematical sciences.

Here are enunciated respectively: (1) the principle of Empiricism, (2) the advocacy of mechanistic science, and (3) the faith in mathematical explanation; and it is upon these three formulations, as upon a rock, that the science and philosophy of the Renaissance built its foundations. From each of Leonardo's theses descended one of the great streams of Renaissance philosophy: from the empirical principle the work of Francis Bacon; from mechanism the work of Thomas Hobbes; and from mathematical explanation that of René Descartes.

Any adequate philosophic treatment of scientific method surely contains both an empirical principle and a faith in mathematical explanation; and, in Leonardo's thinking, as in scientific procedure generally, there need be no conflict between them. Yet they do represent two poles of emphasis, each capable of exaggeratedly excluding the other. Moreover, the peculiar accidents of Renaissance scientific achievement did present some evidence for their mistaken separation: for the revival of medical studies on the one hand and the novel blooming of mathematical physics on the other emphasized opposite virtues in scientific methodology. This polarity was represented by the opposing figures of Vesalius and Galileo.

In the mid-16th century Andreas Vesalius, a Belgian physician, was astounding all of Europe with the unbelievable precision of his anatomical dissections and drawings. Having invented new tools for this precise purpose, he successively laid bare the vascular, the neural, and the musculature systems of the human body; and this procedure seemed to demonstrate the virtues of empirical method, of physiological experiment, and of the precision and disciplined skill in sensory observation, which made his demonstrations classics of inductive procedure.

Galileo's experiential dynamics

Only slightly later, the Italian physicist Galileo, following in the tradition already established by Copernicus and Johannes Kepler, founders of modern astronomy (but without their more mystical and metaphysical eccentricities), attempted to do for terrestrial and sidereal movements what Vesalius had managed for the structure of the human body—by creating his experiential dynamics, however, with the help of hypotheses supplied by the quantitative calculations of mathematics. In Galileo all of the most original scientific directions of the Renaissance came to a head: the revival of Alexandrian mathematics, the experimental use of new instruments like the lens and the telescope, the search for certainty in physics based upon the undoubted applicability of mathematical theory, and the underlying faith that the search for absolute certainty in science was reasonable because matter in motion accorded with a model of mathematical simplicity. In Galileo also were some of the recurrent themes of 16th- and 17th-century philosophy: an atomism that relates changes in the relations of physical bodies to the corpuscular motion of their parts, the reduction of all qualitative differences to quantitative reasons, and the resultant important distinction between "primary" and "secondary" qualities. The former—including shape, extension, and specific gravity—were considered to be in fact a constituent part of nature and therefore "real." The latter—such as colour, odour, taste, and relative position—were taken to be simply the effect of bodily movements upon perceiving minds and therefore ephemeral, "subjective," and essentially irrelevant to the nature of physical reality.

Rise of Empiricism and Rationalism. The scientific contrast between the rigorous observational techniques of Vesalius and Galileo's reliance upon mathematical theory received further expression in the contrast between the respective philosophies of Francis Bacon and René Descartes. And, indeed, in its more abstract formulation as the contrast between Rationalism and Empiricism, it was to dominate the philosophical controversies of the 17th and 18th centuries and to present a dilemma hardly to be resolved before the advent of Immanuel Kant.

The Empiricism of Francis Bacon. Flourishing around the turn of the 17th century, Sir Francis Bacon, Baron Verulam, Viscount St. Albans (and briefly lord chancellor of England), was the oustanding apostle of Renaissance Empiricism. Less an original metaphysician or cosmologist than the advocate of a vast new program for the advancement of learning and the reformation of scientific method, Bacon's vision of philosophy was that of a new

technique of reasoning that should re-establish natural science upon a firm foundation. In the *Advancement of Learning* (1605) he charted the map of knowledge: history, which depends upon the human faculty of memory; poetry, upon that of imagination; and philosophy, upon man's reason. To reason, however, Bacon assigned a completely experiential function. Fifteen years later, in his *Novum Organum*, he made this clear: because, he said, "we have as yet no natural philosophy which is pure, . . . the true business of philosophy must be . . . to apply the understanding . . . to a fresh examination of particulars." A technique for "the fresh examination of particulars" thus constituted his chief claim to philosophic distinction.

Examination of particulars in tables of discovery

Bacon's hope for a new birth of science hinged not only upon vastly more numerous and varied experiments but chiefly upon "an entirely different method, order, and process for advancing experience." This method consisted in the construction of what he called "tables of discovery." He distinguished three kinds: tables of presence, of absence, and of degree (*i.e.*, in the case of any two properties, such as heat and friction, instances in which they appeared together, instances in which one appeared without the other, and instances in which their amounts varied proportionately); and the ultimate purpose of these tables was to order facts in such a way that the true causes of phenomena (the subject of physics) and the true "forms" of things (the subject of metaphysics—the study of the nature of Being) could be inductively established.

Bacon's was no raw Empiricism; his profound sense of fact and his belief in the primacy of observation were meant to be used for eliciting laws and generalizations. Also, his search for forms was quite un-Platonic: a form for him was not an essence but a permanent geometric or mechanical structure. His enduring place in the history of philosophy lies, however, in his single-minded advocacy of experience as the only source of valid knowledge and in his profound enthusiasm for the perfection of natural science. It is in this sense that "the Baconian spirit" continued as a source of inspiration: his elaborate classification of the sciences inspiring the French Encyclopaedists of the 18th century and his Empiricism inspiring the English philosophers of science of the 19th century.

Hobbes's system of physics and moral and civil philosophy

The mechanism of Thomas Hobbes. During his long lifetime, the English political philosopher Thomas Hobbes was acquainted with both Bacon and Galileo. With the first he shared a strong concern for philosophical method; with the second, an overwhelming interest in matter in motion. His philosophical efforts, however, were more inclusive and more complete than those of either of these contemporaries. He was a comprehensive thinker within the scope of an exceedingly narrow set of presuppositions, and he produced one of the most systematic philosophies of the early-modern period—an almost completely consistent description of nature, man, and civil society according to the tenets of mechanistic Materialism.

Hobbes's account of what philosophy is and ought to be clearly distinguished between content and method. As method, philosophy is simply reasoning or calculating by the use of words as to the causes of phenomena. When a man reasons forward from causes to effects, he reasons synthetically, and, when he reasons from effects backward to causes, he does so analytically. (His strong deductive and geometric bias favoured the former.) Hobbes's dogmatic metaphysical presupposition was that the basic reality is matter in motion. The real world is a corporeal universe in constant movement, and the phenomena, the causes and effects of which it is the business of philosophy to lay bare, are either the mutual action of bodies or the quaint effects of bodies upon minds. From this assumption follows Hobbes's classification of the fields that form the content of philosophy: (1) physics, (2) moral philosophy, and (3) civil philosophy. Physics is the science of the motions and actions of natural bodies conceived in terms of cause and effect. Moral philosophy (or, more accurately, psychology) is the detailed knowledge of "the passions and perturbations of the mind"—*i.e.*, how minds are "moved" by desire, aversion, appetite, fear, anger, and envy. And civil philosophy concerns the concerted actions of men in a commonwealth—how in detail the wayward wills of men are constrained by power (force) in the prevention of civil disorder and the maintenance of peace.

Hobbes's philosophy was a bold Renaissance restatement of Greek atomistic Materialism with applications to the realities of Renaissance politics that would have seemed strange to its ancient originators. But there are also elements in it that make it characteristically English. For Hobbes's conventionalist account of language led him to a nominalistic position—that is, to a position denying the reality of universals (general or common concepts)—in much the same fashion as did Bacon's exaggeration of particulars. Moreover, Bacon's general emphasis upon experience also had its analogue in Hobbes's sensationalist theory of knowledge: the notion that all knowledge has its origin in sense impressions and that all sensations are caused by the action of external bodies upon the organs of sense. Empiricism has been a basic and recurrent expression of British mentality, and its nominalistic and sensationalist roots were already clearly evident in both Bacon and Hobbes.

Rationalism of Descartes. But it was not their philosophy that was to dominate the last half of the 17th century but rather that of René Descartes, a French gentleman who signed himself "Lord of Perron" and who lived the 20 most productive years of his life in the tolerant and hospitable Dutch republic. Descartes is a crucial figure in the history of philosophy, who combined (however unconsciously or even unwillingly) the influences of the past into a new synthesis that seemed so striking in its originality and yet so congenial to the scientific temper of the age as to make him in the minds of all later historians the progenitor of the modern spirit in philosophy.

Synthesis of past and present thought

From the past there seeped into the Cartesian synthesis doctrines about God from Anselm and Aquinas, a theory of the will from St. Augustine, a deep sympathy with the Stoicism of the Romans, and a skeptical method taken indirectly from the ancient Skeptics Pyrrho and Sextus Empiricus. But Descartes was also a great mathematician, who invented analytic geometry, who made many physical and anatomical experiments, who knew and profoundly respected the work of Galileo, and who withdrew from publication his own cosmological treatise *Le Monde* ("The World") after Galileo's condemnation by the Inquisition in 1633.

Each of the maxims of Leonardo, which compose the Renaissance world view, found its place in Descartes: the Empiricism of his physiological researches described in his *Discours de la méthode* (1637), the mechanistic interpretations of the physical world and human action detailed in the *Principia Philosophiae* (1644) and *Traité des passions de l'âme* (1649), and the mathematical bias that dominates his theory of method in the *Regulae ad Directionem Ingenii* (published posthumously in 1701) and his metaphysics in the *Meditationes de Prima Philosophia* (2nd ed. 1642). But of these three, it is the mathematical strain that clearly predominates.

Bacon and Descartes, the founders of modern Empiricism and Rationalism, respectively, shared two pervasive Renaissance tenets: an enormous enthusiasm for physical science; and the pragmatic belief that knowledge means power—that the ultimate purpose of theoretical science is to serve the practical needs of men.

In his *Principia* Descartes defined philosophy as "the study of wisdom" or "the perfect knowledge of all one can know." Its chief utility is "for the conduct of life" (morals), "the conservation of health" (medicine), and "the invention of all the arts" (mechanics). He expressed the relation of philosophy as theoretical inquiry to practical consequences in the famous metaphor of the tree of philosophy whose root is metaphysics, whose trunk is physics, and whose branches are, respectively, morals, medicine, and mechanics. The metaphor is revealing for it indicates that, for Descartes (as for Bacon and for Galileo), the major concern was for the trunk (physics) and that he busied himself with the "roots" only in order to provide a firm foundation for the trunk. Thus the *Dis-*

cours de la méthode, which provides a synoptic view of the Cartesian philosophy, shows it to be *not* (as with Aristotle or Whitehead) a metaphysics founded upon physics but rather—that more characteristic product of the 17th century—a physics founded upon metaphysics.

Elements in Cartesian synthesis

Descartes's mathematical bias was expressed in his determination to ground natural science not in sensation and probability (as did Bacon) but in a principle of absolute certainty. Thus his metaphysics in essence consisted of three principles:

1. To employ the procedure of complete and systematic doubt to eliminate every belief that does not pass the test of indubitability (skepticism);
2. To accept no idea as certain that is not clear, distinct, and free of contradiction (mathematicism);
3. To found all knowledge upon the bedrock certainty of self-consciousness, so that "I think, therefore I am" becomes the only innate idea unshakable by doubt (subjectivism).

From the indubitability of the self, Descartes deduced the existence of a perfect God; and, from the fact that a perfect being is incapable of falsification or deception, made the inference that those ideas about the corporeal world that he has implanted within man must be true. The achievement of certainty about the natural world was thus guaranteed by the perfection of God and by the clear and distinct ideas that are his gift.

The Cartesian metaphysics was the fountainhead of Rationalism in modern philosophy, for it suggests that the mathematical criteria of clarity, distinctness, and absence of contradiction among ideas are the ultimate test of both meaningfulness and truth. This stance is profoundly anti-empirical. Bacon had said, however, that "reasoners resemble spiders who make cobwebs out of their own substance"; and he might well have been speaking of Descartes, for the Cartesian self is just such a substance, from which the innate idea of God originates and with which all deductive reasoning begins. For Descartes the understanding is vastly superior to the senses, and, in the final question of what constitutes truth in science, only man's reason can ultimately decide.

Cartesianism after Descartes

Cartesianism was to dominate the intellectual life of the Continent until the end of the 17th century. It was a fashionable philosophy, appealing alike to learned gentlemen and highborn ladies; and it was one of the few philosophical possibilities to offer competition to the decadent Scholasticism still being taught in the universities. Precisely for this reason it constituted a serious threat to established religious authority. In 1663 the Catholic Church placed Descartes's works upon the Index of Forbidden Books, and the University of Oxford forbade the teaching of his doctrines. Only in the liberal Dutch universities, such as Groningen and Utrecht, did Cartesianism make serious headway.

Certain features of the Cartesian philosophy made it an important starting point for subsequent philosophical speculation. Being essentially the meeting ground of the medieval and the modern world views, it accepted the doctrines of Renaissance science, while attempting to ground them metaphysically in the medieval notions of God and the human mind. Thus a certain dualism between God the creator and the mechanistic world of his creation and between mind as a spiritual principle and matter as mere spatial extension was inherent in the Cartesian position; and a whole generation of French Cartesians (among them Arnold Geulincx, Nicolas Malebranche, and Pierre Bayle) wrestled with the resulting problems of the interaction and reconciliation between the counterposed entities.

Rationalism of Spinoza and Leibniz. But two philosophers of genius carried on the tradition of continental Rationalism: the Dutch Jew Benedict de Spinoza in the mid-17th century and his younger contemporary Gottfried Wilhelm Leibniz, a Leipzig scholar and polymath. Bacon's philosophy had been a search for method in science, and Descartes's basic aim had been the achievement of scientific certainty; but Hobbes and Spinoza provided the most comprehensively worked out speculative systems of the early-modern period. In certain respects they had much in common: a mechanistic picture of the world, with its events guided by a strict determinism, and even a political philosophy in each case looking for political stability based upon centralized power. Yet Spinoza introduced a conception of philosophizing that was new to the Renaissance, something more personal and morally oriented—philosophy as a quest for the wisdom of life, for the achievement of human perfection.

Spinoza's aim, terminology, and method

In conducting this search, Spinoza borrowed much of the basic apparatus of Descartes: the aim at a rational understanding of principles, the terminology of "substance" and of "clear and distinct ideas," and a mathematical method that seeks to convert philosophic knowledge into a complete deductive system using the geometric model of Euclid's *Elements*. Spinoza viewed the universe pantheistically as a single infinite substance, which he called "God," with the dual attributes (or aspects) of thought and extension, and which he differentiated into plural "modes" (or particular things); and he attributed to this world as a whole the properties of a timeless logical system—of a complex of completely determined causes and effects. In so doing, Spinoza was simply seeking for man the series of "adequate" ideas that furnish the intellect and constitute human freedom. For ultimately, for Spinoza, the wisdom that philosophy seeks is achieved when one views the universe in its wholeness, through the "intellectual love of God," which merges the finite individual with the eternal unity and provides the mind with the pure joy that is the final achievement of its search.

The basic elements of the Spinozistic world view are given in his one great work, the *Ethics*, whereas Leibniz' philosophy has to be pieced together from numerous brief expositions or fragments, which seem to be mere intermissions or philosophic interludes in an otherwise busy life. But the philosophic form is deceptive. Leibniz was a mathematician and jurist (inventor of the infinitesimal calculus and codifier of the laws of Mainz), diplomat, historian to royalty, and court librarian in a princely house; yet he was also one of the most original philosophers of the early-modern period. His chief contributions were in the fields of logic, in which he was a truly brilliant innovator, and metaphysics, in which he provided a third alternative to the Rationalist constructions of Spinoza and Descartes. Leibniz saw logic as a mathematical calculus. He was the first to distinguish "truths of reason" from "truths of fact" and to contrast the "necessary" propositions of logic and mathematics (which express identities), which hold for all possible worlds, with the "contingent" (or empirical) propositions of science, which hold only for certain existential conditions; and he saw clearly that, as "the principle of contradiction" controls the first, so "the principle of sufficient reason" governs the second.

A pluralism of monads

In metaphysics Leibniz was a pluralist (as opposed to the dualism of Descartes's thought and extension and the monism of Spinoza's single substance, which is God). There were for him an infinite number of spiritual substances (which he called "monads"), each different, each a percipient of the universe around it, and each mirroring that universe from its own point of view. The chief significance of Leibniz, however, lies not in his differences from Descartes and Spinoza but in the extreme Rationalism that all three shared. In the *Principes de la nature et de la grâce fondés en raison* (1714), he stated the maxim that can stand for the entire school:

> True reasoning depends upon necessary or eternal truths, such as those of logic, numbers, geometry, which establish an indubitable connection of ideas and unfailing consequences.

Literary forms and sociological conditions. The literary forms in which philosophical exposition was couched in the early-modern period ranged from the scientific aphorisms of Bacon and the autobiographical meditations of Descartes to the systematic prose of Hobbes and the episodic propositional format of Leibniz. Two basic tendencies, however, can be discerned:

1. The early-Renaissance commitment to the dialogue

form (already noted), inspired by the rediscovery of the Platonic dialogues;

2. The later prevalence of the systematically ordered treatise, undoubtedly influenced by the enormous prestige of deductive mathematics.

The concept of serial order stressed by geometry, in which the reasoner passes from more universal axioms to more specific derivative propositions, influenced in turn the style of Hobbes, Descartes, and Spinoza. The order of presentation in Hobbes's *Leviathan* and in Descartes's *Principia Philosophiae* reflects this serial concern, while Spinoza's *Ethics* utilizes the Euclidean method so formalistically as almost to constitute an impenetrable barrier to the basic lucidity of his thought.

Medieval philosophy was characteristically associated with the centring of Christian pedagogy in the medieval university with its texts, readings, learned authorities, Disputed Questions, Quodlibetal Questions (brief academic discussions), and its Summas. It is a singular fact, however, that from the birth of Bacon in 1561 to the death of Hume in 1776—*i.e.*, for 200 years—not one first-rate philosophic mind in Europe was permanently associated with a university.

Non-professional status of philosophers

The fact is that, as the age of the saint passed into that of the gentleman, philosophers too reflected this profound change in their titles, their social status, and their economic situation. Sir Francis Bacon was a lawyer, judge, and attendant upon the royal court. Thomas Hobbes was the perpetual tutor and companion of young noblemen. René Descartes, son of a noble family, travelled and studied at leisure, retiring to Holland to live out his life on inherited income. Gottfried Wilhelm Leibniz, courtier, diplomat, and scholar, became a privy councillor and baron of the Holy Roman Empire. Thus philosophers were often of the lesser nobility or were closely associated with the nobility, to whom—like poets—they dedicated their works; and they lived not by philosophy but for it: independently, by pensions, gifts, inherited income, or in the households of the nobility.

Thus, philosophy in the 16th and 17th centuries was clearly the preoccupation of a widely scattered elite; and this meant that, despite the printed essay, much philosophical communication took place within a small, but at the same time loose and informal, circle. Treatises were circulated in manuscript; comments and objections were solicited; and a vast polemical correspondence was built up. Prior to its publication, Descartes prudently sent his *Meditationes* to the theologians of the Sorbonne for comment; and, after its publication, his friend Mersenne sent it to Hobbes, Antoine Arnauld, and Pierre Gassendi among others, who returned formal "objections," to which Descartes in turn replied. In addition, the 17th century possessed a rich repository of philosophical correspondence, such as the letters that passed between Descartes and the scientist Christiaan Huygens, between Spinoza and Henry Oldenburg (one of the first secretaries of the Royal Society), and between Leibniz and Arnauld. But philosophers were also familiar with the great monarchs and administrators of the age: Descartes giving philosophical instruction to Queen Christina of Sweden, Leibniz being intimate with Queen Sophia Charlotte of Prussia, and Spinoza enjoying the personal friendship of the Dutch politician Johan de Witt.

The chief fact, however, remains the sharp separation of creative philosophers from the formal centres of learning: Hobbes expressed extreme contempt for the decadent Aristotelianism of Oxford; Descartes, despite his prudence, scorned the medievalists of the Sorbonne; and Spinoza refused the offer of a professorship of philosophy at Heidelberg with polite aversion. It was to be another 100 years before philosophy returned to the universities, which the chief Renaissance thinkers had abandoned.

THE ENLIGHTENMENT

Although they both lived and worked in the late 17th century, Sir Isaac Newton and John Locke were the true fathers of the Enlightenment. Newton was the last of the scientific geniuses of the age, and his great *Philosophiae Naturalis Principia Mathematica* (1687) was the culmination of the entire movement that had begun with Copernicus and Galileo—the first great physical synthesis based upon the application of mathematics to nature in every detail. The basic idea of the authority and autonomy of reason, which dominated all philosophizing in the 18th century, was, at bottom, the consequence of Newton's work.

Seminal influence of Newton's *Principia*

Copernicus, Kepler, Bacon, Galileo, and Descartes—scientists and methodologists of science—performed like men urgently attempting to persuade nature to reveal her secrets. Newton's comprehensive mechanistic system made it seem as if at last she had done so. It is impossible to exaggerate the enormous enthusiasm that this fact kindled in all of the major thinkers of the 18th century from Locke to Kant. For the new enthusiasm for reason that they all instinctively shared was based not upon the mere advocacy of propagandists like Descartes and Leibniz but upon the conviction that, for the intellectual conquest of the natural world, reason had really worked.

Classical British Empiricism and its basic tasks. Two major philosophic problems remained: to account for the genetic origins of the reason that had proved so successful and to shift its application from external nature to man. John Locke's *Essay Concerning Human Understanding* (1690) was devoted to the first; and David Hume's *Treatise of Human Nature* (1739–40), "being an attempt to apply the method of experimental reasoning to moral subjects," was devoted to the second.

Shift to epistemological and Empiricist philosophy

These two basic tasks reflect a shift in the direction in which philosophizing had moved in the late Renaissance. For the Renaissance preoccupation with the natural world had represented a certain "realistic" bias. Hobbes and Spinoza had each produced a metaphysics. They had been interested in the real constitution of the physical world. Moreover, the Renaissance bias in favour of mathematics had generated the profound interest in rational principles, necessary propositions, and innate ideas that was so prevalent in the philosophies of Leibniz and Descartes. On the other hand, the Enlightenment, in turning from the realities of nature to account for the structure of the mind that knows it so successfully and in attempting an experiential account of the furnishings of that mind, settled on the sensory components of knowledge rather than on the merely mathematical. Thus the school of so-called British Empiricism (John Locke, George Berkeley, and David Hume) dominated the perspective of Enlightenment philosophy until the time of Kant. And this school philosophized in terms of ideas rather than things and of experience rather than innate necessary principles. Whereas the philosophy of the late Renaissance had been metaphysical and Rationalistic, that of the Enlightenment was epistemological and Empiricist.

Origin and nature of reason in Locke and Berkeley. Locke's *Essay Concerning Human Understanding* thus marked a decisively new direction for modern philosophizing, because it proposed what amounts to a new criterion of truth. The design of his essay was "to inquire into the origin, certainty, and extent of human knowledge," which involved three tasks:

1. To discover the origin of men's ideas;
2. To exhibit their certainty and evidential value;
3. To examine the claims of all knowledge that is less than certain.

What was crucial for Locke, however, was that the second task is dependent upon the first. Following the general Renaissance custom, Locke defined an "idea" as a mental content, as "whatever is the object of the understanding when a man thinks"; but, whereas for Descartes and the entire Rationalistic school the certainty of ideas had been a function of their self-evidence—*i.e.*, of their clarity and distinctness—for Locke their validity hinged expressly upon the mode and manner of their origin. A genetic criterion of truth and validity replaced an intrinsic one.

Locke's exhaustive survey of mental contents is useful, if elaborate. Though he distinguished between ideas of sensation and ideas of reflection, the whole thrust of his efforts and those of his Empiricist followers was to re-

duce the latter to the former, to minimize the originative power of the mind in favour of its passive receptivity to the sensory impressions received from without. Locke's classification of ideas into simple and complex was an attempt to distinguish mental contents such as blueness or solidity, which come from a single sense like sight or touch, and those such as figure, space, extension, rest, and motion, which are the product of several senses combined, on the one hand, from those complicated and compounded (complex) ideas of universals such as triangle or gratitude, of substances, and of relations such as identity, diversity, and cause and effect, on the other.

Locke's effort to build a total world

Locke's *Essay* was a dogged attempt to produce the total world of man's conceptual experience out of a set of elementary sensory building blocks, moving always from sensation toward thought and from the simple to the complex. The basic outcome of his epistemology was therefore:

1. That the ultimate source of men's ideas is sensation;
2. That all mental operations are a combining and compounding of simple sensory materials into complex conceptual tools.

It was a theory of knowledge based upon a kind of sensory atomism, which sees the mind as an agency of discovery rather than of creation and views its ideas as "like" the objects that are the sources of the sensations it receives. But it sees also that an important distinction must still be made between those "primary qualities" such as solidity, figure, extension, motion, and rest, which are the actual characteristics of objects themselves, and those "secondary qualities" such as colour, taste, and smell, which are simply the internal consequences of how the mind is affected by them. This important Lockean distinction (already found in Galileo) was only a mirroring in the theory of knowledge of the physics of Sir Isaac Newton, which was its contemporary.

It was precisely this dualism presupposed by the science of the time between primary qualities, which belong to matter, and secondary qualities, which belong to mind, that Locke's successor George Berkeley sought to overcome. Though Berkeley was a bishop in the Anglican Church who wanted to combat "atheistic Materialism" and to sustain the power of God and spirituality, his importance for the theory of knowledge lies rather in the way in which he demonstrated that, in the end, primary qualities are reducible to secondary qualities. His Empiricism led to a denial of abstract ideas, because he believed that general notions are simply fictions of the mind and vehemently denied that one may validly distinguish between objects and the sensory impressions that repose in the mind. Science, he argued, can easily dispense with the concept of matter: nature is simply that which men perceive by their senses, and this means that sense data can be considered as "objects for the mind" rather than as "qualities adhering in a substance." A thing is simply a recurrent group of sense qualities. With this important reduction of substance to quality, Berkeley thus became the true father of the epistemological position known as phenomenalism, which has remained an important influence in British philosophizing to the present day.

Basic science of man in Hume. The third, and in many ways the most famous, of the British Empiricists was the 18th-century Skeptic David Hume. Hume's philosophic intention was to reap, humanistically, the harvest sowed by Newtonian physics, to apply the method of natural science to human nature, and to create a basic science of man. The paradoxical result of this admirable purpose, however, was to create a skeptical crisis more devastating than that of the early French Renaissance and to reduce human certainty once more to the state that it was in before Descartes had reached the dogmatic halting point in his procedure of methodical doubt.

Sense impressions and association of ideas

Hume followed Locke and Berkeley in approaching the problem of knowledge from a psychological perspective. He too found the origin of knowledge in sense impressions. But whereas Locke had found a certain trustworthy order in the compounding power of the mind, and Berkeley had found mentality itself expressive of a certain spiritual power, Hume's relentless analysis discovered as much contingency in mind as in the external world. All uniformity in perceptual experience, he held, comes from "an associating quality of the mind." The "association of ideas" is a fact, but the relations of resemblance, contiguity, and cause and effect that it produces have no intrinsic validity, because they are the product of an inexplicable "mental habit." Thus the causal principle, upon which all knowledge rests, indicates no necessary connections between things but is simply the accident of their constant conjunction in men's minds. Moreover, the mind itself, far from being an independent power, is simply "a bundle of perceptions" without unity or cohesive quality. Hume's denial of a necessary order of nature, on the one hand, and of a substantial or unified self, on the other, precipitated a philosophic scandal from which Enlightenment philosophy was not to be definitely rescued until the work of Kant.

Nonepistemological movements in the Enlightenment. Though the school of British Empiricism represented the mainstream of Enlightenment philosophy until the time of Kant, it was by no means the only type of philosophy that the 18th century produced. For the Enlightenment, which was based upon a few great fundamental ideas—such as the dedication to reason, the belief in intellectual progress, the confidence in nature as a source of inspiration and value, and the search for tolerance and freedom in political and social institutions—produced many cross-currents of intellectual and philosophic expression.

Materialism and scientific discovery. The profound influence of Locke spread to France, where it not only produced the skeptical Empiricism of Voltaire but also united with the mechanistic side of the teachings of Descartes to create an entire school devoted to a sensationalistic Materialism. Julien de La Mettrie in *L'Homme-machine* (1747; Eng. trans., *Man a Machine*, 1750), Étienne de Condillac in his *Traité des sensations* (1754), and Paul, baron d'Holbach, in his *Système de la nature* (1770) represented a limited world view in which matter in motion is the only reality, determining the functioning of the human brain and its sensations according to ironclad and necessary laws. This position even found its way into many of the articles of the great French encyclopaedia edited by Denis Diderot and Jean d'Alembert, which was almost a complete compendium of the scientific and humanistic accomplishments of 18th-century intellectual life.

Optimism and the beginning of many disciplines

Though the Middle Ages and the Renaissance had not referred to themselves by these names, the 18th century called itself "the Enlightenment" with self-conscious enthusiasm and pride. It was an age of optimism with a sense of new beginnings. Great strides were made in chemistry and biological science. Jean, chevalier de Lamarck, Georges Cuvier, and Georges, comte de Buffon, were perfecting a system of animal classification. And, in the eight years between 1766 and 1774, Henry Cavendish discovered hydrogen; Daniel Rutherford, nitrogen; and Joseph Priestley, oxygen. It was the period when foundations were being laid in psychology and the social sciences and in ethics and aesthetics. Anne-Robert-Jacques Turgot, Marquis de Condorcet, and Montesquieu in France, Giambattista Vico in Italy, and Adam Smith in England marked the beginning of history, economics, sociology, and jurisprudence as sciences. Hume, Jeremy Bentham, and the British moral-sense philosophers were turning ethics into a specialized field of philosophical inquiry; and Anthony, 3rd earl of Shaftesbury, Edmund Burke, Johann Gottsched, and Alexander Baumgarten were laying the foundations for a systematic aesthetic.

Social and political philosophy. But, outside of the theory of knowledge, the most significant contribution of the Enlightenment came in the field of social and political philosophy, as Locke's *Two Treatises of Civil Government* (1690) and Jean-Jacques Rousseau's *Du contrat social* (1762) proposed a justification of political association grounded in the newer political requirements of the age. The Renaissance political philosophies of Machiavelli, Bodin, and Hobbes had centred around the absolute power of kings and rulers. But the Enlightenment theories of Locke and Rousseau turned rather to the free-

Freedom, equality, justice, rights

dom and equality of citizens. It was a natural historical transformation. The 16th and 17th centuries had comprised the age of absolutism; the political problem had been largely that of internal order, and political theory had been presented in the language of national sovereignty. But the 18th century was the age of the democratic revolutions (including the French Revolution); the political problem was that of freedom and the revolt against injustice, and political theory was expressed in the idiom of natural and inalienable rights.

Locke's political theory was an express denial of the divine right of kings and the absolute power of the sovereign as enthroned in the doctrines of Hobbes. Instead, he insisted that all men have a natural right to freedom and equality. The state of nature in which men originally live is not, as in Hobbes, intolerable; but it has certain inconveniences, and so men band together to form society, as Aristotle taught, "not simply to live, but to live well." Political power can never be exercised apart from its ultimate purpose, which is the common good; for men enter the political contract in order to preserve life, liberty, and property.

Locke thus stated one of the fundamental principles of the liberal tradition: that there can be no subjection to power without consent, although once political society has been founded, there is an obligation to submit to the decisions of the majority. It is the legislature that makes these decisions, although the ultimate power of choosing the legislature rests with the people; and even the powers of the legislature are not absolute, because the laws of nature remain as a permanent standard and as principles of protection against any arbitrary authority.

Rousseau's more radical political doctrines were built upon Lockean foundations. For him, too, the convention of the social contract formed the basis of all legitimate authority among men, although his conception of citizenship was much more organic, much less individualistic than Locke's. The surrender of natural liberty for civil liberty means that all individual rights (among them property rights) become subordinate to the general will. For Rousseau the state is a moral person whose life is the union of its members, whose laws are acts of the general will, and whose end is the liberty and equality of the citizens. It follows that, when any government usurps the power of the people, the social compact is broken; and not only are the citizens no longer compelled to obey, but they also have an obligation to rebel. Rousseau's defiant collectivism was clearly a revolt against Locke's systematic individualism; for him the fundamental category is not "natural person" but "citizen." Nevertheless, however much they differed, in these two social theorists of the Enlightenment is to be found the germ of all modern liberalism: its faith in representative democracy, in civil liberties, and in the basic dignity of man.

Professionalization of philosophy. In his *Éléments de philosophie* (1759), Jean d'Alembert, an 18th-century French mathematician and Encyclopaedist, wrote:

> Our century is the century of philosophy par excellence. If one considers without bias the present state of our knowledge, one cannot deny that philosophy among us has shown progress.

D'Alembert was calling attention to that reflective self-examination for which the 18th century is famous, and he was undoubtedly referring to the activities of mathematicians like himself, jurists, economists, and amateur moralists rather than to narrow philosophical specialists. But the 18th century was clearly the "century of philosophy par excellence" in a more technical sense also. For it was the period in which philosophizing first began to pass from the hands of gentlemen and amateurs into those of true professionals. The chief sign of this shift was the return of reputable philosophy to the universities.

University of Halle and Christian Wolff

This transformation first occurred in Germany and is chiefly associated with the University of Halle (founded 1694). In the time of the generation that lies between Leibniz (died 1716) and Kant (born 1724), the philosophical climate changed profoundly. The chief representative of this change was Christian Wolff, who taught philosophy at Halle and was the intermediary between the ideas of Leibniz and those of Kant and the profoundly different conceptions of philosophizing for which they stood.

Kant later called Wolff "the real originator of the spirit of thoroughness in Germany"; and Wolff was indeed a pioneer in those techniques that transform philosophy into a professional discipline: the self-conscious adoption of a systematic approach and the creation of a specialized philosophical vocabulary. Wolff carefully distinguished the various fields of philosophy; wrote textbooks in each of them, which were used in the German universities for many years; and created many of the specialized philosophical terms that have survived to the present day.

The German Enlightenment was the first modern period to produce "specialists in philosophy." In England, philosophizing in the universities did not become serious until well after the time of Hume, but already philosophical fields had been sufficiently distinguished to be represented by distinct professorships. The titles professor of mental or moral or metaphysical philosophy, as they arose at Oxford and Cambridge, were the product of the late 18th and early 19th centuries. Two other factors of the German Enlightenment, however, are also relevant: (1) the founding of the first professional journals and (2) the rising concern of philosophy with its own history.

Journals and histories of philosophy

The learned journal, like the scientific society, was an innovation of the 17th century. But what had begun as a general intellectual endeavour became in the German 18th century a specifically philosophical enterprise; and a rash of journals broke out, such as the *Acta Philosophorum* (Halle, 1715–26); the *Philosophische Büchersaal* (Leipzig, 1741–44); and the short-lived *Neues philosophisches Magazin* (Leipzig, 1789–91), devoted exclusively to the philosophy of Kant.

More interesting still is the flowering of voluminous German histories of philosophy after 1740. By the 18th century there was already a vast accumulation of historical materials, and the self-conscious feeling that philosophy constitutes a specific field the past of which is worth examination and careful ordering combined with the German spirit of thoroughness to produce a series of massive histories such as Johann Brucker's *Historia Critica Philosophiae*, 6 vol.; Johann Buhle's *Lehrbuch der Geschichte der Philosophie*, 8 vol.; Dietrich Tiedemann's *Geist der spekulativen Philosophie von Thales bis Berkeley*, 6 vol.; and Gottlieb Tennemann's *Geschichte der Philosophie*, 11 vol.

Critical examination of reason in Kant. All of these developments led directly to Immanuel Kant, professor at Königsberg, the greatest philosopher of the modern period, who marks the true culmination of the philosophy of the Enlightenment. Historically speaking, Kant's great substantive contribution was to relate both the sensory and the a priori elements in knowledge and thus to mend the breach between the extreme Rationalism of Leibniz and the extreme Empiricism of Hume. But in addition to the brilliant content of his philosophical doctrines, Kant is responsible for three crucial philosophical innovations: (1) a new definition of what philosophy is, (2) a new conception of philosophical method, and (3) a new structural model for the writing of philosophy.

Kant's definition of philosophy culminated the Enlightenment, for it took reason to be the very heart of the philosophic enterprise. Philosophy's sole task, in his view, is to determine what reason can and cannot do. Philosophy, he said, "is the science of the relation of all knowledge to the essential ends of human reason"; and its true aim is both constructive ("to outline the system of all knowledge arising from pure reason") and critical ("to expose the illusions of a reason that forgets its limits"). Philosophy is thus a calling of great dignity, for its aim is wisdom, and its practitioners are themselves "lawgivers of reason." But in order for philosophy to be "the science of the highest maxims of reason," the philosopher must be able to determine the source, the extent, and the validity of human knowledge and the ultimate limits of reason. And these tasks require a special philosophic method.

Sometimes Kant called this the "transcendental method," but more often the "critical method"; for his pur-

The transcendental, or critical, method of examining reason

pose was to reject the dogmatic assumptions of the Rationalist school, and his wish was to return to the semiskeptical position with which Descartes had begun before his dogmatic pretensions to certainty took hold. Kant's method was to conduct a critical examination of the powers of an a priori judging reason and to inquire what reason can achieve when all experience is removed. The method was based upon a doctrine that he himself called "a Copernican revolution" in philosophy (by analogy with the change from geocentric to heliocentric cosmology): the assumption not that man's knowledge must conform to objects but that objects must conform to man's apparatus of knowing. The question then became: What is the exact nature of that knowing apparatus?

Unlike Descartes, Kant could not question *that* knowledge exists. Mathematics and Newtonian physics were too real for any Enlightenment mentality to entertain this doubt. Kant's methodological question was rather: *How* is mathematical and physical knowledge possible? What must be the structure of man's knowing process to have made these sciences secure? Exactly the attempt to answer these questions was the task of Kant's great *Critik der reinen Vernunft* (1781; Eng. trans., *Critique of Pure Reason*, 1929).

But Kant's great aim was to examine reason not merely in one of its domains, but in each of its employments, according to the threefold structure of the human mind, which he had taken over from Wolff. Thus the critical examination of reason in thinking (science) is undertaken in the *Critik der reinen Vernunft*, that of reason in willing (ethics) in the *Kritik der praktischen Vernunft* (1788; Eng. trans., *Critique of Practical Reason*, 1949), and that of reason in feeling (aesthetics) in *Kritik der Urteilskraft* (1790; Eng. trans., *Critique of Judgment*, 1951).

Literary forms. The literary format of Enlightenment philosophizing was essentially simple and straightforward. Except for an occasional reversion to the dialogue form as in Berkeley's *Three Dialogues Between Hylas and Philonous* (1713) and Hume's *Dialogues Concerning Natural Religion* (1779), it consisted of inquiries, discourses, treatises, dissertations, and essays, generally well written in clear, relatively nontechnical, prose style. But Kant not only introduced a formidable technical philosophical terminology into his works but was, in fact, the originator of a new philosophical form—the "critique" or "critical examination"—which had its own special architectonic structure. Each of Kant's three critiques consists of the same division into three parts: (1) an "Analytic," or analysis of reason's right functioning; (2) a "Dialectic," or logic of error, showing the pitfalls into which a careless reason falls; and (3) a "Methodology," which is an arrangement of rules for practice. It is a form that was unique with Kant, but it raised certain problems of "oppositional" thinking, to which 19th-century philosophers such as Hegel, Schopenhauer, and Kierkegaard were subsequently to turn.

THE 19TH CENTURY

The end of Enlightenment

Kant died in 1804. Formally, it was the end of the Enlightenment. But the 19th century ushered in new philosophical problems and new conceptions of what philosophy ought to do. It was a century of great philosophic diversity and variety. In the Renaissance the chief intellectual fact had been the rise of mathematics and natural science, and the tasks that this fact imposed upon philosophy determined its direction for two centuries. In the Enlightenment attention had turned to the character of the mind that had so successfully mastered the natural world, and Rationalists and Empiricists had contended for mastery until the Kantian synthesis. As for the 19th century, however, if one single feature of its thought could be singled out for emphasis, it might be called the discovery of the irrational. But many philosophical schools were present, and they contended, one with another, in a series of distinct and powerful oppositions: Pragmatism against Idealism; Positivism against irrationalism; Marxism against liberalism.

Politically, the 19th century began with the consulate of Napoleon and ended with the Golden Jubilee of Queen Victoria; but it is the intellectual and social changes that fell in between that have philosophic consequences. These changes were chiefly: the Romantic movement of the 1820s and 1830s, which was a poetic revolt against reason in favour of feeling; the maturation of the Industrial Revolution, which caused untold misery within society and called forth a multitude of philosophies of social reform; the Revolution of 1848 in Paris, Germany, and Vienna, which symbolized class divisions and first enthroned in the European consciousness the concepts of "the bourgeoisie" and "the proletariat"; and, finally, the great surge in biological science with Darwin and the publicizing of the idea of biological evolution. Romanticism influenced both German Idealism and philosophers of irrationalism. Experiences of economic discord and social unrest produced the ameliorative social philosophy of English Utilitarianism and the revolutionary doctrines of Karl Marx. And the developmental ideas of Darwin provided the prerequisites for American Pragmatism.

A synoptic view of philosophy in the 19th century reveals an interesting chronology. The early century was dominated by the German school of absolute Idealism (Johann Fichte, Friedrich Schelling, and G.W.F. Hegel). The midcentury was marked by a rebirth of interest in science and its methods (Auguste Comte in France and John Stuart Mill in England) and by liberal (Mill) and radical (Marx) social theory. The late century saw a second flowering of Idealism, this time in England (T.H. Green, F.H. Bradley, and Bernard Bosanquet) and, with Charles Sanders Peirce and William James, the rise of American Pragmatism. The new philosophies of the irrational in the highly individual thinkers Søren Kierkegaard, Arthur Schopenhauer, and Friedrich Nietzsche ran through the century in its entirety.

German Idealism of Fichte, Schelling, and Hegel. The Enlightenment, inspired by the example of natural science, had accepted certain bounds to the possibility of knowledge; *i.e.*, it had recognized certain limits to reason's ability to penetrate ultimate reality by methods that surpass the boundaries of scientific method. In this particular modesty, the philosophies of Hume and Kant were much alike. But the early 19th century marked a resurgence of the metaphysical spirit at its most ambitious and extravagant extreme. German Idealism reinstated the speculative pretensions of Leibniz and Spinoza at their height. This turn was partly a consequence of the Romantic influence but, more importantly, of a new alliance of philosophy not with science but with religion. It was not accidental that all of the great German Idealists were university professors, whose fathers were Protestant pastors or who had themselves studied theology: Fichte at Jena and Leipzig (1780–84); Schelling and Hegel at the Tübingen seminary (1788–95). And it is probably this circumstance that gave to German Idealism its intensely serious, its quasi-religious, and its dedicated character.

Resurgence of religiously inspired metaphysics

The consequence of this religious alignment was that philosophic interest shifted from Kant's *Critique of Pure Reason* (in which he had attempted to account for natural science and denied the possibility of certainty in metaphysics) to his *Critique of Practical Reason* (in which he had explored the nature of the moral self) and his *Critique of Judgment* (in which he had treated of the purposiveness of the universe as a whole). For absolute Idealism was based upon three premises:

1. That the chief datum of philosophy is the human self and its self-consciousness;
2. That the world as a whole is spiritual through and through; is, in fact, something like a cosmic Self;
3. That, in both the self and the world, it is not primarily the intellectual element that counts but, rather, the volitional and the moral.

Thus, to understand the self, self-consciousness, and the spiritual universe became for Idealistic metaphysics *the* task of philosophy.

From the point of view of doctrine, Fichte, Schelling, and Hegel had much in common. Fichte, professor of philosophy at the newly founded University of Berlin (1809–14) and a great symbol of German patriotism

through the Napoleonic Wars, combined in a workable unity the subjectivism of Descartes, the cosmic monism of Spinoza, and the moral intensity of Kant. He saw human self-consciousness as the primary metaphysical fact through the analysis of which the philosopher finds his way to the cosmic totality that is "the Absolute." And, just as the moral will is the chief characteristic of the self, so also is it the activating principle of the world. Thus Fichte provided a new definition of philosophizing that made it central in dignity in the intellectual world. The sole task of philosophy is "the clarification of consciousness." And the highest degree of self-consciousness is achieved by the philosopher, because he alone recognizes "Mind," or "Spirit," as the central principle of reality.

Hegel: "the rational is the real"

This line of thought was carried further by G.W.F. Hegel, Fichte's successor at Berlin and perhaps the single most comprehensive and influential thinker of the 19th century. Kant's problem had been the critical examination of reason's role in human experience. For Hegel, too, the function of philosophy is to discover the place of reason in nature, in experience, and in reality; to understand the laws according to which reason operates in the world. But, whereas Kant had found reason to be the form that mind imposes upon the world, Hegel found it to be constitutive of the world itself—not something that mind imposes but that it discovers. As Fichte had projected consciousness from mind into reality, so Hegel projected reason; and the resultant Hegelian dictates—that "the rational is the real" and that "the truth is the whole"—although they express an organic and a totalitarian theory of truth and reality, tend to blur the usual distinctions that previous philosophers had made between logic and metaphysics, between subject and object, and between thought and existence. For the basic tenet of Idealism, that reality is spiritual, generates just such a vague inclusiveness.

To the Fichtean foundations, however, Hegel added one crucial corollary: that the Absolute, or Whole, which is a concrete universal entity, is not static but undergoes a crucial development in time. Hegel called this evolution "the dialectical process." By stressing it, Hegel accomplished two things: (1) he indicated that reason itself is not eternal but "historical," and (2) he thereby gave new meaning and relevance to the changing conditions of human society in history—which added to the philosophic task a cultural dimension that it had not possessed before.

The philosopher's vocation, in Hegel's view, was to approach the Absolute through consciousness, to recognize it as Spirit expressing and developing itself ("realizing itself" was his own phrase) in all of the manifold facets of human life. For struggle is the essence of spiritual existence, and self-enlargement is its goal. For these reasons the various branches of intellect and culture become stages in the unfolding of the World-Spirit:

1. The psychological characteristics of man (habit, appetite, judgment) representing "Subjective Spirit";
2. His laws, social arrangements, and political institutions (the family, civil society, the state) expressing "Objective Spirit";
3. His art, religion, and philosophy embodying "Absolute Spirit."

What began, therefore, in Hegel as a metaphysics of the Absolute ended by becoming a total philosophy of human culture.

Positivism and social theory in Comte, Mill, and Marx. The absolute Idealists wrote as if the Renaissance methodologists of the sciences had never existed. But if, in Germany, the Empirical and scientific tradition in philosophy lay dormant, in France and in England in the middle of the 19th century it was very much alive. In France, Auguste Comte wrote his great philosophical history of science, *Cours de philosophie positive* (1830–42) in six volumes. Influenced by Bacon and the entire school of British Empiricism, by the doctrine of progress put forward by Turgot and Condorcet during the 18th century, and by the very original social reformer Henri de Saint-Simon, Comte called his philosophy "Positivism," by which he meant a philosophy of science so narrow that it denied any validity whatsoever to "knowledge" not derived through the accepted methods of science. But the *Cours de philosophie positive* made its point not by dialectic but by an appeal to the history of thought, and here Comte presented his two basic ideas:

Comte's *Philosophie positive*

1. The notion that the sciences have emerged as sciences in strict order, beginning with mathematics and astronomy, being followed by physics, chemistry, and biology in that order, and culminating in the new science of sociology, to which Comte was the first to ascribe the name;
2. The so-called "law of the three stages," which views thought in every field as passing progressively from superstition to science by first being (*a*) religious, then (*b*) abstract, or metaphysical, and finally (*c*) positive, or scientific. Comte's permanent contribution was to initiate an antireligious and an antimetaphysical bias in the philosophy of science that has passed into the 20th century.

In mid-19th-century England the chief representative of the Empirical tradition from Bacon to Hume was John Stuart Mill. Mill's theory of knowledge, best presented in his *Examination of Sir William Hamilton's Philosophy* (1865), was not particularly original but rather a judicious combination of the doctrines of Berkeley and Hume; but it symbolized his mistrust of vague metaphysics, his denial of the a priori element in knowledge, and his determined opposition to any form of intuitionism. It is in his enormously influential *System of Logic* (1843), however, that Mill's chief theoretical ideas are to be found.

This work, as part of its subtitle, *the Principles of Evidence and the Methods of Scientific Investigation,* shows, was concerned less with formal logic than with scientific methodology. Mill made here the fundamental distinction between deduction and induction, defined induction as the process by which men discover and prove general propositions, and presented his "four methods of experimental inquiry" as the heart of the inductive method. These methods were, in fact, only an enlarged and refined version of Francis Bacon's "tables of discovery." But the most significant section of *A System of Logic* was its conclusion: book 6, "On the Logic of the Moral Sciences."

Mill had taken men's experience of the uniformity of nature as the warrant of induction. Here he reaffirmed the belief of Hume that it is possible to apply the principle of causation and the methods of physical science to moral and social phenomena. These may be so complex as to yield only "conditional predictions," but in this sense there *are* "social laws." Thus Comte and Mill agreed upon the possibility of a true social science.

Mill's *Logic* was extremely influential, and it continued to be taught at Oxford and Cambridge well into the 20th century; but in the end his importance lay less in logic and theory of knowledge than in ethics and political theory. For Mill was the great apostle of political liberalism in the 19th century, a true follower of John Locke. And, just as Locke and Rousseau had represented the liberal and the radical wings of social theory in the early modern period, so Mill and Karl Marx represented the liberal and the radical approaches to social reform 100 years later.

Mill's political liberalism and ethics

Raised by social reformers (his father James Mill and Jeremy Bentham) to be a social reformer himself, Mill's social theory was an attempt, by gradual means arrived at democratically, to combat the evils of the Industrial Revolution. His ethics, expressed in his *Utilitarianism* (1861), followed the formulations of Bentham in finding the end of society to consist in the production of the greatest quantity of happiness for its members, but he gave to Bentham's cruder (but more consistent) doctrines a humanistic and individualistic slant. Thus, the moral self-development of the individual becomes the ultimate value in Mill's ethics.

This trend was also expressed in his essay *On Liberty* (1859) and *Considerations on Representative Government* (1861). In the former he stated the case for the freedom of the individual against "the tyranny of the majority," presented strong arguments in favour of complete freedom of thought and discussion, and argued that no state or society has the right to prevent the free development of human individuality. In the latter he pro-

vided a classic defense for the principle of representative democracy, asked for the adequate representation of minorities, urged renewed public participation in political action for necessary social reforms, and pointed up the dangers of class-oriented or special-interest legislation.

Marx and social revolution

A radical counterbalance to Mill's liberal ideas was provided by Karl Marx, a German philosopher, social revolutionary, and political economist. Taking over from Hegel the idea of estrangement (which Hegel had used in a metaphysical sense), Marx used this notion prior to 1848 to indicate the alienation of the worker from the enjoyment of the products of his work, the crass treatment of human labour as a mere commodity (and man as a thing), and, in fact, the general dehumanization of man in a selfish, profit-seeking capitalist society.

In the famous *Communist Manifesto* (1848), Marx, yielding to the revolutionary temper of the times, called (as Rousseau had done before the French Revolution) for the violent overthrow of the established order. All of history, Marx said, is the struggle between exploiting minorities and the underlying population, between bourgeois and proletarians; and he advocated the formation of a Communist Party to stimulate proletarian class consciousness toward the seizure of power and the institution of a just and democratically managed Socialist society.

Marx's revolutionary fervour may have tended to dampen his philosophic reputation in the West, and his philosophic achievement remains a controversial point; but certain of his ideas (some Hegelian in inspiration, some more original) have endured. Among these are the ideas:

1. That society is a moving balance (dialectic) of antithetical forces that produce social change;
2. That there is no conflict between a rigid economic determinism and a program of revolutionary action;
3. That ideas (including philosophic theories) are not purely rational and thus independent of external circumstance but depend upon the nature of the social order in which they arise.

Independent and irrationalist movements. The end of the 19th century saw a flowering of many independent philosophical movements. After Hegel was almost forgotten in Germany, his influence migrated to England, where T.H. Green, F.H. Bradley, and Bernard Bosanquet initiated a new Hegelian renaissance. Bradley's *Appearance and Reality* (1893) constituted the high-water mark of the rediscovery of Hegel's dialectical method. In America, a strong reaction against Idealism led to the beginnings of the Pragmatic movement initiated by Charles Sanders Peirce and William James. Peirce was an exact logician who recognized that the function of all inquiry is to eradicate doubt and that the meaning of a concept consists in the practical consequences that the concept might be said to have. James transferred Peirce's pragmatic theory of meaning into a pragmatic theory of truth and, in his *Will to Believe* (1897), asserted that men have a right to believe even in the face of inconclusive evidence and that, since knowledge is an instrument for the sake of life, the true test of a belief is the practical consequences that it entails. Meanwhile, in Austria, Franz Brentano, who taught at Vienna from 1874 to 1895, and Alexius Meinong, who taught at Graz, were developing an empirical psychology and a theory of objects, which were to have considerable influence upon the new philosophy of Phenomenology.

Irrationalism in Kierkegaard and Schopenhauer

It was not, however, any of these late-19th-century developments but, rather, the emphasis upon the irrational, which started almost at the century's beginning, that gave the philosophy of the period its peculiar flavour. Hegel, despite his commitment to systematic metaphysics, had nonetheless carried on the Enlightenment tradition of faith in human rationality. But soon his influence was challenged from two different directions. Just before midcentury, the Danish Christian thinker Søren Kierkegaard challenged the logical pretensions of the Hegelian system; and one of his contemporaries, Arthur Schopenhauer, himself a German Idealist and constructor of a bold and imaginative system, contradicted Hegel by asserting that the irrational is the truly real.

Kierkegaard's criticism of Hegel was an appeal to the concrete as against the abstract. He satirized Hegelian Rationalism as a perfect example of "the academic in philosophy"—of detached, objective, abstract theorizing and system building, blind to the realities of human existence, to its subjective, living, emotional character. What a man requires in life, said Kierkegaard, is not infinite inquiry but the boldness of resolute decision and commitment. Man's essence is not contained in thinking but in the existential conditions of his emotional life, in his anxiety and despair. The titles of three of Kierkegaard's books—*Frygt og Baeven* (1843; Eng. trans., *Fear and Trembling*, 1939), *Begrebet Angest* (1844; Eng. trans., *The Concept of Dread*, 1944), *Sygdommen til Døden* (1849; Eng. trans., *The Sickness unto Death*, 1941)—indicate his preoccupation with states of consciousness quite unlike the usual philosophic concentration on cognition and the validity of knowledge.

Schopenhauer, even though, for a short time, he competed unsuccessfully with Hegel at the University of Berlin, soon withdrew and thereafter waged a lifelong battle against academic philosophy. His own system, though orderly and carefully worked out, was written in a vivid and engaging literary style. Schopenhauer agreed with Kant that the world of appearances, of phenomena, is governed by the conditions of space, time, and causality. But he held that science, which investigates this world, cannot itself penetrate the real world behind appearances, which is dominated by a strong, blind, striving, universal cosmic Will that expresses itself in the vagaries of human instinct, in sexual striving, and in the wild uncertainties of all animal behaviour. Everywhere in nature one sees strife, conflict, and inarticulate impulse; and these, rather than rational processes or intellectual clarity, are man's true contacts with ultimate reality.

Schopenhauer's great work *Die Welt als Wille und Vorstellung* (Eng. trans., *The World As Will and Idea*, 1883) was published in 1819; and Kierkegaard's uneven masterpieces appeared between 1843 and 1849. But Friedrich Nietzsche, the third of the irrationalist triumvirate, wrote between 1872 and 1889. A prolific but unsystematic writer, presenting his patchwork of ideas in swift atoms of thought, Nietzsche saw the task of the philosopher as that of a man who destroys old values, creates new ideals, and through them a new civilization. He agreed with Schopenhauer that mind is an instrument of instinct to be used in the service of life and power, and he held that illusion is as necessary to man as truth. Nietzsche spent much time in the analysis of such states as resentment, guilt, bad conscience, and self-contempt.

Nietzsche's Dionysian irrationalism

Kierkegaard, Schopenhauer, and Nietzsche provided for the 19th century a new, nonrational conception of human nature, and they viewed the mind not with the rational clarity of Locke and Hume but as something dark, obscure, hidden, deep. But, above all, they initiated a new style of philosophizing. Schopenhauer wrote like an 18th-century essayist; Kierkegaard was a master of the methods of irony and paradox; and Nietzsche used aphorism and epigram with conscious literary intention. For these three, the philosopher should be less a crabbed academician than a man of letters.

THE 20TH CENTURY

Despite the tradition of philosophic "professionalism" established during the Enlightenment by Wolff and Kant, philosophy in the 19th century was still largely created by men outside of the universities. Comte, Mill, Marx, Kierkegaard, Schopenhauer, and Nietzsche were not professors. Only the German Idealist school was rooted in academic life. Today, however, it is difficult to find one first-rate philosophic mind outside of the academy (George Santayana after his early years and Jean-Paul Sartre are the notable exceptions). The agencies of professionalism—the philosophic congress, the national philosophical societies, the narrowly specialized journals—have become increasingly important. Philosophers more and more employ a technical vocabulary and deal with specialized problems; and they write not for a broad intellectual public but for one another.

Professionalism also has: (1) sharpened the divisions

between philosophic schools and (2) made the definition of what philosophy is and ought to be, a matter of the sharpest controversy. Philosophy has become extremely self-conscious about its own method and nature. Moreover, intellectual competitiveness has been further sharpened by geographical and political considerations. The tradition of clear analysis, inaugurated by Locke and Hume, still dominates the Anglo-Saxon world; the Hegelian tradition of speculative metaphysics and the Nietzschean tradition of bold psychological generalization still dominate the Continent. And the very special framework of thinking established by Karl Marx still dominates philosophy in the Socialist world.

Individual philosophies of Bergson, Dewey, and Whitehead. Except, then, for philosophical Marxism and a few individual philosophers such as Henri Bergson, John Dewey, and A.N. Whitehead, who evade easy classification, the main currents of contemporary philosophy are: (1) Analytic philosophy with its two chief branches, (*a*) Logical Empiricism and (*b*) Linguistic Analysis; and (2) Continental philosophy with its two branches, (*a*) Existentialism and (*b*) Phenomenology.

Henri Bergson, John Dewey, and Alfred North Whitehead have been called the three most important speculative philosophers of the first half of the 20th century. The French Bergson and the American Dewey shared an instrumental theory of mind; *i.e.*, influenced by Darwinism, they both held that mind has emerged in the course of biological evolution as an instrument of man's adaptation to his environment and, therefore, that man's mental functions are chiefly utilitarian agencies of action. Bergson and the English Whitehead were both adherents of a process philosophy; *i.e.*, each held that actuality is, like a river, fluent, that ultimate reality is mobile and dynamic. Yet, in fact, each of the three defined philosophy differently and saw it as performing a uniquely different task. Bergson's vision of philosophy was intuitional, Whitehead's was speculative, and Dewey's was pragmatic.

Bergson's two ways of knowing

Bergson, in the *Introduction à la métaphysique* (1903) and in his masterpiece, *L'Évolution créatrice* (1907), distinguished between two profoundly different ways of knowing: the method of analysis, which is that of science; and the method of intuition, which is just that intellectual sympathy by which men enter into objects and persons and identify with them. All basic metaphysical truths, Bergson held, are grasped by philosophical intuition. This is how men know their deepest selves, the duration, which is the essence of all living things, and the vital spirit, which is the mysterious creative agency in the world.

For Whitehead, philosophy was primarily metaphysics (or "speculative philosophy"), the effort "to frame a coherent, logical, necessary system of general ideas in terms of which every element of our experience can be interpreted." Whitehead's philosophy was, thus, an attempt to survey the world with a large generality of understanding, an end toward which his great trilogy, *Science and the Modern World* (1925), *Process and Reality* (1929), and *Adventures of Ideas* (1933), was directed.

While Bergson and Whitehead were principally metaphysicians and philosophers of culture, Dewey was an all-around philosopher who dominated the fields of ethics, metaphysics, and methodology in the United States for many years and who stressed the unity, interrelationship, and organicity of all forms of philosophic knowledge. He is chiefly notable, however, because his notion of philosophy stressed so powerfully the conceptions of practicality and moral purpose. One of the guiding aims of Dewey's philosophizing was the effort to find the same warranted assertibility for ethical and political as for scientific judgments. Philosophy, he said, should be oriented not to professional pride but to human need.

The social thought of Mill and Marx presented opposed solutions to the social problems of the 19th century; that of Dewey and Lenin presented opposed solutions to the problems of today. Not revolution, but the continuous application of the method of intelligence to social affairs was Dewey's answer. He believed in social planning, in conscious intelligent intervention to produce desirable social change; and he proposed a new "experimentalism" in social affairs as the guide to enlightened public action to promote the aims of a democratic community. His pragmatic social theory is the major social philosophy that liberal democracy has produced in the modern world.

Marxist thought. The framework of 19th-century Marxist thought, augmented by the philosophical suggestions of Lenin, still serves as the starting point of all philosophizing in the Socialist countries of eastern Europe. To Marx's conception of the dialectic (that the social world progresses through the rise and fall of oppositions), Lenin added a strong tinge of metaphysical Materialism (material things and their systems of relations exist independently of mind, and the laws of nature are objective) and a naïvely Realist theory of knowledge (ideas and sensations are true copies of independently existing things). But much of Lenin's thinking was also devoted to rather practical issues like the tactics of violence and the role of the Communist Party in bringing about and consolidating the proletarian revolution.

Unity of theory and practice in Marxism

Later Marxism has continued this concern with practical issues, because it represents the basic Marxist conception of what philosophy is and ought to be. For Marxism (like Pragmatism) tries to assimilate theoretical issues to practical needs. It asserts the basic unity of theory and practice by finding that the function of the former is to serve the latter. Marx and Lenin both held that theory is always in fact expressive of class interests; consequently, they wished philosophy to be transformed into a tool for furthering the class struggle: not abstractly to discover the truth but concretely to forge the intellectual weapons of the proletariat is philosophy's dominant task. Thus philosophy becomes inseparable from ideology.

Since the discovery and publication in 1927 and 1932 of some of Marx's early writings, many have sensed a breath of fresh air in Marxist philosophizing outside the Soviet Union. For the concern of the young Marx with alienation, with a theory of the nature of man, and with moral values has given Marxism a new humanistic dimension and has inspired some notable revisionist thinking in Poland, Hungary, and particularly in Yugoslavia.

Analytic philosophy. *Logical Positivism.* Logical Positivism, or Logical Empiricism, the earliest branch of modern Analytic philosophy was jointly inspired by Hume and by the new logic of Russell and Whitehead, authors of the *Principia Mathematica* (3 vol.; 1910–13). The school, formally instituted at the University of Vienna in a seminar of Moritz Schlick in 1923, continued there as the Vienna Circle until 1938. Its great period began in 1926 when Rudolf Carnap, who became a leading semanticist and philosopher of science, arrived at the University. Its manifesto of 1929, *Wissenschaftliche Weltauffassung: Der Wiener Kreis* ("Scientific Conception of the World: The Vienna Circle"), and its journal *Erkenntnis* ("Knowledge"), founded a year later, marked its self-consciousness as a philosophical movement.

Logical Empiricism's basic contribution has been a profound alteration in the conception of the role that philosophy itself must play. Philosophy, it claimed, must henceforth be scientific. It should seek less a content than a function: it should produce not complicated pictures of the world but clear thinking. This was best stated by Ludwig Wittgenstein in his *Tractatus Logico-Philosophicus* (1922), first published as *Logische-philosophische Abhandlung* (1921):

> The object of philosophy is the logical clarification of thoughts. Philosophy is not a theory but an activity. A philosophical work consists essentially of elucidations. The result of philosophy is not a number of 'philosophical propositions,' but to make propositions clear.

Despite this emphasis upon philosophy as a pure activity, Logical Empiricism did propound, at the same time, a series of revolutionary theses:

1. All *meaningful* discourse consists either of (*a*) the formal sentences of logic and mathematics or (*b*) the factual propositions of the special sciences;
2. Any assertion that claims to be factual has meaning only if it is possible to say how it might be verified;
3. Metaphysical assertions, coming under neither of the two classes of (1), are *meaningless*;

4. All statements about moral, aesthetic, or religious values are scientifically unverifiable and meaningless.

Logical Empiricism's radical denial of the meaningfulness of metaphysics and of assertions of value at first produced something of a philosophical scandal. But meanwhile, Bertrand Russell and his student Wittgenstein (who had emigrated from Austria) were propounding similar doctrines in England; and, after the Nazis overran Austria and Carnap, Hans Reichenbach (a Berlin Positivist), and many others from the Vienna Circle moved to America, this philosophy proved remarkably influential in the Anglo-American world. The Logical Empiricists were mainly interested in three basic themes: logic, language, and perception. Whereas Russell began with logic, turned to problems of perception, and ended with semantics, Carnap, having begun with perception in *Der logische Aufbau der Welt* (1928; *The Logical Structure of the World*, 1967), turned to problems of semantics in *Logische Syntax der Sprache* (1934; Eng. trans., *The Logical Syntax of Language*, 1937) and ended with logic in *Meaning and Necessity* (1947). But of these three themes, it was that of language that proved most enduring. This emphasis Logical Empiricism shared with its successor, Linguistic Analysis.

Linguistic Analysis. Sometimes called "ordinary language" Analysis or even "Oxford philosophy" from its present stronghold, this movement was, in fact, largely the product of two philosophers of the first half of the century who were associated with the University of Cambridge, G.E. Moore and Wittgenstein. Moore made the examination of the assertions of other men philosophically popular—*i.e.*, the practice of directing one's critical energies to the mistakes of his contemporaries. The major subjects of his interest were ethics and the theory of knowledge; his thought was always Realistic and commonsensical, and he introduced into philosophy an unbelievably precise and closely applied analytical method. It was Moore's passion for clarity and his infinite pains "to get everything *exactly* right" that served as moral inspiration to a succeeding generation of younger men who had attended his Cambridge lectures over a span of 30 years.

Seminal influence of Moore and Wittgenstein

Wittgenstein had begun as a kind of adjunct to the Vienna Circle. There was a time when his philosophical position was much like that of Russell and Carnap; but as he later became more skeptical of the foundations of mathematics and logic, his interest turned from logic and artificial language systems toward a critical examination of ordinary natural language. This change was principally registered in his *Philosophical Investigations*, posthumously published in 1953, which has become the true bible of Linguistic Analysis. For it is here that Wittgenstein showed how a man's entire world is constituted by his linguistic experience and suggested that "all philosophy is critique of language." Wittgenstein thought that to ask "Why do we use this particular word or expression?" was the crucial philosophical question, since a focussing of philosophy not upon the world but upon the mechanisms of linguistic use would solve most of the perplexities that have plagued philosophizing. Thus Linguistic philosophy was to perform a therapeutic function.

Wittgenstein's example found many followers in the United States and, particularly, in England. There philosophers Gilbert Ryle, J.L. Austin, and P.F. Strawson have examined "category mistakes," "systematically misleading expressions," "mental-conduct concepts" (such as "other minds"), and all of the major "perception words" such as "looking," "seeing," "sensing," "feeling," and the like. And the effect of this concentration not upon things or ideas but upon words has, for members of this school, turned the customary works on ethics, aesthetics, or the philosophy of religion into treatises entitled "The Language of Ethics" or "The Language of Aesthetics" or "The Language of Religion." And these efforts are all, in Wittgenstein's terms, "a battle against the bewitchment of our intelligence by means of language."

Continental philosophy. The Analytic philosophy that, by the mid-1970s, had dominated Anglo-American philosophical thinking for almost half a century has had comparatively little influence on the continent of Europe. For there the metaphysical and speculative tradition remained strong; and in the 1950s and 1960s the interest in both, but particularly in Phenomenology, posed an increasing threat to philosophical Analysis in Britain and the United States. Continental philosophy may be divided into Phenomenology and Existentialism, but the division is not sharp. Thinkers such as Martin Heidegger, Jean-Paul Sartre, and Maurice Merleau-Ponty combine the two strands. And the phenomenological method has been one of the formative forces in Existentialism.

Phenomenology of Husserl and others. Edmund Husserl, a German mathematician turned philosopher, was the true father of Phenomenology. An extremely complicated and technical thinker, whose views changed considerably over the years, his chief contributions were the phenomenological method, developed early, and the concept of the life-world, appearing only in his later writings. Husserl proposed the phenomenological method as a technique for conducting phenomenological analyses —*i.e.*, for making possible "a descriptive account of the essential structures of the directly given." The emphasis here is upon the immediacy of experience, the attempt to isolate it and set it off from all assumptions of existence or causal influence and to lay bare its actual intrinsic structure; for it is this structure that constitutes its essence. Phenomenology restricts the philosopher's attention to the pure data of consciousness uncontaminated by metaphysical theories or scientific assumptions. Husserl's concept of the life-world expressed this same idea of immediacy. It is the individual's personal world as directly experienced, with the ego at the centre and with all of its vital and emotional colourings.

Husserl's phenomenological method and life-world

With the appearance of the *Jahrbuch für Philosophie und Phänomenologische Forschung* (1913–30), under Husserl's chief editorship, his personal philosophizing flowered into an international movement. Its two most notable adherents were Max Scheler, a scholar of life-philosophy, whose *Formalismus in der Ethik und die materiale Wertethik* was published in the *Jahrbuch* (1913–16), and the ontological Existentialist Martin Heidegger, whose famous *Sein und Zeit* (Eng. trans., *Being and Time*, 1962) appeared in the *Jahrbuch* in 1927. Despite the differences in their individual philosophies, their work showed clearly the influence of the phenomenological method: in Scheler's careful explorations of the role that emotion plays in men's moral values and in his descriptive analyses of the human attitudes of resentment, sympathy, and love; and in Heidegger's startlingly original investigations of human existence with its unique dimensions of being-in-the-world, dread, care, and being toward death. In all of these painstaking and enormously detailed inquiries, however, both Scheler and Heidegger held to the phenomenological principle that philosophy is not empirical but is the strictly self-evident insight into the structure of experience. Later, Maurice Merleau-Ponty, a French student of philosophical psychology, in his *Phénoménologie de la perception* (1945), took over Husserl's conception of the life-world and used the notions of the lived body and its facticity to build up a hierarchical order of man's lived experience.

Scheler, Heidegger, and Merleau-Ponty

Existentialism of Jaspers and Sartre. Continental Existentialism, true to its roots in Kierkegaard and Nietzsche, is oriented about two major themes: (1) the analysis of human Being and (2) the centrality of human choice; thus its chief theoretical energies are devoted to ontology and decision. Existentialism as a philosophy of human existence finds its best spokesman in the German Karl Jaspers, who came to philosophy from medicine and psychology. As a philosophy of human decision, its spokesman is the French philosopher and playwright Jean-Paul Sartre. These two preoccupations lead to two different conceptions of philosophy's function.

For Jaspers, as for Dewey, the aim of philosophy is practical; for Dewey, however, it guides human doing, whereas for Jaspers its purpose is the achievement of human Being. Philosophizing is an inner activity by which the individual finds and becomes himself: it is a *revelation of Being*. It is an attempt to answer the question of what man is and what he can become; and this

Human existence and choice in Jaspers and Sartre

activity, wholly unlike that of science, is one of mere thought through the "inwardness" of which a man becomes aware of the deepest levels of Being.

But if, for Jaspers, philosophy is devoted to "the illumination of existence," that illumination is achieved when a person recognizes that human existence is revealed most profoundly in his experience of those "extreme" situations that define the human condition—conflict, guilt, suffering, and death. It is in man's confrontation with these extremes that he achieves his existential humanity.

Sartre, too, has some concern for man's Being and his dread before the threat of Nothingness. But Sartre finds the essence of this Being in man's liberty—in his duty of self-determination and his freedom of choice—and therefore spends much time in describing the human tendency toward "bad faith"—reflected in man's perverse attempts to deny his own responsibility and to flee from the truth of his inescapable freedom. Sartre, like Schopenhauer and Nietzche, considers himself a man of letters and has written novels and plays that assert the Existential dogma of human freedom and explore the inexhaustible mechanisms of bad faith. It is not that Sartre overlooks the legitimate series of obstacles that freedom has to face in the givens of one's place, past, environment, fellowmen, and death; but his Existentialist bias demands that man surmount these limitations by acts of conscious decision. For only in acts of freedom does human existence achieve authenticity.

Concluding comments. In generally surveying the field of contemporary philosophy, it seems clear that, in the 50 years around the mid-20th century, philosophizing has been uncommonly concerned with problems of language, symbolism, and communication. Renaissance philosophy was primarily preoccupied with nature, with an external physical world and the objects contained within it. The Enlightenment turned to the mind that knows the world; its philosophy spoke of the genesis of ideas, the relation of concepts, the quality of appearances. But current philosophizing largely states its problems in terms of symbolic manipulation and the characteristics of words.

Nor is this merely the preoccupation of Analytical philosophy: Dewey was interested in social communication; Whitehead wrote a little volume on *Symbolism: Its Meaning and Effect* (1927); Heidegger has turned to poetry and the etymology of words for the revelation of Being; Ernst Cassirer, a German Neo-Kantian, has produced a "philosophy of symbolic forms"; and Jaspers has tried to decipher the meanings reflected in human speech and gesture.

Apart from this underlying tendency, there seems little prospect for philosophical unification. The scientific and the metaphysical tempers still pursue their opposite courses, and the subjectivity of Existentialism and the objectivity of Logical Positivism still express their opposition in mutual contempt. Thus, in the contemporary philosophical universe, multiplicity and division still reign. (A.W.L.)

General histories: G.W.F. HEGEL, *Vorlesungen über die Geschichte der Philosophie*, 3 vol. (1840–44; Eng. trans., *Lectures on the History of Philosophy*, 1892–96); FRIEDRICH UEBERWEG, *Grundriss der Geschichte der Philosophie*, 12th ed., 5 vol. (1923–28; Eng. trans. from 4th ed., *A History of Philosophy from Thales to the Present Time*, 2 vol., 1872–74); WILHELM WINDELBAND, *Lehrbuch der Geschichte der Philosophie*, 14th ed. with supplement "Die Philosophie im zwanzigsten Jahrhundert" by HEINZ HEIMSOETH (1948; Eng. trans., *A History of Philosophy*, 1905, with a brief notice on English thought replacing Heimsoeth's supplement), a problems approach, particularly good on Kant and German Idealism; ALFRED WEBER, *Historie de la philosophie européenne*, 7th ed., 3 vol. (1905; Eng. trans., *History of Philosophy*, 1925, with supplement by RALPH B. PERRY); FRANK THILLY, *A History of Philosophy*, 3rd ed. rev. by LEDGER WOOD (1957); EMILE BREHIER, *Histoire de la philosophie*, new ed., 2 vol. (1941–47), particularly good on French thinkers, less so on English; JULIAN MARIAS, *Historia de la filosofía*, 22nd ed. (1966; Eng. trans., 1967); BERTRAND RUSSELL, *A History of Western Philosophy* . . . (1946); W.T. JONES, *A History of Western Philosophy*, 2nd ed. (1969); F.C. COPLESTON, *History of Philosophy*, 8 vol. (1946–66); JOHN HERMAN RANDALL, *The Career of Philosophy*, 2 vol. (1962–65), an informed, comprehensive, and judicious treatment. The best source for bibliographic information in philosophy is the annual *Répertoire bibliographique de la philosophie*, which the Institut Supérieur de Philosophie at Louvain began publishing in 1949.

Ancient Greek and Roman philosophy: (*Studies*): The most detailed work on the whole course of Greek and Roman philosophy is still EDUARD ZELLER, *Die Philosophie der Griechen*, 7th ed., 3 pt. (1920–23; Eng. trans. from earlier ed., *History of Greek Philosophy*, 2 vol., 1881–97). Still more detailed and up to date is the Italian translation of Zeller's first two volumes by RUDOLF MONDOLFO, with a wealth of additional notes and discussions. Equally thorough and up to date will be the great work by W.K.C. GUTHRIE, *A History of Greek Philosophy* (1962–), when completed; 3 vol. have appeared to date. For short introductions to Greek philosophy in English, see M.E.J. TAYLOR, *Greek Philosophy* (1924); REX WARNER, *The Greek Philosophers* (1958); and the excellent one by W.K.C. GUTHRIE, *The Greek Philosophers from Thales to Aristotle* (1960). For somewhat more detailed ones, see (in addition to the above work by Copleston) CORNELIA J. DE VOGEL (ed.), *Greek Philosophy*, 3 vol. (1950–59). (*Collections of fragments and works*): An influential source from perhaps the 3rd century AD is DIOGENES LAERTIUS, *Peri biōn dogmatōn kai apophthegmatikōn tōn en philosophia eudokimēsantōn* (Eng. trans., *Diogenes Laërtius: Lives of Eminent Philosophers*, 2 vol., 1925). The best comprehensive collection of the fragments of the pre-Socratic philosophers is still HERMANN DIELS and WALTHER KRANZ, *Die Fragmente der Vorsokratiker*, 11th ed., 3 vol. (1961–64), made more readily accessible for English-speaking readers by KATHLEEN FREEMAN, *Ancilla to the Pre-Socratic Philosophers: A Complete Translation of the Fragments* . . . (1948). A good selection of texts from the whole history is CORNELIA J. DE VOGEL, *Greek Philosophy: A Collection of Texts, Selected and Supplied with Some Notes and Explanations*, 3 vol. (1950–59). A more comprehensive edition of the main extant works and fragments of Epicurus is CYRIL BAILEY, *Epicurus: The Extant Remains* (1926), with short critical apparatus, translation, and notes. The works of Plato and Aristotle have been edited with English translations in the "Loeb Classical Library." (*Bibliographies*): The most detailed bibliography to 1925 is in KARL PRAECHTER, *Die Philosophie des Altertums*, 12th ed. (1926, reprinted 1953); the most complete bibliography from 1926 to 1963 is WILHELM TOTOK, *Handbuch der Geschichte der Philosophie*, vol. 1, *Altertum* (1964), 353 pages of bibliography, including ancient Indian philosophy.

Medieval philosophy: MAURICE DE WULF, *Histoire de la philosophie médiévale*, 6th ed., 3 vol. (1934–47; Eng. trans., 3rd ed., 2 vol., 1935–38, with reissue of vol. 1, 1952), contains much valuable information but has been superseded by more recent histories. ETIENNE GILSON, *History of Christian Philosophy in the Middle Ages* (1955), is the best account of medieval philosophy. AIME FOREST, FERNAND VAN STEENBERGHEN, and MAURICE DE GANDILLAC, *Le Mouvement doctrinal du IX^e^ au XIV^e^ siècle* (1951), traces doctrinal developments from the 9th to the 14th century. FERNAND VAN STEENBERGHEN, *La Philosophie au XIII^e^ siècle* (1966), gives a different interpretation of 13th-century philosophy from that of Gilson. His *Aristotle in the West* (1955), is a valuable account of the introduction of Aristotle's works into western Europe. DAVID KNOWLES, *The Evolution of Medieval Thought* (1962), is the work of an eminent historian of medieval religion. ARMAND A. MAURER, *Medieval Philosophy* (1962), sketches medieval philosophy from Augustine to the Renaissance. The following are short accounts of philosophy in the Middle Ages: GORDON LEFF, *Medieval Thought: St. Augustine to Ockham* (1958); PAUL VIGNAUX, *Philosophie au moyen âge*, 3rd ed. (1958; Eng. trans., *Philosophy in the Middle Ages*, 1959); JULIUS R. WEINBERG, *A Short History of Medieval Philosophy* (1964). Useful information about medieval Arab and Jewish philosophy is contained in T.J. DE BOER, *The History of Philosophy in Islam* (Eng. trans. 1903); GOFFREDO QUADRI, *La Philosophie arabe dans l'Europe médiévale* (French trans. 1947); ISAAC HUSIK, *A History of Mediaeval Jewish Philosophy* (1916, reprinted 1969); and GEORGES VAJDA, *Introduction à la pensée juive du moyen âge* (1947). Collections of translated texts include RICHARD MCKEON, *Selections from Medieval Philosophers*, 2 vol. (1929–30); HERMAN SHAPIRO, *Medieval Philosophy: Selected Readings from Augustine to Buridan* (1964); ARTHUR HYMAN and JAMES J. WALSH (eds.), *Philosophy in the Middle Ages: The Christian, Islamic, and Jewish Traditions* (1967); and JOHN F. WIPPEL and ALLAN B. WOLTER (eds.), *Medieval Philosophy, from St. Augustine to Nicholas of Cusa* (1969).

Modern and contemporary philosophy: (Comprehensive classical studies): JOHANN EDUARD ERDMANN, *Versuch einer wissenschaftlichen Darstellung der Geschichte der neuern Philosophie*, 3 vol. (1834–53; Eng. trans., *A History of Philosophy*, 3 vol. 1891–93); KUNO FISCHER, *Geschichte der neuern Philosophie*, 5th ed., 2 vol. (1909–12; partial Eng. trans., *History of Modern Philosophy: Descartes and His School*, 1887); HARALD HOFFDING, *Den nyere Filosofis Historie: En Fremstilling af Filosofiens Historie fra Renaissancens Slutning til vore Dage*, 2 vol. (1894–95; Eng. trans., *A History of Modern Philosophy*, 2 vol., 1900, reprinted 1955). *(Contemporary works)*: RAYMOND KLIBANSKY (ed.), *Philosophy in the Mid-Century: A Survey* (1958), and *Contemporary Philosophy* (1968), broad coverage in essays by leading scholars; ALBERT WILLIAM LEVI, *Philosophy and the Modern World* (1959), a broad treatment; WOLFGANG STEGMULLER, *Hauptströmungen der Gegenwartsphilosophie*, 4th ed. (1969; Eng. trans., *Main Currents in Contemporary German, British, and American Philosophy*, 1969), narrower, more technical treatment; WALTER KAUFMANN (ed.), *Existentialism from Dostoevsky to Sartre* (1956), selections with introductions; MARVIN FARBER (ed.), *L'Activité philosophique contemporaine en France et aux États-Unis*, 2 vol. (1950; Eng. trans., *Philosophic Thought in France and the United States: Essays Representing Major Trends in Contemporary French and American Philosophy*, 2nd ed., 1968). *(Chiefly Anglo-American)*: JOHN PASSMORE, *A Hundred Years of Philosophy*, 2nd ed. (1966); G.J. WARNOCK, *English Philosophy Since 1900*, 2nd ed. (1969); HERBERT W. SCHNEIDER, *A History of American Philosophy*, 2nd ed. (1963), standard reference work with excellent bibliographies. *(Chiefly continental)*: INNOCENTIUS M. BOCHENSKI, *Europäische Philosophie der Gegenwart*, 2nd ed. (1951; Eng. trans., *Contemporary European Philosophy*, 1956); MICHELE FEDERICO SCIACCA, *La filosofia oggi*, 3rd ed., 2 vol. (1958; Eng. trans., *Philosophical Trends in the Contemporary World*, 1964); HERMANN NOACK, *Die Philosophie Westeuropas im zwanzigsten Jahrhundert* (1962); HERBERT SPIEGELBERG, *The Phenomenological Movement*, 2nd ed., 2 vol. (1965–66); ANNA-TERESA TYMIENIECKA, *Phenomenology and Science in Contemporary European Thought* (1962). For specific individuals and schools of philosophy, see the bibliographies of relevant articles.

Phonetics

Phonetics is the study of pronunciation. The subject has two main branches—the description of the way in which the speech organs are used to produce the sounds of speech, and the specification of the resulting sound waves. A great deal of attention is also given to studying how languages and the dialects within a language differ in the sounds they use. Phonetics is thus part of linguistics, which is the study of human language as a whole, but its subject matter also overlaps with that of other disciplines such as physiology and acoustics.

Phonetics is a necessary part of linguistics, not only for adequately describing different languages but also for explaining the processes of word and sentence formation, and for understanding historical sound changes. Some knowledge of the subject is also useful for speech pathologists and for teachers who are concerned with the teaching of pronunciation. Because the movements of the vocal organs are the most rapid, intricate, and precisely controlled of all human muscular activities, knowledge of the processes that are involved in their control is also of considerable interest to physiologists and neurophysiologists.

STANDARDS OF PRONUNCIATION

Phoneticians are often expected to be concerned with standards of pronunciation. From a phonetician's point of view, however, everybody has an accent, and there is no such thing as good or bad speech. What is called good speech is simply that style of speech preferred by a particular class or group of people. One form of speech may become accepted as a standard within a region, or even within a country as a whole; however, what is accepted by a certain group may not, in many instances, be acceptable to another.

It should also be remembered that there are no genetic or racial characteristics that determine the way in which a child speaks. As a person grows up, he usually continues to talk in the way he wanted to talk during his formative years, when he was trying to win the approval of those who were important to him; *e.g.*, his parents. An accent thus marks a person as belonging, usually by birth, to a particular group of people. With the exception of those who suffer from disorders of speech, such as cleft palate, there is nothing to prevent anyone from changing his accent, provided he devotes enough effort to the problem. In doing so, a person can make use of phoneticians' descriptions of speech styles used by other groups.

Determinants of pronunciation

Within the English-speaking world there is no single way of speaking that is accepted as the most prestigious, but each country or region does have its own standard forms. In the United States there are several regions—*e.g.*, New England, New York City, the Appalachian Mountains, and Texas—that have characteristic styles of speech. At the same time, there is a growing tendency for news commentators on television and radio, actors, particularly those in commercials, and others who want to reach a wide audience throughout the country to use a style of speech that is comparatively free of local regional characteristics, and that is spoken by a large proportion of the population who live in the Midwest and the Far West. This style is sometimes called General American.

In Britain the situation is different. In Scotland and Wales there are regional accents; but in England, in addition to several local accents, there is an accent known as Received Standard English, or, as a technical term in phonetics, RP (Received Pronunciation, in the sense of received that means acceptable at court). This is spoken all over England and indicates not the regional origin of the speaker but rather that he belongs to a certain social class. Other English-speaking countries, such as Ireland, Canada, Australia, New Zealand, and, in another category, India, Ghana, and Nigeria, also have their own forms of English with their own regional standards.

ARTICULATORY PHONETICS

The traditional method of describing speech sounds is in terms of the movements of the vocal organs that produce them. The main structures that are important in the production of speech are the lungs and the respiratory system, together with the vocal organs shown in Figure 1. The airstream from the lungs passes between the vocal cords, which are two small muscular folds located in the larynx at the top of the windpipe. The space between the

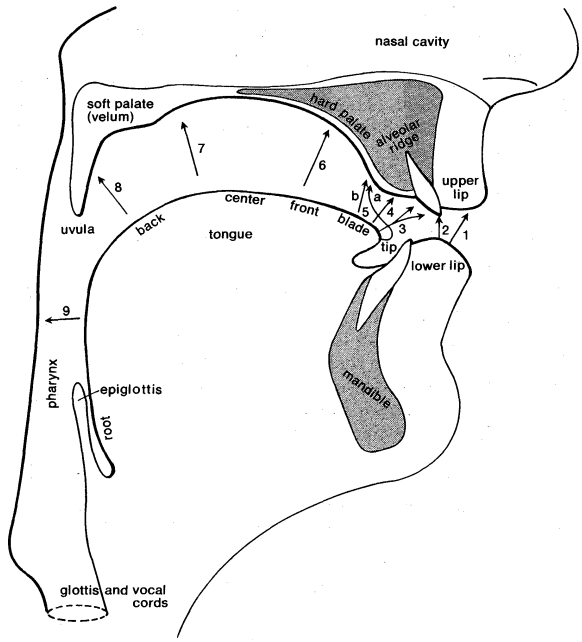

Figure 1: *Location of vocal organs and possible places of articulation.*
(1) Bilabial. (2) Labiodental. (3) Dental and interdental. (4) Alveolar. (5) Postalveolar; (a) retroflex, (b) palato-alveolar. (6) Palatal. (7) Velar. (8) Uvular. (9) Pharyngeal.

vocal cords is known as the glottis. If the vocal cords are apart, as they are normally when breathing out, the air from the lungs will have a relatively free passage into the pharynx (see Figure 1) and the mouth. But if the vocal cords are adjusted so that there is a narrow passage between them, the airstream will cause them to be sucked together. As soon as they are together there will be no flow of air, and the pressure below them will be built up until they are blown apart again. The flow of air between them will then cause them to be sucked together again, and the vibratory cycle will continue. Sounds produced when the vocal cords are vibrating are said to be voiced, as opposed to those in which the vocal cords are apart, which are said to be voiceless.

Voiced and voiceless sounds

The air passages above the vocal cords are known collectively as the vocal tract. For phonetic purposes they may be divided into the oral tract within the mouth and the pharynx, and the nasal tract within the nose. Many speech sounds are characterized by movements of the lower articulators—*i.e.*, the tongue or the lower lip—toward the upper articulators within the oral tract. The upper surface includes several important structures from the point of view of speech production, such as the upper lip and the upper teeth; Figure 1 illustrates most of the terms that are commonly used. The alveolar ridge is a small protuberance just behind the upper front teeth that can easily be felt with the tongue. The major part of the roof of the mouth is formed by the hard palate in the front, and the soft palate or velum at the back. The soft palate is a muscular flap that can be raised so as to shut off the nasal tract and prevent air from going out through the nose. When it is raised so that the soft palate is pressed against the back wall of the pharynx there is said to be a velic closure. At the lower end of the soft palate is a small hanging appendage known as the uvula.

As may be seen from Figure 1, there are also specific names for different parts of the tongue. The tip and blade are the most mobile parts. Behind the blade is the so-called front of the tongue; it is actually the forward part of the body of the tongue and lies underneath the hard palate when the tongue is at rest. The remainder of the body of the tongue may be divided into the centre, which is partly beneath the hard palate and partly beneath the soft palate; the back, which is beneath the soft palate; and the root, which is opposite the back wall of the pharynx.

The major division in speech sounds is that between vowels and consonants. Phoneticians have found it difficult to give a precise definition of the articulatory distinction between these two classes of sounds. Most authorities would agree that a vowel is a sound that is produced without any major constrictions in the vocal tract, so that there is a relatively free passage for the air. It is also syllabic. This description is unsatisfactory in that no adequate definition of the notion syllabic has yet been formulated.

Consonants. In the formation of consonants, the airstream through the vocal tract is obstructed in some way. Consonants can be classified according to the place and manner of this obstruction. Some of the possible places of articulation are indicated by the arrows going from one of the lower articulators to one of the upper articulators in Figure 1. The principal terms that are required in the description of English articulations, and the structures of the vocal tract that they involve are: bilabial, the two lips; dental, tongue tip or blade and the upper front teeth; alveolar, tongue tip or blade and the teeth ridge; retroflex, tongue tip and the back part of the teeth ridge; palato-alveolar, tongue blade and the back part of the teeth ridge; palatal, front of tongue and hard palate; and velar, back of tongue and soft palate. The additional places of articulation shown in Figure 1 are required in the description of other languages. Note that the terms for the various places of articulation denote both the portion of the lower articulators (*i.e.*, lower lip and tongue) and the portion of the upper articulatory structures that are involved. Thus velar denotes a sound in which the back of the tongue and the soft palate are involved, and retroflex implies a sound involving the tip of the tongue and the back part of the alveolar ridge. If it is necessary to distinguish between sounds made with the tip of the tongue and those made with the blade, the terms apical (tip) and laminal (blade) may be used.

Classification of consonants

There are six basic manners of articulation that can be used at these places of articulation: stop, fricative, approximant, trill, tap, and lateral.

Stops. Stops involve closure of the articulators, so that the airstream cannot go out of the mouth. This manner of articulation can be considered in terms of nasal and oral stops. If the soft palate is down so that air can still go out through the nose, there is said to be a nasal stop. Sounds of this kind occur at the beginning of the words *my* and *nigh*. If, in addition to the articulatory closure in the mouth, the soft palate is raised so that the nasal tract is blocked off, then the airstream will be completely obstructed, the pressure in the mouth will be built up, and an oral stop will be formed. When the articulators come apart the airstream will be released with a plosive quality. This kind of sound occurs in the consonants in the words *pie, tie, kye, buy, die,* and *guy*. Many authorities refer to these two articulations as nasals, meaning nasal stops (closure of the articulators in the oral tract implied), and stops, meaning oral stops (raising of the soft palate to form a velic closure implied).

Fricatives. A fricative sound involves the close approximation of two articulators, so that the airstream is partially obstructed and a turbulent airflow is produced. The mechanisms used in the production of these sounds may be compared to the physical forces involved when the wind "whistles" round a corner. Examples are the initial sounds in the words *fie, thigh, sigh* and *shy*. Some authorities divide fricatives into slit and grooved fricatives, or rill and flat fricatives, depending on the shape of the constriction in the mouth required to produce them. Other authorities divide fricatives into sibilants, as in *sigh* and *shy*, and nonsibilants, as in *fie* and *thigh*. This division is based on acoustic criteria (see below).

Varieties of fricatives

Approximants. Approximants are produced when one articulator approaches another but does not make the vocal tract so narrow that a turbulent airstream results. The terms frictionless continuant, semivowel, and glide are sometimes used for some of the sounds made with this manner of articulation. The consonants in the words *we* and *you* are examples of approximants.

Trills. A trill results when an articulator is held loosely fairly close to another articulator, so that it is set into vibration by the airstream. The tongue tip and blade, the uvula, and the lips are the only articulators than can be used in this way. Tongue tip trills occur in some forms of Scottish English in words such as *rye* and *ire*. Uvular trills are comparatively rare but are used in some dialects of French, but not Parisian French. Trills of the lips are even rarer but do occur in a few African languages.

Taps. A tap is produced if one articulator is thrown against another, as when the loosely held tongue tip makes a single tap against the upper teeth or the alveolar ridge. The consonant in the middle of a word such as *letter* or *Betty* is often made in this way in American English. The term flap is also used to describe these sounds, but some authorities make a distinction between taps as defined here and flaps, in which the tip of the tongue is raised up and back and then strikes the alveolar ridge as it returns to a position behind the lower front teeth. Some languages—*e.g.*, Hausa, the principal language of Northern Nigeria—distinguish between words containing a flap and words containing a tap. The distinction between a trill and a tap is used in Spanish to distinguish between words such as *perro*, meaning "dog," and *pero*, meaning "but."

Laterals. When the airstream is obstructed in the midline of the oral tract, and there is incomplete closure between one or both sides of the tongue and the roof of the mouth, the resulting sound is classified as a lateral. The sounds at the beginning and end of the word *lull* are laterals in most forms of American English.

The production of many sounds involves more than one of these six basic manners of articulation. The sounds at the beginning and end of the word *church* are stops combined with fricatives. The articulators—tongue tip or

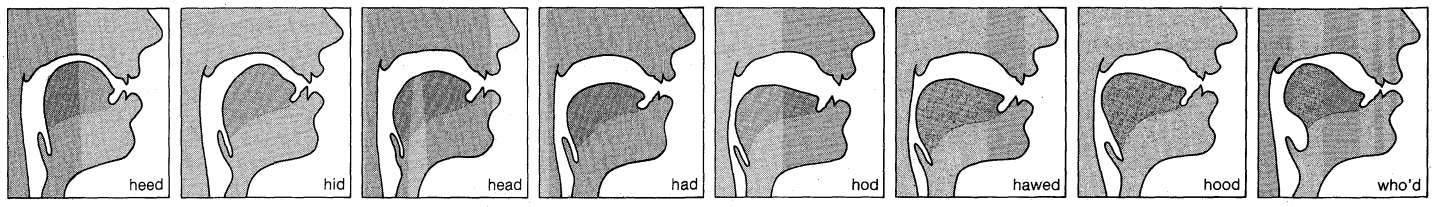

Figure 2: Tongue position for several vowel sounds.

blade, and alveolar ridge—come together for the stop, and then, instead of coming fully apart, they separate only slightly so that a fricative is made at the same place of articulation. This kind of combination is called an affricate. Lateral articulations may also occur in combination with other manners of articulation. The laterals in a word such as *lull* might more properly be called lateral approximants, in that the airstream passes out freely between the sides of the tongue and the roof of the mouth without a turbulent airstream being produced. But in some sounds in other languages the sides of the tongue are closer to the roof of the mouth and a lateral fricative occurs; an example is the sound spelled *ll* in Welsh words such as *llan* "church" and the name *Lluellyn*.

Affricates

Secondary articulations. When an approximant articulation occurs at the same time as another articulation is being made at a different place in the vocal tract, the approximant is said to form a secondary articulation. There are special terms for some of these possibilities. Added lip rounding is called labialization; it occurs in the formation of several English sounds—*e.g.*, during the pronunciation of the palato-alveolar fricative at the beginning of the word *shoe*. Raising of the front of the tongue while simultaneously making another articulation elsewhere in the vocal tract is called palatalization. It is the distinguishing characteristic of the soft consonants in Russian and also occurs, to a lesser extent, in English; *e.g.*, in the first consonant in the word *leaf*. Raising of the back of the tongue to form a secondary articulation is called velarization; it occurs in the last consonant in the word *feel*, which therefore does not contain the same sounds as those in the reverse order in the word *leaf*. Retracting of the root of the tongue while making another articulation is called pharyngealization; it occurs in Arabic in what are called emphatic consonants.

The states of the glottis, places of articulation, and manners of articulation discussed above are sufficient to distinguish between the major contrasts among the consonants of English and many other languages. But additional possibilities have to be taken into account in a more detailed description of English, or in descriptions of several other languages. Among these possibilities are variations in the timing of the states of the glottis. In addition to the contrast between the voiced and voiceless states of the glottis that occur during an articulation, there may be variations in the state of the glottis during the release of the articulation. Thus both the *p* in *pin* and that in *spin* are voiceless bilabial stops, but they differ in that the glottis remains in a voiceless position for a short time after the release of the bilabial stop in *pin*, whereas in *spin* the voicing starts as soon as the lips come apart. When there is a period of voicelessness during the release of an articulation, the sound is said to be aspirated. The main difference between the consonants in *pea* and *bee*, when these words are said in isolation, is not that the one is voiceless and the other voiced, but that the first is aspirated and the second is unaspirated. Some languages distinguish between both voiced–voiceless and aspirated–unaspirated sounds. Thus Thai has contrasts between voiceless aspirated stops, voiceless unaspirated stops, and voiced unaspirated stops.

States of the glottis

Several languages use more than just the voiced and voiceless states of the glottis. In Hindi and many of the other languages of India, some sounds are produced while the vocal cords are vibrating for part of their length but are apart, so that a considerable amount of air escapes between them at one end. This phenomenon is known as breathy voice, or murmur. Other languages have sounds in which the vocal cords are held tightly together so that only part of their length can vibrate. This kind of sound, which is usually very low pitched, is sometimes called creaky voice, or vocal fry. It is used to make contrasts between consonants in several American Indian languages. An additional glottal state that is widely used —*e.g.*, in the Austronesian (Malayo–Polynesian) languages of the Philippines—is a glottal stop, a tight closure of the two vocal cords. This articulation also occurs in many forms of English as the usual pronunciation of *t* in words such as *bitten* and *fatten*.

Types of airstream. In English, all sounds are produced with an airstream caused by the expiration of the air from the lungs. This is known as a pulmonic airstream. Other mechanisms for producing an airstream also occur. If there is a glottal stop and the closed glottis is moved rapidly upward or downward it can act like a piston pushing or pulling the air in the pharynx. This is the glottalic airstream mechanism. When there is an upward movement of the closed glottis the resulting sound is called an ejective. Amharic, the national language of Ethiopia, uses this mechanism to produce both ejective stops and fricatives, which contrast with the more usual stops and fricatives made with a pulmonic airstream mechanism. A downward movement of the glottis is used in the production of implosive sounds, which occur in many American Indian, African, and other languages. The use of movements of the tongue to suck air into the mouth is known as the velaric airstream mechanism; it occurs in the production of clicks, which are regular speech sounds in many languages of southern Africa.

To summarize, a consonant may be described by reference to seven factors: (1) state of the glottis, (2) secondary articulation (if any), (3) place of articulation, (4) type of airstream, (5) central or lateral articulation, (6) velic closure—oral or nasal, and (7) manner of articulation. Thus the consonant at the beginning of the word *swim* is a (1) voiceless, (2) labialized, (3) alveolar, (4) pulmonic, (5) central, (6) oral, (7) fricative. Unless a specific statement is made to the contrary, consonants are usually presumed to have a pulmonic airstream and no secondary articulation, and it is also assumed that they are not laterals or nasals. Consequently, points 2, 4, 5, and 6 are often disregarded and a three-term description —*e.g.*, voiceless alveolar fricative is sufficient.

Factors in consonant description

Vowels. Vowels traditionally have been specified in terms of the position of the highest point of the tongue and the position of the lips. Figure 2 shows these positions for eight different vowels. The highest point of the tongue is in the front of the mouth for the vowels in *heed*, *hid*, *head*, and *had*. Accordingly, these vowels are classified as front vowels, whereas the vowels in *hod*, *hawed*, *hood*, and *who'd* are classified as back vowels. The tongue is highest in the vowels in *heed* and *who'd*, which are therefore called high, or close, vowels, and lowest in the vowels in *had* and *hod*, which are called low, or open, vowels. The height of the tongue for the vowels in the other words is between these two extremes, and they are therefore called midvowels. Lip positions may be described as being rounded, as in *who'd*, or unrounded or spread, as in *heed*.

The specification of vowels in terms of the position of the highest point of the tongue is not entirely satisfactory for a number of reasons. In the first place, it disregards the fact that the shape of the tongue as a whole is very different in front vowels and in back vowels. Second, although the height of the tongue in front vowels varies by approximately equal amounts for what are called equidistant steps in vowel quality, this is just not factually true in descriptions of back vowels. Third, the width of

the pharynx varies considerably, and to some extent independently of the height of the tongue, in different vowels.

Tenseness and laxness

Some authorities use terms such as tense and lax to describe the degree of tension in the tongue muscles, particularly those muscles responsible for the bunching up of the tongue lengthways. Other authorities use the term tense to specify a greater degree of muscular activity, resulting in a greater deformation of the tongue from its neutral position. Tense vowels are longer than the corresponding lax vowels. The vowels in *heed* and *hayed* are tense, whereas those in *hid* and *head* are lax.

In many languages there is a strong tendency for front vowels to have spread lip positions, and back vowels to have lip rounding. As will be seen in the next section, this results in vowels that are acoustically maximally distinct. But many languages—*e.g.*, French and German—have front rounded vowels. Thus French has a contrast between a high front unrounded vowel in *vie,* "life," and a high front rounded vowel with a very similar tongue position in *vu,* "seen," as well as a high back rounded vowel in *vous,* "you." Unrounded back vowels also occur —*e.g.*, in Vietnamese.

Nasalized vowels, in which the soft palate is lowered so that part of the airstream goes out through the nose, occur in many languages. French distinguishes between several nasalized vowels and vowels made with similar tongue positions but with the soft palate raised. Low vowels in many forms of English are often nasalized, especially when they occur between nasal consonants, as in *man.*

Cardinal vowels

Because of the difficulty of observing the precise tongue positions that occur in vowels, a set of eight vowels known as the cardinal vowels has been devised to act as reference points. This set of vowels is defined partly in articulatory and partly in auditory terms. Cardinal vowel number one is defined as the highest and farthest front tongue position that can be made without producing a fricative sound; cardinal vowel number five is defined as the lowest and farthest back vowel. Cardinal vowels two, three, and four are a series of front vowels that form auditorily equidistant steps between cardinal vowels one and five; and cardinal vowels six, seven, and eight are a series of back vowels with the same sized auditory steps as in the front vowel series. Phoneticians who have been trained in the cardinal vowel system are able to make precise descriptions of the vowels of any language in terms of these reference points.

Suprasegmentals. Vowels and consonants can be considered to be the segments of which speech is composed. Together they form syllables, which in turn make up utterances. Superimposed on the syllables there are other features that are known as suprasegmentals. These include variations in stress (accent) and pitch (tone and intonation). Variations in length are also usually considered to be suprasegmental features, although they can affect single segments as well as whole syllables. All of the suprasegmental features are characterized by the fact that they must be described in relation to other items in the same utterance. It is the relative values of the pitch, length, or degree of stress of an item that are significant. The absolute values are never linguistically important, although they may be of importance paralinguistically, in that they convey information about the age and sex of the speaker, his emotional state, and his attitude.

Many languages—*e.g.*, Finnish and Estonian—use length distinctions, so that they have long and short vowels; a slightly smaller number of languages, among them Luganda (the language spoken by the largest tribe in Uganda) and Japanese, also have long and short consonants. In most languages segments followed by voiced consonants are longer than those followed by voiceless consonants. Thus the vowel in *cad* before the voiced *d* is much longer than that in *cat* before the voiceless *t*. Variations in stress are caused by an increase in the activity of the respiratory muscles, so that a greater amount of air is pushed out of the lungs, and in the activity of the laryngeal muscles, resulting in significant changes in pitch. In English, stress has a grammatical function, distinguishing between nouns and verbs, such as *an insult* versus *to insult.* It can also be used for contrastive emphasis, as in *I want a RED pen, not a black one.*

Pitch and intonation

Variations in laryngeal activity can occur independently of stress changes. When they do so, the resulting pitch changes can affect the meaning of the sentence as a whole, or the meaning of the individual words. The pitch pattern in a sentence is known as the intonation. In English the meaning of a sentence such as *That's a cat* can be changed from a statement to a question by the substitution of a mainly rising for a mainly falling intonation. Pitch patterns that affect the meanings of individual words are known as tones and are common in many languages. In Chinese, for example, a syllable that is transliterated as *ma* means "mother" when said on a high tone, "hemp" on a midrising tone, "horse" on the falling-rising tone, and "scold" on a high-falling tone.

ACOUSTIC PHONETICS

Speech sounds consist of small variations in air pressure that can be sensed by the ear. Like other sounds, speech sounds can be divided into two major classes—those that have periodic wave forms (*i.e.*, regular fluctuations in air pressure) and those that do not. The first class consists of all the voiced sounds, because the vibrations of the vocal cords produce regular pulses of air pressure.

Fundamental frequency

From a listener's point of view, sounds may be said to vary in pitch, loudness, and quality. The pitch of a sound with a periodic wave form—*i.e.*, a voiced sound—is determined by its fundamental frequency, or rate of repetition of the cycles of air pressure. For a speaker with a bass voice, the fundamental frequency will probably be between 75 and 150 cycles per second. Cycles per second are also called hertz (Hz); this is the standard term for the unit in frequency measurements. A soprano may have a speaking voice in which the vocal cords vibrate to produce a fundamental frequency of over 400 hertz. The relative loudness of a voiced sound is largely dependent on the amplitude of the pulses of air pressure produced by the vibrating vocal cords. Pulses of air with a larger amplitude have a larger increase in air pressure.

The quality of a sound is determined by the smaller variations in air pressure that are superimposed on the major variations that recur at the fundamental frequency. These smaller variations in air pressure correspond to the overtones that occur above the fundamental frequency. Each time the vocal cords open and close there is a pulse of air from the lungs. These pulses act like sharp taps on the air in the vocal tract, which is accordingly set into vibration in a way that is determined by its size and shape. In a vowel sound, the air in the vocal tract vibrates at three or four frequencies simultaneously. These frequencies are the resonant frequencies of that particular vocal tract shape. Irrespective of the fundamental frequency that is determined by the rate of vibration of the vocal cords, the air in the vocal tract will resonate at these three or four overtone frequencies as long as the position of the vocal organs remains the same. In this way a vowel has its own characteristic auditory quality, which is the result of the specific variations in air pressure caused by the superimposing of the vocal tract shape on the fundamental frequency produced by the vocal cords.

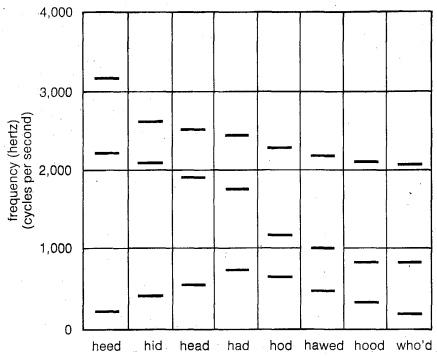

Figure 3: Schematic spectrogram showing frequencies of the first three formants of the vowels in similar English words.

Vowel formants. The resonant frequencies of the vocal tract are known as the formants. The frequencies of the first three formants of the vowels in the words *heed, hid, head, had, hod, hawed, hood,* and *who'd* are shown in Figure 3. Comparison with Figure 2 shows that there are no simple relationships between actual tongue positions and formant frequencies. There is, however, a good inverse correlation between one of the labels used to describe the tongue position and the frequency of the first, or lowest, formant. This formant is lowest in the so-called high vowels, and highest in the so-called low vowels. When phoneticians describe vowels as high or low, they probably are actually specifying the inverse of the frequency of the first formant.

Most people cannot hear the pitches of the individual formants in normal speech. In whispered speech, however, there are no regular variations in air pressure produced by the vocal cords, and the higher resonances of the vocal tract are more clearly audible. It is quite easy to hear the falling pitch of the second formant when whispering the series of words *heed, hid, head, had, hod, hawed, hood, who'd.* Conversely, the auditory effect of the second and higher formants is lessened when speaking in a creaky voice. Under such conditions, it is possible to hear the rise in pitch of the first formant during the first four of these words, and the fall in pitch during the last.

Consonant formants. Voiced consonants such as nasals and laterals also have specific vocal tract shapes that are characterized by the frequencies of the formants. They differ from vowels in that in their production the vocal tract is not a single tube. There is a side branch formed when the nasal tract is coupled in with the oral tract, or, in the case of laterals, when the oral tract itself is obstructed in the centre. The effect of these side branches is that the relative amplitudes of the formants are altered; it is as if one or more of the possible superimposed variations in air pressure had been lessened because it had been trapped in the cavity formed at the side. Nasals and laterals can therefore be specified in terms of their formant frequencies, just like vowels. But in a complete specification of these consonants the relative amplitudes of the formants also have to be given, because they are not completely predictable.

Other voiced consonants such as stops and approximants (semivowels) are more like vowels in that they can be characterized in part by the resonant frequencies—the formants—of their vocal tract shapes. They differ from vowels in that during a voiced stop closure there is very little acoustic energy, and during the release phase of a stop and the entire articulation of a semivowel the vocal tract shapes are changing comparatively rapidly. These transitional movements can be specified acoustically in terms of the movements of the formant frequencies.

Pitch of voiceless sounds

Voiceless sounds do not have a periodic wave form with a well-defined fundamental frequency. Nevertheless, some sensations of pitch accompany the variations in air pressure caused by the turbulent airflow that occurs during a voiceless fricative, or in the release phase of a voiceless stop. This is because the pressure variations are far from random. During the first consonant in *sea* these have a tendency to be at a higher centre frequency, and hence a higher pitch, than in the pronunciation of the first consonant in *she.* There is also a difference in the average amplitude of the wave form in different voiceless sounds. All voiceless sounds have much less energy—*i.e.*, a smaller amplitude—than voiced sounds pronounced with the same degree of effort. Other things being equal, the fricatives in *sin* and *shin* have more amplitude—*i.e.*, are louder—than those in *thin* and *fin.*

In summary, speech sounds are fairly well defined by nine acoustic factors. The first three factors include the frequencies of the first three formants; these are responsible for the major part of the information in speech. Characterizing the vocal tract shape, these formant frequencies specify vowels, nasals, laterals, and the transitional movements in voiced consonants. The frequencies of the fourth and higher formants do not vary significantly. The fourth factor is the fundamental frequency—roughly speaking, the pitch—of the larynx pulse in voiced sounds, and the fifth, the amplitude—roughly speaking, the loudness—of the larynx pulse. These last two factors account for suprasegmental information; *e.g.*, variations in stress and intonation. They also distinguish between voiced and voiceless sounds, in that the latter have no larynx pulse amplitude. The centre frequency of the high-frequency hissing noises in voiceless sounds constitutes the sixth acoustic factor, and the seventh is the amplitude of these high-frequency noises. These two factors characterize the major differences among voiceless sounds. In more accurate descriptions it would be necessary to specify more than just the centre frequency of the noise in fricative sounds. The eighth and ninth factors include the amplitudes of the second and third formants relative to the first formant; the amplitudes of the formants as a whole are determined by the larynx pulse amplitude. These latter factors are the least important in that they convey only supplementary information about nasals and laterals.

Sound spectrograph

Instruments for acoustic phonetics. The principal instrument used in acoustic phonetic studies is the sound spectrograph. This device gives a visible record of any kind of sound. A spectrographic analysis of the phrase *speech pictures* is shown in Figure 4. The time of occurrence of each item is given on the horizontal scale. The vertical scale shows the frequency components at each moment in time, the amplitude of the components being shown by the darkness of the mark. (Figure 3 diagrams

By courtesy of Peter Ladefoged, University of California, Los Angeles

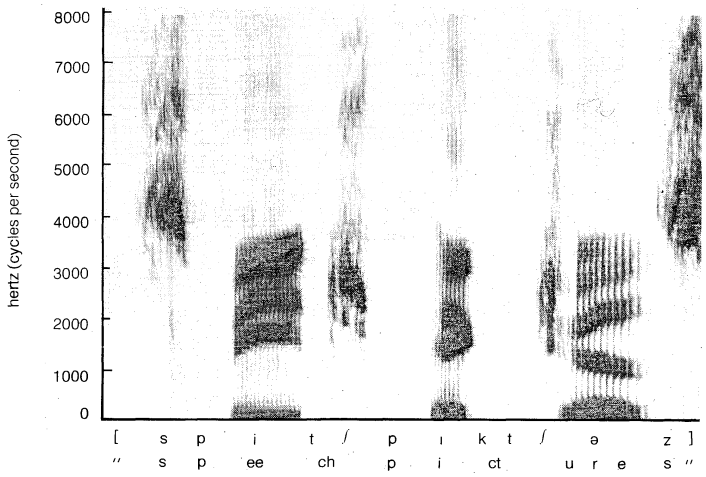

Figure 4: A spectrogram of the phrase "speech pictures." The horizontal dimension represents time, and the vertical scale represents frequency. The amplitude of the component frequencies at each moment in time is shown by the darkness of the mark.

the formant frequencies in a set of English vowels in the same way and might be regarded as a schematic spectrogram.) In the phrase *speech pictures* the first consonant has a comparatively random distribution of energy, but, as Figure 4 shows, it is mainly in the higher frequencies. The second consonant is a voiceless stop, which produces a short gap in the pattern. The next segment, the first vowel, has four formants that appear as dark bars with centre frequencies of 300, 2,000, 2,700, and 3,400 hertz. Each of the other segments has its own distinctive pattern.

Much information has also been gained from the use of speech synthesizers, which are instruments that take specifications of speech in terms of the acoustic factors summarized above and generate the corresponding sounds. Some speech synthesizers use electronic signal generators and amplifiers; others use digital computers to calculate the values of the required sound waves. Good synthetic speech is hard to distinguish from high-quality recordings of natural speech. The principal value of a speech synthesizer is its precisely controllable "voice" that an experimenter can vary in a systematic way to determine the perceptual effects of different acoustic specifications.

LINGUISTIC PHONETICS

Phonetics is part of linguistics in that one of the main

Relation of phonetics to linguistics

aims of phonetics is to determine the categories that can be used in explanatory description of languages. One way of looking at the grammar of a language is to consider it to be a set of statements that explains the relation between the meanings of all possible sentences in a language and the sounds of which they are composed. In this view, a grammar may be divided into three parts: the syntactic component, which is a set of rules describing the ways in which words may form sentences; the lexicon, which is a list of all the words and the categories to which they belong; and the phonological component, which is a set of rules that relates phonetic descriptions of sentences to the syntactic and lexical descriptions.

Phonological rules. In the lexicon of a language, each word is represented in its underlying, or basic, form, which discounts all of the alternations in pronunciation that are predictable by phonological rules. For example, there are phonological rules that will account for the variations in the placement of stress and the alternations of vowel quality that occur in sets of words such as *harmOny*, *harmOnic*, *harmOnious* and *melOdy*, *melOdic*, *melOdious*. The rules that predict the pronunciation of the capitalized *O*'s are general, rather than specific for each word, and the grammar should state such rules so that the regularities are revealed. Accordingly, each of these words must be entered in the lexicon in a way that represents simply its underlying form, and that allows the alternations that occur to be generated by phonological rules. The underlying form is known as the phonemic—sometimes morphophonemic, or phonological—representation of the word. The phonemes of a language are the segments that contrast in the underlying forms. American English may be said to have at least 13 vowel phonemes, which contrast in the underlying forms of words such as *bate*, *bat*, *beat*, *bet*, *bite*, *bit*, *bout*, *but*, *boat*, *dot*, *bought*, *balm*, and *boy*. Some authorities consider that there are additional vowel phonemes exemplified in the words *bush* and *beaut(y)*, but others believe that these can be derived from the same underlying vowel as that in the word *bud*. Phonemes are traditionally written between slanting lines, as /p/, /m/, or /l/.

The variants of phonemes that occur in phonetic representations of sentences are known as allophones. They may be considered to be generated as a result of applying the phonological rules to the phonemes in underlying forms. For example, there is a phonological rule of English that says that a voiceless stop such as /p/ is aspirated when it occurs at the beginning of a word (*e.g.*, in *pin*), but when it occurs after a voiceless alveolar fricative (*i.e.*, after/s/), it is unaspirated (*e.g.*, in *spin*). Thus the underlying phoneme /p/ has an aspirated and an unaspirated allophone, in addition to other allophones that are generated as a result of other rules that apply in other circumstances. Allophones are conventionally written inside brackets—*e.g.*, [p] or aspirated [p^h].

Classes of phonemes

In stating phonological rules it is necessary to refer to classes of phonemes. Consider part of the rule for the formation of the plural in English: there is an extra vowel in the suffix if the word ends in the same sound as occurs at the end of *horse, maze, fish, rouge, church*, or *judge*. The plural forms of words of this kind are one syllable longer than the singular forms. The phonological rules of English could simply list the phonemes that behave in the same way in the rules for plural formation; the rules for the possessive forms of nouns and for the 3rd person singular of the present tense of verbs are similar in this respect. The rules are more explanatory, however, if they show that these phonemes behave in a similar way because they form a natural class, or set, whose members are defined by a common property. In the case of these plural forms, the phonemes are all, and only, those that have a high-frequency fricative component; they may be called the sibilant, or strident, phonemes.

Other phonological rules that refer to natural classes of phonemes have already been mentioned. The rule about voiceless stops being aspirated in some circumstances and unaspirated in others refers to the subset of phonemes that are both voiceless and stops. Similarly, the variations in vowel length in *cat* and *cad* can be stated with reference to the set of phonemes that are vowels, and also to the set that comprises both voiceless sounds and stops.

Features. Each of the phonemes that appears in the lexicon of a language may be classified in terms of a set of phonetic properties, or features. Phoneticians and linguists have been trying to develop a set of features that is sufficient to classify the phonemes in each of the languages of the world. A set of features of this kind would constitute the phonetic capabilities of man. To be descriptively adequate from a linguistic point of view, the set of features must be able to provide a different representation for each of the words that is phonologically distinct in a language; and if the feature set is to have any explanatory power it must also be able to classify phonemes into appropriate natural classes as required in the phonological rules of each language.

In the earlier work on feature sets, emphasis was placed on the fact that features were the smallest discrete components of language. Not much attention was paid to their role in classifying phonemes into the natural classes required in phonological rules. Instead, they were considered to be the units to which a listener attends when listening to speech. Features were justified by reference to their role in distinguishing phonemes in minimal sets of words such as *bill, pill, fill, mill, dill, sill, kill.*

Jakobson, Fant, and Halle features. As a result of studying the phonemic contrasts within a number of languages, Roman Jakobson, Gunnar Fant, and Morris Halle concluded in 1951 that segmental phonemes could be characterized in terms of 12 distinctive features. All of the features were binary, in the sense that a phoneme either had, or did not have, the phonetic attributes of the feature. Thus phonemes could be classified as being consonantal or not, voiced or not, nasal or not, and so on. In 1968, Noam Chomsky and Morris Halle stated that nearer 30 features are needed for a proper description of the phonetic, and linguistic, capabilities of man. In agreement with Jakobson, they claimed that each feature functions as a binary opposition that can be given the value of plus or minus in classifying the phonemes in underlying forms. But they suggested that the features may require more precise systematic phonetic specifications.

Binary quality of features

Chomsky–Halle features. Some of the binary features proposed by Chomsky and Halle are listed in Table 1. The first group comprises major class features, because these features are required for dividing sounds into classes such as vowels, consonants, and semivowels. There are several problems in giving satisfactory definitions of the phonetic properties of these features, but there is no doubt that binary oppositions of this kind are needed for describing phonological patterns.

The next group, the manner of articulation features, includes continuant/noncontinuant (in which noncontinuant is exactly equivalent to the notion of stop as defined above), and delayed release (the comparatively slow parting of the articulators that occurs in an affricate). The source features refer to the action of the vocal cords (voice) or to fricative noise mechanisms (strident).

The cavity features include nasal and lateral, which are used in the same sense as they were in the section on articulatory phonetics, and the features that determine the place of articulation of consonants and the quality of vowels. The most important features specifying the place of articulation of consonants are anterior, made in the

Table 1: Part of the Set of Features Proposed by Chomsky and Halle (1968)

Major class features	Cavity features
consonantal	nasal
syllabic	lateral
sonorant	anterior
Manner of articulation features	coronal
continuant	high
delayed release	low
tense	back
Source features	round
voice	
strident

Coronal	−	−	−	−	−	−	+	+	−	+	+	+	+	+	+	+	+	−	−
Round	−	+	−	−	−	+													
Tense	+	+	+	+	−	−													
Voice							+	+	−	−	+	−	+	+	−	+	−	−	−
Continuant							+	+	−	−	−	+	+	−	+	+	+	−	+
Nasal							−	−	−	−	−	−	−	+	−	−	−	−	−
Strident							−	−	−	−	−	−	−	−	+	+	+	−	−
Lateral							−	+	−	−	−	−	−	−	−	−	−	−	−

front of the mouth, and coronal, made with the tip or blade of the tongue raised toward the teeth or teeth ridge. These two features can be used to specify four places of articulation: bilabial (+anterior, −coronal); dental, or alveolar (+anterior, +coronal); postalveolar, or palatoalveolar (−anterior, +coronal); velar (−anterior, −coronal). There is still some disagreement concerning whether consonantal places of articulation are specified appropriately by binary oppositions of this kind.

Vowels and binary features

There is even more disagreement over the advisability of describing vowels in terms of binary features. Chomsky and Halle use the features high/nonhigh and low/nonlow to specify the height of the tongue, midtongue positions being considered to be simply those that are −high, −low; the feature back/nonback is employed to specify the front/back distinctions among vowels. But these three features can be combined to specify only six basic tongue positions: high front, high back, midfront, midback, low front, and low back. It is true that each of these possibilities can have tense/nontense (lax) variants and rounded/nonrounded (spread) variants. But the Chomsky–Halle feature system does not permit the specification within underlying forms of central vowels, nor of more than three degrees of tongue height. Moreover, their binary oppositions of vowel height do not make it clear that the difference between low vowels and midvowels is the same as that between midvowels and high vowels.

Table 2 shows the feature composition of a number of segments that occur in English. The phonetic symbols at the top of each column are used with the values discussed in the following section.

PHONETIC TRANSCRIPTION

There are many different kinds of phonetic transcription. In some circumstances a phonetic symbol can be simply an abbreviation for a phonetic description. The symbol [s] may then be regarded as exactly equivalent to the phrase "voiceless, alveolar, fricative." When a linguist tries to describe an unknown language he begins by writing it down using symbols in this way. Later, when he has learned about the function of sounds and the underlying forms in the language, he might make a more systematic transcription, known as a broad transcription, in which each phoneme is represented by a simple symbol.

Occasionally it is convenient to use a transcription in which some of the allophones are represented by specific symbols, or some of the phonemes are designated by the symbols for a more restricted set of categories. If, for example, the transcription were to be used in teaching pronunciation, the difference between the aspirated and unaspirated allophones of /p/ might be represented by transcribing *pan* as [pʰan] and *span* as [span]; or the vowel phoneme in each of these words might be designated by the more specific symbol [æ], which represents a low front vowel of a certain type. In a narrow transcription the symbols are more specific, either because allophones are differentiated, or because the phonetic quality of the sounds is shown more precisely.

Narrow transcription

The most widely used set of symbols is that of the International Phonetic Association (IPA). The latest version of the IPA chart is shown in Table 3. In general, the consonants have the same values as the corresponding letters in many European languages; the vowel symbols have similar values to the corresponding letters in a language such as Italian.

EXPERIMENTAL PHONETICS

Experimental phonetics employs the methods of investigation commonly used in other disciplines—*e.g.*, physics, physiology, and psychology—for measuring the physical and physiological dimensions of speech sounds and their perceptual characteristics. The sound spectrograph and speech synthesizers were mentioned in the section on acoustic phonetics. Other techniques include the use of X-rays; air-pressure and air-flow recording; palatography, a method of registering the contacts between the tongue and the roof of the mouth; and cinematography. All of these techniques have been used for studying the actions of the vocal organs.

Much of the work in experimental phonetics has been directed toward obtaining more accurate descriptions of the sounds that characterize different languages. There have also been several studies aimed at determining the relative importance of different features in signalling contrasts between sounds. But experimental phoneticians are probably most concerned with trying to discover the central cerebral processes involved in speech.

Motor theory of speech perception

One issue of this kind that has been extensively discussed is the so-called motor theory of speech perception. There is a great deal of evidence that the way in which people speak greatly influences their perception of what is said to them. For example, speakers of Spanish cannot pronounce the different vowels in words such as *ship* and *sheep* in English. These people also have difficulty in hearing the difference between these two vowels. But when they have learned, by trial and error methods, to say them correctly, then they can easily hear the difference. Similarly, using synthetic speech stimuli it is possible to make a series of consonant sounds that go by acoustically equidistant steps from [b] through [d] to [g]. When listeners hear these synthetic sounds they do not consider the steps between them to be auditorily equidistant. The steps that correspond to the large articulatory movements between the consonants are heard as being much larger than the equal size acoustic steps that do not correspond to articulatory movements occurring in the listener's speech. Facts such as these have led some phoneticians to believe that the perception of speech is structured more in motor—articulatory—terms than in acoustic terms. Other phoneticians have claimed that the evidence does not really distinguish between these two possibilities but demonstrates simply that the perception of speech is structured in terms of linguistic categories.

Perception and size of speech units

Another major problem is the size of the units that are involved in the perception of speech. Some authorities have claimed that a listener distinguishes between words by making a series of binary decisions concerning the features in each segment that he hears. Others hold that the listener takes in information in much larger temporal pieces and perhaps processes speech in terms of units of at least the size of a syllable. All authorities agree on the importance of context. Speech conveys information in a redundant way. Experiments have shown that a listener need attend to only a part of the information presented to him in order to understand all that is being said.

Table 3: The International Phonetic Alphabet*
(revised to 1951)

*Secondary articulations are shown by symbols in parentheses.
Other sounds—palatalized consonants: ʇ, ɗ, etc.; palatalized ʃ, ʒ : ʄ, ʒ̠. Velarized or pharyngalized consonants: ɬ, ɗ, ʐ, etc. Ejective consonants (with simultaneous glottal stop): p', t', etc. Implosive voiced consonants: ɓ, ɗ, etc. ɾ fricative trill. ʊ, ɻ (labialized θ, ð, or s, z). ɬ, ʒ (labialized ʃ, ʒ). ǀ, ǃ, ǂ (clicks, Zulu *c*, *q*, *x*). ɺ (a sound between r and l). ɳ Japanese syllabic nasal. ʃ (combination of x and ʃ). ʍ (voiceless w). ɪ, ʏ, ɷ (lowered varieties of i, y, u). ɜ (a variety of ə). ɵ (a vowel between ø and o).
Affricates are normally presented by groups of two consonants (ts, tʃ, d , etc.), but, when necessary, ligatures are used (t͡s, t͡ʃ, d͡ʒ, etc.), or the marks ‿ or ‿ (f‿s or t‿s, etc.). ‿ ‿ also denote synchronic articulation (m‿ŋ = simultaneous m and ŋ). c, ɟ may occasionally be used in place of tʃ, dʒ, and ʦ, ʣ for ts, dz. Aspirated plosives: ph, th, etc. r-coloured vowels: eɹ, aɹ, ɔɹ, etc., or $e^{ɹ}$, $a^{ɹ}$, $o^{ɹ}$, etc., or ɐ̯, ä̯, ɒ̯, etc.; r-coloured ə: əɹ or $ə^{ɹ}$ or ɹ or ə̯ or ɚ.
Length, stress, pitch—: (full length). ˑ (half length). ˈ (stress, placed at beginning of the stressed syllable). ˌ (secondary stress). ˉ (high level pitch); ˍ (low level); ˊ (high rising); ˏ (low rising); ˋ (high falling); ˎ (low falling); ˆ (rise-fall); ˇ (fall-rise).
Modifiers— ˜ nasality. ˭ breath (l̥ = breathed l). ˬ voice (s̬ = z). ʻ slight aspiration following p, t, etc. ˷ labialization (n̪ = labialized n). ̪ dental articulation (t̪ = dental t). ʲ palatalization (ż = ʐ). ̣ specially close vowel (ę = a very close e). ̩ specially open vowel (ę = a rather open e). ̟ tongue raised (e̟ or ę̟ = ę). ̠ tongue lowered (e̠ or ę̠ = ę). ˖ tongue advanced (u˖ or ʉ̟ = an advanced u, t̠ = t̪). - or ̈ tongue retracted (i- or =i̠, t̠ = alveolar t). ˃ lips more rounded. ˂ lips more spread. Central vowels: ï (= i), ü (= ʉ), ë (= ə̟), ö (= ɵ), ë, ɜ̈.
̩ (e.g. n̩) syllabic consonant. ̯ consonantal vowel. ʃ˕ variety of ʃ resembling s, etc.

A related problem is that of the temporal structure of speech production. There may be very little structure, and a speaker may simply time the movements of his vocal organs by allowing each gesture to run its course before starting on the next one. Alternatively, he may impose a hierarchical structure on the gestures by requiring, for instance, each major stress in a sentence to occur at some predetermined moment, and the articulatory movements to be speeded up or slowed down depending on the number of movements that have to occur before the major stress. There is some evidence in favour of this latter possibility as a result of experiments in which a speaker is asked to say a given phrase first slowly and then fast. When he is speaking at a rate that is twice as fast as some other rate, then the interval between the major stresses is about halved. But the duration of each segment is not halved. The consonants are only slightly reduced in length, whereas the vowels are considerably shortened. Some authorities have used the results of experiments of this kind to argue that the stress group is the major unit in the temporal organization of speech.

HISTORY OF PHONETICS

The earliest phoneticians were the Indian grammarians who wanted to preserve what they thought to be the correct pronunciation of Sanskrit. Their motives were religious, in that it was very important to them that their holy works should be pronounced in the traditional way. The works of Pāṇini, a Sanskrit scholar who lived about 2,300 years ago, are still highly regarded by grammarians.

None of the classical civilizations of the Mediterranean basin produced any phonetic descriptions of comparable importance, but it must be remembered that the Greeks were primarily responsible for the greatest phonetic invention of all time—the development of a writing system in which syllables are represented in terms of their component parts. All other writing systems suffer either from ambiguity in that many different syllables have to be written in the same way, or from requiring a very large number of different symbols. The realization that each vowel and each consonant could be represented by a separate symbol made it possible to write down any word that was said with a small inventory of symbols.

In Renaissance times, Leonardo da Vinci made numerous observations on the physiology of speech. Apart from a few individual pieces of work that did not have much influence on the development of phonetic knowledge, however, there were no systematic descriptions of speech until the 17th century. Then grammarians such as John Wallis (1616–1703) included lengthy sections on speech in their work, and several publications by teachers of pronunciation and spelling reformers show that the method of production of most speech sounds was becoming generally understood.

It was not until the rise of linguistic science in the 19th century that the forerunners of modern phonetics can be clearly discerned. Following the earlier work of Sir Isaac Pitman and Alexander J. Ellis, Alexander Melville Bell published *Visible Speech* in 1867. This book proved to be a milestone in the history of phonetics, in that it provided a greatly improved set of categories for describing the sounds of any language. By using a very detailed notational system, Bell and his co-workers, including his son, Alexander Graham Bell, the inventor of the telephone, were able to write down small variations in speech sounds with an accuracy previously impossible.

The emergence of phonetics as an independent field can be said to date from this time. The German scholar Eduard Sievers published his book on the physiology of speech sounds in 1876, and the *Handbook of Phonetics*, by the great English phonetician Henry Sweet, appeared in the following year. Scholars in many other European countries were becoming interested in describing and comparing the sounds of languages. Paul Passy in France and Otto Jespersen in Denmark joined with Bell, Sievers, and Sweet, and many others to form the International Phonetic Association in 1886.

International phonetic association

The leading phonetician during most of the first half of the 20th century was Daniel Jones, who started teaching in 1907 and retired as Professor of Phonetics at University College in London in 1949. He was president of the International Phonetic Association from 1950 until his death in 1967 at the age of 86. His numerous publications, particularly those on the pronunciation of the British accent known as RP (see above *Standards of pronunciation*), served as a model for phoneticians all over the

world. Their influence can be seen in the phonetic aspects of the work of American linguists such as Leonard Bloomfield, Bernard Bloch, Kenneth Pike, and many other leading figures in the period before the recent work of Chomsky and Halle.

The phonetic roots of Chomsky and Halle's work derive from the distinctive feature theories originated by the linguists in Prague headed by Nikolay S. Trubetskoy and Roman Jakobson. The culmination of Trubetskoy's work was his *Grundzüge der Phonologie* (1939; Eng. trans., *Principles of Phonology*, 1969), published in the year after he died. Jakobson, who emigrated to the United States in 1941, collaborated with Gunnar Fant and Morris Halle on a complete statement of the theory of distinctive features; this appeared in 1951.

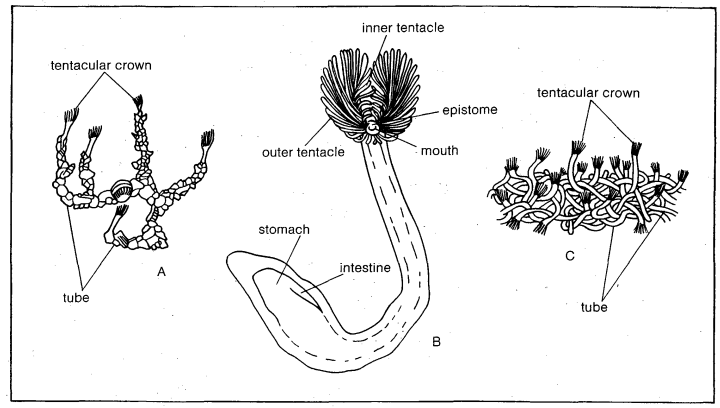
(P.N.L.)

Phoronida

Phoronids, which comprise the phylum Phoronida, are little-known marine invertebrate animals characterized by an elongated, nonsegmented body that is topped by a tuft of tentacles. Each adult lives within a membranous tube to which sand particles, shells, and other materials may adhere. A few species penetrate calcareous shells and rocks; most phoronids, however, burrow in sand or mud. The animal extends its tentacles beyond the tube to feed and breathe; when disturbed, however, a phoronid quickly retreats into its tube. The sedentary (*i.e.*, permanently attached to some surface) adults lead quiet lives, feeding, growing, and reproducing. An adult lives several years, each year producing young that may number thousands. The free-swimming young, called actinotrochs, live several weeks as members of the oceanic plankton before changing to young adults.

Although most phoronids are found intertidally or in shallow ocean regions in temperate zones, their habitats also include tropical regions and ocean depths. In general, phoronids are not common; certain species, however, may carpet the bottoms of shallow bays. Phoronids are of little practical value to man, but their unusual life cycle and obscure ancestry have made them objects of biological interest. Since their discovery in 1846, phoronids have been associated with every animal phylum, and despite continued investigations, the phylogeny of phoronids is not yet known with certainty.



Natural history. A phoronid may be male, female, or contain the reproductive organs of both sexes. The gonads are simple, and paired excretory funnels double as ducts (called gonoducts) for releasing eggs or sperm. The eggs, fertilized within the phoronid, usually pass directly into seawater and develop there as members of the plankton; in a few cases, early embryos are protected within the tentacles of the parent, and only the advanced stages are planktonic.

The actinotroch larva has a straight digestive tract and excretory tubules called protonephridia. Adults have three body regions, each of which contains a body cavity called a coelom. The body wall of the larval trunk pushes inward during development; during metamorphosis of a larva to an adult, this invagination turns outward, forming the body wall of the adult trunk and simultaneously drawing out the digestive tract to establish the U shape of the adult gut. Metamorphosis, which lasts only a few minutes, changes the actinotroch larva from an organism adapted for a planktonic environment into a sessile adult, specialized for a habitat at the bottom of the ocean.

Asexual reproduction is known for one species. All phoronids undergo autotomy, however, during which the lophophoral region, containing tentacles, mouth, anus, excretory organs, and nervous tissue, is pinched off. Autotomy occurs when conditions are unfavourable; after suitable conditions again are present, the phoronid regenerates the lost parts.

Phoronids have formed few symbiotic associations; one species is known to live with an anemone, and a ciliated protozoan lives on another species. Although phoronids have few predators, fish may nibble at the tentacles of individuals that fail to retract quickly within their tube.

The structure of phoronids.
(A) *Phoronis psammophila* with tubes coated with rock grains and shells. (B) Young adult, *Phoronis architecta*. (C) Aggregation of *P. hippocrepia*.

Form and function. The adult body can be divided into three regions. The trunk extends almost the length of the animal (from 0.5 to 25 centimetres). A small distal region called the lophophore includes a ring of tentacles; lophophores vary in shape from an indented circle to an elaborate double spiral. The third region is a very small liplike epistome that overhangs the mouth. Each body region contains a coelom. The coelom of the lophophore extends into each tentacle and is continuous with the small coelomic channels of the epistome. The large trunk coelom is subdivided by mesenteries that support the digestive tract, blood vessels, excretory organs, and gonads.

The adult digestive tract is U shaped; as a result, the mouth is next to the anus. The tentacles encircle the mouth (but not the anus), and their cilia create water currents that bring diatoms and other planktonic food close to the mouth. Trapped in mucus, organisms are ingested, pass through the esophagus, and are broken down in the stomach. Nutrients are distributed to all organs by the circulatory and coelomic fluids. Indigestible wastes are eliminated through the anus. The closed circulatory system consists of arteries, veins, and capillary networks for respiratory exchange and nutrient transfer. Hemoglobin in nucleated red blood cells serves as a respiratory pigment. The nervous system is simple.

Evolution and classification. The relationship of phoronids to other animals is controversial. They have not been preserved in the geological record, although fossil tubes (called *Scolithus*) may belong to phoronids. Embryological stages often are useful in relating animal groups, but the actinotroch larva of phoronids is unique. On the basis of adult body form, especially similar body regions, the phoronids are grouped near the colonial bryozoans and the shell-bearing brachiopods. The sixteen species in the phylum Phoronida are very similar in body form; only two genera, *Phoronis* and *Phoronopsis* (and no higher groups), are recognized.

Phosphate Minerals

The phosphate minerals are those containing phosphorus, a reactive element that combines readily with oxygen. In the course of this oxidation, phosphorus becomes a positively charged atom (an ion) surrounded by and bonded to four oxygen ions that are arranged as a tetrahedron. This arrangement is called the orthophosphate ion, or more simply the phosphate ion; it is the basic building block of all phosphate minerals.

Importance of the phosphate minerals

There are more than 200 reported species of phosphate minerals, but most are rare; and some are of questionable validity. By far the most widely distributed and commercially important phosphate minerals are those of the apatite group, principally the fluoride bearing species, fluorapatite. This mineral is ubiquitous as an accessory mineral in all rock types of all geological ages. Sedimentary rocks composed principally of fluorapatite are termed phosphorites or phosphate rock.

Phosphate rock is a raw material for many industrial and agricultural products. Commonly, it is reacted with acid to yield a superphosphate, a soluble component for inorganic fertilizers. Various forms of phosphorus compounds are used extensively in detergents, plasticizers, insecticides, and in water treatment. The world reserve of phosphate rock is ample for more than 1,000 years at present rates of consumption. Major deposits are in the northwestern and southeastern United States, North Africa, and Europe.

Monazite is the second most important phosphate mineral, because of its content of rare earth oxides. These comprise a group of elements of similar chemical properties that are used as additives in glass, alloys, and solid state devices. Monazite is associated with zircon and titanium minerals in placer concentrates (alluvial deposits) derived from igneous (crystalline) rocks. There are extensive monazite deposits in the southeastern United States, Australia, India, Brazil, and Africa.

Ornamental varieties and crystal localities

Turquoise is a secondary mineral that generally occurs as cryptocrystalline-massive aggregates—*i.e.*, the individual crystals are too small to be seen. Variegated turquoise green has been valued since antiquity as a gemstone. The best specimens have for centuries come from the ʿAlī Mīrzā Kūh, near Neyshābūr, Iran, but good materials have been obtained from the Sinai Peninsula. In the United States there are several turquoise localities in Arizona, New Mexico, Nevada, and Colorado.

Gemlike crystals of yellow-green fluorapatite from the open-pit iron mines of Cerro Mercado, Durango, Mexico, are so readily available that they are used in mineral sets that represent Mohs scale of hardness (ranging from talc [1] to diamond [10]; apatite is [5]). Beautiful faceted stones are cut from this material, but the lack of hardness limits their value. Pegmatites of New England, especially Mt. Apatite at Auburn, Maine, are famous for their coloured apatite crystals. Southern California pegmatites (very coarse-grained igneous-like rocks) have yielded fine specimens, but they are rare. Marble in Sussex County, New Jersey, and Grenville marble in Ottawa County, Quebec, and in Haliburton County, Ontario, have yielded good specimens, some very large.

Deposits with enormous crystals of apatite occur in Kola Peninsula, Soviet Union. Fine, clear crystals are found in veins at Saint Gotthard, Switzerland; deposits also occur in Europe, South America, and Asia.

This article treats the physical and chemical properties of the principal phosphate minerals and their occurrence in nature in terms of environmental conditions of formation. For further information on the relation of phosphate minerals to other mineral groups, see MINERALS. See also CRYSTALLOGRAPHY, for general coverage of structural arrangements and symmetry elements of crystals, and the articles PHOSPHORITES and GEMSTONES, for additional information on economic deposits of phosphate minerals and ornamental varieties, respectively.

DESCRIPTIVE MINERALOGY

The phosphate tetrahedron has a net negative charge of three, and this can be supplemented by additional negative charges from hydroxyls (OH—) or halogens (*i.e.*, fluoride, chloride, bromide, and iodide). Cations (positively charged ions) then balance these charges. A simple classification of phosphate minerals consists of subdivision into the anhydrous group; the hydrous group with hydroxyls or halogens; and the hydrous group with hydroxyls or halogens and water.

Anhydrous phosphate minerals. *Xenotime.* Xenotime is an yttrium phosphate (YPO_4) that occurs as an accessory mineral in igneous rocks and pegmatites. The mineral generally is found as small, brown, tetragonal crystals —those referable to three mutually perpendicular crystallographic axes, two of which are of equal length and the third shorter or longer—which are similar in form, structure, and properties to zircon. Although it can be confused with zircon, it has inferior hardness and perfect cleavage (*i.e.*, a tendency to split along crystallographic planes) perpendicular to one of the two equal axes of the tetragonal system. Xenotime provides the simplest example of balancing of the phosphate anion group (with a negative charge of three) by a trivalent cation with both the phosphorus and the yttrium in fourfold coordination —*i.e.*, bound to four oxygens (see CHEMICAL BONDING).

Berlinite. Berlinite is a rare aluminum phosphate ($AlPO_4$) mineral that has been found at a single locality in Sweden. The mineral resembles quartz in its form, structure, and properties.

Monazite. Monazite [$(Ce,La)PO_4$] is an accessory mineral in igneous and metamorphic rocks and pegmatites. The crystals are monoclinic (*i.e.*, referable to three unequal crystallographic axes, two intersecting obliquely and the third perpendicular to both of them), generally small, and euhedral (perfectly formed). They have a flattened tabular form with angular terminations. Although the cerium–lanthanum ratio of the mineral ordinarily is about 1:1, most monazite contains thorium that substitutes for the rare earths and causes metamictization (alterations caused by radioactive emanations) of the structure. Because of the range of composition and metamictization, the physical properties show considerable variation. Colour is tan to brown, and hardness on the Mohs scale ranges from 5 to 5.5. The cerium–lanthanum phosphate has a density of about 4.6, but thorium substitution results in increased density, to 5.4. The mineral can be distinguished from sphene by its optical characteristics, and from zircon and xenotime on the basis of external form.

Berlinite, xenotime, and monazite are referred to different crystal systems, thus illustrating the crystallographic changes that result from increased ionic radii of the cation.

Whitlockite. Whitlockite [$Ca_3(PO_4)_2$] is a rare phosphate mineral found in the Palermo pegmatite, New Hampshire, and also in some phosphorite rock and cave deposits. It is the simplest mineral in which the charge of the phosphate anion is satisfied by divalent cations (in this case by three calcium ions). The crystals are hexagonal (referable to three equal crystallographic axes that intersect at 120°, in a plane perpendicular to a fourth axis of different length), clear or white, and are optically distinguishable from apatite, an important phosphate mineral discussed later (see below *Apatite series*).

Triphylite and lithiophilite. Triphylite ($LiFePO_4$) is one end member of a solid solution series (a single crystalline phase that varies in chemical composition within finite limits—between end members) in which lithium and ferrous iron combine with the phosphate anion. Lithiophilite ($LiMnPO_4$) is the other end member, manganese replacing the iron. Physical properties vary with composition, but hardness typically is 4.5, and density is about 3.3. Colour ranges from bluish-green for the ferrous member to yellow-brown for the manganese member. The solubility of the minerals in acid and its fusibility are distinctive tests. Triphylite and lithiophilite are orthorhombic (referable to three mutually perpendicular crystallographic axes of unequal length) and have a structure similar to that of olivine, an iron–magnesium silicate. Thus, the phosphorus has tetrahedral (fourfold) coordination, and both the lithium and iron or

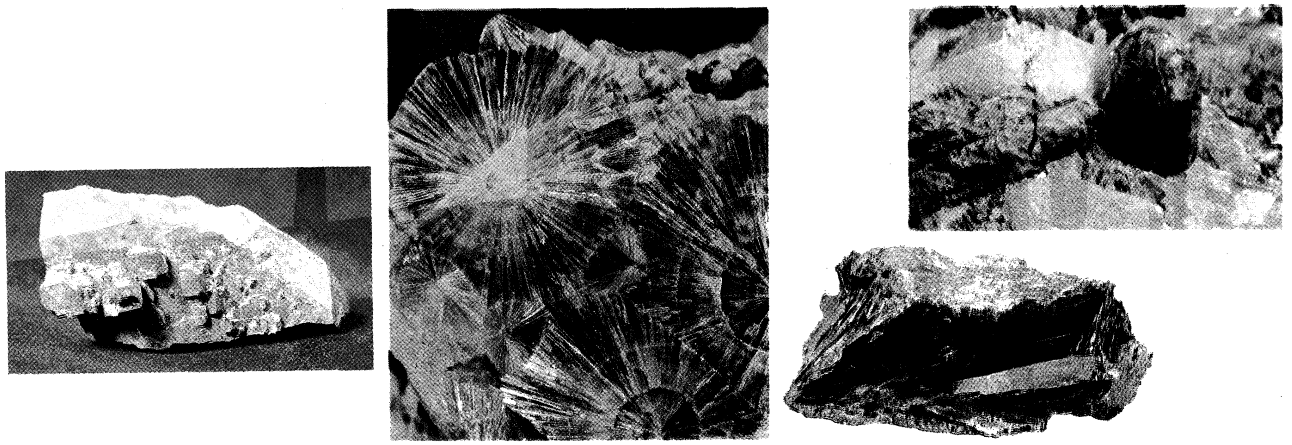

Figure 1: (Left) Monazite from Elk Mountain, New Mexico. (Centre) Wavellite from Buckville, Arkansas. (Top right) Fluorapatite on limestone from Renfrew, Ontario, Canada. (Bottom right) Vivianite from Wannon River, Victoria, Australia.

Gerard, (top right) Mary A. Root, (bottom right) Emil Javorsky

manganese atoms are surrounded by six oxygens, which is octahedral coordination.

Triphylite and lithiophilite occur in pegmatites and are commonly distinctive because of a dark altered surface or zone. Most material is massive, and rare crystals lack distinct faces.

Apatite minerals and their structure

Phosphate minerals containing hydroxyl or halogens. *Apatite series.* Apatite is the name for a mineral series that is subdivided with each name indicating the major halogen or hydroxyl; the general formula is $Ca_{10}(PO_4)_6(OH,F,Cl)_2$. Thus, there is fluorapatite (containing fluoride), chlorapatite (containing chloride), and hydroxylapatite (containing hydroxyl). The mineral exhibits toleration of extensive substitutions for phosphate and for calcium. Some of these chemical variants have mineral species names. Besides the chemical variants of the calcium phosphate apatites, numerous compounds can be synthesized that exhibit a structure identical or closely related to that of apatite. The name collophane is sometimes given to the massive, seemingly noncrystalline apatite that is the principal constituent of phosphate rock.

Most good crystals of apatite are fluorapatite, which occurs disseminated in igneous and metamorphic rocks and in ore deposits. Crystals are euhedral hexagonal prisms that generally range from clear to various hues of yellow and green; crystals of all colours occur in nature, however. The mineral serves as the reference material for the hardness of 5 on Mohs scale. It has a density of 3.2 and is distinguished from beryl and quartz on this basis and by reason of its hexagonal form and inferior hardness.

The apatite structure (Figure 2) is basically a hexagonal column with six calcium ions lying at each corner of the hexagon in a plane. Each of these calcium ions is surrounded by eight oxygens. At the centre of the hexagonal column lies the fluoride ion that is surrounded by three calcium ions, in a plane parallel to that containing the six calcium, but at a different level in the structure. Two phosphorus ions lie off each join or connection of two of the calciums of the hexagonal ring. Each phosphorus ion shares oxygens with calcium of both the sixfold ring and the threefold group. Thus, the structure appears as a framework with hexagonal form and a central cavity; this cavity is blocked twice in a repeat (unit) distance by centrally located fluoride that is strongly bonded to three calcium ions, however. The great stability of this structure is shown by the lack of polymorphic transitions (changes to other forms) with heating and by a melting point in excess of 1,600° C (2,900° F).

Good crystals of hydroxylapatite are extremely rare. They occur in three known localities in talc schists (foliated metamorphic rocks) or serpentine rocks. Their rarity indicates that crystallizing apatite is a scavenger for minute quantities of fluoride in the system—which is why fluorapatite predominates in nature.

Hydroxylapatite is similar to fluorapatite in properties and structure. Structural changes involve only the substi-

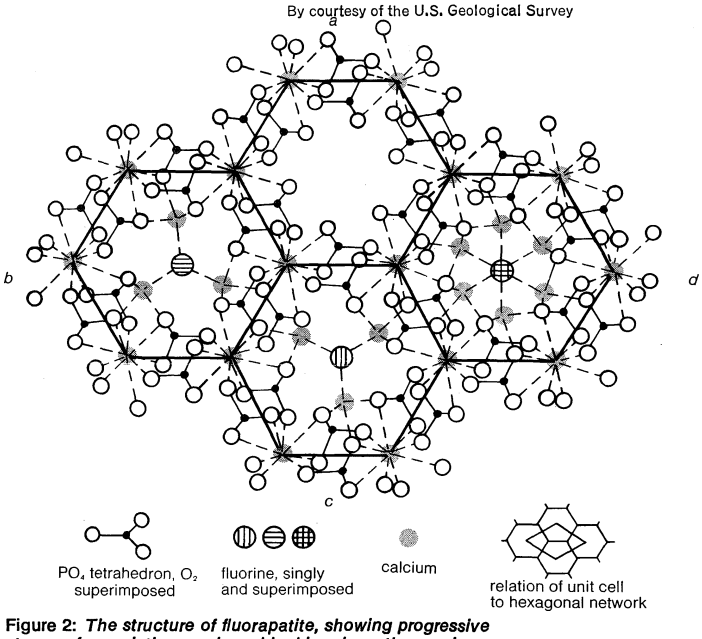

Figure 2: *The structure of fluorapatite, showing progressive stages of completion as viewed looking down the c axis.* (*a*) Incomplete structure, showing hexagonal framework and unoccupied channels; (*b, c*) addition of the two planar groups of three channel-calcium atoms and one fluoride atom, each at a different vertical height in the structure; and (*d*) complete structure.

tution of hydroxyl for fluoride. Either the fluoride or the oxygen of the hydroxyl lies in the plane containing the three calciums; the hydrogen of the hydroxyl lies on an axis normal (perpendicular) to the plane, however. Thus, with the central axis of the hexagonal structure vertically oriented, the hydrogen is either above or below the oxygen. In an ideal crystal all of the hydrogens of the hydroxyl would tend to point either down or up. In real crystals it is likely that the column containing the hydroxyls has domains such that for part of the column the hydroxyls are oriented down and for other parts the direction is up. Such directional orientation destroys the centre of symmetry and imparts to the crystal the property of piezoelectricity (the ability to develop electric surface charges when subjected to stress).

Hydroxylapatite and chlorapatite

Chlorapatite is rare. It is reported from some meteorites, and it occurs in gabbro (igneous rocks rich in iron and magnesium) and related rocks in southeastern Nor-

way. The density of chlorapatite is about 3.2, and the structure is similar to that of other apatites but differs in the position of the halogen. Because the chloride ion is 1.8 Å (one angstrom unit [Å] equals 10^{-8} centimetre) in size, it lies between two of the triangular calcium planes and not within the plane, as does the fluoride ion. Thus, chloride is surrounded by six calciums compared to three for fluoride.

Most apatite from igneous and metamorphic rocks is fluorapatite; that is, it contains approximately two fluorides per unit cell. A complete series between fluorapatite and hydroxylapatite is possible, however, and can be synthesized in the laboratory. Intermediate members of the series are rare in nature.

Chlorapatite is not structurally similar to either fluorapatite or hydroxylapatite because chloride occupies a different site. Natural crystals are known that contain appreciable fluoride and chloride. Furthermore, these crystals have physical properties that fall between those of fluorapatite and chlorapatite. This indicates either that (1) the fluorapatite structure can accommodate appreciable chloride substitution, even though complete substitution is impossible, (2) that the crystals are disordered (irregularity of arrangement involving some randomness in site filling), or (3) there are domains or layers that alternate from the fluorapatite to the chlorapatite structure.

Trace elements in apatite

Apatite is a receptive host for trace elements—*i.e.*, elements present in very minor amounts; and it accommodates extensive substitution in both the cation and anion site. Apatite is especially receptive to substitution of divalent cations larger than calcium; for example, strontium and barium. Apatite is less tolerant for divalent ions smaller than calcium, such as magnesium, which inhibits the formation of apatite. Although the apatite structure tolerates some substitution of manganese, cadmium, and other base metals, concentration is generally small because of their low natural abundance. Apatite contains, at trace element levels, arsenic and vanadium as the arsenate and vanadate ions substituting for phosphate.

Some substitutions in apatite involve a concomitant exchange of several different ions in order to maintain a charge balance. Sodium and sulfate, for example, may substitute for calcium and phosphate with no change in net charge. Likewise, sulfate and silicate may exchange for two phosphates with no change in net charge.

The carbonate problem

Many crystals of apatite show some effervescence of carbon dioxide when dissolved in acid. A number of hypotheses have been advanced to account for this carbon dioxide; basically, they fall into two groups. One postulate is that the carbon dioxide occurs in the structure, and the other is that it occurs adsorbed or absorbed on the crystal surfaces or is present as a calcium carbonate phase. Both hypotheses have supporting data, and these have been obtained primarily on different materials. Carbonate-apatite formed under metamorphic or hydrothermal conditions is well crystallized and of sufficient size to be amenable to detailed optical and X-ray examination. The crystal size makes untenable any model involving large surface areas. Carbonate-apatite formed at low temperatures, however, is poorly crystallized and of minute size, yielding a large surface area. For this material, models involving surface sorption or a poorly crystallized, admixed, second phase are plausible.

The carbonate ion is a plane of three oxygens with a central carbon and a net charge of minus two. There is no identical arrangement in the apatite structure. An early hypothesis was that the carbonate group replaces and therefore excludes halogen. This was questioned because of the inadequate size of the site for the carbonate group and because analyses showed more than enough halogens to fill the halogen sites. Polarized infrared studies of material, prepared by a high-temperature treatment of chlorapatite under a pressure of one atmosphere of carbon dioxide, lend credence to this substitution.

The three oxygens of the carbonate group are identical in form to the three oxygens found on any face of a phosphate tetrahedron. It has been proposed that a carbonate group replaces a phosphate tetrahedron, yielding a vacancy that formerly was occupied by the fourth oxygen of the tetrahedron. This vacancy may be filled with a fluoride ion, a substitution that maintains charge neutrality and can account for the excess fluoride shown in some analyses. Or the vacancy may persist, and the charge difference of a carbonate may be balanced by sodium substituting for calcium, a coupled substitution. The basic premise that carbonate substitutes for phosphate is supported by many chemical analyses of natural carbonate-apatite, which show an inverse relationship of phosphate and carbonate content (see further CARBONATE MINERALS).

Water content

Analyses of apatite that formed at low temperatures show as much as four times the amount of water that can be assigned to the hydroxyl site. As with carbonate, some water may be sorbed and thus related to the large surface areas. Other crystals of moderate size contain excess water, however, indicating that sorption is not the only process involved.

It has been proposed that water is incorporated in the apatite structure in three sites. First, water as the hydronium ion (H_3O^+) may substitute for calcium. It is further postulated that the hydronium ion, after incorporation in the structure, may lose a water molecule, leaving behind a hydrogen ion, or proton, in a calcium site. Second, water may be incorporated in the structure as a tetrahedral form of four hydroxyls ($H_4O_4^{4-}$). The $H_4O_4^{4-}$ tetrahedron can be charge compensated by a concomitant carbonate substitution; it is efficient for the incorporation of water in the structure; and it can fill phosphate sites in phosphorus deficient apatites. Third, it is postulated that water displaces a hydroxyl. This complete displacement could yield an apatite containing 3.6 percent water, but it would require a charge compensation. The HPO_4^{2-} ion may substitute in apatite, but this ion is inefficient for the incorporation of much water in the apatite structure. It is likely that water is incorporated in apatite by a combination of the methods described and that no single model can account for all of the apatites with excess water.

Pyromorphite. Pyromorphite [$Pb_{10}(PO_4)_6Cl_2$] is a member of a phosphate group containing an arsenate and vanadate equivalent, mimetite and vanadinite, respectively. All are closely related to chlorapatite, although some are monoclinic, as is a polymorph of chlorapatite. Pyromorphite is olive-green, yellow, or gray; and it has a hardness of 3.5 to 4 and a density of 7. Crystals appear as hexagonal prisms, commonly tapered. The mineral occurs in the oxidized zone of lead ore deposits.

Amblygonite. Amblygonite [$(Li,Na)Al(PO_4)(F,OH)$] is triclinic (referable to three inclined crystallographic axes of differing lengths), and it occurs as equant to short prismatic crystals. The colour is white to creamy white, the hardness 5.5 to 6, and the density is 3.11. It fuses easily and is soluble in acid with difficulty. Amblygonite occurs in granitic pegmatite and can be mistaken for albite, a sodium-rich feldspar mineral.

Lazulite. Lazulite [$(Mg,Fe)Al_2(PO_4)_2(OH)_2$] means blue stone, and this colour is its most distinctive feature. It is monoclinic, has a hardness of 5.5 to 6, and a density of 3.08. Lazulite occurs in granitic pegmatites and aluminum and silica-rich metamorphic rocks.

Phosphate minerals containing water. *Brushite.* Brushite is very similar to gypsum ($CaSO_4 \cdot 2H_2O$) in form, structure, and physical properties, but in its composition HPO_4^{2-} replaces SO_4^{2-} of the gypsum, thus yielding the formula $CaHPO_4 \cdot 2H_2O$. Precipitated gypsum has a long prismatic or needlelike form, and usually the crystals are twinned. Brushite has a blocky prismatic form, and twinning, the intergrowth of two or more grains of the same crystalline phase according to some crystallographic pattern, is much rarer than in gypsum.

At low temperature, brushite loses both water molecules and forms monetite ($CaHPO_4$). Both monetite and brushite are rare minerals, found in phosphorites formed from guano, and are the only phosphate minerals containing principally the HPO_4^{2-} ion, even though this ion is the most abundant phosphate ion in natural aqueous solutions.

*Acid igneous rocks are those rich in silica and basic igneous rocks are those rich in iron and magnesium. †The term grade in metamorphism refers to the extent or degree of alterations of a rock from its original state. ‡Authigenic minerals in sedimentary rocks are those formed in place, during the transformation of sediments to rock; this is in contrast to detrital minerals, which are transported grains of pre-existing rocks.

Vivianite. Vivianite [$Fe_3(PO_4)_2 \cdot 8H_2O$] is monoclinic, with phosphate tetrahedrons linked with ferrous iron in octahedral coordination. This linking yields a sheet structure having a perfect cleavage in one direction; it is rare to find crystals or massive material lacking this cleavage. Vivianite, colourless when first mined, darkens rapidly to a very deep blue, or purple; it has a hardness of 1.5 to 2, a density of 2.7, and occurs as bladelike crystals.

Vivianite occurs in gossans (hydrated iron oxide deposits that usually form above iron sulfide veins or ore bodies) or from the weathering of primary phosphate minerals of pegmatites. It is present in fossil teeth, bones, and in phosphatic shells or hard parts of organisms, to which it imparts a blue colour.

Phosphate minerals containing water and hydroxyl. *Wavellite.* Wavellite is an aluminum phosphate containing water and hydroxyl, and it has the formula $Al_3(PO_4)_2(OH)_3 \cdot 5H_2O$. It is a secondary mineral found in near surface deposits of alumina-rich rocks. The mineral commonly occurs as concretions, starlike forms, and masses that radiate out from a common centre; it is associated with limonite, an iron oxide. Wavellite has a hardness of 3.25 to 4, a density of 2.37, and crystallizes in the orthorhombic system. Wavellite tolerates limited substitution of ferric iron for aluminum, and this results in a colour range from yellowish-tan to light green.

Turquoise. Turquoise is a copper and aluminum phosphate containing water and hydroxyl with the formula $CuAl_6(PO_4)_4(OH)_8 \cdot 4H_2O$. It is a secondary mineral prized as a semiprecious material for polishing and carvings. Most turquoise occurs as cryptocrystalline-massive nodules or vein fillings; crystals are extremely rare. The mineral is triclinic (referable to three inclined crystallographic axes of unequal lengths) and is distinctive by reason of its green hue and waxy lustre. Turquoise is commonly associated with limonite, chalcedony, and kaolinite (a clay mineral). Bone turquoise is a name incorrectly applied to fossil teeth and bone coloured with vivianite.

Copper and uranium phosphates

Autunite. Autunite is a secondary uranium phosphate mineral with the formula $Ca(UO_2)_2(PO_4)_2 \cdot 10\text{–}12H_2O$. It crystallizes in the tetragonal system, and specimens appear tabular, foliated, and even micaceous (in tablets, thin plates, and sheets). The mineral is distinctive by reason of its form, bright yellow to green-yellow colour, and strong fluorescence. Autunite readily loses water and inverts to metaautunite, a compound with two to six water molecules in its formula.

OCCURRENCE OF PHOSPHATE MINERALS

Phosphorus ranks tenth in abundance of elements in the crust of the Earth, but its absolute abundance is only about 0.1 percent by weight of all crustal material. Calcium is 32 times more abundant than phosphorus, and calcium phosphates are therefore likely to form. Sodium, magnesium, and aluminum also are abundant elements, but phosphate compounds of these elements are limited because of their high solubility and small range of thermal stability. Phosphate compounds of lithium, yttrium, cerium, lanthanum, copper, and uranium are rare because of the low natural abundance of these cations. The occurrence of phosphate, therefore, can be related principally to environmental temperatures in nature and to those rocks the formation of which involved enrichment of rare elements (see the Table).

Natural environments. *Calcium phosphates.* Fluorapatite is ubiquitous in terrestrial rocks. It is stable under conditions of elevated temperatures and pressures, and it can be synthesized at any temperature below its melting point (1,600° C, or 2,900° F). The wide distribution results from the abundance of calcium in most environments. Fluoride is present in small concentrations, but the crustal average of fluoride is about three times that necessary to combine with phosphorus to yield fluorapatite. Fluorapatite forming in seawater appears an enigma because of the low concentration of fluoride compared to the abundance of water. It is hydroxyl, not water, that competes with fluoride in the apatite structure, however, and the hydroxyl activity (a thermodynamic measure of concentration) occurring in seawater is only one-tenth to one-hundredth of the fluoride activity.

Derivation of fluoride

Hydroxylapatite occurs only in talc schists and a serpentinite. The mineral is absent in igneous rocks, even though it is thermally stable to high temperatures. It is possible that hydroxylapatite results from basic solutions active during metamorphism of the rocks. A carbonate-bearing hydroxylapatite is the mineral constituent of bone and teeth, and with fossilization such material becomes enriched in fluoride, forming a fluorcarbonate apatite. This exchange is so slow that more than a century ago it was proposed as a crude age-dating method. Although unsatisfactory for such purposes it does demonstrate that hydroxylapatite can scavenge fluoride from dilute solutions.

Chlorapatite is very rare and is limited to gabbroic rocks and meteorites. Chlorapatite is absent in marine phosphorites, even though the chloride concentration of sea-

water is thousands of times that of fluoride. Similarly, chlorapatite can be synthesized at high temperatures, but it cannot be synthesized from an aqueous solution at low temperatures. Because the halogen or hydroxyl of apatite is bound to calcium, an explanation may lie in the relative solubilities of calcium fluoride, hydroxide, and chloride in aqueous solutions. Pyromorphite, being a lead chloride apatite, indicates a high chloride environment during its formation as an alteration product of galena (lead sulfide).

Whitlockite differs chemically from apatite because it contains more phosphorus and is anhydrous. It occurs in a pegmatite with apatite, an environment in which there is little calcium. It also occurs in guano deposits in which highly phosphate-rich leachates react, under acid condition and near surface temperature, with limestone. Brushite also forms by the same process. Laboratory experiments show that the pH (a measure of the acidity of solutions ranging from 0 to 14; acid solutions have a pH of less than 7, whereas the pH of alkaline solutions is greater than 7) for brushite formation must be less than 6.5; at higher pH values, apatite forms. Monetite cannot be synthesized from simple aqueous solutions at 25° C (77° F), suggesting that its natural occurrence may be from dehydration of brushite.

Anhydrous phosphates. Xenotime, monazite, and triphylite are anhydrous phosphates, each of which contains an element with crustal abundance of only 20 to 60 parts per million. Being anhydrous, the minerals are stable at high temperatures, but they cannot form until crystallization of a magma (high-temperature silicate melt within the Earth) enriches the residual melt in these rare elements. Consequently, their occurrence is principally in acid igneous rocks and pegmatites.

Lithium requirements

Hydrous phosphates. Amblygonite and lazulite are hydrous phosphates and therefore unstable in dry magmatic systems (*i.e.*, those without water), and, in addition, amblygonite requires a system rich in lithium. Lazulite could form in a hydrous magmatic system, but there is generally sufficient calcium, which has a greater affinity for phosphate, to form apatite instead of lazulite. Thus, lazulite's formation in igneous rocks is limited by the availability of phosphorus, which is controlled by calcium, whereas amblygonite is limited in temperature and the availability of lithium. Pegmatites present an environment for both minerals. Lazulite may also form in quartz veins and calcium-poor metamorphic rocks.

Hydrous phosphates with water. Wavellite, vivianite, turquoise, and autunite are minerals that contain from four to 12 waters of crystallization (water molecules that form part of the crystal structure), and all lack stability above 200° C (390° F). Thus, they occur under near-surface conditions and commonly as an alteration product of other minerals. Wavellite has wide distribution as a secondary mineral in weathered or reworked phosphorites. Vivianite contains ferrous iron and therefore requires reducing conditions (an oxygen-free environment) for formation. Consistent with this requirement is its occurrence with peat, lignite, organic sediments, and glauconite. Autunite contains uranium and therefore is common as a weathering product of uraninite. Turquoise is formed by supergene (downward percolating) acid solutions reacting with apatite and copper sulfide ores in alumina-rich rocks.

Experimental studies. Most experimental studies of phosphate minerals have been concerned with a limited aspect of crystal chemistry or solubility. A further limitation is that most studies are on simple systems or under conditions such that the results have little application to the environments of formation.

The binary system $CaO–P_2O_5$ has been studied extensively, but the only compound to be synthesized from it having a natural mineral equivalent is whitlockite. This compound undergoes a polymorphic transition at about 1,200° C (2,200° F) to another form that may possibly be pertinent to the occurrence of whitlockite in some meteorites.

The binary systems $CaCl_2–Ca_3(PO_4)_2$ and $CaF_2–Ca_3(PO_4)_2$ were studied more than a half century ago. Fluorapatite has been shown to have a melting point in excess of 1,600° C (2,900° F), and chlorapatite is reported to melt slightly above 1,500° C (2,700° F); the polymorphism of chlorapatite was unrecognized in the early work, however.

Studies of the ternary systems $CaO–P_2O_5–H_2O$, $CaO–P_2O_5–HF$, and $CaO–P_2O_5–HCl$ or the fluoride or chloride salts of the acids are so incomplete, especially at elevated pressures, that generalizations are unjustified.

Chemical variants of apatite have received much study because of their biological and geological importance. Many crystal–chemical studies relate substitution of various ions to crystallinity and dimensional changes, length of the a_0 and c_0 lattice parameters (see Figure 3). Lattice

Chemical composition and lattice change

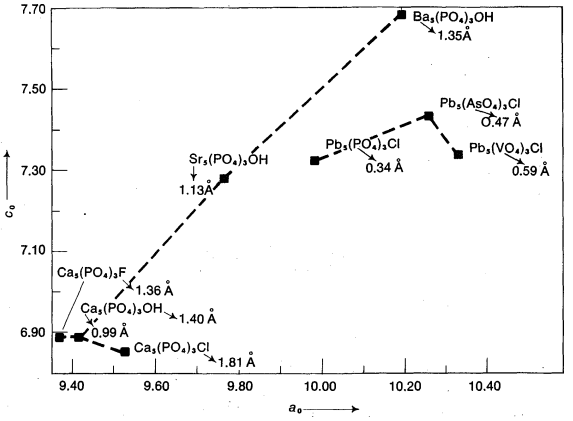

Figure 3: Relation of length of lattice parameters a_0 and c_0 in apatite and related compounds, and ionic substitution. Note that substitution of a large cation for Ca results in an equal increase of a_0 and c_0, whereas substitution in the halogen site results in an increase of a_0 and a decrease of c_0 (see text).

parameters of apatite and related compounds show that: (1) substitution of an increasingly large cation in the calcium site causes about an equal increase in a_0 and c_0; (2) substitution of a large ion in the halogen site causes an increase in the a_0 direction but a decrease in c_0; (3) and, for the pyromorphite series, increased ion size in the phosphate site yields increased a_0 and slightly increased c_0.

The many studies concerned with the solubility of apatite have produced a multitude of values because of the chemical variants of the mineral. Application of the data to natural systems is plagued by insufficient knowledge of the activity of the various species of phosphate ions in a complex solution.

The polymorphism of berlinite, $AlPO_4$, has been studied in detail because of its similarity to the silica system. Berlinite transforms at 814° C (1,500° F) to a tridymite form, with succeeding transformation at 1,025° C (1,877° F) to a cristobalite form that melts in excess of 1,600° C (2,900° F). (Tridymite and cristobalite are high temperature forms of quartz.) Of the $AlPO_4$ polymorphs, only berlinite occurs naturally.

HOWIE, and J. ZUSSMAN, *Rock-Forming Minerals*, vol. 5, *Non-Silicates* (1962), provides a description and discussion of apatite and monazite; J.R. VAN WAZER "Phosphorus and Its Compounds," *Chemistry* 1:419–556 (1958), a comprehensive review of the chemistry of phosphorus compounds with a chapter on condensed phosphates and salts of orthophosphoric acid; R.W.G. WYCKOFF, *Crystal Structures*, 2nd ed., vol. 3 (1965), includes a summary of structural data for phosphate minerals.

(D.R.S.)

Phosphorites

Phosphorus is an element that is present in about 200 minerals in amounts up to 5 percent or more. Most of the phosphorus in the earth's crust and in phosphorites, which are minable phosphate deposits, occurs in minerals of the

apatite family of calcium phosphates (see PHOSPHATE MINERALS). Although phosphorus is an essential constituent for all living organisms, it is one of the least abundant of the mineral nutrients. Its average content in soils and rocks of the earth's crust is 0.12 percent, whereas that of iron is 5 percent, of calcium 3.6 percent, of potassium 2.6 percent, and of magnesium 2.1 percent. Thus, when phosphorus is removed from the soil by crops, it must be replaced artificially by the addition of phosphate fertilizers. Phosphorus is also used widely in manufacturing industries. Nearly all of the phosphate fertilizers and phosphorus for industrial uses are obtained from naturally occurring rocks that contain high concentrations of phosphate-bearing minerals. Thus the availability of large quantities of phosphorites is of primary importance to agricultural and industrial nations.

Uses of phosphate

Seventy percent or more of all phosphate is used in most countries for agricultural purposes; most of this is made into fertilizers. The rest is used in making elemental phosphorus and phosphoric acid, which are, in turn, made into organic and inorganic chemicals used in preparing detergents, water softeners, leavening agents (for baking), plasticizers, insecticides, and many other products. Elemental phosphorus is also used in military smoke screens and incendiary bombs, phosphorus alloys, and pesticides. In addition, phosphoric acid is used for fertilizers, animal-feed supplement, beverages, photographic chemicals, dental and silicate cements, ceramics, catalysts, and an oil-refining agent. A complete list of phosphate compounds would embrace almost every manufacturing process and nearly all chemical techniques.

Principal types of phosphate deposits. Mineral deposits of phosphate are of six principal types, listed in approximate order of size and world importance: (1) marine phosphorites; (2) igneous apatite deposits; (3) residual phosphorites; (4) phosphatized rock; (5) river pebble; and (6) guano.

Marine phosphorites are blanket-like deposits that form on the sea floor as the result of organic or inorganic precipitation of carbonate-fluorapatite from seawater, generally in low latitudes in areas where cold, phosphate-rich water upwells onto the continental shelves. They are commonly associated with beds of black carbonaceous shale, chert or diatomite, sandstone, and minor amounts of limestone. The phosphatic layers consist mainly of pellets and nodules ranging from less than 0.1 to 20 millimetres or more in diameter. Fish teeth, scales, and bones, phosphatic brachiopod shells, and casts of small pelecypods and other fossils are common in many deposits. Individual layers are as much as 15 feet or more in thickness, may extend over hundreds of square miles, and contain millions or even billions of tons. Unweathered deposits, including those found on the present sea bottom, commonly do not contain more than about 30 percent phosphorus pentoxide (P_2O_5), but deposits that have been enriched by the leaching and oxidation of impurities may contain as much as 38 percent. Less phosphatic sandstones and shales are upgraded by separating the phosphatic particles from the matrix by screening, washing, or flotation. The marine phosphorites and some of the associated black shales contain many minor metals, some of which may be recoverable as by-products. Examples are vanadium, uranium, zinc, rare earths, and selenium.

Igneous apatite deposits are found as inclined sheets or irregular masses of intrusive igneous rock, veins, or replacement bodies, which are derived from the cooling and crystallization of silicate melts within the earth's crust. They are associated with other rocks of igneous origin, such as nephelite-syenite and carbonatite, and, in many places, with magnetite or ilmenite ores. The apatite masses range in size from thousands to millions of tons and may contain as much as 35 percent P_2O_5 (in the fertilizer industry the phosphate content is sometimes also reported as bone phosphate of lime [BPL] or tricalcium phosphate [TCL], both of which are equal to 2.18 times the P_2O_5 content). The richest deposits are used without beneficiation. The phosphate in some of the apatite-bearing ilmenite and magnetite ores is recovered as a by-product of the milling or smelting of the titanium or iron ore.

Residual phosphate deposits develop by decomposition of phosphatic limestones, located within humid and tropical climatic regions. These deposits, consisting of phosphate pellets and nodules left behind when the calcium carbonate of the limestone is removed by solution, lie on an irregularly weathered bedrock surface. In hilly country, residual phosphate deposits are narrow and conform to the outcrop pattern of the strata; but in valleys or flat country, the deposits are blanket-like. These deposits may be several feet or more in thickness and contain 30 to 38 percent P_2O_5. The higher grade deposits are utilized directly, but lower grade deposits must be beneficiated by washing, screening, or flotation in order to yield a salable product. Phosphate reserves in residual deposits amount to many millions of tons.

Phosphatized rocks develop in regions of tropical and subtropical climate when phosphate dissolved from phosphatic rocks or guano by percolating water is again deposited, by reprecipitation, in openings or replaces the minerals of limestone, igneous rocks, or clay that lie at a lower horizon. Where the phosphatized rocks are limestone, the deposits consist of apatite; but where the phosphatized rocks are igneous rocks or clay, the deposits are iron or aluminum phosphates such as strengite, crandallite, and wavellite. Some phosphatized rocks contain as much as 38 percent P_2O_5, and reserves in individual deposits may be scores of millions of tons.

River-pebble deposits consist of phosphate pellets and nodules weathered out of marine phosphatic limestone, located in humid climatic regions of low relief. The pellets and nodules are reconcentrated by stream action. Most river-pebble deposits do not contain sufficient phosphate to be mined profitably, but those in Florida have been mined and beneficiated cheaply enough to produce a commercial product. River-pebble deposits range from a few thousand to many millions of tons in size.

Guano deposits

Guano deposits form by the accumulation of seafowl or bat droppings. The largest deposits are found on islands in low latitudes along western margins of continents and in the zone of the equatorial countercurrent. Guano deposits generally are small; the larger contain a few tens of millions of tons at the most. Modern guano contains 10 to 12 percent P_2O_5; old leached guano contains 20 to 32 percent P_2O_5. Slightly decomposed deposits contain soluble ammonium alkali oxalates, sulfates, and nitrates and a variety of magnesium and ammonium magnesium phosphates; but decomposed guano consists largely of calcium phosphates such as monetite, brushite, and whitlockite.

Phosphate deposits in the United States. Examples of each of the principal types of phosphorites are present in the U.S. Although phosphate concentrations are known in 28 states, production has come largely from six fields: (1) land-pebble deposits of west central Florida; (2) phosphatized (hard-rock) deposits of Florida; (3) north Florida–south central Georgia; (4) North Carolina; (5) brown-rock deposits of Tennessee; and (6) marine phosphorites and phosphatic shales of Idaho, Montana, Utah, and Wyoming. Potentially important deposits occur also in Alaska, western California, and on the sea bottom off the California coast.

The land-pebble phosphates of Florida are blanket-like deposits covering about 2,600 square miles of west central Florida. They consist partly of residual pellets and nodules derived from phosphatic limestone of the Hawthorn Formation of Miocene age (7,000,000 to 26,000,000 years ago) and partly of residuum reworked and redeposited in the overlying Bone Valley Formation of Pliocene age (2,500,000 to 7,000,000 years ago). The phosphate deposits range from 1 to 50 feet thick and average 12 feet. They consist of nearly equal amounts of phosphate pellets and nodules, sand, and clay. The phosphate zone is overlain by as much as 60 feet of overburden, which is removed by large draglines before the phosphate is mined by similar methods. Phosphorite particles are beneficiated by washing, screening, and flotation methods. In areas of deep weathering, the upper part of the deposits has been leached and clay, in the matrix, has been altered to aluminum phosphate. River pebble derived from erosion of the Bone Valley deposits was once a source of substantial

production but is no longer mined. The hard-rock phosphate deposits of northwestern peninsular Florida are phosphatized limestone fragments and plates in the Alachua Formation of Pliocene age. These deposits are small, but some contain as much as 35 percent of P_2O_5. They are mined and beneficiated by the same methods as are used in the land-pebble fields.

The Tennessee brown-rock deposits, located in the southwestern part of Tennessee, are residual deposits derived from the weathering of phosphatic limestones of the Hermitage, Bigby, and Leipers formations, all of Ordovician age. The deposits conform closely to the outcrop pattern of the parent limestones on the rolling, hilly topography. The thickest phosphate deposits fill solution-enlarged joints (locally called cutters) in the phosphatic limestones. These deposits also are mined by open-pit methods and are beneficiated to produce a marketable product.

The marine phosphorites and phosphatic shales of the western field are in the Phosphoria Formation of Permian age. Phosphate rock is mined in Idaho, Wyoming, Montana, and Utah by open-pit and underground methods. Minable layers range from 3 to 20 feet in thickness and contain from 20 to 32 percent P_2O_5.

The north Florida–south central Georgia and North Carolina phosphorites are marine deposits of Miocene age, first developed during the early 1960s.

Minable reserves of phosphorites in the U.S. are about several billion tons, and reserves of lower-grade deposits are many times larger. About one-quarter of U.S. mine production is exported.

Phosphate deposits in other countries. The principal sources of phosphate rock outside the U.S. until the early 1950s were the marine phosphorites of Morocco, Tunisia, Algeria, and the U.A.R.; the igneous apatites of the Kola Peninsula, U.S.S.R.; and phosphatized rocks derived from the leaching of guanos on some islands of the Pacific and Indian oceans (particularly Ocean, Nauru, Makatea, and Christmas islands). Since then, large deposits of marine phosphorites have been discovered in Jordan, Israel, Syria, the Spanish Sahara, Senegal, Togo, Angola, Australia, Mexico, and Peru, and deposits that are or may be adequate for domestic needs occur in other countries. World reserves of phosphorites are shown in the Table.

World Reserves and Potential Resources of Phosphate Rock and Apatite

country	million long tons of P_2O_5
Morocco	21,000
U.S.	14,500
U.S.S.R.	7,600
Tunisia	2,000
Algeria	1,000
Brazil	600
Peru	450
Egypt	200
Togo	120
Spanish Sahara	100
Islands of the Pacific and Indian oceans	40
Senegal	40
Other countries	700
Total	48,350

Photius

Though he did not intend to initiate a schism with the West or with the Roman see, Photius, the patriarch of Constantinople from 858 to 867 and again from 877 to 886, became the focus of Byzantine pretensions to cultural superiority, which led to the Photian Schism. He was responsible for the first list of Latin theological deviations from the standpoint of Greek Orthodoxy. The most notable scholar among the Byzantine ecclesiastical authorities and civil servants who preserved the classics of ancient Greece—both pagan and Christian—he was also the author of a lexicon and numerous theological works.

Photius, lead seal. In the Dumbarton Oaks Research Library and Collection, Washington, D.C.

Family background and early career

Photius was related through his father to Tarasius, a civil servant who was patriarch from 784 to 806, and through his mother to the empress Theodora and her brother Bardas, who was a power behind the throne from 842 to 866. The circle to which both families belonged had strained relations with some army officers, who wished to reduce the expense of government by an educated civil service, and with monks who distrusted the worldly wisdom of bureaucrats. In controversies that had arisen over the place of pictures (icons) in Christian worship, the learned civil servants resisted the iconoclasts (the destroyers of sacred images), who had support in the army. When the icons were restored in 787, however, and again after renewed controversy in 843, the civil servants were lenient with the former iconoclasts, whereas the monks, especially the Studites of the monastery of St. John of the Stoudion would have purged them, as dangerous heretics, from all important positions.

The parents of Photius were condemned to exile by an iconoclast council, probably in 815, and took him with them. Since his birthdate is not known, it is not clear whether he was a small child or a student at the time. Early in the regency of Theodora (842–856), after his parents had died in exile, Photius became a distinguished teacher. A circle gathered round him for regular readings in classical and Christian prose literature, including medical and scientific works. On the basis of notes taken at these readings, which continued after he left the schools for the civil service, he composed his *Myriobiblon* or *Bibliotheca*, a digest of Greek prose literature, with more than 270 articles. This work was begun on a diplomatic mission in the Muslim world and most probably completed during his temporary retirement from public life after 867.

Promotion to patriarch of Constantinople

He became first secretary of state, probably before 855, and in 858 he was promoted through all the ecclesiastical orders to be made patriarch of Constantinople on Christmas Day, replacing the austere Ignatius, who had fallen out with Bardas. The deposition of Ignatius offended not only the Studites and other monks, who objected to the promotion of a civil servant, but also Pope Nicholas I, who did not understand the role of laymen educated in theology and in Byzantine civilization. Photius offended him further by refusing to restore dioceses transferred

from the Roman to the Byzantine patriarchate during the iconoclastic controversy. The importance of these dioceses had been increased by the conversion to Christianity of leading chiefs among the Slavonic nations (the Moravians, Croats, and Bulgarians); jurisdictionally they might belong to either the Roman or the Byzantine patriarchate. As conflicts developed among Roman, German, and Byzantine missions, Photius wrote a circular letter to the other Eastern patriarchs complaining of theological, liturgical, and other innovations by Latin missionaries in Bulgaria. At a council in Constantinople in 867, he condemned and excommunicated Nicholas I, who had refused to recognize him as the lawful patriarch—thus bringing about the Photian Schism—and in letters to other bishops had represented him as a persistent adversary of the West.

By this time, however, the fall of Bardas had weakened the position of Photius. When he protested against the murder of the emperor Michael III by Basil the Macedonian, he was deposed, in the autumn of 867, and Ignatius was restored. Pope Adrian II, who had just succeeded Nicholas I at Rome, now envisioned a settlement of the differences between Rome and Constantinople. The terms proposed by his legates to a council in Constantinople in 869–870, however, were unacceptable to many Byzantine ecclesiastics. Ignatius himself in 870 consecrated bishops for Bulgaria. Without help from the friends of Photius, however, he could neither reach a satisfactory settlement of tensions between East and West nor solve the internal problems of the Byzantine Orthodox Church.

Photius returned to the court before 876 as tutor to the princes of the imperial family, and at the death of Ignatius in 877 or 878 he also returned to the patriarchate. Though some of the monks resented his return, as they had objected to his first promotion, he now won support from Rome, since Pope John VIII was in need of Byzantine naval assistance against the Moors, who were harrying the Italian coastline. The Pope sent legates to a new council at the church of Hagia Sophia in Constantinople in 879–880. In the resulting settlement, Bulgaria was assigned to the Roman patriarchate, but the continued presence of Greek bishops secured its cultural links with the East. Bulgaria soon became a centre from which the Byzantine liturgy in the language of the Macedonian Slavs spread to other Slavonic-speaking lands.

Rome did not press its claims to Greek dioceses in Italy and Greece under the jurisdiction of Constantinople, and the Roman legates consented to the Byzantine demand to condemn Western additions to the Nicene Creed, without explicit mention of the contentious use of the word *filioque* (Latin: "and the Son"), whereby the Holy Spirit was said by some to proceed from the Father "and the Son." This interpolation had been introduced into the Nicene Creed in Spain and had spread among the Franks, but it was not yet in use in Rome. Photius' Latin was limited, and on the *filioque* controversy his information was inadequate, though he showed more understanding of the question in his later work on *The Mystagogia of the Holy Spirit*, completed in or after his second patriarchate.

The *filioque* controversy

The settlement between Rome and Constantinople was once thought to have been obtained by fraud and repudiated by Pope John VIII, but most likely it was accepted by the Pope. John VIII was murdered in 882, and his successor, whose position was irregular, was probably not recognized at Constantinople. Photius was in communion not only with John but also with Adrian III (884–885) and with Stephen V in 886. In that year, he resigned the patriarchate on the accession to the throne of his pupil the emperor Leo VI. The Pope suspected that the resignation of Photius had been forced upon him to make way for another pupil, Prince Stephen, but if he was over 80 years old it may well have been voluntary. He died on February 6, perhaps 891, but the year is not certain.

BIBLIOGRAPHY. FRANCIS DVORNIK, *The Photian Schism: History and Legend* (1948, reprinted 1970), supersedes the older view of the contribution of Photius to the schism between the Eastern and Western Churches that is summarized by J. RUINAUT in *Le Schisme de Photius* (1910); and by LOUIS BRÉHIER, "The Greek Church: Its Relations With the West up to 1054" and "Attempts at Reunion of the Greek and Latin Churches," vol. 4, pp. 246–273, 594–626, *The Cambridge Medieval History* (1923). Informative articles by F. DVORNIK, "Constantinople and Rome," and H. GREGOIRE, "The Amorians and Macedonians, 842–1025," appear in vol. 4, pt. 2, pp. 431–472, 105–192, *The Cambridge Medieval History*, new ed. (1966), with useful bibliographies. See CYRIL MANGO (ed. and trans.), *The Homilies of Photius* (1958). Other works of his are still most easily accessible in J.P. MIGNE (ed.), *Patrologiae Graeco-Latina*, vol. 101-104 (1860) with the *Myriobiblon* or *Bibliotheca* filling volume 103. Of the older books, J.B. BURY, *A History of the Eastern Roman Empire from the Fall of Irene to the Accession of Basil I., A.D. 802–867* (1912); and J.M. HUSSEY, *Church and Learning in the Byzantine Empire, 867–1185* (1937), especially the chapter on "Learning Under the Macedonians in the Ninth and Tenth Centuries," pp. 22–36, may still be used with profit.

Photochemical Reactions

Photochemical reactions are chemical processes initiated by the absorption of energy in the form of visible, infrared, or ultraviolet radiation. The immediate consequence of this absorption is called the primary photochemical process. Subsequent changes, called secondary processes, are part of photochemistry. The process by which a photochemical reaction is carried on is photolysis.

Photochemistry differs from most other aspects of chemistry in one regard. If an atom or molecule absorbs energy from a beam of light, it gains far more energy that it ever could by other methods; *e.g.*, from ordinary heating. Consequently, photochemical processes are sometimes extremely efficient for the conversion of energy from light into chemical energy. The most important single photochemical process for living systems, photosynthesis, is of this type: green plants convert light energy into stored chemical energy by producing carbohydrates from carbon dioxide and water. Many other natural processes are wholly or partly photochemical. Ozone in the upper atmosphere, which shuts out most of the Sun's intense ultraviolet radiation, is produced by the action of light on oxygen molecules: sunlight breaks some of the molecules into atoms, which combine with other oxygen molecules to make ozone.

Bleaching laundry in sunlight is at least partly a photochemical process, and so is the darkening of white lithopone (zinc sulfide) paint. Photography is based on a photochemical process, the action of light on grains of silver chloride or silver bromide.

GENERAL CONSIDERATIONS

Kinds of photochemical effects. The action of light on a chemical system may take various forms:

1. Light may act as a booster to maintain a reaction that might otherwise proceed at an imperceptibly slow rate, the reacting molecules exchanging little or no net energy with their environment. Some molecular rearrangements (reactions that alter the geometry of individual molecules) fall into this category.

2. Light may act as a trigger, initiating a reaction that, once started, can proceed spontaneously. An example is the initiation of the reaction between hydrogen (formula, H_2) and chlorine (Cl_2) to give hydrochloric acid (HCl). Hydrogen and chlorine can be kept mixed together for an indefinite period at room temperature in a dark container; but if violet or ultraviolet light reaches the mixture, the two substances react explosively, giving off considerable stored chemical energy as heat. The primary photochemical process in this case is the formation of two chlorine atoms from a chlorine molecule, Cl_2.

3. In some photochemical processes, absorbed light converts the reacting molecules to a new state, higher in energy than their initial state; in this case the energy of the absorbed light is converted into chemical potential energy and is stored that way. Most photochemical processes occurring in biological systems are of this type; *e.g.*, ultraviolet irradiation converts ergosterol, found in plant and animal tissues, into a biologically active substance, vitamin D.

4. A photochemical system may store light energy from the Sun as chemical energy and then, only incidentally to the photochemical process, release that energy as electrical energy. This reaction occurs in the solar battery, used to supply the power in satellites and space vehicles.

All these processes have one common characteristic: each, at some stage, requires that a large quantity of energy be available to a single reacting atom or molecule. The requirement may be a thermodynamic one; that is, that the products simply contain more stored energy than the reactants. Alternatively, the requirements may be kinetic; in this case the products may store more or less energy than the reactants, but some step along the reaction path requires a large quantity of energy to surmount a barrier, as it were. (The hydrogen–chlorine reaction has as its barrier the requirement that a chlorine–chlorine bond be broken to convert a chlorine molecule into its two constituent atoms.) In more complex molecules, the rearrangement from one shape to another exhibits an energy barrier because, between the initial and final structures, there must be a series of intermediate shapes of higher potential energy than either the initial or final shapes.

The theoretical aspects of photochemistry are derived largely from the principles of atomic and molecular physics and of quantum mechanics, while its analytical methods are mainly those of spectroscopy. The reader therefore may profitably consult the articles ATOMIC STRUCTURE; LIGHT; MOLECULAR STRUCTURE; MECHANICS, QUANTUM; and SPECTROSCOPY, PRINCIPLES OF.

The development of photochemistry. The hydrogen–chlorine reaction cited above, perhaps the first recognized photochemical reaction, was first observed about 1801 and studied in detail some 40 years later. That only the absorbed light can affect a chemical reaction was recognized early, but this qualitative idea could not be stated as a quantitative law until the development of the modern theory by Einstein. Early photochemistry was largely confined to the identification of reaction products, often resulting from the action of sunlight.

Einstein's work in light absorption

The basic process by which light is absorbed by matter was first proposed by Einstein (1905, 1912, 1916). His work was directed particularly toward the photoelectric effect, in which the primary result of the absorption of radiation by a metal is the emission of free electrons; but the interpretation is general and provides the foundation of modern photochemistry: a beam of light is a beam of photons, or quanta (energy packets), of electromagnetic radiation (see below *Photochemical quantities*). The energy of each photon is proportional to the frequency of the light and the total number of photons is proportional to the intensity of the light. The primary photochemical process then follows directly from the absorption of one photon by one atom or molecule. (Exceptions may occur if the radiation field is very intense; then the concentration of photons may be so high that some molecules absorb two photons.)

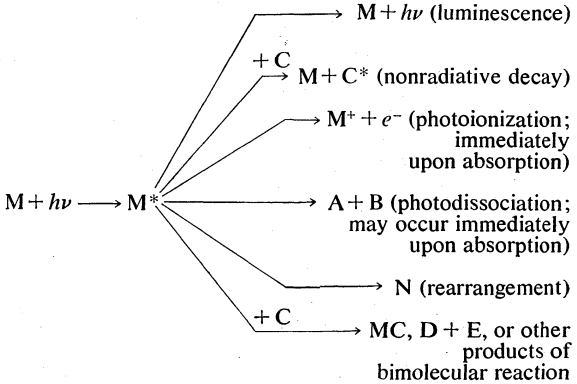
After 1910 a German physicist, Emil Warburg, began a detailed study of the formation of ozone (O_3) by the action of ultraviolet light on the normal oxygen molecule (O_2). This work represented the first measurement of the number of product molecules formed for each quantum of energy absorbed: the quantum yield of the reaction. In the next few years most of the foundations of modern photochemistry were completed.

The role of chain reactions in photoprocesses was first elucidated for the hydrogen–chlorine reaction in the period 1913–25, and photochemistry grew steadily in the next three decades. From about 1955 the field expanded rapidly as it came to be used as a tool for the synthesis of organic molecules and was extended to the study of very short wavelengths (including X-rays and gamma rays) and of chemical phenomena produced by the optical amplifier, or laser, the acronym for light amplification by stimulated emission of radiation.

THE PHOTOCHEMICAL PROCESS

Photochemical quantities. The most fundamental ideas and the basis of all quantitative interpretations in photochemistry are the quantum-mechanical principles that all energy exists in packets, called quanta, and that the quanta of electromagnetic radiation, called photons, act like particles. The energy of each photon is directly proportional to the frequency of light—a relationship that is expressed by the equation $E = h\nu$. In this equation, E is the energy in ergs, and the frequency in cycles per second is symbolized by the Greek letter nu, ν. The constant of proportionality, h, is called, after its discoverer the German physicist Max Planck, Planck's constant; it has the value 6.625×10^{-27} erg-second. (One erg equals the work required to cause a mass of one gram to accelerate at one centimetre per second per second through one centimetre.) Alternatively, since the frequency, ν, and the wavelength, symbolized by the Greek letter lambda, λ, of light are related to c, the velocity of light (3×10^{10} centimetres per second), by the equation $\nu\lambda = c$, the energy of a quantum can be related to the wavelength of the corresponding radiation rather than to its frequency. This relationship is expressed by the equation $E = hc/\lambda$. When E is expressed in ergs and λ in angstrom units, the proportionality becomes $2 \times 10^{-8}/\lambda$; when E is in electron volts per photon, however, it becomes $12{,}400/\lambda$; and when E is in kilocalories (kcal) per mole of photons it is $2.85 \times 10^{5}/\lambda$. The angstrom unit (Å) is 10^{-8} centimetre and is commonly used to designate wavelength. The electron volt (eV), 1.602×10^{-12} erg, is the usual unit for measuring energies of individual particles in atomic physics.

By means of these quantities the relationship between ordinary chemistry and photochemistry can be expressed more precisely in terms of some simple magnitudes. Green light, for example, has a wavelength of about 5000 angstroms. (The entire visible region lies between about 4000 and 7000 angstroms.) A photon of green light, consequently, has an energy of about 2.5 electron volts, or an einstein (one mole of photons) of green-light photons has an energy of 57 kilocalories. Ultraviolet light of wavelength 2500 angstroms has just twice as much energy per photon or per mole. By comparison, a weak chemical bond requires an energy of about one electron volt to be broken, while a very strong bond requires more than 10 electron volts. In contrast, however, two molecules colliding at room temperature strike each other with an energy of only about 0.05 electron volt.



Absorption of electromagnetic energy. The history of a photochemical reaction necessarily begins with the absorption of a quantum of electromagnetic energy by an atom or molecule. Initially, the absorbing molecule or atom is in a state in which its energy is relatively low.

Types of energy in absorbers

The energy contained in the absorber is essentially of four types: (1) kinetic energy of motion through space (translational energy); (2) energy of rotational motion about its centre of mass; (3) energy of vibration of the component atoms against each other if the species is a molecule; and (4) energy of the negatively charged electrons moving in the field of force produced by the other electrons and the positively charged nuclei. The energy change initiating a photochemical process virtually always involves excitation of one electron from a state of low energy to a state of higher energy. When the absorber is a molecule, changes in rotational and vibrational energy usually also occur; the translational energy of an atom or molecule is almost completely unaffected when a quantum of radiation is absorbed, except in the case of gamma radiation.

Usually, in the initial low-energy state of an absorber, the electrons are in their lowest possible state of energy; that is, their lowest quantum state. The electrons cannot absorb all incident radiation, but only those quanta with energies corresponding to the allowed quantum jumps for that particular absorber. It has been determined that a hydrogen atom in its lowest state can absorb only those quanta having energies that fit the expression $13.7\ (n^2 - 1)/n^2$ eV, in which n may equal 2, 3, . . . ; according to this condition, it cannot absorb a six-electron-volt photon, for example. The energies that quanta must have in order to be absorbed by a molecule or atom correspond to the characteristic frequencies of the absorption spectrum of that substance.

Primary photochemical step. The occurrence of a photochemical reaction, then, begins with the absorption of a light quantum of suitable energy. The energy is used mainly or entirely to raise one electron into an excited state, with the result that the molecule or atom itself is in an activated state. The primary photochemical step then occurs; it may take the form of any of a number of different processes, as shown schematically below, in which M is the absorber; A and B indicate products formed by dissociation of M; C is a second substance, which interacts with M; N is a rearrangement product of M; D + E are secondary products that result from the interaction of M and C; e^- is an electron; and the asterisk designates electronically excited substances.

For each kind of molecule, more than one kind of excitation usually is possible. One of the origins of continuous absorption is photo-ionization, in which case the excited state of the electron is one in which it is free to escape from the atom or molecule, leaving behind a charged particle, or ion. It is the one case in which absorption and primary reaction are essentially identical. Photo-ionization can be thought of as a prototype—perhaps the most elementary photochemical process. Continuous absorption is characteristic of a transition in which a new free particle is produced: it may be an electron, as in photo-ionization, or it may be an atom or a molecular fragment. These latter two classes of particle are produced by photodissociation, a second type of photochemical process, which usually occurs when the electron being excited moves away from a locale where it can participate in a chemical bond into some other region where it is unable to use its attraction to pull two nuclei together. In normal photodissociation the excited electron remains bound to one or the other of the products of the photolysis. Photodissociation is sometimes almost as directly linked to the absorption process as photo-ionization is, but it can also be considerably slower.

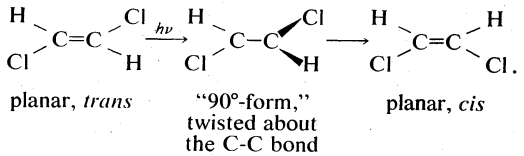


Photo-ionization and photodissociation

Absorption in a line or band spectrum leaves all the particles bound together with their geometrical configuration essentially unchanged, at least for a short time (10^{-14} second). The change produced by such an absorption involves the excitation of one electron from a closely held low-energy state to a more loosely bound excited state. In many cases there are two or more possible excited states and several electrons that could undergo a transition; because each spectral line or band corresponds to one specific electronic transition, however, it is frequently possible for an experimenter to study one kind of electron excitation at a time. This condition can be achieved by irradiating the sample with light lying only in the energy range corresponding to the transition that the experimenter is interested in. An experiment of this type can often be done with light of almost a single pure frequency (monochromatic light).

As soon as an electron is excited and the molecule is in an activated state, several events can occur. The molecule may return to its initial state, without reacting, in either of two ways: it may radiate, giving up a light quantum by luminescence; or it may lose its excitation energy, without radiating or reacting, by undergoing nonradiative decay, a process that requires effective collision partners to carry off the excitation energy. Nonradiative decay usually goes through two stages. In the first step, little or no energy is lost; the energy of electronic excitation is simply converted into vibrational energy (called intersystem crossing, or internal conversion). In the second stage, the excess energy is given up to the environment gradually through a succession of collisions.

Luminescence and nonradiative decay

If the excited molecule does react, it may do so in any of several ways. It may undergo photo-ionization or photodissociation, as indicated above. Or it may undergo an intramolecular reaction (an internal rearrangement) or an intermolecular process. An example of intramolecular rearrangement is the conversion of *trans*-1,2-dichloroethylene into its *cis* isomer (a molecule with identical numbers and types of atoms but different arrangement of them). In the equation for this reaction, the lines represent single covalent bonds and the shaded lines provide perspective; *i.e.*, their pointed ends are away from the viewer, their blunt ends toward the viewer:

The product, in this case, has almost the same energy as the starting compound; the excitation energy required to reach the twisted intermediate form must be given off somehow by the product, usually by collision.

Primary intermolecular reactions may involve nothing more than the transfer of a quantum of energy, as with mercury (Hg) and ethylene (C_2H_4):

$$Hg\,(vapour) + h\nu \longrightarrow Hg^*$$

$$Hg^* + C_2H_4 \longrightarrow Hg + C_2H_4^*,$$

leaving the excited ethylene to undergo secondary reaction. The intermediate kind of primary nondissociative reaction uses collisions in a way akin to the nonradiative decay process. An excited molecule undergoes a collision that converts it into a new reactive state without removing much of its excitation energy. The collision may change the geometry of the reactive molecule into a form that can rearrange bonds or dissociate readily, or it may change the electronic state of the molecule through internal conversion or intersystem crossing. Changes in electronic state usually involve only the single excited electron, but sometimes the molecular geometry is also involved.

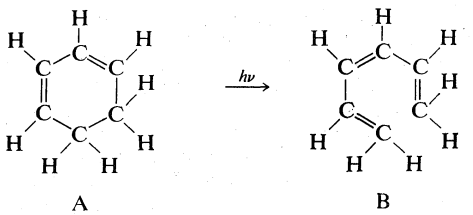
In order for any state, be it the initial excited state or any subsequent one, to play a part in a photochemical reaction, it must endure long enough for the reaction to occur. Each photochemical reaction competes with radiative and nonradiative de-excitation to consume the activated molecules. A few typical numerical examples will illustrate the way this competition goes on. Fast luminescence, called fluorescence, occurs with a half life of about 10^{-8} second; *i.e.*, roughly half of the excited molecules in any sample will radiate their excitation energy away in about 10^{-8} second provided they have an allowed path for fluorescence and provided they are not destroyed faster by some other process. Simple dissociations of excited molecules occur much faster: an excited molecule in an unstable state dissociates in about the time it takes an atom to go through one vibrational period, or about 10^{-13} second. Consequently, a molecule excited to a truly dissociating state has virtually no chance to radiate and will indeed follow the path of dissociation. Other unimolecular processes may occur with characteristic times ranging from 10^{-13} second up to a few seconds, if no other process interferes.

Radiative processes can also be slow. Slow luminescence is called phosphorescence and is the result of emission of a quantum from a molecule undergoing a relatively improbable transition. Fluorescence is the result of an "al-

Fluorescence and phosphorescence

lowed" transition. Phosphorescence frequently is characterized by a lifetime for the excited molecule between 10^{-5} and 10^{-2} second, but many cases outside these bounds are known. Fluorescence, phosphorescence, dissociation, and some rearrangements involve only a single molecule and have specific rates (rate per unit of reactant concentration) or lifetimes for reactant molecules that are independent of the number of molecules present. Processes involving two molecules have specific rates that depend on the concentration of collision partners, because these rates depend on the frequency of collisions. The maximum rate for a bimolecular reaction is just the collision rate; this rate, about 10^9 per second in the normal atmosphere, is attained only if the reaction occurs with every collision.

In solution, the maximum bimolecular rate is governed by the rate at which the reactive species can diffuse together through the liquid or solid medium. Like the collision frequency, the maximum encounter rate represents an upper limit for the rate of reaction. Rates in solution are inversely proportional to the solvent viscosity, with the result that bimolecular processes generally proceed slower in glycerin, for example, than in water. Bimolecular de-excitation processes are usually limited by the rate at which the internal electronic state can change.



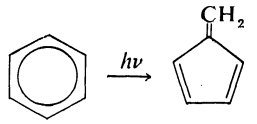
Any molecule that may decay or react in more than one way will follow the fastest of these ways. Comparison of the reaction rates shows that dissociation usually is fastest, if it can occur; fluorescence is fast in gases but is slow relative to collisions, nonradiative decay, and bimolecular reactions in solutions.

When a molecule changes its electronic state without direct absorption of light, as in nonradiative decay or internal conversion, it may go into a new excited state, which, left alone, would be short-lived (less than about 10^{-6} second); or it may go into a long-lived (metastable) excited state. Both types of reaction are known in photochemistry, but the long-lived states are particularly important in storing energy for chemical processes. The most important of the last named kind of transition is a singlet–triplet transition—singlets and triplets being electronic states that differ in having paired and unpaired electrons, respectively.

Triplet state

Triplets are the most commonly found phosphorescing states. They cannot radiate rapidly and are therefore among the most long-lived excited species. For this reason triplets are frequently the primary products of photochemical reactions. Excited singlets are sometimes found, but they more often decay, often to triplets. Triplets can be identified by their magnetic properties; by contrast with singlets, the individual electron magnets of a triplet do not cancel each other so that triplets exhibit weak magnetism (paramagnetism), which can be detected by suitable techniques.

An interesting case in which the entire photochemical process occurs in the primary reaction is that of valence tautomerization; *i.e.*, the inter-conversion of molecular structures that differ very little in the relative positions of their atoms but have different arrangements of chemical bonds, as in the photoisomerization of 1,3-cyclohexadiene shown in the structural formulas below:



A B

Though structures A and B are nearly identical geometrically, they represent different states of the electrons.

Secondary steps. If an excited molecule does not return by a direct path to its lowest energy state, then it must dissociate, react with neighbours or itself, or revert to a new electronic state, still having some excitation energy. These are the primary steps (above). Any subsequent step is a secondary reaction. An example is the primary dissociation of an oxygen molecule (O_2) into two oxygen atoms; the only secondary reaction of importance in pure oxygen is combination of oxygen atoms with oxygen molecules to produce ozone (O_3). Both ozone and oxygen can then go on to attack hydrocarbons, in typical urban atmospheres.

Rearrangement reactions

Reactions in which atoms move from one site to another within a molecule—that is, rearrangement reactions—may be interpreted as secondary reactions following the photoexcitation process. Benzene irradiated with light between 2000 and 3000 angstroms rearranges (in low quantum yield) to the unstable hydrocarbon fulvene with the movement of a hydrogen atom, as shown in the structural formulas below:

benzene fulvene

in which the circle within the hexagon represents six electrons of benzene; the first step involves only the excitation of one of these six relatively free electrons, which do not participate in carbon–hydrogen bonds to any significant degree. Thus, only in a secondary step following photoexcitation can the atoms rearrange to the molecular structure of the product.

Frequently, the primary photochemical process is used as a tool to permit the secondary reactions to be studied. Photosensitized reactions often fall into this category. Mercury atoms can absorb light from a mercury lamp very efficiently and then, in their excited state, collide with other molecules and transfer their excitation to them. This technique has been used to dissociate nitrous oxide (N_2O) and provide free oxygen atoms. The reaction sequence proceeds as shown below:

$$Hg + h\nu \longrightarrow Hg^*$$

$$Hg^* + N_2O \longrightarrow Hg + N_2 + O.$$

(The alternative mode of decomposition, to give NO + N, has not been found to occur.) Then the oxygen atoms may react with whatever other substances are present. Measuring the amount of nitrogen produced in such a photolysis gives directly the number of oxygen atoms that were available for reaction.

Chain reactions

If a primary step involves dissociation of a molecule into two radicals (molecular fragments with single or unpaired electrons), the secondary steps are often chain reactions. About 1923 it was recognized that there were certain cyclic processes, called chain reactions, in which reaction of an active intermediate with a molecule of starting material to give a product necessarily also produced a new active intermediate. The hydrogen–chlorine reaction is an example. Light dissociates a few chlorine molecules into atoms, which then attack hydrogen molecules to give hydrogen chloride product and hydrogen atoms. The hydrogen atoms react with chlorine molecules to produce more hydrogen chloride and chlorine atoms. The reactions are:

$$h\nu + Cl_2 \longrightarrow 2Cl$$

$$Cl + H_2 \longrightarrow HCl + H$$

$$H + Cl_2 \longrightarrow HCl + Cl.$$

Reactions of this kind require an initiator (light, in this case) and a propagating mechanism and may involve a separate terminating step. Termination actually occurs either when the concentration of at least one reactant becomes very low or when another substance (*e.g.*, oxygen or iodine) is present to react more rapidly with the radicals than can the hydrogen or chlorine molecules. The reaction must also be exothermic (heat-releasing) or nearly thermoneutral (that is, neither releasing nor absorbing heat), otherwise it may cool the system so that it no longer reacts. In the reaction just cited, considerable heat is generated—usually much faster than it is radiated

or transferred to the vessel walls—and an explosion is the result. An even more unstable situation—violently explosive—arises if one radical initiator produces more than one new radical.

Chain reactions always produce many product molecules for every quantum of energy absorbed; *i.e.*, the quantum yield may be much greater than one for the reaction. Reactions involving no chain processes necessarily have quantum yields near or below one, while a chain reaction may have a quantum yield of 80,000. Even a rough measurement of quantum yield will generally show whether a reaction proceeds through a chain mechanism.

EXPERIMENTAL METHODS

The methods of studying photochemical reactions have been developed chiefly to deal with problems of three kinds, which are: (1) getting the desired light energy into the system being studied; (2) determining the progress of the reaction—getting immediate pertinent information from the experiment; and (3) determining, from the results of individual experiments, the broader inferences for which the study is carried out. Photochemists commonly try to determine from a series of individual reactions the mechanism of a reaction—*i.e.*, the behaviour of each atom throughout the progress of the reaction.

Illuminating the sample. Providing suitable illumination for photochemical reactions, the experimenter has four controls: (1) The frequency, or energy, of the light can be controlled. (2) The intensity of the light can be varied to control the rate at which photons arrive at the sample and thereby to control the number of excited molecules present at one time. (3) The time of illumination can be varied to control the total number of excited molecules produced. (4) The polarization of the light may be selected.

In the earliest photochemical observations the Sun was the source. No control could be exerted, of course, on the frequency of light coming from the source itself, but simple controls of the light reaching the sample were available through the use of sample containers of differing composition; *e.g.*, flint glass transmits very little ultraviolet radiation (of wavelengths less than about 3600 angstroms), borosilicate (Pyrex) glass transmits light of wavelengths above about 3000 angstroms, and some fused silica is transparent to wavelengths shorter than 1700 angstroms. The next simplest way to control the wavelength reaching the sample is to interpose a suitable filter in the light path. Filters may transmit broad bands of frequencies or narrow and nearly monochromatic bands. A more complex step is the use of the monochromator, a device (usually a prism or grating) that disperses light and permits the continuous variation of its frequency.

Incandescent sources, such as the Sun and ordinary electric tungsten-filament lamps, emit light of all frequencies, the total intensity and the distribution of intensity depending primarily on the source temperature. For higher intensities it is often possible to use the emission spectrum of an atomic or molecular vapour. Some common sources use mercury, cadmium, sodium, xenon, hydrogen, or deuterium in an electric-arc discharge to provide intense and steady fluxes of radiant energy. If the lamp pressures are low, the light emitted by mercury, cadmium, or xenon is restricted to a few, intense, well-separated wavelengths, from which it is easy to select one.

Conventional steady arcs, discharge tubes, and incandescent sources are inadequate for very intense illumination. High flux of quanta requires a flash tube, a pulsed X-ray or gamma source, a laser, or the radiation from an electron accelerator such as a synchrotron. The most intense monochromatic source is the pulsed laser, which can deliver as much as 10^9 watts of power for 10^{-11} second at a single wavelength.

Monitoring the reaction. The course of a photochemical reaction may be observed by many physical and chemical methods. Often it is sufficient to know what the final reaction products are, which can be determined by established methods of qualitative identification.

In other cases, the information sought from a photochemical reaction can be derived only by examining the intermediates—the species present during the course of the reaction but not at the end. Sometimes an indirect observation identifies an intermediate; methyl (CH_3), ethyl (C_2H_5), and other radicals react with metal surfaces and can be detected by their ability to remove a metal mirror from the walls of a vessel. More direct methods of studying the intermediates are available in many cases.

Use of flash-kinetic spectroscopy

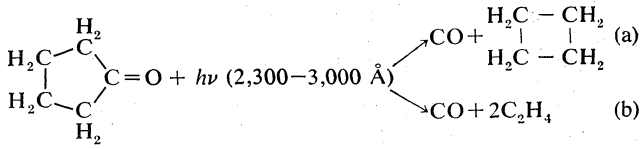
Transient intermediates can be found and identified in some photochemical reactions proceeding at their natural rapid rates. One method of doing this is flash-kinetic spectroscopy: a rapid photolysis is effected by an intense flash, which is followed by a second flash from a small lamp acting as a light source for absorption spectroscopy (analysis based on absorption of radiation according to the energy content of the sample's molecules and the perturbing effects of surrounding molecules). With ultrafast laser pulses, reactions can be studied at time intervals as short as 10^{-12} second after they are initiated. The method has been particularly successful for identification of spectra of such small transient species as the amino (NH_2), aldehyde (CHO), cyanate (NCO), and methyl (CH_3) radicals and of such more complex species as the phenyl radical (C_6H_5). Gases, liquids, and solids can be examined by flash-kinetic spectroscopy to determine the time dependence in the absorption spectrum. This can be carried out in a series of photolyses, taking spectra at progressively later times after photolysis and accumulating the data, or one can move a film or an image during the event to obtain a streak photograph of the reacting system.

As a complement to the optical absorption spectrum of a rapidly reacting mixture, one can study the time dependence of the mass spectrum (the array of charged particles sorted according to their masses). The so-called time-of-flight mass spectrometer is capable of scanning the mass spectrum of a gas being sampled as often as once every 10^{-5} second. A particular mass that appears only during the middle stages of a reaction is associated with an intermediate.

Quantum yield

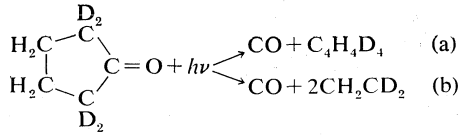
Possibly the most fundamental quantitative measurement of a photochemical process is that of quantum yield, which may be determined from a knowledge of the absolute emission characteristics of the exciting source and of the absolute absorbing ability of the absorbing species; or the measurement may be made as a relative one, by using as a comparison and standard a reaction the absolute quantum yield of which is precisely known. Absolute measurements are usually much more difficult than relative ones, and so the relative method is more common; but the standards must come from absolute measurements.

The standard reaction that is most reliable for solutions is the photolytic decomposition of highly purified uranyl oxalate. The quantum yield of this reaction is well established as a function of wavelength, temperature, intensity, and concentration of various ions, particularly hydrogen ions. For gas-phase reactions, other standards are available; *e.g.*, the photolysis of hydrogen iodide, the quantum yield of which is precisely two for a wide range of conditions.



Determining the mechanisms. Determining the actual path of a photochemical reaction frequently requires setting up hypothetical models corresponding to different possible mechanisms; finding from its kinetic equations how each model system depends on concentrations, light intensity, and any other pertinent variables; and then deciding, from experimental variations, which model best describes the system. Using this method, investigators have shown how simple alkyl iodides—*e.g.*, methyl iodide (CH_3I)—decompose on photolysis and how the fragments must react. The methyl iodide system is interesting in that at least part of the energy of the absorbed photon stays in the reactive species long enough to assist in one crucial step. The steps of the mechanism and the evidence used to determine the role of each step are as shown in the Table.

Labelling. Other than direct detection of intermediates, the most powerful tool for elucidating mechanisms



Steps in the Photolysis of Methyl Iodide

step	equation	methods of studying individual step
Primary step	$CH_3I \xrightarrow{h\nu} CH_3 + I$	brought about by near-ultraviolet radiation; quantum yield approximately 1, as shown by separate experiments using scavengers for iodine atoms and methyl radicals; presence of radicals shown by kinetic spectroscopy
Normal secondary steps	$2CH_3 + M \rightarrow C_2H_6 + M$ $2I + M \rightarrow I_2 + M$	M is an inert collision partner that carries away energy; ethane (C_2H_6) and iodine (I_2) molecules demonstrated by analysis of products
Inhibiting secondary steps (recombinations)	$CH_3 + I \rightarrow CH_3 + I$	rate determined from low-pressure, low-intensity photolysis to minimize three-body collisions
	$CH_3 + I + M \rightarrow CH_3I + M$	rate determined from high-intensity photolysis to maximize frequency of radical–radical collisions
Other secondary steps	$CH_3 + CH_3I \rightarrow CH_4 + CH_2I$	inferred from presence of methane (CH_4) in products; thermochemistry requires either reactant to have 9 kcal per mole excess energy
	$CH_2I + I + M \rightarrow CH_2I_2 + M$	inferred from presence of methylene iodide (CH_2I_2) in products
	$2CH_2I \rightarrow ICH_2CH_2I$	inferred from presence of 1,2-di-iodoethane (ICH_2CH_2I) in products

is probably the use of isotopic labelling. For example, deuterium (the hydrogen isotope that has twice the mass of ordinary hydrogen) can be used in place of hydrogen, or one of the other carbon isotopes in place of carbon-12, at selected sites in the starting material; the tagged atoms then can be located at particular positions in the product molecules. An example of the information isotopic substitution can give in a favourable case is in the photolytic decarbonylation (loss of carbon monoxide) of cyclopentanone. The process has alternative paths (a) and (b):

The use of a specific tetradeuterated species (*i.e.*, containing four deuterium atoms) shows that the paths are mutually exclusive. No ethylene of the formula C_2D_4 is formed, and therefore the ethylene cannot be a product of an intermediate in which all four carbon atoms are equivalent. The reaction is this:

Quenching. A good method, and one of the oldest in photochemistry, for determining both kinetic constants and mechanisms is the study of fluorescence quenching. If a large molecule (*e.g.*, anthracene, pyrene, or acridine) is photoexcited and does not react, in general it will fluoresce. If a species is added that reacts rapidly with the photoexcited substance, fluorescence will no longer occur; *i.e.*, it will be quenched. This method has made possible the determination of the strengths of acids in excited electronic states; of the rate of combination of two anthracene molecules (dimerization; dimer: double molecule formed by the union of two identical simpler molecules—*e.g.*, C_4H_8 is a dimer of C_2H_4); and of rates of long-range transfer of energy.

APPLICATIONS

In synthetic chemistry. Because absorption of a light quantum is frequently a property of a single group of atoms within a molecule, photochemistry sometimes provides the best means for producing a chemical reaction at a specific molecular site. This application becomes especially valuable when thermal excitation would be unselective or would destroy the reactant. Photochemical syntheses include elimination reactions and the formation of isomers and dimers.

Photolytic syntheses are sometimes most effective if the reactants are held rigidly by a solid lattice, so that a reactant molecule absorbing a quantum is fixed in a favourable orientation for reaction. Solid-state photolyses of this kind have been used in the synthesis of the dimers of maleic and fumaric acids.

In radiation chemistry. The photochemistry associated with high-energy radiation (X-rays and gamma rays) is closer to the chemistry of electron-bombarded materials than to the photochemistry of visible-ultraviolet radiation. High-energy electron or photon bombardment produces, in addition to excited neutral molecules, ionized species, which are products of very fast secondary processes, not of the primary quantum absorption process. The basic processes associated with high-energy radiation are simply too fast to lead to any chemistry in the traditional sense of bond formation or breakage. Radiation chemistry is largely concerned with determining what the first-formed new chemical species are and what reactions they undergo: it assumes a particularly important role in the understanding of how living beings react to radiation and how they can be protected against its damaging effects (see RADIATION EFFECTS ON MATTER).

Products of secondary processes

In atmospheric photochemistry. The phenomena of terrestrial and planetary atmospheres—*e.g.*, atmospheric structure, auroras, radiation shielding, and weather—depend on the chemical constituents of the atmosphere and the radiation striking it. The Earth's atmosphere is largely molecular nitrogen and molecular oxygen at the Earth's surface, but it contains quite a different set of atomic and molecular components at high altitudes, largely because of the radiation that these upper layers absorb. The photochemical processes that take place are covered in the articles ATMOSPHERE and IONOSPHERE. The very rich chemistry of polluted atmospheres is a comprehensive model that exhibits many aspects of photochemistry. Brown nitrogen dioxide absorbs sunlight and uses this energy to initiate chain reactions of hydrocarbons with oxygen. The nitrogen oxides return to pick up more sunlight, while the partially oxidized hydrocarbon molecules undergo secondary reactions and may even absorb light to start new photochemical processes.

Photoelectric Effect

The photoelectric effect is a phenomenon in which electric charges are liberated from a material when it absorbs radiant energy. Usually, the photoelectric effect is thought of as the ejection of electrons from the surface of a metal plate when light falls on it. In the broad sense, however, the phenomenon can take place when the radiant energy

is in the region of visible or ultraviolet light, X-rays, or gamma rays; when the material is a solid, liquid, or gas; and when the charges liberated are electrons or ions (charged atoms or molecules).

Investigations around the beginning of the 20th century on photoelectric phenomena led theoretical physicist Albert Einstein to propose the theory that light can be wavelike and yet behave like streams of discrete particles, or quanta of energy. From this beginning grew the quantum mechanics of modern physics, without which there would be no understanding of phenomena occurring on the molecular, atomic, or nuclear scale. The photoelectric effect is the basis of operation of such devices as the television camera, photographic light meters, image intensifiers for telescopes, cells for the conversion of solar energy, and detectors for all kinds of spectrometry.

Discovery and early work. The first recorded observation of the photoelectric effect, or photoemission, occurred in 1839 when it was reported that an electric current generated by a cell composed of two metallic electrodes immersed in a conducting solution, or electrolyte, will increase when the cell is illuminated and that the extent of the increase will depend on the wavelength of the illuminating light. In another experiment, an investigator a few decades later noticed that there is a change of resistance of selenium with illumination. The photoelectric effect was actually and explicitly discovered in 1887 by a German physicist, Heinrich Rudolf Hertz, who observed that ultraviolet light changes the lowest voltage at which sparking takes place between given metallic electrodes. At the close of the 19th century, it was established that a cathode ray (produced by an electric discharge in a rarefied-gas atmosphere) consists of discrete particles, called electrons, each bearing an elementary negative charge (see ELECTRON). In 1900 Philipp Edward Anton Lenard, a German physicist, studying the electrical charges liberated from a metal surface when it was illuminated, concluded that these charges were identical to the electrons observed in cathode rays. It was further discovered that the current (given the name photoelectric because it was caused by light rays), made up of electrons released from the metal, is proportional to the intensity of the light causing it for any fixed wavelength of light that is used. In 1902 it was proved that the maximum kinetic energy of an electron in the photoelectric effect is independent of the intensity of the light ray and depends on its frequency.

The observations that (1) the number of electrons released in the photoelectric effect is proportional to the intensity of the light and that (2) the frequency, or wavelength, of light determines the maximum kinetic energy of the electrons indicated a kind of interaction between light and matter that could not be explained in terms of classical physics. The search for an explanation led in 1905 to Einstein's fundamental theory that light, long thought to be wavelike, can be regarded alternatively as composed of discrete particles (now called photons), equivalent to energy quanta.

Einstein's fundamental theory and equation

In explaining the photoelectric effect, Einstein assumed that a photon could penetrate matter, where it would collide with an atom. Since all atoms have electrons, an electron would be ejected from the atom by the energy of the photon, with great velocity. The kinetic energy of the electron, as it moved through the atoms of the matter, would be diminished at each encounter. Should it reach the surface of the material, the kinetic energy of the electron would be further reduced as the electron overcame and escaped the attraction of the surface atoms. This loss in kinetic energy is called the work function, symbolized by omega (ω).

According to Einstein, each light quantum consists of an amount of energy equal to the product of Planck's universal constant (h) and the frequency of the light (indicated by the Greek nu, ν). Einstein's theory of the photoelectric effect postulates that the maximum kinetic energy of the electrons ejected from a material is equal to the frequency of the incident light times Planck's constant, less the work function. The resulting photoelectric equation of Einstein can be expressed by $E_k = h\nu - \omega$, in which E_k is the maximum kinetic energy of the ejected electron, h is a constant, later shown (see below) to be numerically the same as Planck's constant, ν is the frequency of the incident light, and ω is the work function.

The kinetic energy of an emitted electron can be measured by placing it in an electric field and measuring the potential or voltage difference (indicated as V) required to reduce its velocity to zero. This energy is equal to the product of the potential difference and an electron's charge, which is always a constant and is indicated by e; thus, $E_k = eV$.

Experimental confirmation of Einstein's equation for the photoelectric effect was provided in 1916 by the investigations of a U.S. physicist, Robert A. Millikan. Proof that Einstein's numerical constant was the same as Planck's constant gave an enormous boost to the then new developing quantum theory and gave plausibility to the Danish physicist Niels Bohr's concept of the structure of the atom in which electrons revolve in prescribed orbits about a nucleus. Einstein's theory thus stimulated a much broader area of physics than the limited field of photoemissive phenomena.

Two more milestones in the history of the photoelectric effect must be mentioned. In 1923 Arthur Holly Compton, a U.S. physicist, discovered an effect, given his name, that relates the directions taken by a photon and an electron, after they meet, with the energy of the collision (see below *Compton effect*). And in 1925, another effect, sometimes called the compound photoelectric effect, or the Auger effect, was discovered by a French physicist, Pierre-Victor Auger (see below *Auger effect*).

Photoemission. *The phenomenon.* Whenever the absorption of a photon by an atom results in the ejection of a free electron, one speaks of photoemissive phenomena. Einstein's equation predicts that the emission current composed of these electrons will be directly proportional to the intensity of the number of photons absorbed in the emitter. The equation is consistent with a three-step model of photoelectric emission from a solid. The first step consists in the absorption of a photon by an atom and the release of an electron, an event that may occur at the surface or at any distance below the surface of the solid on which the light waves fall; the penetration depends on the degree of absorption (called the absorption coefficient) of the material for the specific frequency of the incident light. If the electron is ejected below the surface, the second step consists in the movement of the electron through the layers of atoms between it and the surface. In this diffusion process the electron may either find no resistance or be hindered by collisions with atoms. In the latter case, the electron may never reach the surface, or if it does it may do so only after losing some of the kinetic energy it acquired from the photon. The third step is the escape of the electron from the surface of the solid, before which the electron must overcome an electrostatic barrier set up by the surface charges. It can do this only if its kinetic energy is high enough.

Temperature dependence. The validity of the Einstein relationship was examined by many investigators and found to be correct but not complete. In particular, it failed to account for the fact that the emitted electron's energy is influenced by the temperature of the solid. The remedy to this defect was first formulated in 1931 by a British mathematician, Ralph Howard Fowler, who, on the assumption that all electrons with energies greater than the work function would escape, established a relationship between the photoelectric current and the temperature in which the current is proportional to the product of the square of the temperature and a function of the incident photon's energy. The equation is $I = \alpha A T^2 \phi(x)$, in which I is the photoelectric current, α and A are constants, and $\phi(x)$ is an exponential series, whose numerical values have been tabulated; the dimensionless value x equals the kinetic energy of the emitted electrons divided by the product of the temperature and the Boltzmann constant of the kinetic theory: $x = (h\nu - \omega)/kT$; in which x is the argument of the exponential series, h is Planck's constant, ν is the frequency of the incident radiation, ω is the work function of the material, k is Boltzmann's constant, and T is temperature.

Fowler's equation

A great advantage of the Fowler equation is its easy comparison with experiment. By plotting the experimental results of temperature, photoelectric current, and the function argument x, the threshold frequency is easily determined. In addition to the convenience of a simple determination of the work function, the equation predicts the correct shape of curves plotted for emission current versus radiation frequency, at least in the vicinity of the threshold value.

An example of the comparison of experimental data with the Fowler theory is given in Figure 1.

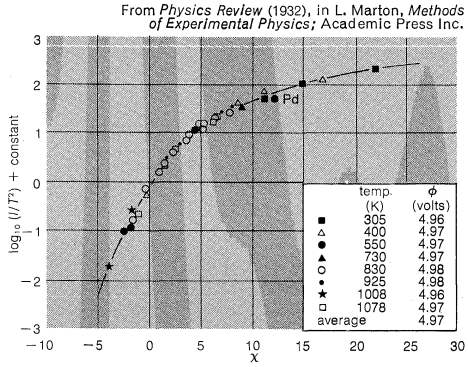

Figure 1: Spectral distribution curve of palladium, based on Fowler's theory.

Originally, most investigations of photoemission centred on the emissive properties of solid metals that are good conductors of electricity. Gradually, with the recognition of the effects of volume and surface impurities, there evolved an interest in the photoelectric emission from insulators, which are nonconductors, and from semiconductors, which conduct electricity only under certain circumstances. The energy distribution of electrons in insulators and semiconductors is different from that of metals. As a consequence, one finds that the photoelectric yield (number of electrons emitted for each incident quantum of radiation) versus energy of the incident photon can be different for materials having the same work function.

Semiconductors, metals, and insulators. The photoelectric effect in semiconductors can be understood only in terms of quantum mechanics. It is possible to think of solids as being composed of tiny crystals, each of which has an orderly array of atoms in three dimensions called a lattice structure. Every electron in the lattice, whether bound to an atom or unbound, has a definite energy, called its energy state. Energy states are influenced by the lattice structure of the crystal. Electrons can change to a higher energy state by absorbing heat or electromagnetic energy. According to the laws of quantum mechanics, only specific discrete energy states may exist, and these are grouped together in energy bands, with the regions between them called forbidden bands. The band of highest energy that is occupied when the crystal is at absolute zero temperature is the valence band. If this band contains states that are unoccupied, it is called a conduction band and the crystal is a metal. If all the states are occupied, the crystal is either an insulator or a semiconductor, depending on whether or not electrons from the valence band can be transferred to the next unoccupied band, which then becomes a conduction band. In a semiconductor the input of energy, in the form of light, can raise a valence electron into the conduction band. Electrons can also be supplied to a semiconductor by atoms having energy levels in the forbidden gap, called impurity atoms. In an insulator the forbidden gap is too large to be bridged easily.

Work function of semiconductors

The work function depends on many factors. It is affected radically by the purity and surface condition of the specimen. Even for a perfectly pure surface it is found to be strongly affected by the crystallographic orientation of the surface. The work function depends on the packing arrangement of the atoms and thus the distances between atoms in the crystal; the most closely packed surfaces have the highest work functions and the less closely packed ones (for the same substance) the lower ones. A polycrystalline surface usually represents the average work function of the most commonly occurring crystallographic orientations.

Another important distinction between pure metals and many semiconductors lies in the light absorption properties of the two. The behaviour of compound photoemitters (*i.e.*, emitters built up of layers of different materials that may or may not have diffused into each other) may be influenced by their absorptivity; *i.e.*, the fraction of light energy absorbed. The simplest case of a compound photoemitter is a metal with an absorbed layer of some chemical impurity or a metal whose surface has undergone a chemical modification. Many metals when oxidized manifest a reduced work function with respect to the pure metal by as much as 1.5 electron volts. Because the work functions of most pure metals are too high for convenient technological applications in visible light, the search for low work function surfaces has been directed toward compound photoemitters. The most important of these emitters are, in chronological order of discovery: the silver–oxygen–cesium cathode, the cesium–antimony cathode, the bismuth–silver–oxygen–cesium cathode, and the different multialkali antimonide cathodes. All modern photoemitter materials combine low work functions with high photoelectric yield.

Compound photoemitters

The time lag between the absorption of a photon and the emission of a photoelectron is short: it appears to be less then 10^{-10} second. Although in this section the discussion has been limited to photoemission from solids, it should be pointed out that much work has been done on photoionization in gases.

Photoconductivity. Many materials exhibit a marked change in electrical conductivity when irradiated. Usually the conductivity increases, although a few instances of the opposite reaction are known. In highly conductive substances, such as metals, the change in conductivity is insignificant. It is most important in semiconductors.

In a semiconductor there are a certain number of "free" electrons occupying energy levels in the conduction band and a certain number of positively charged "holes" left in the valence band by the free electrons that entered the conduction band because of the natural vibrations of atoms. During irradiation of the substance, the generation of free charge carriers (electrons and holes) increases, producing an increased conductivity, continuing until the carriers generated by the photon absorption can no longer move through the material. The fundamental electronic processes can be manifold, depending upon the band structure of the material, the imperfections in the material, and other factors. One of the most important factors in determining photosensitivity (*i.e.*, the change in conductivity per photon absorbed) is the free-carrier lifetime, which must be finite because recombination or neutralization takes place between negatively charged electrons and positively charged holes and there are thus fewer electrons available for the conduction process. This process can vary from 10^{-2} second to 10^{-12} second, not only from substance to substance but also in a single substance having varying degrees of imperfections or impurities. For a thorough study of photoconductivity it is thus important to employ materials that are well defined structurally, preferably single crystals. The lifetimes of the charge carriers determine the response time of the photoconductor to changes in the light stimulation; the observed decay time of the photoconductivity can be related to the lifetime of the free carriers by an equation in which the decay time, indicated by tau, subscript zero (τ_0), equals the lifetime, indicated by tau (τ), multiplied by the ratio of the density of trapped carriers, indicated by n, subscript t (n_t), and density of free carriers, indicated by n: $\tau_0 = \tau\ (n_t/n)$. The lifetime depends on the nature of the recombination process of the charge carriers, and many different mechanisms are possible.

Photosensitivity

Another important factor determining photosensitivity is the light absorption characteristic of the photoconductors. When the photon energy is greater than the forbidden energy gap of the solid, each photon creates a free

pair—a free electron and a free hole. If the photon energy is much larger than the band gap (as, for instance, the photon energy of X-rays), the absorption of a single photon can give rise to many free pairs. The optical absorption cross sections are incompletely known.

In practice, the ideal photoconductor with a fast and a linear, or directly proportional, response to the stimulation is almost nonexistent. Photoconductors show a number of secondary effects, a few of which may be mentioned here. Sensitive photoconductors may have response times measured in hours or days when operated at extremely high resistivities. The photocurrent may be reduced, or quenched, by the addition of further radiation, the wavelength of which is long compared with the radiation inducing photoconductivity. Similar to this infrared quenching is thermal quenching. Quenching may be explained in terms of raising an electron from the valence band to a sensitizing centre. This change can be achieved either by an infrared photon or by thermal excitation. As the free holes excited by light are caught in centres whose capture cross section for electrons is very small, moving these holes to other centres whose capture cross section for electrons is large can reduce markedly the lifetime of the free electrons. Negative photoconductivity may be due to unobserved quenching effects.

Photovoltaic effect. The photovoltaic effect consists in the generation of an electromotive force as a consequence of the absorption of radiation; that is to say, a current will flow across the junction of two dissimilar materials when light falls upon it. The primary effect is photo-ionization; *i.e.*, the production of equal numbers of positive and negative charges. One or both charges can then migrate to a region in which charge separation can occur. This charge separation happens normally at a potential barrier between two layers of the solid material.

For a large photovoltaic effect, the change of potential at the barrier should be large and the distance over which the carrier has to move should be small. This effect implies an abrupt change in some property of the material, including an abrupt change of the conductivity. The response time of the photovoltaic effect is relatively short, although not as instantaneous as photoemission.

Energy conversion device

An important characteristic of the photovoltaic effect is its relatively high efficiency as a device to convert the energy of radiation to electrical current. Extensive literature exists on conversion efficiencies for sunlight, showing experimental efficiencies reaching 14 percent in contrast to the theoretically expected efficiencies of 24 percent.

Other photoelectric effects. *Auger effect.* Photoemissive phenomena are well-known for the higher energy ranges in the X-ray and gamma regions because such penetrating radiation can release photoelectrons from inner atomic shells. If a vacancy is produced in an inner shell because of the removal of an electron through the photoelectric process, the vacancy will be filled by an electron from a less tightly bound state; the resulting excess energy may cause the simultaneous emission from the atom of a second electron, called an Auger electron, from another less tightly bound state. This is the Auger effect, which is generally, but not exclusively, observed at higher energies. A given inner vacancy can be followed by a great number of different Auger transitions. This fact, coupled with the development of high resolution spectroscopy and improved methods for the study of low-energy electrons, makes the Auger effect an important tool in the exploration of many nuclear processes such as capture and internal conversion. Also, the knowledge of the energies and intensities of Auger electrons gives information about transition probabilities, both in atoms and in molecules. Conversely, Auger spectroscopic lines with precisely known energies can be used for the energy calibration of conversion electrons—electrons that are ejected from their shells when a nucleus loses its excitation energy.

Use in energy calibration

Compton effect. In the collision between a higher energy photon and an electron initially at rest, the photon will share some of its energy and momentum with the electron, and the photon and electron will take off in divergent paths. The laws for the conservation of energy and momentum show that kinetic energy of the electron is strongly dependent on the energy of the photon, whereas the Compton shift in wavelength of the photon is independent of the energy. The Compton shift of wavelength between the incident and scattered photon, which represents an increase in wavelength before and after collision, is equal to the product of two terms: the first term is the ratio Planck's constant to the rest mass of an electron (according to relativity, a body has the least mass when at rest relative to the observer) times the velocity of light; the second term is the difference between 1 and the cosine of the angle that the scattered photon makes with the path of the incident photon. In equation form, $\Delta\lambda = (h/m_0c)(1 - \cos\theta)$, in which $\Delta\lambda$ represents the shift in wavelength, h is Planck's constant, m_0 is the rest mass of the electron, c is the velocity of light, and θ is the scattering angle of the photon. The term h/m_0c that corresponds to a 90° scattering angle of the photon is called the Compton wavelength for all electrons. It is a fundamental atomic unit of length having a numerical value of 2.4262×10^{-10} centimetre.

Atoms, electrons, and nuclei can interact with electromagnetic radiation in many possible ways. Whereas at low energies the photoelectric effect dominates, and at very high energies pair production (the conversion of a photon into an electron and a positron) is prevalent, there exists a broad range of energies in which the attenuation of radiation depends almost exclusively on Compton scattering (Figure 2).

From S. Flugge (ed.), *Encyclopedia of Physics*, in L. Marton, *Methods of Experimental Physics;* Academic Press Inc.

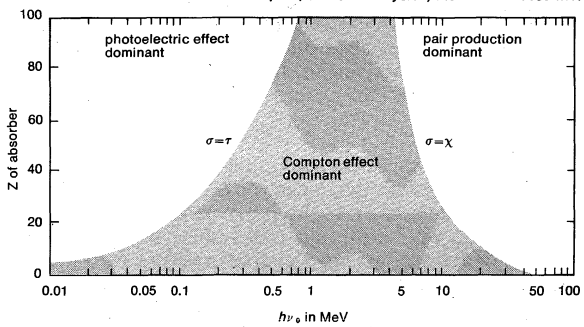

Figure 2: Locus of equal atomic cross sections for Compton and photoelectric interactions ($\sigma = \tau$) and for Compton and pair-production interactions ($\sigma = \chi$). The incident photon energy is $h\nu_0$, and Z is the atomic number of the atoms in the absorber.

Photonuclear effects. If the energy of the photon is sufficiently high, its wavelength becomes comparable with nuclear dimensions (the diameter of a nucleus) and a variety of nuclear reactions take place. The process most akin to the atomic photoelectric effect is the direct photoemission of a neutron or proton from the nucleus. More complicated interactions involve either the emission of heavier particles (alpha particles, tritium, deuterium), many particles, or photofission. Much valuable information about the nuclear photoeffect has been obtained from studies of the inverse reaction; *i.e.*, those in which the bombarding particle is captured by a nucleus and a photon is emitted. Experimental studies of elastic and inelastic photon scattering have resulted in important data, as have studies of elastic and inelastic electron scattering, with and without the detection of coincident outgoing reaction products. The cross section for these reactions shows a broad spectrometer peak in the region of 13,000,000 to 25,000,000 electron volts of photon energy, which has been called the giant dipole resonance. The width of this peak varies between 3,000,000 and 10,000,000 electron volts and is smallest for closed-shell nuclei (according to the shell model of the atomic nucleus, neutrons and protons move in concentric shells; the exclusion principle postulates that a shell is closed when it contains its quota of particles, and a closed-shell nucleus is one having its outermost shell completely occupied) and is greatest for nonspherical nuclei. At high energies (greater than 140,000,000 electron volts) photoemission processes become important.

Applications. The many technological variants of photoemissive devices take advantage of a response that is linear with light intensity, coupled with an extremely short response time. A photoemissive device (photodiode) can be coupled with a suitable amplifying system, its sensitivity thus extended to the detection of single photons. The best known amplifying system, the photomultiplier, consists of a suitable set of secondary emitters built into the same container. The disadvantages of this system are its limited spectral response: most photocells or photomultipliers are limited to the visible and ultraviolet ranges of electromagnetic radiation. Even at their peak performances, these devices give about 10 percent quantum efficiency, and these peak performances are limited to a narrow part of the spectrum. Much effort has been spent on the properties and preparation of suitable photoemissive material adapted to different applications.

The photomultiplier

Photodiodes and photomultipliers are being applied in a growing number of fields such as the control of industrial products and of manufacturing processes, the measurement of light intensities, scintillation counters, facsimile transmission, spectral analysis, and many others.

Photodiodes and photomultipliers integrate the light falling over the surface of the photoemitter to give the total amount received. Image converters, image intensifiers, television camera tubes, and image storage tubes take advantage of the point-by-point emission of the photocathode. In the first two examples, an optical image incident on a semitransparent photocathode is used to transform the light image into an "electron image." The electrons released by each element of the photoemitter are focussed by an electron-optical device onto a fluorescent screen, reconverting it in the process again into an optical image. This process can be carried out in a single step or in several steps, amplifying the image at each step.

Television camera tubes

In the most common type of television camera tubes, the first step, as with the image converter, is to transfer an electron image from the photocathode onto a thin insulating target, where, through emission of secondary electrons, a pattern of positive charges results. An independent electron beam scans the target, is influenced by the charges residing on its surface, and conveys the information to a secondary electron multiplier. The amplified signal goes to the external circuit.

Photoconductors, too, have been widely used, mostly in the form of thin film devices, for storage tubes, television pickup tubes, display devices, radiation-controlled variable resistances, electronic switches, image amplifiers, X-ray intensifiers, and, last but not least, for electrophotography.

As radiation detectors, photoconductors offer an extension of the spectral range to lower incident photon energies than obtainable with photoemitters. Infrared detectors have been described, such as indium–antimony detectors, that have a lower energy limit of 0.15 electron volt. Special detectors for the infrared are commercially available with a low energy limit corresponding to 0.030–0.040 electron volt. Germanium and silicon detectors are widely used for X-ray and gamma ray detection and spectral analysis.

Photovoltaic devices have been used extensively as photographic light meters and similar devices and have gained prominence as energy conversion devices, mainly because of their high efficiency in the visible region of the spectrum. Solar-cell arrays have been developed that can provide the necessary power for the operation of many electrical devices.

Finally, serious attempts are being made to apply the Auger effect for analytical purposes, attempts made possible because high-resolution electron-energy techniques can distinguish between Auger peaks belonging to neighbouring elements and thus can determine trace amounts of elements and their relative proportions.

BIBLIOGRAPHY. An extensive history of the photoelectric effect may be found in P. GORLICH, *Photoeffekte*, vol. 1 (1962); see also R.J. MAURER, "Photoelectric Effect," in E.U. CONDON and H. ODISHAW (eds.), *Handbook of Physics*, 2nd ed., pt. 8, ch. 5 (1967). A detailed treatment of photoelectric phenomena is given by G.L. WEISSLER, "Photoionization in Gases," and "Photoelectric Emission from Solids," in S. FLUGGE (ed.), *Encyclopedia of Physics* (*Handbuch der Physik*), vol. 21, pp. 304–382 (1956). Photoengraving

Engraving is the broad term describing the procedure used in making printing plates, in which printing and nonprinting areas are distinguished by their height with respect to the general plane of the surface, the artistic decoration created by mechanically incising a design into a surface, and the creation of original works of art by tooling or etching an image into the surface of a metal (or plastic) plate and transferring the resultant image to paper. For detailed information on these last two subjects, see PRINTMAKING. This article is limited to consideration of the procedures whereby a printing surface useful in the production of multiple ink-on-paper images is produced.

The term photoengraving is correctly applied to the procedures discussed here, since the use of light energy, as involved in photographic processes, is essential. A distinction must be made between a relief (or letterpress) printing plate, in which the ink-carrying (or image-bearing) surface coincides with the general level of the plate surface, with nonimage portions cut below the surface, and intaglio (or gravure) printing surfaces, in which the ink-carrying image elements are incised into the plate surface. In letterpress printing, a uniform film of ink is distributed over the surface of the plate and transferred from the individual image elements to the receiving paper surface. In intaglio printing, the plate is flooded with a low-viscosity (thin) ink, then wiped with a blade (doctor blade) to remove any ink adhering to the surface. The doctoring action leaves the incised intaglio image filled with ink; later, as paper is brought into contact with this image and pressure is applied, surface-tension and capillary-action forces cause the ink to transfer from the plate to the paper.

Letterpress and intaglio printing

HISTORY

Wood engravings. The earliest engraved printing units were wood engravings, in which the nonimage areas of an illustration were removed by carving them from the surface of a flat wood block. The oldest known illustration printed from a wooden block was a Buddhist scroll discovered in 1866, in Korea. While the dating of the print is not exact, it is believed to have been prepared about AD 750. The Chinese *Diamond-Sūtra*, dated 868, incorporates a woodcut title page and text that includes numerous woodcut images.

From the 8th- and 9th-century dates above, it is clear that the use of woodcuts (images cut into a surface parallel to the wood grain) and wood-block engravings (images incised into the end grain of an assembled block) antedates the invention of movable type. The earliest extant example of a European print from a wood engraving to which a reliable date may be attributed is a print entitled "St. Christopher," dated 1423, discovered in the library of the Carthusian monastery in Buxheim, Germany. Another authenticated example of 15th-century wood-block printing is the "Apocalypse of St. John," printed in 1450, after a 14th-century manuscript.

Early etched plates. Plates engraved in wood continued to find use in printing application through the late-medieval and early-modern periods. Plates made of copper, pewter, and other metals were also produced, by a process in which an image in wax or bitumen was drawn on, or transferred to, the surface of the plate and nonimage areas removed by action of appropriate acids.

Preparation of intaglio printing plates by a procedure that involved coating a metal plate with an etchant-resis-

tant substance (ground) such as wax, bitumen, or shellac, scratching through this substance (ground) to expose the plate surface, then etching in acids is also a late-medieval European development. This process, however, developed as a medium of artistic expression, rather than a technique for the mass production of printed images.

Early use of light-sensitive materials

The first experimental application of light-sensitive materials to the production of printing surfaces was by Joseph Nicéphore Niepce, of France, an early researcher in lithography who began his experiments about 1813. He is credited with having produced the first permanent photograph. In 1826 Niepce coated a pewter or copper plate with a photosensitive asphaltum and exposed the surface to bright sunlight through an etching of a portrait, which served as a positive image. Sunlight passing through the background of the etching hardened the asphaltum, while the protected areas, under the inked portion of the etching, were developed in oil of lavender and white petroleum to create an image in exposed metal. This image was then etched into the plate, and from the intaglio image, prints were made on a copperplate press.

Though this basic discovery was of historical importance, it did not bring about the immediate use of photoengraved images for printing, and many other attempts to produce engravings by exploitation of the photosensitivity of various natural compounds were made by experimenters in Europe and the United States. The origin of the modern photoengraving process rests, however, on the report (1839) by a Scottish scientist and inventor, Mungo Ponton, of the light-sensitive properties of certain chromium salts (compounds). But Ponton, who demonstrated the chemical change that occurs when glue containing a dichromate (a compound containing two atoms of chromium) is acted upon by light, was not concerned with preparation of printing plates, and it remained for W.H. Fox Talbot, an English pioneer in photography, to propose the use of dichromated colloids such as albumin as an etchant-resistant for preparation of intaglio printing surfaces.

Early-19th-century work on production of chemically etched letterpress printing plates antedated, in many instances, the invention of photography. A researcher in Paris developed a process for the preparation of engravings on zinc. His work involved transfer of an image to the zinc plate by mechanical means, using ink or wax, and the removal of the nonprinting areas in a series of etching operations, each of which involved applying a coating of ink to the sidewalls of the etched lines by means of resilient rollers. The ink served to protect the lines of the engraving from the action of the etching acid, so that the printing area was not reduced.

Wet-collodion photography. The introduction in 1851 of a so-called wet-collodion process for photography provided a means for producing a photographic negative as the basic element in the preparation of engravings. In this process, a glass plate is coated with an alcohol–ether solution of collodion (cellulose nitrate) containing halide salts (compounds of such elements as chlorine, fluorine, etc. of the halogen family) of various alkali and alkaline-earth metals. While still wet, the plate is immersed in a silver nitrate solution, producing light-sensitive silver salts in the collodion layer. Without drying the film of collodion, the plate is placed in the camera and exposed, followed by development in ferrous sulfate solution and chemical "intensification" to produce an image of greater opacity. The image consists of deposits of metallic silver and other heavy metals imbedded in the collodion layer.

This photographic process also provided a method of stripping the photographic image from the glass plate, permitting assembly of a number of images for plate making, and also making possible the geometric reversal of the image needed in letterpress plate making to produce a right-reading print on paper. The wet-collodion process was used extensively in engraving until the 1930s, when the introduction of commercially coated stripping films led to its gradual replacement.

The halftone process. Since the letterpress printing process provides a uniform coating of ink on all printing elements, no provision can be made for reproducing tones intermediate between black and white by varying the thickness of the ink film laid down by the press. The production of shades of gray was then the role of the halftone process, in which the image is broken up into dots and variations of gray tones are obtained by varying the size of the dots, thus controlling the amount of ink laid down in a given area.

Halftone feasibility proved

The feasibility of the method was demonstrated about 1850, when a halftone image was produced by photography through a screen of loosely woven fabric. The screen was placed some distance forward of the plane of the receiving photographic surface (film or plate) and had the effect of breaking the gray tones of the subject into dots of varying sizes, through a combination of geometric and diffraction effects involving the spacing of screen from the image surface, the size of the openings in the screen, distance from lens to image plane, and the size of the aperture in the lens. It was obvious that a screen designed for this use could consist of a pattern on a glass or other firm, transparent surface.

A French patent of 1857 described a screen with parallel lines scratched in a single direction in an opaque background. As early as 1869 an image with a crossline halftone was produced in the *Canadian Illustrated News.* Later, in 1882, a crossline halftone was produced using a single-direction screen, by making half the exposure with the screen in one position and half with the screen rotated a quarter turn. Two brothers, Max and Louis Levy, of Philadelphia, in 1890 produced the first commercial halftone screens. The Levy brothers coated selected plates of high-quality optical glass with a lacquer, in which parallel lines were cut. The ruled lines were then etched with hydrofluoric acid and filled with an opaque material. Two such plates were cemented face to face with the lines at 90°, the edges sealed, and the assembly bound in a metal frame.

There has been no significant change in the methods of making halftone screens since those developed by the Levy brothers. Other screen patterns, including triangular dot patterns and the grained (mezzograph) screen, have been proposed, but none has produced consistently satisfactory results. For special effects, screens having straight or wavy line patterns and screens that produce a pattern of circular lines, concentric about a point that is chosen to be the focal point of the readers' interest, are in use. These screens are generally produced photographically from hand- or machine-drawn patterns and are used in the form of contact screens.

Basis for selection of screen ruling. Halftone screens may be obtained with line frequencies of 50 to 400 lines per inch (one inch equals 25.4 millimetres). The coarser screens are used for reproductions printed on coarse papers, the fine screens for higher quality reproductions on highly finished and coated papers. Screens in the 50–85-line frequency range are used primarily in newspaper illustration, while 100-, 110-, and 120-line halftones are suitable for highly polished papers and for some magazines, where single-colour and some multicolor work is involved. The 120-, 133-, and 150-lines-per-inch screens are generally used for colour illustrations in magazines and books printed on coated papers, when picture detail is important. Screens of 175 and more lines per inch are seldom used in letterpress printing, since the inks tend to fill the screens, causing difficulties in the press run. Such screens, however, do have some use in printing by offset lithography. In general, where paper quality permits, the finer screens are used when reproduction of fine detail is important. But since the letterpress process requires that the diameter of the finest highlight dot should not be less than 0.0015—0.002 inch, the use of very fine screens will lead to loss of image contrast, since some 3 to 5 percent of the picture area, in highlights, will be ink covered.

"Altone Gradar Screen"

An interesting development in glass screens was the "Altone Gradar Screen," manufactured in Germany. These are glass screens, ruled and etched in the usual manner, but with the rulings of the two glass elements filled with a transparent magenta lacquer of two different optical densities. When the screens are assembled, lines in one direction exhibit a density different from that of lines in

the perpendicular direction, and the intersections have a density equal to the sum of the densities of the two lacquers. The effect is to provide elongated halftone dots, with improved tonal reproduction in intermediate gray tones on coarse paper such as newspaper stock.

Contact screens. Perhaps the most significant recent advance in the halftone process has been the use of contact screens—films bearing a gray or magenta-dyed image of the light-distribution pattern behind a conventional halftone screen. The screen is placed in contact with the surface of a high-contrast film, in the image plane. The image, as recorded on the film surface, has the characteristic of a halftone exposed through a glass screen, with significant improvements in rendition of detail of the subject. Though first proposed in 1855 and developed by a number of later investigators, this technique was not fully exploited commercially until the 1940s. The contact screen eliminates certain diffraction effects inherent in glass screens, frees the operator from some of the lens-diaphragm restrictions imposed by the glass screen, and eliminates the necessity that lens opening, bellows extension, screen distance from the focal plane, and screen ruling all be in a particular relationship.

Contact screens are made with a silver (gray) screen pattern image and with a magenta dye image. The dyed screen gives some additional control over halftone negative quality through use of colour filters on the camera.

The "benday" process. An entirely mechanical procedure for production of a halftone image on a metal printing plate is the "benday" process (1879), named after its inventor, a New York newspaper engraver. This process utilizes a series of celluloid screens bearing raised images of dot and line patterns. The screen surface is covered with a waxy ink and the ink transferred, by pressure and rolling, to prepared portions of a metal plate. By selecting different screen patterns for transfer to different parts of the image, a mechanically produced halftone image is rendered. The ink image is reinforced with powdered resins and the plate etched. This process has been supplanted by completely photomechanical techniques.

Special effects. Such techniques as dropping out the highlights from the halftone negative (*i.e.*, eliminating the dots in these areas) in order to achieve increased contrast in illustrations were studied and introduced by several individuals. Such a method was patented in 1893, and in 1925 a camera attachment was introduced making it possible to impart a slight motion to the image on the film and thus reduce exposure to the point at which small highlight halftone dots were not printed or developed.

The most successful of the highlighting methods were those employing fluorescence phenomena, in which an object produces visible light when illuminated with ultraviolet light. In 1938, for example, the fluorographic process, in which fluorescing materials were incorporated in the artist's pigments, was patented. Similar pigments, designed for colour correction in watercolour illustrations, were patented in 1935 and 1938. Another process introduced shortly thereafter utilized a fluorescing paperboard. All of these processes were based on the same procedure: making an exposure under normal lighting for overall reproduction and then making an additional correcting exposure under ultraviolet light. The fluorescence produced by the ultraviolet illumination provided additional exposure in the affected areas that gave the necessary correction for highlighting or colour correction, by eliminating the screen pattern from "white" areas, in the case of monochrome, or reducing printing dot sizes, in critical areas of colour work.

Process developments. The discovery of the halftone screen was primarily responsible for the development and growth of photoengraving; further growth was related to other developments in the printing and allied industries.

Effect of colour film on printing developments

The introduction in 1935 of the first practical colour film for amateur and professional use probably did more to accelerate printing developments than any single invention. By making bulky studio-type colour cameras obsolete and permitting the use of readily portable camera equipment, previously limited to monochrome photography, for the production of colour images, on-the-spot colour photography became possible, greatly increasing the use of coloured illustrations. At approximately the same time, the commercial production of coated paper and heat-drying printing inks for letterpress printing began. Many colour developments for films, printing processes, and materials followed.

Electrolytic etching. The electrolytic principle, in which the plate being etched is an anode (positive electrode) in an electrolytic bath, was first applied to producing printing plates in 1912. The passage of direct current through the bath causes metal ions to leave the positively charged copper plate, resulting in an image in relief. The technique never achieved widespread popularity and has been supplanted today by new chemical etching processes except for specialized uses outside the graphic arts.

Chemical etching—traditional and powderless processes. Early methods of etching zinc and copper, methods that have persisted in some areas to the present day, were tedious and inexact and could be learned only through trial-and-error training. The principal difficulty stemmed from the fact that the chemical removal of metal from nonimage areas proceeds in all directions. Thus, etching done perpendicular to the plate surface to achieve the depth required for satisfactory printing also proceeds sideways, causing reduction in width of lines and dots of the printing image and also undercutting halftone dots—producing a below-surface dimension smaller than the printing surface. This leads to a mechanically weakened dot that may collapse under printing pressure.

Some success in overcoming this problem has been achieved by depositing an etchant-resistant material about the sidewalls of etched lines and dots, thus preventing lateral etching. The method of rolling a waxy ink onto sidewalls of lines and dots, called gillotage, has found wide use among European engravers. The "powdering" process, most widely used in the United States, involves brushing a resinous powder (dragons' blood) against the sides of partially etched lines and dots and fusing, with heat, to provide an etchant-resistant coating. A number of repetitions of the operation—etching, application of the protective material, and etching again, are needed before sufficient depth is attained. Results of this process are dependent upon the skill of the operator and on such ambient conditions as temperature and relative humidity, since these affect the performance of the powder. A major step toward solving the problem—in fact, the most important development in the field of etching since photoengraving was invented—came with introduction of a process of etching a magnesium plate without the use of powder. Experimenters found that by adding an oily material and a surface-active (wetting) agent to the nitric acid bath and controlling the conditions under which the plate was etched, they could produce characters in relief with adequate etching depth and virtually no printing-area loss during the etching. Later adapted to the etching of zinc, the process was quickly adopted by engravers in all parts of the world.

Powderless etching of copper

With this major hurdle in the etching of zinc and magnesium overcome, attention turned to copper, and in 1954 it was found that a powderless etching process for copper was possible if an organic compound (thiourea) was added to the iron chloride etching bath. Further refinements in the process and the introduction of new compounds to add to the etching bath followed.

Electromechanical plate making. While these developments in chemical etching were taking place, other experiments were being conducted to assess the feasibility of replacing traditional methods with the techniques of electronics, optics, and mechanics. The first successful result of these efforts was a device, introduced in 1947, that optically scanned a picture and simultaneously reproduced it as a relief printing plate on a plastic sheet. This device found wide application, particularly in newspaper plants, where photoengraving procedures were time-consuming and therefore costly. Within a short time, machines were developed that were capable of making etched plates in metals.

Meanwhile, investigators in the United States discovered about 1950 that some methacrylate compounds could be

quickly polymerized (turned into a polymer, or organic molecule with repeating chains of similar atoms) by exposure to light. Nylon was also found to have photosensitive properties, and by 1958 both materials were being offered for use in printing plates. Another plate-making system, reportedly based on light-sensitive urethane resins, was introduced in 1968.

Colour scanners. Paralleling the development of the electromechanical engraving machine, experimenters in the United States and Europe independently devised a number of electromechanical devices that automatically produce, from a colour-transparency image, corrected film negatives from which the four printing plates used in full-colour reproduction can be prepared. In one of these, a photographic transparency, wrapped around a glass cylinder, is scanned by a narrow beam of light. After passing through the transparency, the light continues through a colour splitter, and the blue, green, and red components are directed onto the sensitive surfaces of photocells. The electronic signals thus generated are modified and amplified in a computer that functions as an electronic analogue of photographic colour-separation processes. The computer activates a series of lamps, which expose the colour-corrected images onto photographic films mounted on another drum, attached to the same shaft as the transparency holder. This development was based on initial experimentation in commercial laboratories in the late 1930s and early 1940s. Other units, based on similar principles but differing in some details of structure and operating procedures, have been manufactured in the United States, West Germany, and Great Britain.

MODERN ENGRAVING TECHNIQUES

In terms of cost, engraving methods range in ascending order as follows: line engravings, halftone engravings, combination line-and-halftone engravings, single-colour, two-colour, and duotone engravings, and process colourplates. Each of the types may be produced in any of the customary metals or plastics. Process colourplates are usually made of copper in the United States and United Kingdom and of zinc elsewhere.

Basic production processes. The essential operations for the production of all types of photoengravings are similar. They include photography, photomechanical operations, etching, finishing, routing, blocking, and proofing.

The process camera

Camera and darkroom equipment. The engravers' camera, called a process camera, is a rigidly built machine designed to allow precise positioning of the lens and copyboard so as to provide control over the enlargement or reduction in size of the copy. It has a colour-corrected lens designed to give the sharpest possible overall image when focussed on a plane surface, without the distortions commonly found (though usually unnoticed) in the average portrait or amateur camera lens. Process cameras are designated as gallery or darkroom types. The gallery camera is freestanding and may be installed in any convenient location, but film must be removed in a light-tight cassette and processed in a separate darkroom. The darkroom camera is installed with its film holder as an integral part of the darkroom wall, giving easy access to the darkroom facilities.

The material to be reproduced, called copy, is mounted on a board or glass-covered copyholder, carried on the bed of the camera. Illumination for exposure is provided by arc lamps or high-intensity gas-discharge lamps. The most common camera lamp systems in late years have involved pulsed-xenon lamps, in which a high-voltage alternating current, passing through a glass tube containing the rare gas xenon, causes the emission of a light rich in the ultraviolet wavelengths.

Virtually all photographic work is done on film coated with high-contrast emulsions especially developed for graphic arts work. The introduction of dimensionally stable film bases has nearly eliminated the use of glass plates. Film emulsions used for halftones yield the extremely high contrast needed for halftone or line reproduction. Stripping film, a laminated film with a soft adhesive layer between the base and the emulsion layer, is widely used to permit images to be removed from the base and properly oriented on the glass or film flat through which the metal plate will be exposed.

In the early days of photoengraving, with wet-plate images on a glass support, it was impossible to process photographic images by any means other than immersion in solutions contained in a shallow pan or tray or by dipping into a tank of solution. Such tank and tray processing remains important but is now being supplanted by the use of automatic film-processing machines. Derived from equipment originally designed for processing of motion-picture film or photostat prints, these consist of belt- or roller-driven apparatus that carries the film through developer, fixing, and washing solutions, and, in most cases, through a drier, permitting delivery of a processed, dried film within three to five minutes after insertion into the machine. Such machines, with different processing solutions, may be used for continuous-tone or lith-type films.

Automatic film processors

Plate coating and printing. Photomechanical operations include cleaning the metal plate surfaces, coating with a light-sensitive solution, drying the coating (known as the top or enamel), and making the exposure on this coating through the negative prepared in the photographic step. Throughout these operations care is required to prevent imperfections such as bubbles, dirt, or scratches in the light-sensitive coating. The zinc, magnesium, or copper is prepared by careful cleaning with pumice and water. The light-sensitive coatings are usually poured over the surface and the plate, held flat, is whirled to ensure uniform coverage by the solution.

Light-sensitive coatings are usually a dichromated colloid material, but light-sensitive resins are also used. "Cold top" enamels are used on zinc and magnesium, which cannot be heated; these are usually slightly alkaline solutions of shellac or polyvinyl alcohol to which a dichromate is added. "Hot top" enamels nearly always contain fish glue as well as some egg albumin, to which is added a dichromate sensitizer. Mixtures of glue and albumin are used when it is necessary to control the etch resistance and the ease with which the edges of the enamel break away during the etching process. Hot top enamels must be set at temperatures of 550°–650° F (285°–345° C) and are used mainly on copper, the crystal structure of which is not altered at these temperatures. Polyvinyl alcohol and shellac resistants are set at temperatures of 350° and 220° F (175° and 105° C) respectively; therefore they are used on zinc and magnesium.

The tops are high-contrast materials that, when exposed to strong ultraviolet light, harden where the light has struck them and lose their solubility in water. Development in water then removes the coating from the unwanted areas of metal, exposing the metal for the etching process. Photosensitive resinous materials find wide application in electronic circuit printing, an operation analogous to photoengraving. They have more limited applications in the making of photoengraved letterpress plates, where they are used especially on zinc and magnesium and where their excellent storage properties permit their application in the metal-finishing plant, obviating the necessity for coating of the resist onto the metal in the photoengraving shop. These resinous materials are developed in organic solvents.

Etching and finishing. Nitric acid is commonly used in etching zinc and magnesium, the strength varying from 6 to 15 percent, depending on the metal. Copper is more readily attacked by ferric chloride (iron chloride), which is commonly used in concentrations of 28–45 percent. The etching may be done in an open tub or tray, though this method does not give the control needed for economical operation and is employed only where control is not critical. Most quality work is carried out in etching machines provided with impellers, devices that break up the etchant into a spray and force it against the plate.

In the conventional etching processes, the acid or iron chloride is used without modification, although great care is needed to prevent overetching. In many cases, especially when making line plates, etchers powder to protect the upper printing areas from attack while continuing to etch

in depth. The powderless etching processes, described earlier, are now almost universally in use, obsoleting the powdering technique. Line plates are usually etched to depths of 0.010 to 0.045 inch. Halftones may be etched to depths of 0.0023 to 0.009 inch, depending on the fineness of the screen. Coarser screens are etched deeper.

Photosensitive plastic plates are not etched in the ordinary sense. Unexposed resins, from nonprinting areas, are washed out with either dilute alkali or alcohol. Overetching is not a problem with this type of plate.

Finishing includes hand operations with engravers' tools, to remove imperfections in the image area of the plate and to improve its outward appearance. In colourplates, finishing also includes colour correction, a process of further etching or burnishing selected areas to improve the fidelity of reproduction. Finally, unwanted metal in the nonprinting areas of the plate is removed by a mechanical routing machine.

Blocking and proofing. Blocking consists of adhering the plates to cherry wood, plywood, or metal blocks to bring the printing surface to type height, which is 0.918 inch. Until the development of thermoplastic adhesives in the 1940s, blocking was always done by nailing the plates to wooden blocks. This tedious and costly operation has been largely replaced by hot mounting, in which process the plate is placed on a block of wood precoated with adhesive and this sandwich is subjected to heat and pressure. Upon cooling, the plate adheres firmly to the block.

Proofing consists in placing the plates on a precision press and taking sample impressions, or proofs that show how the plates will print during a regular press run.

Colourplate production. The first printed colour work was produced manually; artists painted in the necessary colours on black-and-white printed sheets. Later, stencils were used to speed this work, and in a further development, colours were printed, either as solids or tints, from hand-engraved plates. All of the work was crude by modern standards, however, and nothing approaching four-colour process printing was possible.

Modern colour printing

Modern colour printing, done with either three or four plates, each using a different colour of ink and overprinting the others, is based on a subtractive system of colours in which intermediate hues are obtained by some combination of two or more of the subtractive, or secondary, colours. The best colour printing is usually done with four process colours: yellow, magenta (blue red), cyan (blue green), and black.

The black plate is used to provide added uniformity of colour reproduction, since it will overcome changes in hue of critical neutral tones that could occur with random or cyclic variations in the amount of ink being transferred to the plate from the press inking system. Further, the use of a black plate aids in maintaining sharpness of picture detail.

In theory, black should result whenever the three subtractive colours are superimposed. Thus, it should be possible to produce black wherever all three of the secondary colours are present without affecting reproduction. Further, any colour that is within the range of colours reproducible with inks on paper can theoretically be obtained by using only black plus the proper pair of the secondary colours. But this has not been found practical because of the nature of printing ink pigments and the lack of total precision in the printing operation. Consequently, it is common practice to use the black plate to supplement the colourplates, portions of which are allowed to print in all except pure white areas of an illustration. The colourplates and the black plate must all be printed in register; *i.e.*, they must be superimposed so that identical portions of the image in each plate colour overprint each other.

Colour separation. In manufacture, the production of an individual colourplate involves the same steps used in producing an ordinary black-and-white engraving, once the etchant-resisting image has been printed on the metal. Prior to this, the only differences lie in the use of colour filters on the engraver's camera and in steps to reduce the range of colour contrast of the copy. Negatives representing the images to be printed with each of the coloured inks are obtained by photographing the colour copy through colour filters. These filters, usually used in the form of thin sheets of dyed gelatin inserted into the lens, are complementary in colour to the coloured printing inks used.

Masking is the use of positive or negative images, taken from one or more of the set of colour-separation negatives and used in register with a given negative, to correct for the deficiencies in printing inks and colour of the copy. Common colour errors corrected by masking include the removal of excessive yellow values and magenta values from the blue (yellow printer) and green (magenta printer) negatives.

Colourplates may be made by the use of two general photographic methods—one indirect and one direct. The indirect method produces either continuous-tone negative images, from which halftone negatives are made, or continuous-tone negatives, from which continuous-tone positives are prepared. In the direct method, screen negatives are prepared directly from the copy through the colour-separation filters and a halftone screen onto a high-contrast panchromatic film or plate to produce a negative ready for transfer to the metal plate.

Proofing of colourplates

The proofing of halftone colourplates for wet printing on high-speed presses (when one colour does not have time to dry before the next is laid down) is a critical operation, for the proofing must be carried out under conditions simulating as closely as possible those that will be encountered on the production press. Specially built proof presses make this possible. In appearance they resemble four conventional press units placed end-to-end, and the sheet of paper is passed in turn over the four plates. However, because the production press employs not the original flat plates but curved duplicates made from them, and because ink and paper specifications are highly variable, exact duplication of production results in a proofing operation is difficult.

Elimination of moiré. A serious problem in colour reproduction is the occurrence of an interference pattern, or moiré, caused by the overprinting of the screens in the colourplates (a similar effect can be obtained by superimposing two pieces of window screening or fine net cloth). Because it is impossible to maintain printing register within the degree necessary to avoid such an effect, it is common practice to rotate the halftone screen when making the negatives so that each of the four plates has its screen pattern in a different position.

Electromechanical engraving machines—colour scanners. Reference has been made to devices for the electromechanical production of relief printing plates. The first of these utilized a heated pyramidal stylus, the motion of which was controlled by an electrical signal from a scanning photocell, to penetrate a plastic plate to a distance inversely proportional to the optical density of copy, thus burning out varying areas from the plate surface. In another machine of the same general type, an oscillating gouge cuts a halftone pattern in a flat plastic or metal plate, under control of a signal from a scanning photocell; in yet another a spiral groove, of varying width, is cut into the surface of a plastic plate wrapped on a rotating cylinder.

The colour scanner has been described elsewhere in this article. The first such units were capable only of producing colour-separation negatives of the same size as the copy that was scanned. In later developments, circuits were provided to produce positive images, and mechanical or electronic devices were developed to allow enlargement or reduction of the size of the final image as compared with size of the original copy. When scanners were first made available, it was believed that their cost would limit their use to a few large plate-making establishments. In the early 1970s, however, acceptance was exceeding expectations.

Production specifications. These include specifications for line plates, halftone specifications, and combination plates.

Line plates. In line illustrations all of the image areas are either black or white, and hence no halftone screen is

required to copy them for use in making a printing plate. Suitable copy consists of line drawings, etchings, etc. The negative as it comes from the process camera is suitable to transfer the line image onto the metal.

Plate preparation, coating, burning in, etching, and finishing are essentially the same as for halftone plates. Certain specifications must be met, however. The nonprinting areas must be etched sufficiently deep to prevent the ink rollers from touching them on the press, and to prevent them from rubbing on the surface of the paper during wet colour printing. For presses with accurately adjustable ink rollers, the etch depth may be as little as 0.01 inch. The same depth is permissible in thin, wrap-around press plates. For conventional printing presses, the minimum etch depth is about twice this. Plates that are to be duplicated by electrotype or stereotype processes may require slightly greater depths, although normal etching ordinarily is sufficient to produce good duplicates. Plates from which rubber duplicates are to be made will require etch depths as great as 0.045 inch.

Halftone specifications. Etch depths in halftone plates need not be as great as those in line plates, but the contour of the halftone dot and the depth of the etched areas are very important. Etch depth in highlight areas, the most critical portions of halftones, varies from 0.006 inch in a 65-line halftone to 0.002 inch in a 133-line.

Combination line-and-halftone plates. These plates must be prepared by assembling, in the negative form, the halftone and the line portions of the illustration and then, after transferring them onto the metal, etching them in two operations, so as to attain the best results for both portions. The powderless etching processes, however, permit easier etching of coarse-screen combination plates for use in newspapers. Combination line-and-halftone plates may also be produced by making two plates in separate operations and mounting them on a single block in proper position with respect to each other.

Engraving techniques applied to intaglio printing processes. Procedures similar to those described for production of letterpress printing surfaces are applicable to the production of intaglio printing surfaces. In intaglio, or gravure, printing, the image to be transferred to paper is etched or incised into the surface of the printing plate or cylinder. The entire surface is covered with ink, and by means of a doctoring, or wiping, operation, excess ink is removed from the surface, leaving only that which is retained in the image areas. Paper is brought into contact with the surface, and, under high mechanical pressures, the ink transfers from plate to paper.

Intaglio printing surfaces

Intaglio printing surfaces are of two general types: line intaglio (sometimes referred to as copperplate gravure), in which the ink-retaining image consists of discrete lines that may vary in width and depth; and gravure (also known as rotogravure), in which both continuous-tone and line copy are reproduced as a series of tiny cells etched into the printing surface. These cells commonly vary in depth, and hence in the volume of ink they will retain. Variations in density are produced on paper by the different amounts of ink that the cells transfer to paper.

In the rotogravure printing process, the walls surrounding each cell act as a support for the doctor blade that removes ink from the printing cylinder or plate surface.

Line intaglio. This process is widely used in the production of bank notes, securities, stamps, and engraved documents. The distinctive sharpness of fine lines and readily discernible differences in ink thickness that the process produces make it a preferred technique for production of bank notes and securities. These appearance characteristics cannot be readily counterfeited by photomechanical processes.

The printing surface is created either by mechanically scratching an acid-resistant ground from the plate surface, as described above, or by use of a photographic positive of the desired line pattern to prepare a photoresist image on the metal. The image is etched into the plate, using the techniques of letterpress line etching, with maximum depth of etch usually less than 0.007 inch. Metals commonly used may be steel, brass, or copper.

When a mechanical engraver is used to expose the metal for etching, a pointer or stylus is used to follow a usually enlarged pattern in a metal or plastic master stencil, causing a diamond stylus, in contact with the lacquer-covered plate surface, to remove the lacquer in a sharply defined pattern. The intaglio image is then prepared by etching the exposed metal with appropriate chemicals.

In printing from intaglio forms, the plate is flooded with an ink of medium viscosity and the surface of the plate wiped clean with either a metal doctor blade or a piece of hard-surfaced paper. To overcome wear of the plate from the abrasion of the wiping mechanism, the surface is frequently protected by an electroplated chromium layer.

Wiped free of excess ink, the plate is brought into contact with the paper surface. A roughly outlined relief image (counter) of the printing pattern is often used to provide high local pressures, forcing the paper into the ink-filled intaglio image. As the paper is pulled from the plate, capillary-attraction and surface-tension forces act to pull the ink from the plate. After drying, the image has a distinctive appearance in which the ink has appreciable thickness, and thin lines have less thickness than wider lines.

Gravure (rotogravure). The gravure printing process is one of the three major processes used for catalogs, magazines, newspaper supplements, cartons, floor and wall coverings, textiles, and plastics. Gravure printing is done with flat plates or, more commonly, with cylindrical surfaces. A screen pattern is superimposed over all image areas; thus the edges of type or lines printed by gravure will have a rough, or sawtoothed, appearance. This does not detract from readability.

Early gravure work

Early work described above formed the basis for modern gravure engraving and printing. Karl Klič (Klietsch) of Bohemia, who was instrumental in making photogravure a practical commercial process, in 1878 exposed a positive transparency over carbon tissue, a film made of coloured gelatin sensitized with potassium dichromate and backed by a sheet of paper. The exposed film was pressed down on a copper plate coated with an even layer of resin or asphalt powder. The carbon tissue was developed in water, making the gelatin swell in inverse proportion to the exposure it had received. The plate was etched with ferric chloride in successive baths of varying strengths. Penetration of the tissue by the etchant, and hence the resulting depth of etch in the metal surface, was controlled by the degree of swelling of the gelatin. Klič's process produced sure and predictable results and became the preferred method for later workers.

In later developments, the irregular grain pattern, produced by use of resinous powders, was replaced by a regular overall pattern of intersecting lines, produced by exposing the carbon tissue to a glass screen bearing an overall pattern of clear lines, intersecting at right angles.

In rotogravure, separate negatives of type matter, other line copy, and continuous-tone copy are assembled and positioned according to a prepared layout. After the negatives are retouched, a continuous-tone positive is made and retouched to ensure desired density values.

A sheet of carbon tissue is next exposed under a gravure screen. This screen is a film or sheet of glass on which fine transparent lines, usually 150–175 per inch, cross at right angles to form opaque squares. The lines of the screen are positioned at an angle of 45° to the axis of the printing cylinder. Their purpose is to provide a support for the doctor blade, which wipes ink from nonprinting areas. The lines of the screen allow the light to penetrate to the film and harden the gelatin. The square "islands" remain soft.

Next, the continuous-tone positive is placed in contact with the carbon tissue and exposed under an arc light. The soft squares are hardened in proportion to the amount of light that penetrates the varying grays of the positive. The carbon tissue is pressed with a rubber roller to a cylinder that has a polished electroplated copper surface. After adhering the exposed carbon tissue to the cylinder surface, it is "developed" with warm water, which has the effect of swelling and removing unhardened gelatin. The result is an image in hardened gelatin, which

varies inversely in thickness according to the density of the photographic positive. The cylinder is rotated in a tray of ferric chloride, producing an etched image in the copper surface. The squares are etched to varying depths, depending on the degree to which they were hardened. The crosslines of the screen, which were entirely light-hardened, are not etched at all. In this way, pits or wells of different depths are etched into the copper. For very long press runs, the cylinder can be plated with nickel or chromium.

Rotogravure printing

In rotogravure printing, the cylinder usually is arranged so that during its rotary movement it passes through a trough filled with a thin solution of fast-drying ink. A thin steel doctor blade moves across the cylinder with a slight oscillating action and removes the ink from the surface, but not from the wells beneath. The cylinder then comes in contact with the paper, and the paper draws the ink out of the wells in the plate. After being printed, the paper shows through thin deposits of translucent ink, thus creating pale grays; heavier ink deposits from the more deeply etched wells appear correspondingly opaque. Thus a full range of tonal values can be printed. Since the ink used in rotogravure printing is quite fluid, it penetrates through the pores of the paper surface, obliterating the screen pattern. In reproducing illustrations, gravure comes closest to simulating continuous-tone copy. In colour printing, a separate cylinder is prepared for each colour.

Other methods. In the so-called Dultgen halftone intaglio process, which is widely used in colour work, two positives are made from the continuous-tone copy, one through a halftone screen or a special contact screen and the other without a screen. The carbon tissue is first exposed to the screened positive, which produces an image of dots of varying sizes, then to the continuous-tone positive, which produces differing degrees of hardening of the dot image. When etched, the dots are of differing sizes and of differing depths. This method thus uses two methods for controlling tonal values.

The Henderson process, sometimes referred to as "direct transfer," or "inverse halftone," gravure, has won some acceptance in the printing of packaging materials. Retouched continuous-tone positives are used in preparation of halftone negatives and, by a contact-printing operation, halftone positives. These positives show dot size variations proportional to the desired print density. The cylinder is coated with a cold-top photoresist, as in letterpress engraving. This resist is then exposed to ultraviolet light, through the positives, and the image developed. The cylinder may then be etched either in ferric chloride solution or in a powderless etching bath, similar to that used for letterpress photoengraving. Tonal variation in the resulting print on paper is caused almost entirely by variation in the area of dots.

(P.F.B.)

Photography, Art of

Photography is essentially the production of a permanent record of an image by the combined action of light and chemical processing. This article is concerned with still photography as an art medium. The technology of such areas as lenses, cameras, films, and processing is treated in PHOTOGRAPHY, TECHNOLOGY OF. Motion pictures are covered in MOTION PICTURES, ART OF and MOTION PICTURES, TECHNOLOGY OF.

As a means of visual communication and expression, photography has marked aesthetic capabilities. In order to understand them, the characteristics of the process itself must first be understood. Of these the first is immediacy. Usually, but not necessarily, the image that is recorded is formed by a lens in a camera. Upon exposure to the light forming the image, the sensitive material undergoes changes in its structure; a latent image is formed, which becomes visible by development and permanent by fixing. With modern materials, the processing may take place immediately or may be delayed for weeks or months. But, either way, the elements of the final image are determined at the time of exposure. This characteristic is unique to photography and sets it apart from other ways of picture making. Although the photographer can control the character of the original image that he captured upon film by the way he develops the negative and prints it, he cannot alter it except by manual techniques.

Immediacy of the photograph

A second characteristic of the photograph is that it can contain more than the photographer can see. The first daguerreotypes, shown to an astounded public in Paris in the winter of 1838–39 by the inventor Louis-Jacques-Mandé Daguerre, were praised because of the amount of detail recorded by them; looking at one with a magnifying glass, it was said, was like looking at nature with a telescope. The rival inventor of photography, William Henry Fox Talbot, after noting this characteristic, commented:

> It frequently happens, moreover—and this is one of the charms of photography—that the operator himself discovers on examination, perhaps long afterwards, that he has depicted many things he had no notion of at the time. Sometimes inscriptions and dates are found upon the buildings, or printed placards most irrelevant, are discovered upon their walls: sometimes a distant dial-plate is seen, and upon it—unconsciously recorded—the hour of the day at which the view was taken.

As photography has become more sophisticated in its technique, its scope has expanded enormously. High-speed photography has made visible motion man has never before seen; with material sensitive to invisible radiation, hidden aspects of nature can be revealed; and, by a combination of photographic, electronic, and space technology, even the planets can be observed in new ways.

Authenticity of the photograph

The seemingly automatic recording of an image by photography has given the process a sense of authenticity shared by no other picture-making technique. The fact that the photograph can show more than the eye can see and that the image is not filtered through the brain of a man and put down by the skill of his hand has given it value as evidence. Ralph Waldo Emerson wrote in his *Journals* of the daguerreotype process: "Tis the true Republican style of painting. The artist stands aside, and lets you paint yourself." The photograph has become, in the popular mind, so much a substitute for reality and of such apparent accuracy that the adage "The camera does not lie" has become a cliché. The tattered photograph a traveller takes out of his wallet to show someone is not, to him, a picture of his child: it is a substitute. Even people who do not travel know the distant parts of the Earth from photographs. And when a person does travel, he often seeks that which he knows from photographs and brings back his own photographs, in which he and his family may sometimes appear, as evidence that he has been somewhere.

This intrinsic characteristic is of such strength that it has dominated the evaluation of photography as an art form. Indeed, photography has been used over and over again as a foil by art critics to denounce paintings that rely heavily upon exact representation of subject matter.

Technical controls

In truth, photography is not the quasi-automatic process that is implied in a technical definition. The photographer has at his command a wide variety of controls. The image can be modified by the optical characteristics of the lens. The type of sensitive material used to record the image is a further control, and the contrast between highlight and

shadow can be changed by variations in development. In printing the negative, the photographer has a wide choice in the physical surface of the paper, the tonal contrast, and the image colour.

The most important control is, of course, the photographer's vision. He chooses the vantage point and the exact moment of exposure. Through experience he knows how the camera will record what he sees. He learns to previsualize the final print. If he has visual imagination and perception, he can make more than a passive record. He can express universal qualities. He can extend the vision of the viewer.

So facile a medium is photography that it is difficult to grasp its aesthetic capabilities and accomplishments. Of the billions of photographs that are taken every year, few can be considered art. Only a relatively small number of camera users are deliberately concerned with the production of photographs to be judged as art. A far greater number look upon photography as a means of communication. While the aim of the commercial photographer, the photojournalist, and the scientist may not primarily be aesthetic, it is significant and remarkably characteristic of the medium that often in their work can be found memorable pictures that reach beyond the particular to the universal. Recognition plays an overwhelming role in photography: recognition by the creative photographer of the picture possibilities presented to him and recognition by the creative editor of aesthetic qualities in photographs that he sees.

This article is divided into the following sections:

I. Equipment, materials, and technique
  Lenses
  Cameras
  Controls in exposure and processing
II. Stylistic and historical development
  The pioneers
  Developments to World War I
  Developments since World War I

I. Equipment, materials, and technique

Creative photography demands a thorough knowledge of photographic technique. By experience and discipline the master photographer works out a personal technique that is adapted to his aesthetic purposes. To assume that there is a standard universal technique is to deny the basic controls that every artist in every medium depends upon. On the other hand, to overemphasize technique to such an extent that it becomes the master, rather than the servant, of the photographer is as great a mistake as to underestimate its importance.

LENSES

Creating the image with the lens

The lens, the most vital part of the photographer's equipment, is the extension of his own eye: through it he creates the image. Perspective, which from the days of the Renaissance to the dawn of the photographic age in the 19th century was a baffling problem to the artist, is automatically created by a lens. So accurate is its image that the rules of perspective can be used in reverse: ground plans of architecture and contour maps of the Earth can be drawn from photographs. When a photographic image looks unnatural, it is likely to be because of the viewer's preconceived notions of "normal vision." Human vision embraces a restricted angle of view. Furthermore, eyes are never static: they scan the field continuously, viewing details in the distance at one instant, those close to at another, and those to the right or to the left at yet another. This visual report is instantly synthesized by the brain. The eye of the camera, its lens, is static. Its field of view is determined by its design. An extreme wide-angle lens can embrace a field of 180°. A long focus telephoto lens may limit the field to but a few degrees.

The size of the photographic image as well as the field of view depends on the focal length of the lens—*i.e.*, the distance between the optical centre of the lens and its image when the camera is focussed at infinity. The longer the focal length is, the smaller is the angle of view and the larger the image. The choice of focal length is a valuable control for aesthetic effect. With a wide-angle lens, the photographer can make foreground objects appear large. With a long-focal-length lens, he can visually compress the distance from foreground to background. Most portrait photographers prefer a lens that has a longer-than-normal focal length to avoid distortion problems.

Controlling the depth of field

Depth of field—or, as it is more commonly but incorrectly called, depth of focus—is a critical control for the photographer. He can render a scene sharp from the immediate foreground to distances as great as infinity, or he can put everything out of focus except what lies in a narrow zone. One of the factors in depth of field is the aperture or lens opening. Decreasing the aperture increases the depth of field. The focal length of the lens is also a factor: the shorter the focal length, the greater the depth. A third factor, distance to the subject, also enters into the depth of field. The closer the distance, the narrower the depth. Thus, the photographer has a number of ways of achieving the depth of field that expresses his intention.

The modern camera lens may reveal vastly more detail than was visible to the naked eye. Lenses, in the past, were deliberately designed to produce soft images. These lenses were particularly popular at the turn of the century, when the ability to render a great amount of detail was considered by many critics to be an aesthetic disadvantage. Today, when the photographer wishes an unsharp image, he uses techniques that allow him to alter the sharp image that his camera lens normally produces.

CAMERAS

The choice of camera depends upon what the photographer wishes to accomplish. If he seeks maximum precision of image, with relatively static subject matter, he may find the classical view camera mounted on a sturdy tripod best suited to his purpose. On the other hand, for swift action and work under low levels of illumination and when complete mobility is essential, a lightweight hand-held camera is preferable.

View cameras. The view camera takes large negatives on glass plates or sheet film. It is of simple construction: a bellows with a ground-glass viewing screen at one end and a board at the other end to which any one of a wide variety of lenses can be mounted. A special feature of many view cameras of great importance to the creative photographer is that the back of the camera can be swung on both the vertical and horizontal axes and its lensboard raised, lowered, or tipped. This flexibility enables the photographer to control the image formed by the lens. This control can be used, for instance, to solve the common problem of photographing a tall building: if the camera is tilted upward, all vertical lines will converge. By swinging the back so that the film plane is exactly perpendicular, the verticals are imaged as parallel lines. If there is too much foreground, the lens board can be raised to eliminate it, without altering the perspective. These controls can be used to create an image that conforms to conventional perspective or can be used for deliberate distortion.

View-camera movements

The view camera gives the photographer maximum control over his image and the large negative size gives an image of maximum definition. It is ideal for landscape, architecture, and formal portraiture—subjects that can be studied before exposure and that will remain relatively static while preparations are made for exposing the film.

Hand cameras. The modern hand camera differs dramatically from the view camera in terms of mechanical complexity, automatic features, and convenience of use. The operation of hand cameras is largely automatic. After one exposure the camera can be reset by moving a single lever. Consequently, photographs can be taken in rapid sequence. Although the negatives are smaller than those produced by a view camera, with modern precision optics, excellent prints can be made from them.

The role of the hand camera

The hand camera seems best suited for recording the stream of life. Its ease of operation allows the photographer to make many exposures, from which at some later date he may choose the image that best expresses his vision.

Hand cameras usually accommodate either roll film or 35-mm film. The negative size with roll film is usually 2¼ by 2¼ inches; with 35-mm film it is usually one by 1½ inches. The types most commonly used for creative photography are single-lens reflex and twin-lens reflex cameras in the roll-film size and single-lens reflex and rangefinder cameras in the 35-mm size.

Roll-film cameras. The single-lens reflex roll-film camera is fitted with ground glass on its top onto which the image formed by the lens is reflected by a mirror set at an angle of 45°. An instant before exposure, the lens is automatically set to the desired taking aperture, or stop, and the mirror moves out of the way to allow the image to fall directly on the film. This arrangement enables the photographer to view the exact image right up to the moment he presses the shutter release. By simply turning a crank, fresh film is brought into the focal plane, the mirror is put in its 45° position, the shutter is cocked, and the diaphragm is opened.

The twin-lens reflex is of simpler construction. It has two lenses of identical focal length. The upper lens, which has neither shutter nor adjustable diaphragm, focusses the image on the ground glass by a mirror permanently fixed at an angle of 45°. The lower lens focusses its image directly on the sensitized film and is fitted with a shutter and adjustable diaphragm. Although of much simpler construction than the single-lens reflex, it has the disadvantage that the user does not see the exact image of the picture he is taking but an approximate one, from a viewpoint slightly higher.

35-mm cameras. The 35-mm single-lens reflex camera operates on the same principle as the larger roll-film version, but the ground glass image is not usually viewed from above but at eye level, through a prism.

The 35-mm rangefinder camera does not permit the photographer to view the image of the lens. Instead, the camera is fitted with an optical finder that shows the field of view and also permits exact focussing by a rangefinder. The photographer focusses the lens by superimposing two images that are visible in the viewfinder.

CONTROLS IN EXPOSURE AND PROCESSING

The operation of the camera gives the photographer one kind of creative control. Another kind is offered by the selection of the film, the processing of the film, and the printing and processing of the print.

Film characteristics

Films. The photographer has a wide choice of negative films, varying widely in light sensitivity, grain, and contrast, among other characteristics. Films that are highly sensitive to light (so-called fast films) tend to be grainy. Processed film consists of a myriad of silver grains. The size of these grains directly affects the quality of the image, particularly when enlargements are made from the negatives. There are occasions on which a photographer may deliberately induce grain for aesthetic purposes, but usually it is desirable to hold grain to a minimum. Films that are less sensitive to light (the so-called slow films) tend to be less grainy. In some films the contrast range can be so narrow that there are no middle tones. Such films, called process films, can be used to produce poster-like effects from scenes having wide tonal ranges.

Modern panchromatic film is sensitive to all the wavelengths of the visible spectrum and even beyond the visible. This range of sensitivity gives the photographer a way of precisely and often dramatically controlling the tones of pictures. Blue sky can be rendered a dark gray or black by putting an orange or red filter over the lens during exposure. Since the red absorbs both blue and green, none of the blue rays present in the sky fall upon the film. In general, a filter lightens objects of its own colour.

With infrared film—that is, film that is particularly sensitive to infrared radiation—startling effects are possible, such as jet black skies, penetration of atmospheric haze, and a stark white rendering of some foliage.

Film processing. The processing of the negative offers the photographer further controls. The purpose of development is to convert to silver those silver halide crystals suspended in the gelatin emulsion that have received light. The purpose of fixing is to remove the silver halide crystals not affected by light. The rendering of tones, which is the very essence of the photographic process, is a function of both exposure and development. Between highlights and shadows an infinite number of tones can be recorded on the film, providing that the brilliance of the highlights does not exceed more than approximately 128 times that of the shadows. If the range is greater, the photographer must sacrifice detail either in the shadows or in the highlights. If the brilliance range is less than one to 128, he can increase the contrast between highlights and shadows. There is no fixed optimum exposure time or developing procedure; the combination of these factors that will produce a print that expresses what the photographer visualized just before releasing the shutter is determined by experience or by calculation.

Printing. While the photographer has many technical controls over his negative, it is in the printing of the negative that he has the greatest control. The U.S. photographer Ansel Adams has used a musical simile: the negative is the score, the print is the performance.

One of the chief characteristics of photography is that the final picture can be made of almost any size. The photographer's first decision, then, is to determine the format of the print. He may wish to retain as much detail as possible and will make his print the exact size of the negative by contact printing, so called because paper is laid in contact with the negative in a frame and then exposed to light. By using an enlarger, which projects an image of the negative on printing paper, he can produce a picture of mural size. How far a negative can be blown up depends on its size, its grain, and the amount of loss of definition that can be accepted.

A second characteristic of photography is the ease with which a portion of the negative can be used for the final picture. This is, of course, not unique to photography. Although it rarely happens, an artist using traditional mediums can present only a part of his original concept. It is common, however, for photographers to trim, or crop, their pictures either after they have printed them or in the process of doing so, by choosing small areas of the negative for enlargement. In photographic aesthetics there are two schools of thought: those who believe that the photographer should previsualize the final print at the moment of exposing the negative and those who believe that the making of the negative is but the first step and that the creative process of selection, emphasis, and composition extends into the darkroom.

Different views of photographic aesthetics

The surfaces of printing papers, their colour and their response to light (sensitometric characteristics), vary widely. The photographer who seeks maximum rendition of detail will usually prefer glossy paper. For subjects with bold, linear compositions, a rough-textured paper may be more suitable. By a simple chemical treatment the blue-black tones of modern printing papers can be converted to a rich brown. If he wishes, the photographer can make his print almost any colour.

As noted earlier, the contrast range of the negative can be controlled by exposure and development. Contrast can also be controlled by the selection of the paper. From the same negative the photographer can produce prints that are "flat," with shadows and highlights rendered as gray tones, or brilliant, with shadows approaching black and highlights white.

Photographers of the 19th century did not limit their printing papers to the gelatin and silver bromide or silver chloride emulsions that are almost universal in the 20th century. They also used papers made light sensitive with iron, platinum, and palladium, or with a mixture of a colloid, such as gum arabic, with potassium bichromate. Often they sensitized the paper themselves, which gave them a wide choice of surfaces. Some of these processes allowed the photographer to control development by manual intervention. Many of these long-obsolete processes are being revived by photographers who seek a greater control over the image than straight photography permits.

There is also a recent tendency to combine photography

Combining photography with other artistic mediums

with other artistic mediums. An artist may introduce a print into a painted or drawn composition. Photomontage, the presentation of two or more photographic images together as a single composition, can be done by pasting cutout photographic prints on a support or by projecting separate negatives on photographic paper that has been masked so that only portions are exposed at a time. By the latter technique, double exposures can be made and thus a wide variety of effects, unique to photography, can be produced.

Colour photography. Many of the creative controls characteristic of black-and-white photography can be used in colour photography. During the original photography, pale-colour filters can be used to alter colour rendition. Different films have different colour characteristics, some emphasizing warm tones, others cool tones. Throughout most of the history of colour photography, the processing of colour film and the making of colour prints has been such an exacting and complex matter that photographers left it to laboratories that specialized in such work. In recent years, however, the processes have been simplified and are being carried out by more and more individual photographers, a change that has opened the door to creative experimentation.

While most colour photographers strive for the reproduction of the colours of nature as they appear to the eye, startling effects can be obtained by departing from reality. Existing colour processes are based on securing records of the red, the green, and the blue rays in negative form and then converting them to the respective complementary colours: cyan, magenta, and yellow. If this order is deliberately changed, completely unreal images are obtained. By the use of infrared emulsion together with the colour records, even greater changes can be made.

II. Stylistic and historical development

THE PIONEERS

Photography came into being through the artistic aspirations of two Frenchmen, Joseph-Nicéphore Niépce and Louis-Jacques-Mandé Daguerre, and two Englishmen, Thomas Wedgwood and William Henry Fox Talbot, at the beginning of the 19th century.

Contributions of Niépce and Daguerre. Niépce, an amateur inventor living in Chalon-sur-Saône, a city 189 miles southeast of Paris, made his contribution to photography through his interest in lithography. In this process drawings were copied by hand onto the lithographic stone. To make the drawings Niépce relied upon his son's artistic skill, but, when his son entered military service, he was left without a draftsman. Not artistically trained, he began to work out a way by which light could draw the pictures he needed. Using a type of asphalt, bitumen of Judea, which changes its solubility in oil of lavender according to its exposure to light, he succeeded, in 1826, in making a crude photograph of the barnyard from an upper window of his country estate. The exposure was so great—a matter of several hours—that the shadows were obliterated as the sun moved from east to west. But the world's first photograph, now preserved in the Gernsheim Collection at the University of Texas, showed the path that others were to follow with more success.

Daguerre was a professional scene painter. Between 1822 and 1839 he was co-proprietor of the Diorama in Paris, an auditorium in which he and his partner Charles-Marie Bouton displayed immense paintings, 45½ by 71½ feet (14 by 22 metres) in size, of famous places and historical scenes, done in a style that emphasized illusion.

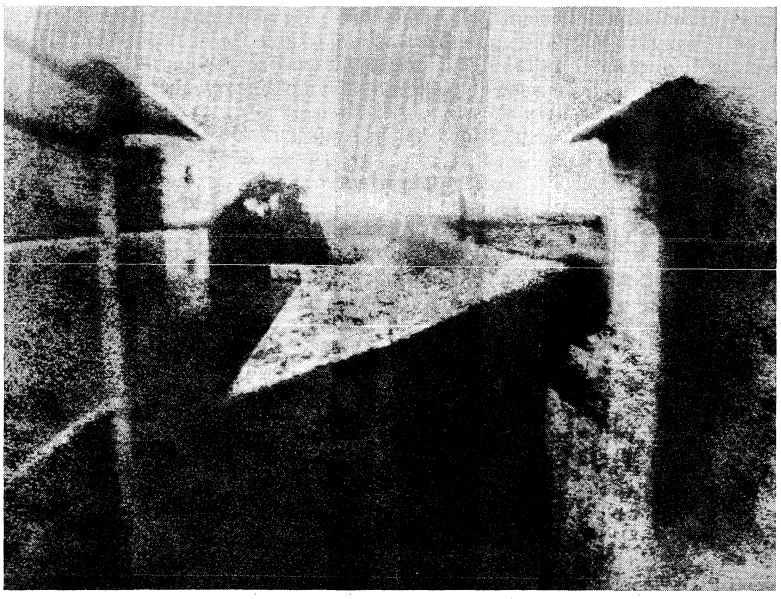
Like so many other artists, Daguerre made his preliminary sketches by tracing the images produced by a camera obscura—a box with a lens at one end, which threw an image on a piece of ground glass. At some time, the precise date is unknown, Daguerre began experiments in recording the camera image "by the spontaneous action of light," to use his own words. Learning of Niépce's work, he wrote to him, and in 1829 the two men formed a partnership. On Niépce's death in 1833, Daguerre continued the research alone, and by 1837 he had produced a photograph of his studio on a silvered copper plate, a photograph that was remarkable for its fidelity and detail.

In 1839 Daguerre and Niépce's son sold full rights to the daguerreotype and the heliograph (as Niépce had named his process) to the French government, in return for annuities for life. On August 19 full working details were published.

The daguerreotype process

To make a daguerreotype, a silver-plated sheet of copper was made light sensitive by exposing the silvered side to the fumes of iodine, which produced silver iodide. After exposure to light in a camera, the plate was exposed to fumes of mercury, which formed an amalgam with the nascent silver formed in the areas of the plate that had been exposed to light. The picture was fixed (made permanent) by removing the unaffected silver iodide with sodium thiosulfate, then called the hyposulphite of soda. Daguerre wrote a booklet describing the process, *An Historical and Descriptive Account of the Various Processes of the Daguerreotype and the Diorama*, which at once became a best seller: more than thirty editions and translations appeared before the end of 1839.

The contributions of Wedgwood and Talbot. In 1802 Thomas Wedgwood, son of the famous potter Josiah Wedgwood, reported his experiments in recording images on paper or leather sensitized with silver nitrate. Although he could record silhouettes of objects placed on the paper, he was not able to make them permanent and, to his disappointment, he failed to record a camera image.



Unaware of the work of Wedgwood and the French pioneers, Talbot, trained as a scientist at Cambridge University, was led to invent a photographic process because of his inability to draw landscapes. On a holiday trip to Italy in 1833, the idea came to him of recording by chemical means the images he observed in his camera obscura. By 1835 he had a workable technique: he made paper light sensitive by soaking it alternately in solutions of common salt (sodium chloride) and silver nitrate. Silver chloride was thus produced in the fibres of the paper. On exposure to light the silver chloride became finely divided silver, dark in tone. He decreased the sensitivity of the unexposed silver chloride by washing it in a strong solution of sodium chloride. The result was a negative, from which he could make any number of positives simply by putting fresh sensitized paper in contact with the negative and exposing it to light. Later, upon the suggestion of the scientist Sir John F.W. Herschel, he fixed his photographs with sodium hyposulphite (now called sodium thiosulfate).

When news of Daguerre's process reached England in January 1839, Talbot rushed publication of his "photogenic drawing" process and subsequently explained his technique in full detail to the members of the Royal Society—six months before the French government divulged working directions for the daguerreotype. There were many others who had similar techniques and who were to claim priority, but to Talbot and Daguerre are owed the two basic processes that were to sweep across the civilized world and establish photography as the most facile and convincing way to produce pictures.

Differences between the two pioneer processes

First criticism. The two pioneer processes were different in several ways. Daguerreotypes were on metal; photogenic drawings were on paper. Each daguerreotype was unique; photogenic drawings could be duplicated endlessly. The aesthetic as well as physical character differed markedly. The daguerreotype rendered detail to a degree that was remarkable; the photogenic drawing, because of the fibrous structure of the paper supporting the silver image, gave a broader, somewhat diffused effect.

The first criticism of photography was necessarily based on a comparison with painting or drawing, since no other standards of picture making existed. The Parisian painter Paul Delaroche, when questioned about the value of the daguerreotype to artists, went so far as to say that "the process completely satisfies art's every need." Photography's remarkable ability to record a seemingly inexhaustible amount of detail was marvelled at again and again. The critics regretted that, because of the great length of exposure, moving objects were not recorded or were ren-

First successful photograph from nature, heliograph on pewter by Joseph-Nicéphore Niépce, 1826.

dered blurry and indistinct. The inability of the first processes to record colours was disappointing, but since the critics were already conditioned to black-and-white prints and drawings, this was not as serious a drawback as the harshness of the tonal scale. The technique of photography was at once recognized as a shortcut to art. No longer was it necessary to spend years in art school drawing from sculpture and from life, mastering the laws of linear perspective and chiaroscuro. As Daguerre boasted in a broadsheet in 1838, "with this technique, without any knowledge of chemistry or physics, one will be able to make in a few minutes the most detailed views . . ."

DEVELOPMENTS TO WORLD WAR I

Spread of the daguerreotype. Daguerre's process rapidly spread throughout the world. Before the end of 1839, travellers were bringing back to Paris daguerreotypes of famous monuments in Egypt, Israel, Greece, and Spain; from them engravings were made that were published in two volumes as *Excursions daguerriennes* between 1841 and 1843. Although his process was published "free to the world" by the French government, Daguerre took out a patent for it in England; the first licensee was Antoine-François-Jean Claudet. The first daguerreotypes in America were made on September 16, 1839, just four weeks after the announcement of the process. Exposures were at first of excessive length—a daguerreotype of King's Chapel, Boston, in the International Museum of Photography, collection in Rochester, New York, bears a label stating that it was made between 4:40 and 5:30 PM on April 19, 1840. At such exposures moving objects could not be recorded, and portraiture was impractical. Even in blazing sunlight and with the face whitened by flour, a person had to sit immobile for minutes on end. Within a few years, however, such improvements had been made in lenses and sensitizing techniques that exposure times were reduced to approximately 20 to 40 seconds. At once daguerreotyping became a flourishing industry. It was generally conceded that the United States led the world in the production of daguerreotypes. In the late 1840s every city had its "daguerrian artist," and villages and towns were served by travelling photographers who had fitted up wagons as studios. In New York City alone there were 77 galleries in 1850. Of these, the most celebrated was that of Mathew B. Brady, who began in 1844 to form a "Gallery of Illustrious Americans," and to that end collected portraits of notables taken by his own and other cameramen. Twelve of the portraits were published by lithography in a folio volume. In Boston the firm of Albert Sands Southworth and Josiah Johnson Hawes produced the finest portraits ever made by the daguerreotype process. They avoided the stereotyped lighting and posing formulas of the average daguerreotypist and did not hesitate to portray their sitters unprettified and "as they were." Lemuel Shaw, a judge of the Supreme Court of

Early daguerrotypes in America

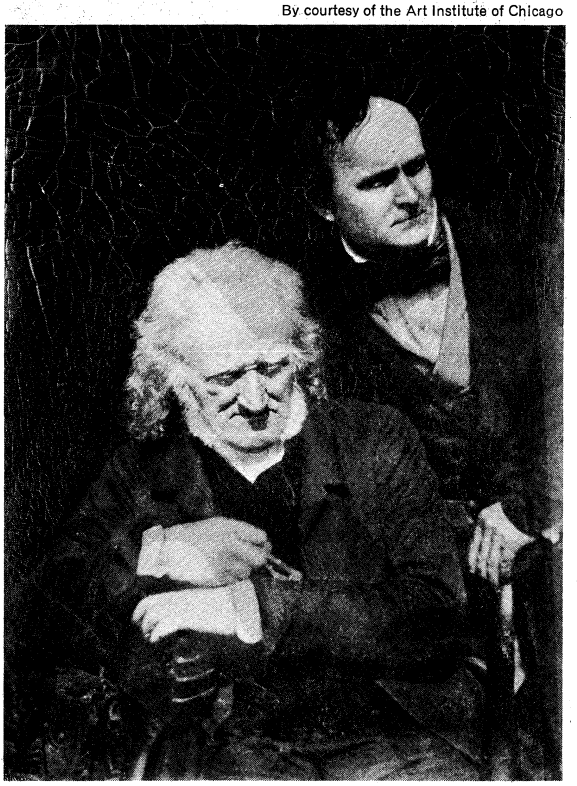
Massachusetts, stands with crumpled coat and unruly locks of hair under a glare of sunshine; Lola Montez, adventuress, dancer, actress, lolls over the back of a chair, a cigarette between her gloved fingers. Cities and towns, as well as their inhabitants, were photographed by American daguerreotypists: the rapid growth of San Francisco was documented month by month and the first history of the city, published in 1855, was illustrated by engravings made from daguerreotypes.



Development and use of the calotype process. By 1840 Talbot had greatly improved his photogenic drawing process by increasing the sensitivity of his prepared paper. At

first this silver chloride paper was allowed to remain in the camera (or beneath a negative) a matter of minutes, until a visible image appeared. Talbot then discovered that a much shorter exposure, which he estimated at 1/60 of the previous exposure, was sufficient to create an invisible (latent) image that could later be changed into a visible image by a chemical process now known as development. The discovery of the theory of the latent image was Talbot's great contribution. He named his improved negative process the calotype, from the Greek meaning "beautiful picture."

Discovery of the latent image

The first and most aesthetically satisfying use made of this improved process was in the work of David Octavius Hill, a Scottish landscape painter, and his partner, Robert Adamson, an Edinburgh photographer. In 1843 Hill decided to paint a group portrait of the ministers who in that year formed the Free Church of Scotland. There were over 400 figures to be painted. Sir David Brewster, who knew of Talbot's process from the inventor himself, suggested to Hill that he make use of this new technique. Hill then enlisted the aid of Adamson, and together they made hundreds of photographs, not only of the members of the church meeting but also of people from all walks of life. Although their sitters were posed outdoors in glaring sunlight and had to endure exposures of upward of a minute, Hill and Adamson managed to retain spontaneity. Hill's vision was dominated by the painting style of the period in lighting and posing, particularly in the placement of the hands. Many of the calotypes are strikingly reminiscent of canvases by Sir Henry Raeburn and other contemporary artists. Indeed, William Etty, a Royal Academician, copied in oils the calotype Hill and Adamson made of him in 1844 and exhibited it as a self-portrait. In addition to their formal portraiture, the partners made a series of photographs of fishermen and their wives at Newhaven, in Edinburgh, and architectural studies.

"John Henning and Alexander Handyside Ritchie," calotype by David Octavius Hill and Robert Adamson, c. 1845.

Calotypes of architectural monuments

The potential of the calotype for recording great monuments of architecture was shown by a number of Frenchmen, many of whom were trained as painters. In the 1850s they began to photograph historical buildings for the government. Working with cameras making photographs as large as 20 by 29 inches (51 by 74 centimetres), Henri Le Secq, Charles Marville, and Charles Nègre produced remarkable calotypes of the cathedrals of Notre-Dame in Paris, Chartres, and Amiens, as well as other structures that were being restored after centuries of neglect. An establishment was set up in Lille, France, by Louis-Désiré Blanquart-Evrard for bulk printing these paper negatives. Among the products of this firm was a superb volume of photographs by the Parisian writer Maxime Du Camp taken during his travels with the writer Gustave Flaubert in Egypt, Israel, and Syria, from 1849 to 1851.

Development and use of the collodion process. Photography was revolutionized in 1851 by the introduction of the collodion process for making glass negatives. This new technique, invented by the English sculptor Frederick Scott Archer, combined the advantages of both the daguerreotype and the calotype processes: the negatives were of glass and recorded detail in a way that rivalled the daguerreotype, and from them quantities of paper prints could be made. The process almost at once became universal, and the popularity of photography increased. The process had one serious drawback: the photographer had to sensitize his plate almost immediately before exposure and expose it and process it while the emulsion was moist. Collodion is a solution of nitrocellulose (gun cotton) in alcohol and ether; when the solvents evaporate, a clear plastic-like film is formed. Since it is then impervious to water, the chemicals used for developing the exposed silver halides and removing the unexposed salts cannot penetrate to them. Despite the drawback that the photographer had to have a darkroom of sorts always available, some of the most memorable photographs of all time were produced by this wet-plate process.

Curiously, in the United States, the new collodion plates were at first used to produce imitation daguerreotypes called ambrotypes. They were simply negatives with a dark backing to make the clear areas of shadows appear dark. In posing and lighting, these popular portraits were identical to daguerreotypes; they were of the same standard sizes, and they were enclosed in the same type of case. They did not approach the brilliancy of the daguerreotype, however. Tintypes, first known as ferrotypes or melainotypes, were merely variations of the ambrotype. Instead of glass the collodion emulsion was coated on thin iron sheets enamelled black. At first they were presented in cases, surrounded by narrow gilt frames, but by the 1860s this elaborate presentation had been abandoned, and the metal sheets were simply inserted in paper envelopes, each with a cutout window the size of the image. Easy to make, inexpensive to purchase, tintypes remained a kind of folk art through the 19th century. Poses were often informal, if not humorous.

Development of the tintype

Portraiture. A new style of portrait, introduced in Paris by André-Adolphe-Eugène Disdéri in 1854, came to be called the *carte-de-visite* because the size of the mounted photograph (four by 2½ inches [ten by six centimetres]) corresponded to that of a calling card. Disdéri used a multilens camera to produce eight negatives on a single glass plate. Each picture could be separately posed, or several exposures could be made at once. The principal advantage of the system was its economy: to make eight portraits the photographer needed to sensitize only a single sheet of glass and make one print, which he then cut up into separate pictures. At first *cartes-de-visite* almost invariably showed the subjects standing. Backgrounds, almost invariably plain in the days of the daguerreotype, became ornate: furniture and such architectural fragments as papier-mâché columns and arches were introduced, and heavy-fringed velvet drapes were hung within range of the camera. With the advent of the cabinet-size (6½ by four inches [17 by ten centimetres]) picture in 1866 the baroque tendencies of the photographer became yet more audacious, so that in 1871 a photographer wrote: "One good, plain background, disrobed of castles, piazzas, columns, curtains and what not, well worked, will suit every condition of life." It was at this period that retouching was introduced, as was the practice of painting over the photograph in oil colours.

Contributions of Nadar, Carjat, and Cameron

In contrast to the excessive reliance on accessories and retouching shown by the popular portrait photographers of Europe and America, the work of two Frenchmen and one Englishwoman stand apart. In their portraiture they reached a level unsurpassed since the daguerreotypes of Southworth and Hawes and the calotypes of Hill and Adamson. These photographers were Gaspard-Félix Tournachon, a Parisian writer, editor, and caricaturist who used the pseudonym of Nadar; Étienne Carjat, likewise a Parisian caricaturist; and Julia Margaret Cameron, wife of a British civil servant.

Nadar took up photography in 1853 as a means of making studies of the features of prominent Frenchmen for inclusion in a large caricature lithograph, the "Panthéon Nadar." He posed his sitters against plain backgrounds and bathed them with diffused light, which brought out every detail of face and dress. He knew most of them, and the powers of observation he had developed as a caricaturist led him to recognize their salient features, which he recorded directly, without the exaggeration that he put in his drawings. When Nadar's photographs were first exhibited, they won great praise in the *Gazette des Beaux Arts*, then the leading art magazine in Europe. Nadar was a colourful man. He had a passion for balloons, and in 1855 he combined his interests by taking the world's first aerial photograph.

Carjat's portraits, less intense perhaps than Nadar's, do have the dignity and distinction of those of his contemporary and rival.

Mrs. Cameron took up photography as a pastime in 1864. Awkward as it was, she used the wet-plate process and began to take portraits of such celebrated Victorians of her acquaintance as Alfred, Lord Tennyson, Thomas Carlyle, Charles Darwin, and Sir John F.W. Herschel. A number of her portraits were shown at the Paris International Exhibition of 1867. Mrs. Cameron used a lens of the extreme focal length of 30 inches (76 centimetres) to obtain a large head size. This lens required such long exposures that the subjects frequently moved. The lack of optical definition plus this accidental blurring was universally criticized, yet the very power of her work won her international praise. This can only be explained by the intensity of her vision. "When I have had these men before my camera," she wrote about her portraits of great men,

> my whole soul has endeavoured to do its duty toward them in recording faithfully the greatness of the inner man as well as the features of the outer man. The photograph thus obtained has almost been the embodiment of a prayer.

Besides these memorable portraits, Mrs. Cameron produced a large number of allegorical studies, of children and young women in costume, acting out biblical scenes or themes based on the poetry of her hero, Tennyson. In making these pictures—which today seem weak and sentimental—she was much influenced by the Pre-Raphaelite painters and the photographic work of Oscar G. Rejlander and Henry Peach Robinson (see below), leaders in the production of photographs that emulated paintings.

Influence of painting. Consideration of photography as an aesthetic medium was given impetus by the formation of photographic societies, made up of both professionals and amateurs, who had been attracted to the camera by the popularity of the collodion process. In 1853 the Photographic Society, parent of the present Royal Photographic Society, was formed in London, and in the following year the Société Française de Photographie was founded in Paris.

At the first meeting of the Photographic Society the president, Sir Charles Eastlake (who was then also president of the Royal Academy) invited the miniature painter, Sir William Newton, to read a paper "Upon Photography in an Artistic View" (*Journal of the Photographic Society*, i, 1853). His argument was that photographs could be useful to the painter so long as they were taken "in accordance (as far as it is possible) with the acknowledged principles of Fine Art." One way by which the photographer could make his results more like works of art, Sir William pointed out, was to throw the subject slightly out of focus. The extreme blue-sensitivity of wet collodion plates rendered the sky areas so dense that they appeared as blank paper on the print. To overcome this failure of the photographic process he recommended liberal retouching, the free use of handwork on the negative.

Combination printing

An outcome of the urge to create photographs that would fit a priori concepts of what "art" should be was the technique of making one print from several negatives. A famous example was by Oscar G. Rejlander, a Swede who had studied art in Rome and was practicing photography in England and used 30 negatives to produce a 31- by 16-inch (79- by 41-centimetre) print titled "The Two Ways of Life," showing, in allegory as obvious as it was sentimental, that the way of the blessed led through good works and the way of the damned through vice. Rejlander, who described the technique in detail in photographic journals, stated that his purpose was to prove to artists the aesthetic possibilities of photography, which they had generally denied. The photograph was shown in the Manchester Art Treasures Exhibition of 1857 and was purchased by Queen Victoria for Prince Albert.

Rejlander's technique stimulated Henry Peach Robinson, a professional photographer who had been trained as an artist, to produce similar combination prints. He achieved fame with a five-negative print, "Fading Away," produced in 1858. The subject, a dying girl, was considered by critics as too painful a subject to be represented by photography. Perhaps the implied authenticity of the camera bothered them, for painters had long presented subjects of far more painful nature.

Robinson became a most articulate member of the Photographic Society, and his teaching was even more influential than his photography. In 1869 appeared the first of many editions and translations of his book, *Pictorial Effect in Photography*. Robinson went a step further than Newton; he offered photographers a set of rules. From an outmoded handbook on painting, he borrowed compositional formulas the use of which, he claimed, would bring artistic success. The student was instructed to arrange his models in pyramidal compositions, and examples from the work of Sir David Wilkie, a popular painter of genre scenes, were given to show how this artist used triangular

Robinson's rules for photography

George Eastman House Collection

compositional schemes. The importance of balance was stressed, and the opposition of light against dark was made clear. The fault of the book lay not only in the assumption that rules set up for one art form can be applied to another but also in its intellectual and academic approach to art.

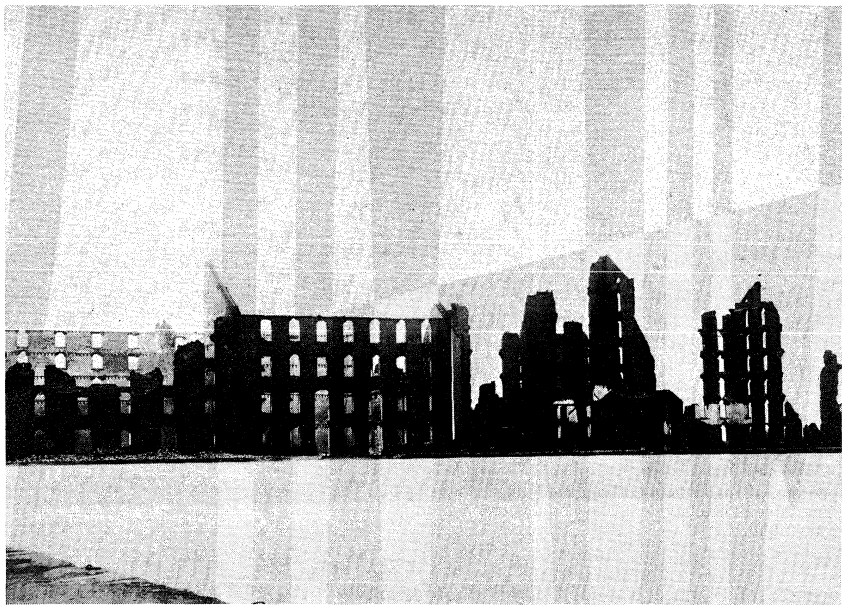
Robinson's work is weak and artificial by present standards of taste. Not only did he practice combination printing—itself a denial of photography's power of conviction—but he preferred to work in the studio, against painted backdrops and with props of natural objects, even foliage, mounted on casters. When he did photograph the real world, he took models with him, dressing them up to play the part of country girls.

So long as photographers maintained that the way to art was by the emulation of painting, critics were reluctant to admit the new medium to an independent aesthetic position. Portraits, when done as sensitively and as directly as those produced by Hill and Adamson, Nadar, and Mrs. Cameron, won the praise of art critics. But sentimental genre scenes, posed and arranged for the camera, lacked that sharp objective truth that is a characteristic of photography. Other photographers, less concerned about artistic issues, were making photographs of the world and man's activities upon it with such extraordinary perception and understanding of the medium that often their work surpassed record making. These men took their cameras to battlefields and to faraway places, often at the risk of their lives.

Combat photography. In 1855 Roger Fenton went from London to the Crimea to photograph the war. He developed his wet plates in a darkroom on wheels, at times under enemy fire. When the Civil War broke out in America, Mathew Brady, a New York daguerreotypist who had been among the first to adopt the wet-plate process, conceived the bold plan of making a photographic record of the hostilities. The *New York Times* on July 21, 1862, commented that Brady was

> the first to make Photography the Clio of the war. . . . His artists have accompanied the army in nearly all its marches, planting their sun batteries by the side of our General's more deathful ones, and "taking" towns and cities, forts and redans, with much less noise, and vastly more expedition. The result is a series of pictures christened "Incidents of the War," and nearly as interesting as the war itself; for they constitute the history of it, and appeal directly to the great throbbing hearts of the North.

Brady's "Incidents of the War"



Brady and his photographers—notably Alexander Gardner and Timothy H. O'Sullivan, who left his employ in the midst of hostilities—produced an amazing record of the battlefield. At his New York gallery, Brady showed pictures of the dead at Antietam. The *New York Times* reported on October 20, 1862:

> Mr. Brady has done something to bring home to us the terrible reality and earnestness of war. If he has not brought bodies and laid them on our dooryards and along the streets, he has done something very like it. . . . It seems somewhat singular that the same sun that looked down on the faces of the slain blistering them, blotting out from the

bodies all semblance to humanity, and hastening corruption, should have thus caught their features upon canvas, and given them perpetuity for ever. But it is so.

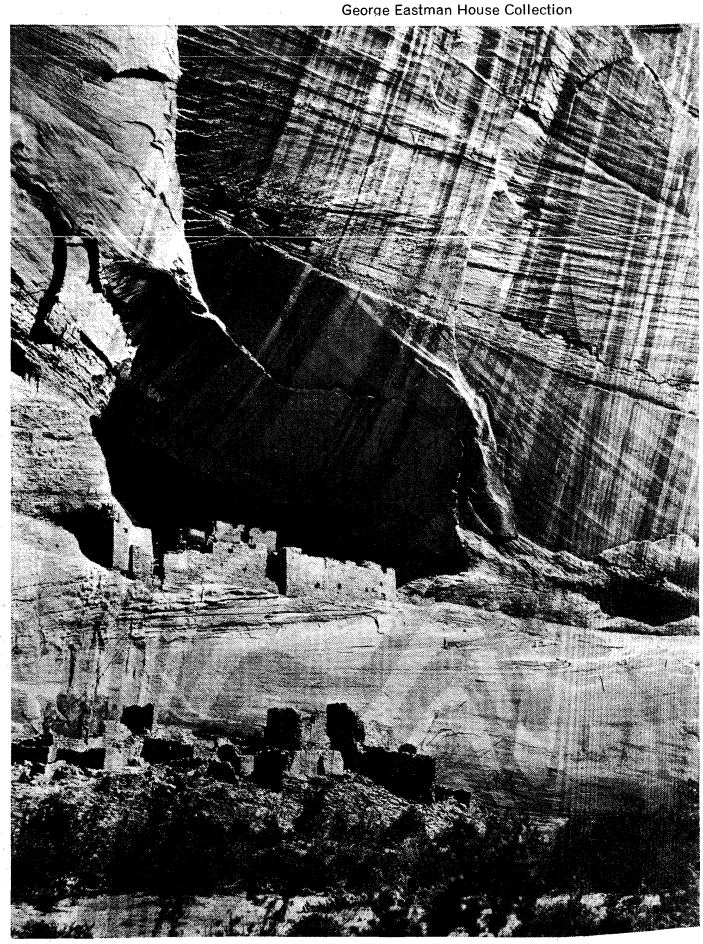
Oliver Wendell Holmes, the American physician and writer, was a great lover of photography and appreciated its specific aesthetic qualities. Of the Civil War photographs he wrote:

> It was so nearly like visiting the battlefield to look over these views, that all the emotions excited by the actual sight of the stained and sordid scene, strewed with rags and wrecks, came back to us, and we buried them in the recesses of our cabinet as we would have buried the mutilated remains of the dead they too vividly represented. (*The Atlantic Monthly*, July 1863.)

To Holmes, the power of the photograph to convince, to carry a sense of authenticity, set it apart from other mediums.

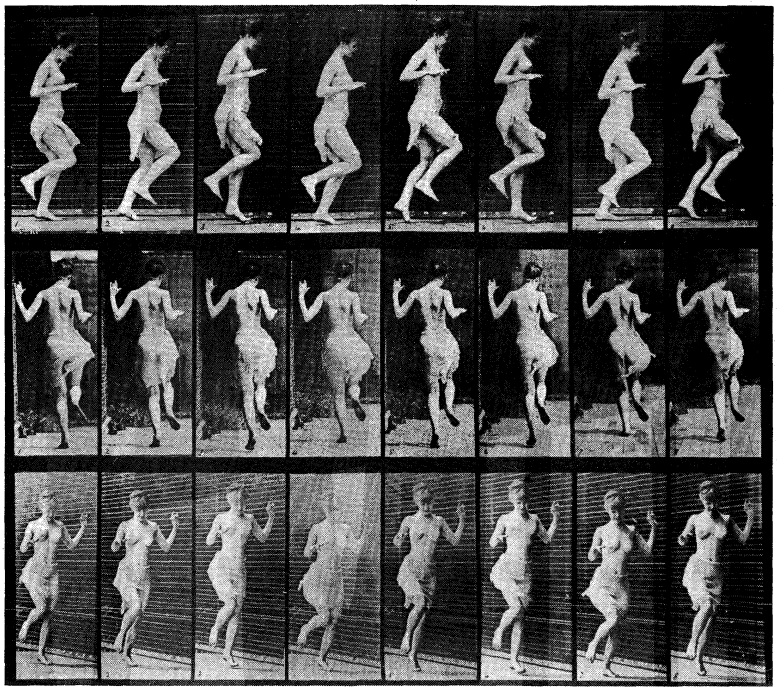
> The very things which an artist would leave out, or render imperfectly, the photograph takes infinite care with, and so renders its illusions perfect. What is the picture of a drum without the marks on its head where the beating of the sticks has darkened the parchment? (*The Atlantic Monthly*, June 1859.)

The camera records the very texture of the scene. The strange becomes familiar. The viewer knows the roughness of the boulders in the memorable photograph "'Home of a Rebel Sharpshooter" by Alexander Gardner. The soldier's gleaming rifle, his crumpled uniform, his pale face—these can be grasped in an instant, without a shadow of doubt. One is transported to the scene, unconsciously convinced of the accuracy of the picture. The response is utterly different from that provoked by a painting or a drawing. For a moment the viewer sees through the eyes of the cameraman.



Long prized for their value as historical documents, the Civil War photographs are now valued for their aesthetic qualities as well. The change came about through a recognition that photography had its own particular aesthetic and that photographs should be seen directly, without comparing them to paintings or to drawings.

Field photography. The last half of the 19th century saw the rapid rise of transportation and travel. The Suez Canal and fast ships brought colonies in the Southern Hemisphere closer to Europe; the transcontinental railroad joined the East and West coasts of the United States, and vast regions beyond the Mississippi became more accessible. Photographers were important members of government surveys and were also commissioned by railroad companies to make publicity pictures of track laying, bridge building, and spectacular scenery through which the new lines ran.



Photography on the American frontier

Of the photographers of the American frontier, two stand out: Timothy H. O'Sullivan, of Civil War fame, and William Henry Jackson. O'Sullivan's photographs of the Southwest are of great beauty, particularly his views of Indian cliff dwellings in the Canyon de Chelly, Arizona, made in 1873. Jackson, self-trained as a painter in Vermont, crossed the plains as a wagon driver. In 1868 he opened a photographic gallery in Omaha, Nebraska. The sedentary life of a portraitist and colourist did not please him, and he began to go into the field to photograph

Indians. The Union Pacific Railroad was under construction, and he received an order to produce 10,000 stereographs. The excellence of his work led F.V. Hayden, a geologist, to hire him to photograph the Yellowstone as part of Hayden's government-financed expedition there in 1871. The photographs Jackson took were influential in the decision by Congress to create the Yellowstone National Park. Later, in 1875, he recorded the immensity of the western landscape, using glass plates as large as 20 by 24 inches (51 by 61 centimetres). "They convey," he wrote in the catalog, "an impression of the real grandeur and the magnitude of mountain scenery that the smaller views cannot possibly impart."

The far corners of the world were reached by intrepid photographers. Francis Frith, an Englishman, exposed negatives in the Egyptian desert of a size rivalling Jackson's; Felice Beato, another Englishman, went to India, China, and Japan; and the Americans John Dunmore and Critcherton went to Labrador, where they made large photographs of icebergs and Eskimo life.

Stereoscopic photography. All of these field photographers also took stereographs. These double pictures, taken with twin-lens cameras, produce a remarkable effect of three dimensions when viewed through a stereoscope. First described in 1832 by an English physicist, Charles Wheatstone, the stereoscope did not become practical until Sir David Brewster, in Scotland, designed a simplified instrument for viewing them, which was exhibited at the 1851 Great Exhibition in the Crystal Palace, London. Queen Victoria was entranced by the stereographs she saw there, and instantly three-dimensional photography became a popular craze. Stereography is uniquely photographic, since no artist could draw two scenes in exact perspective from viewpoints separated only 2½ inches (six centimetres)—the normal distance between human eyes.

The illusion of looking at reality in a well-photographed stereoscopic view is remarkable. The aesthetics of two-dimensional picture making cannot be applied to these views. Indeed, many art critics hold that stereography is so rooted in illusion that such pictures can never be of lasting value. The millions of stereographs that were circulated in the years before newspaper reproduction of photographs did, however, have an enormous impact.

Instantaneous photography and the dry plate. The technology of photography took an important step forward as a result of the development of the dry plate coated with gelatin containing silver salts. By 1880 it was no longer necessary for the photographer to sensitize his own plates: he could buy them ready-made and could process them long after exposure. There was a further advantage: gelatin plates were about 60 times more sensitive than collodion plates. The simplicity and flexibility of the new process not only attracted an ever-increasing number of people to photography, but it led to new aesthetic considerations.

The development of the dry plate

Earlier, collodion plates had been used to make instantaneous photographs. Street scenes in London, Paris, and New York showed pedestrians and vehicles stopped in their tracks. Oliver Wendell Holmes found these records invaluable in his study of the human gait—a field in which as a physician he was deeply concerned. He noted that the camera shows the attitudes of legs and arms in ways different from the visual impression of them. "No artist," he wrote in 1863, "would have dared to draw a walking figure in attitudes like some of these."

Fifteen years later, the artistic world was amazed at the photographs of horses taken by Eadweard Muybridge in California. Using a series of cameras ranged side by side opposite a reflecting screen, with their shutters released by the breaking of threads as the horse dashed by, Muybridge secured sets of sequence photographs of successive phases of the gallop, the trot, the pace, and the walk.

In 1878, when the pictures were published internationally in the popular and scientific press, it was difficult to believe that they were accurate. To prove that his photographs were correct, Muybridge threw them upon a screen one after the other with a lantern-slide projector he had built for the purpose; the result was the world's first motion-picture presentation. This memorable event took place at the San Francisco Art Association in 1880.

These famous photographs were taken with wet plates. Later, with the new gelatin plates, Muybridge was able to improve his technique greatly, and, at the invitation of the University of Pennsylvania, he produced 781 sequence photographs of many kinds of animals as well as men and women, both clothed and nude, engaged in a wide variety of activities.

Growth in amateur photography. With the increased speed of negative materials, the camera was freed from the tripod. This not only simplified picture taking but was to open up a wholly new vision. With the hand camera

"Pond in Winter" by Peter Henry Emerson, 1888.

the very flux and flow of life could be captured, and an aesthetic based upon this capability was to be developed; but the first impact of the new, simplified gelatin process was its role in the growth of amateur photography. A great variety of hand cameras became available at relatively low cost; photography became available to all. Box cameras predominated. At first they were called "detective cameras" because they were inconspicuous and pictures could be taken with them without attracting the subject's attention.

Invention of the Kodak camera

Of these, the most famous was the Kodak camera, invented by the American George Eastman in 1888. In place of glass plates, it contained a roll of negative material sufficient for taking 100 pictures, each 2½ inches (six centimetres) in diameter. After exposing the last negative, the entire camera was sent to one of the Eastman factories (Rochester, New York, or Harrow, Middlesex), where the roll was processed and printed. "You Press the Button, We Do the Rest" was Eastman's description of the Kodak system. At first Eastman's so-called "American film" was used in the camera. This film was paper based, and the gelatin layer containing the image was stripped away after development and fixing and transferred to a transparent support. In 1889 this troublesome manipulation was eliminated with the introduction of film on a transparent plastic base of nitrocellulose. With the Kodak camera and the myriad of other similar cameras that followed in its wake, photographs of the most casual sort were taken by the million.

Concern with photography as an art form. The snapshot era made everybody an artist—or so thought the multitude. But art is not so lightly won, and those amateurs who were seriously concerned with photography as an art banded together in societies. At a meeting of the Camera Club of London in 1886, Peter Henry Emerson, physician by profession and an ardent amateur photographer, gave a lecture on "Photography, a Pictorial Art," in which he attacked the artificiality of the photographs of Henry Peach Robinson, then still highly popular, and quite generally accepted by the public as outstanding examples of the artistic use of the camera. *The Illustrated London News*, for example, featured full page wood-engravings of Robinson's best picture of the year. Despite his failings, Emerson's vehement and passionate plea for the return to natural subjects was indeed salutary. Of greater importance was his advice that photographers should respect the photographic process, and limit their controls to those that were inherent.

In his book, *Naturalistic Photography for Students of the Art* (1889), he further developed his theories. He believed that photography was potentially a great creative art, and that it did not need to be bound to rules set up for painting. "*Naturalism*," he wrote,

> is an *impersonal* method of expression, a more or less correct *reflection* of nature wherein (1) truth of sentiment, (2) illusion of truth of appearance (so far as is possible) and (3) decoration are of first and supreme importance.

Emerson sought a scientific basis for pictorial photography. He analyzed the physiology of vision in order to find out how the camera can simulate human perception. He reasoned that since the eye sees distinctly only a small part of what lies before it, while the surrounding area appears indistinct, it should be possible to reproduce this phenomenon by control of focussing. Only a small part of the photograph, he argued, should be sharp; the rest should be slightly out of focus. The fallacy in this theory of vision is that the eye, unlike the lens of a camera, is a living organism, which scans the field of view constantly so that the mind receives a composite report and the impression of full detail. Emerson's naturalistic theory was an advance in that he believed the photographer should rely entirely on controls that were themselves part of the photographic process; in addition to control through differential focussing, he advised the careful use of developing and printing methods.

Emerson's photographs of natural subjects

Emerson took a large number of photographs of the life of the simple country folk on the Norfolk Broads. These photographs were far removed from the artificial genre studies of Robinson and close to the graphic work of the French painter J.-F. Millet, which Emerson greatly admired. Imbued with a deep artistic feeling, Emerson's photographs, published in limited editions in handsome folio volumes, inspired other amateurs to seek inspiration in nature.

If Emerson was not the first to use the newly invented platinotype, he was the first to popularize its use for artistic ends. In this printing paper, the salts of iron and platinum replaced those of silver as the light-sensitive material. Platinotypes had a long and delicate tonal scale, and the choice of paper surface ranged from smooth to the rough texture of watercolour paper.

In 1891 Emerson renounced the art claims he had made for photography. A great artist, he said, had shown him that the mere reproduction or translation of nature was not art. The fallacy of this argument lay, of course, in the definition of art: to Emerson the words "art" and "paint-

"The Big White Cloud, Lake George, New York" by Edward Steichen, 1903.
By courtesy of the Museum of Modern Art, New York

ing" were almost synonymous. He dramatically published his retraction in a black-bordered pamphlet, "The Death of Naturalistic Photography."

In his writings, Emerson had much to say about photographic exhibitions. He felt that they were poorly organized. He recommended that photographs be framed in simple white molding and hung on one line, not plastered over gallery walls with little or no space between them. Especially he felt that photographs produced as art objects should be shown apart from work done for scientific, technical, and other nonaesthetic purposes.

Dissatisfaction with the scientific bias of the Photographic Society under the presidency of Sir William Abney caused a split in the society in 1892, when a group of pictorially minded members, under the leadership of H.P. Robinson and George Davison, formed a new society for the exclusive purpose of furthering "the development of the highest form of art of which photography is capable." They named the society the Linked Ring and held annual exhibitions, for which they chose the word salon, to show their artistic allegiance. By 1901 it was their proud boast that "through the *Salon* the Linked Ring has clearly demonstrated that pictorial photography is able to stand alone and that it has a future entirely apart from that which is purely mechanical."

In 1887 Emerson, judging a competition for *The Amateur Photographer*, had awarded a prize to Alfred Stieglitz, a young American who was studying photography in Germany. It was the first award that Stieglitz had received, and the first recognition of one who was to carry pictorial photography to a high level and be the constant champion of all that was progressive in photography and other forms of modern art.

Stieglitz's contributions to photography

When Stieglitz returned to the United States in 1890 after his student years in Berlin, he found that photography was a passing craze and that the New York Society of Amateur Photographers had threatened to change their organization into a bicycling club. After serving as editor of the *American Amateur Photographer* for a number of years, Stieglitz organized a sympathetic group in the Camera Club, New York City, and founded a handsome periodical, *Camera Notes and Proceedings*, which was outstanding for the unusually high quality of its reproductions of work not only by the members but by leaders in the pictorial movement in Europe and America. Stieglitz was one of the first to demonstrate the pictorial possibilities of the hand camera with his photographs of New York under all weather conditions. In an article, "The Hand Camera—Its Present Importance," after pointing out the dangers of casual snapshooting, he advised the reader to

> choose your subject, regardless of figures, and carefully study the lines and lighting. After having determined upon these watch the passing figures and await the moment in which everything is in balance; that is, satisfies your eye. This often means hours of patient waiting. My picture, "Fifth Avenue, Winter," is the result of a three hours' stand during a fierce snow-storm on February 22d, 1893, awaiting the proper moment.

Stieglitz championed many photographers who shared his conviction in the artistic capabilities of the camera. Three stand out: Edward Steichen, Clarence H. White, and Gertrude Käsebier. Steichen, trained as a painter, took up photography first as an aid in making drawings for the lithographic firm that employed him. From photographic magazines, he saw the creative possibilities of the camera and sent pictures to the Philadelphia Salon in 1899, where they instantly won praise. Passing through New York on his way to Paris in the following year, Steichen visited Stieglitz, who bought some of his photographs and encouraged him to continue with the camera as well as with brush and canvas. The first large showing of his photographs was in London, in the "New American School" exhibition of 1900. Steichen's soft-focus landscapes and portraits, reminiscent of Whistler in their use of flat tones and bold cutting of edges, were very controversial. In Paris he met the sculptor Auguste Rodin and produced a series of portraits of him and interpretive photographs of his work. He mastered the newly introduced gum print process. This technique gave the photographer the utmost manual control. He coated paper with watercolour pigment of any desired tint mixed with gum arabic and potassium bichromate. On exposure to light beneath a negative, the pigment became insoluble according to the amount of light received. The print was "developed" simply by bathing it in water. If desired, areas could be eliminated by brushing them with hot water.

Steichen's gum prints

Clarence H. White, of Newark, Ohio, and later New York, had a delicate sense of light. He preferred the platinotype process for printing, which gave delicate tonal rendering.

Gertrude H. Käsebier was a professional portraitist

who used unusual poses and had an especially fine feeling for children.

Formation of the Photo-Secession

In 1902 Stieglitz, with Steichen, White, Käsebier, and other friends, disturbed by the lack of standards and the general conduct of photographic exhibitions in the United States, formed a society, the Photo-Secession. They chose the word "secession" to show their split with the status quo, just as avant-garde German and Austrian painters had used the same word to make manifest their independence of officialdom. The record of the Photo-Secession is contained in 50 issues of *Camera Work*, published by Stieglitz between 1903 and 1917; this quarterly publication contained superb reproductions of photographs and extensive reviews and articles. The Photo-Secession had a gallery, which came to be known as 291 from the street number on Fifth Avenue, New York City, where it was located. There Stieglitz showed not only pictorial photographs but also modern art selected at first by Steichen in Paris. At 291 Americans saw, long before the Armory Show of 1913 made them popular, lithographs by Cézanne, drawings by Picasso, and sculpture by Matisse. If critics were amazed that Stieglitz, the champion of photography, was showing avant-garde modern art, he would reply that 291 was an experimental gallery, where photography would take its natural place along with the more traditional forms of picture making.

"The Steerage" by Alfred Stieglitz, 1907.

In 1915 Stieglitz and his friends published the periodical *291*, which printed a handsome 11- by 14-inch photogravure of his photograph "The Steerage," with essays praising Stieglitz for his triumph over the machine.

The last two issues of *Camera Work* contained photographs by Paul Strand, which showed a new approach. There were views looking down from unusual angles; there were bowls in quasi-abstract arrangements; there was a group of powerful open-air portraits taken in the streets of the lower East Side of New York. These portraits had been taken with a 45° prism fitted over the lens, so that the subjects were unaware that they were being photographed. Alvin Langdon Coburn, one of the first of the Photo-Secessionists, made a series of photographs in 1912 looking down from tall buildings, which he exhibited as "New York from Its Pinnacles"; they were remarkable for the way in which emphasis was placed on form. He pushed this interest in abstraction to the total elimination of recognizable subject matter in his "Vortographs," some of which were published in *Photograms of the Year* in 1917.

DEVELOPMENTS SINCE WORLD WAR I

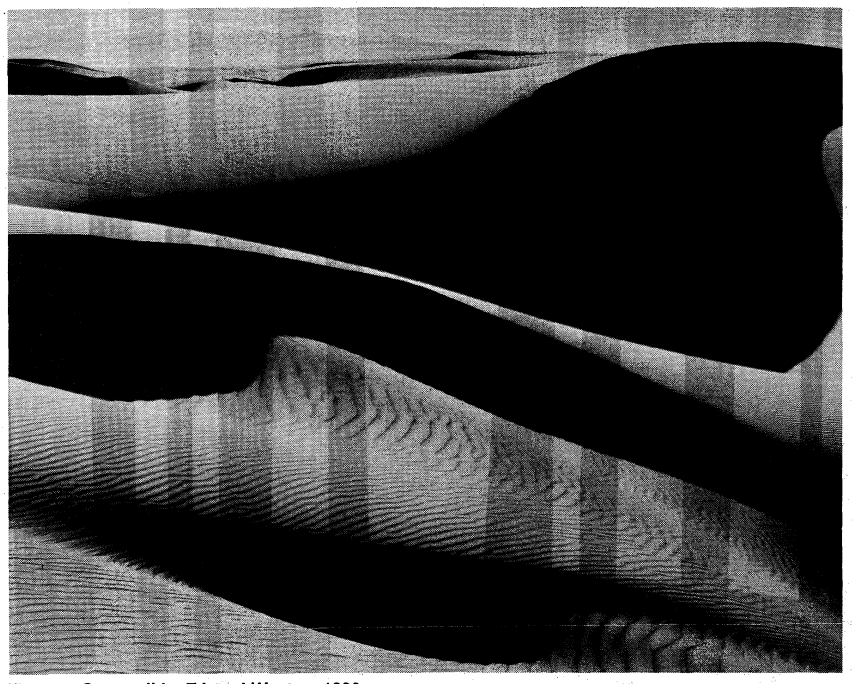
The new vision of the '20s. At the close of World War I, Steichen, who had been in command of aerial photography for the American Expeditionary Forces, abandoned the broad, quasi-impressionistic style for which he was so famous for sharply focussed photographs taken with lighting more familiar to the stage than to the portrait studio. His portraits of celebrities, taken for *Vanity Fair* and *Vogue* magazines, are a monumental record of the actors and actresses, artists and writers, thinkers and teachers of the '20s and '30s.

Steichen's new style

The painter Charles Sheeler used the camera to record the stark beauty of Pennsylvania barns and the forms of industrial structures.

To Stieglitz this revaluation of photographic aesthetics was in fact a strengthening of the beliefs he had held since his student days. He was to produce his most powerful work in the 1920s—his series of portraits of his associates at the galleries that succeeded 291 after 1917, when the building in which it was located was torn down; his views of New York, taken from the windows of his apartment or gallery; and especially photographs of cloud forms that he called "Equivalents" because through them he could express his intense emotion. Ill health forced him to abandon the camera in 1936, but he continued to maintain an art gallery until his death in 1946.

In California, Edward Weston, already honoured for his flatly composed, softly lit, and often sentimental landscapes and figure pieces, turned around 1920 to a more direct and realistic use of the camera, with a certain emphasis upon abstract form that he never allowed to detract from the recognition of subject matter. "The camera should be used for a recording of *life*," he wrote in 1924, "for rendering the very substance and quintessence of the *thing itself*, whether it be polished steel or palpitating flesh." He formulated a working method based on the use of the classic view camera for 8- by 10-inch (20- by 25-centimetre) negatives, a sharp-cutting lens, well stopped down to ensure great depth of field, and the complete avoidance of artificial lighting. He printed the negatives by contact on glossy-surfaced paper to secure maximum detail. This technique was a logical outgrowth of his theory of previsualization. In 1934 he wrote,



> The conception must be seen and *felt* on the camera groundglass complete in every detail; all values, textures, exact dimensions must be considered once for all, for with the shutter's release the isolated image becomes unalterably fixed. Developing the negative and making the final print, completes the original conception. This is the procedure in straight, *real* photography.

Weston's theory of previsualization

Retouching of any kind was inadmissable.

Paul Strand, whose striking close-ups and semi-abstract photographs Stieglitz had first exhibited, developed a style equally rigorous and self-disciplined during the same period. Working in Maine, the Gaspé, the Southwest, and Mexico, he produced powerful landscapes, direct portraits, and minute details of driftwood and plant life. Throughout his long career, Strand has emphasized the feeling of place in a way unequalled by any other photographer. In 1950 Nancy Newhall collaborated with him in editing *Time in New England*, a collection of his photographs with a selection of writings by New Englanders from the first settlers to the present day. When Strand moved to France, he wrote a series of similar publications on France, Italy, the Hebrides, and Egypt. None celebrate well-known capital cities; they concentrate upon life in small communities. Asked to define his sphere of interest, Strand once replied that he considered himself a photographer of people.

Viewing the negatives of Strand led Ansel Adams in 1930 to make photography his career. He was then studying the piano and photographing for his own sat-

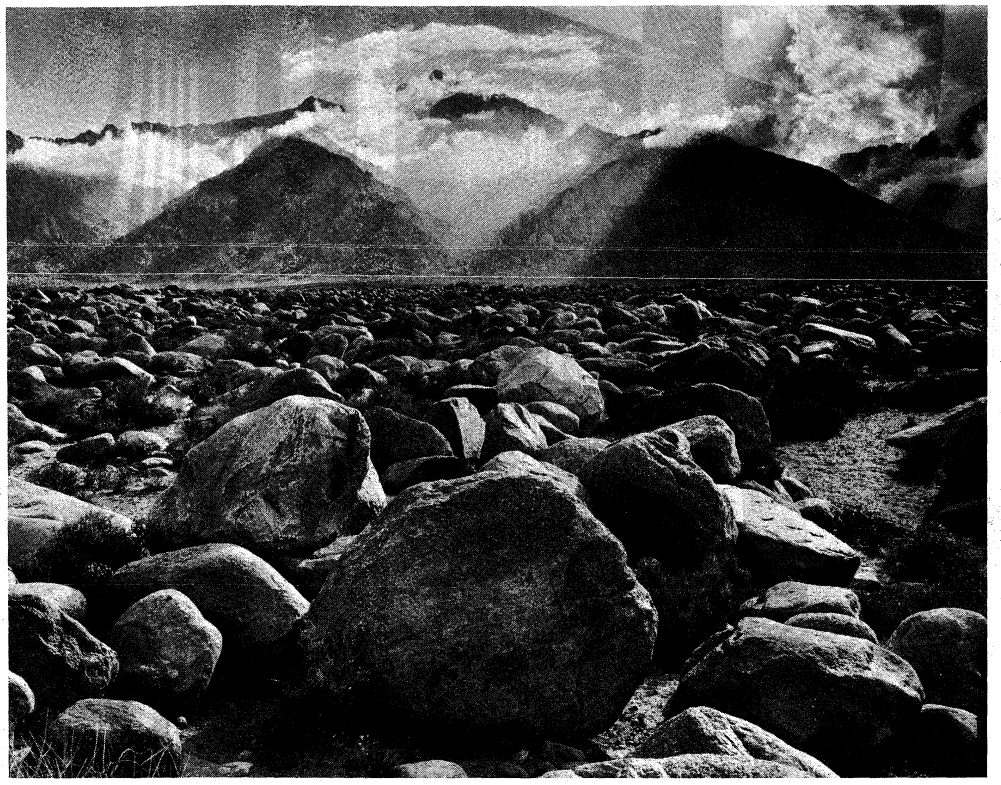
Cole Weston

tisfaction. He now determined to put his whole effort into photography. Long interested in nature—his first photographs were of the Sierra Nevada Range and Yosemite National Park—he refined and sharpened his technique. In 1932, with Willard Van Dyke, he founded an informal society, Group f.64, so named for the setting of the aperture of the lens that gave maximum depth of field. Edward Weston was an honoured member of the group and wrote the foreword to Adams' book *Making a Photograph*, published by the London Studio in 1935. This was the first of his many technical manuals to stress the concept of previsualization and to define in precise terms a functional aesthetic based upon the characteristics of the photographic medium. Adams' great contribution has been in what he calls "the interpretation of the natural scene." His photographs "Mount Williamson—Clearing Storm" (1944) and "Sierra Nevada from Lone Pine" (1944) are classics.



An approach somewhat similar to that of Weston, Strand, and Adams was to be found also in the work of Albert Renger-Patzsch, a professional photographer who spent most of his life in Essen, Germany. Using large tripod cameras, composing with deliberation and care on ground glass, he approached the world in a direct manner. He abhorred the casual and the accidental, and like Weston he insisted that the final image should exist, in all its completeness, before the exposure was made and that the print should directly record this image in full detail. His work was first exhibited in 1925, and four years later his most famous book appeared, *Die Welt ist schön* ("The World is Beautiful"). The very title set the work apart in a period when artists were more concerned with creating abstractions than interpreting the environment. Renger-Patzsch looked hard at the world. The photographs are stark, easily read; their challenge is their presentation of beauty in the ordinary.

Eugène Atget. At this same period, the photographs of Eugène Atget first became appreciated. Beginning

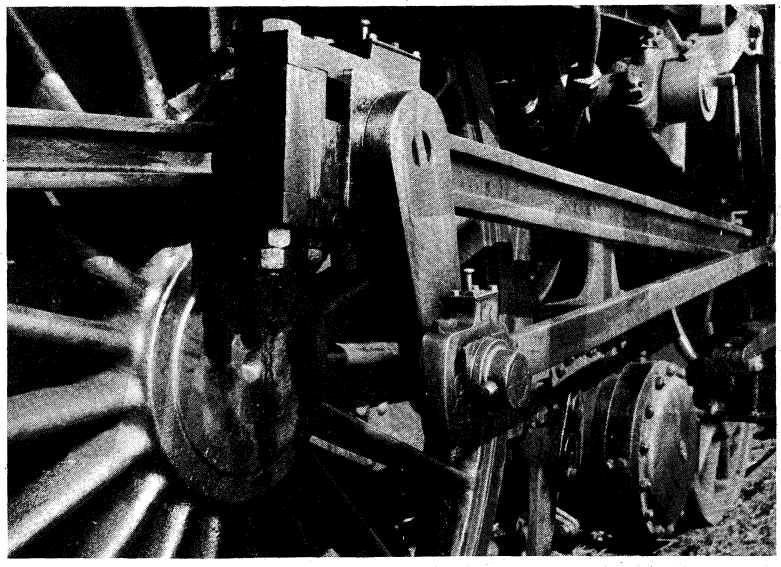
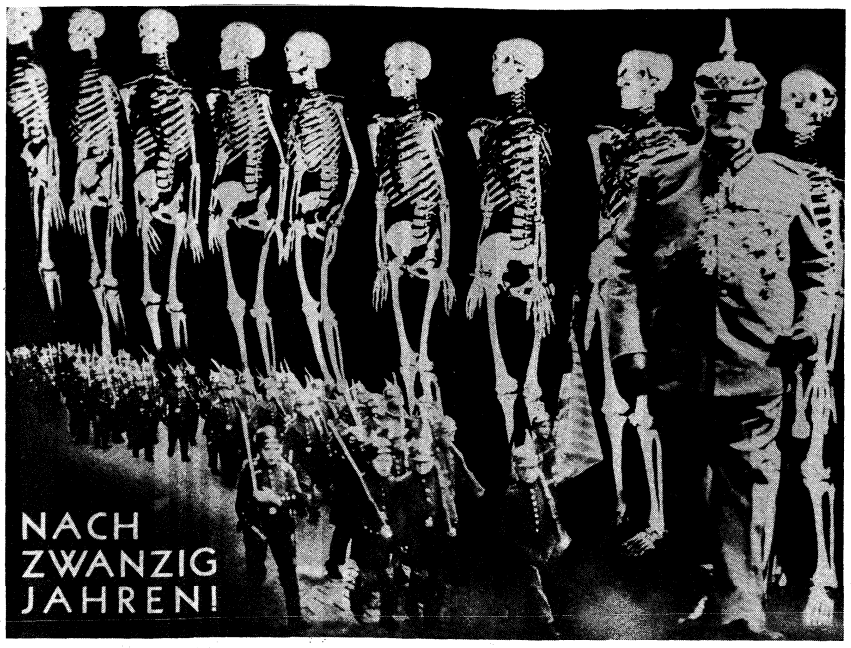
Ansel Adams

around 1898, this French photographer produced a series of photographs of Paris and its environs that were direct, straightforward, and poetic in their sympathetic rendering of the very fabric of the city. He photographed shop fronts, buildings, carrousels, carriages of all kinds, and the people who earned their living in the streets. Unknown to the photographic world, Atget worked alone, earning a meagre living selling prints to architects, painters, and historians. The beauty of his photographs attracted the attention of Man Ray, an American painter living in Paris and a member of the Surrealist group, who published a few of them in the periodical *La Revolution surréaliste* in 1926. Upon Atget's death in 1927 his entire collection of prints and negatives was saved for posterity by the U.S. photographer Berenice Abbott; they are now in the collection of the Museum of Modern Art, New York.



Influence of abstract art. In 1918 Christian Schad, a member of the Dada group of modern artists in Zürich, arranged small miscellaneous objects directly on photographic paper. Upon exposure to light, the paper darkened more or less or not at all, according to the opacity or transparency of the objects. These "Schadographs," as they came to be called, were minor contributions to the Dada movement and would be forgotten except that Man Ray and László Moholy-Nagy used like techniques.

Contributions of Man Ray



Man Ray was supporting himself by making fashion photographs in 1922 when he accidentally set a glass funnel, a graduate, and a thermometer on a piece of photographic paper, thus producing "Rayographs."

> I turned on the light; before my eyes an image began to form, not quite a simple silhouette of the objects as in a straight photograph, but distorted and refracted by the glass more or less in contact with the paper.

At the same time, in Berlin, Moholy-Nagy began to make similar cameraless photographs. Although identical in technique, the work of each was quite different. Man Ray emphasized the distorted but recognizable object; Moholy-Nagy the play of light, no matter how abstract. The former brought to photography the vision of the Surrealists; the latter, that of the Constructivists.

As a teacher in the influential Bauhaus art school, Moholy-Nagy explored the potential of the unconventional use of the camera as a means of discovering form. He delighted in the worm's-eye and the bird's-eye view. He considered the negative an end as well as a means. Amazed at the power of the medium to make visible the invisible, he collected X-rays, photomicrographs, astronomical, and ultrahigh-speed photographs. When in 1925 he put together a book of these pictures titled *Painting, Photography, Film,* the eyes of the world were opened to the scope and breadth of photography as a tool for vision.

"Photogram," photogram by László Moholy-Nagy, 1926.

Photomontage. A marked characteristic of the new art that was evolving in the first decades of the 20th century was the free combining of mediums. Paintings could no longer be classified as oil, watercolour, or tempera; sculpture was not limited to wood, bronze, or marble. The Cubist painters began to glue on their abstract canvases words clipped from newspapers, labels from bottles, and even actual objects. The critic Guillaume Apollinaire wrote in 1913: "You may paint with whatever material you please, with pipes, postage stamps, postcards or playing cards, candelabra, pieces of oil cloth, collars, wall paper or newspaper." The extension of this collage technique (from the French *coller*, meaning "to glue") to photography was logical. The Austrian Raoul Hausmann, one of the pioneers, has said that the idea of photomontage came to him in 1918 when he chanced to see a colour lithograph of a grenadier with a portrait photograph pasted on the place of the head. The German John Heartfield, the greatest master of photomontage, claimed that the origin lay in postcards that he and his friend the German artist George Grosz sent to friends at the front during World War I. These were

The photomontage technique

> a mischmasch of advertisements for hernia belts, student song books and dog food, labels from schnaps and wine bottles, and photographs from picture papers, cut up at will in such a way as to say, in pictures, what would have been banned by the censors if we had said it in words.

The photomontages of Hausmann, Grosz, and Heartfield have a savage quality, reflecting their protest against the upheaval of German society following World War I. Violent contrasts of the scale and perspective of the image elements, the ruthless cropping of heads and bodies, the substitution of machine parts for vital organs, and other seeming illogical juxtapositions, were carefully calculated to have a shock effect. During the Third Reich, Heartfield's anti-Fascist montages were among the strongest protests made by any visual artist.

The montages of the Constructivists are more architectural: space is created with the purely photographic self-portrait of the Russian artist El Lissitzky (1924) and a fantasy world is built by Moholy-Nagy in his "Leda and the Swan." The power of montage lies in the tensions set up by the juxtaposition of disparate visual elements.

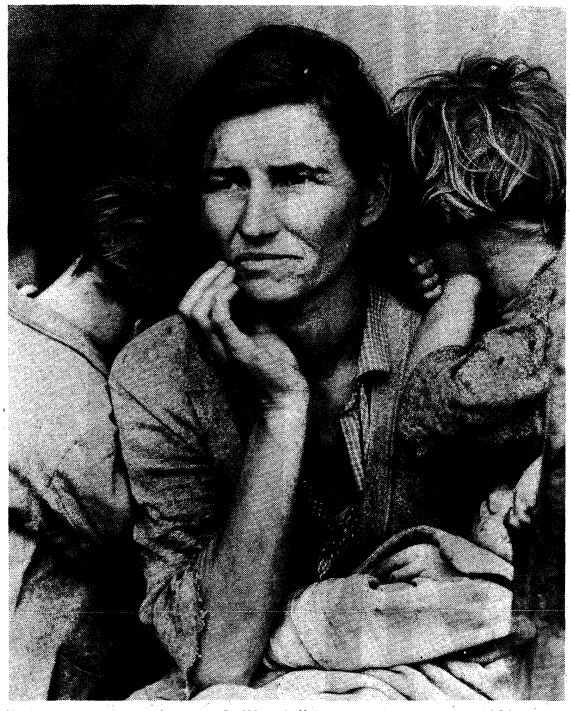
Instantaneous photography. In contrast to the production of such basically synthetic compositions as those produced by the masters of photomontage, and the analytical use of the camera to reveal aspects of the world previous-

'Children in Seville, Spain" by Henri Cartier-Bresson, 1933.
Henri Cartier-Bresson—Magnum

ly unknown or unseen, was the formation of an aesthetic based on the power of the camera to record life in the fraction of a second. Throughout its history, one of the characteristics of photography that most impressed the public was the relatively short length of time required to make pictures. Not only was the photographer seemingly more efficient than artists using other mediums, but he could reveal action hardly visible to the unaided eye. Throughout the 19th century this essential time factor was not considered an aesthetic one: indeed, the revelation by Muybridge of the true attitudes of figures and animals in motion had been scorned by artists—even though many of them made use of his findings. One of the earliest recognitions of the aesthetic value of the instantaneous image came with Moholy-Nagy's investigations of the manifold power of the camera to reveal the unseen and thus to expand vision. Most of the pictures that he reproduced in his influential book, *Painting, Photography, Film*, were not the work of conscious artists, but of press photographers, scientists, and amateurs.

To make a photograph of rapid action and then from scores of photographs to discover in some of them a new vision of great beauty is to use photography as a tool rather than a medium. The ability to train oneself to perceive the significant in the fraction of a second and to use the camera with such speed and precision that the instantaneous perception is preserved forever is a great creative gift. The gift is evident in the work of the Hungarian André Kertész as early as 1915 and in his later work in Paris during the 1920s. The Frenchman Henri Cartier-Bresson began around 1930 to develop the style that he later called the search for the "decisive moment." To him the camera is an "extension of the eye." With extraordinary precision he perceives a fully composed picture of the most fleeting scenes. Unlike many other photographers, he does not crop or recompose his pictures after they have been taken: every detail of a Cartier-Bresson photograph is present in the negative. He prefers the miniature 35-mm-film camera. When he finds a picture possibility he stalks his prey unobtrusively, working with his camera to a visual climax.

Cartier-Bresson's instantaneous image



Documentary photography. The value of the photograph as a record of the world and man's achievements had been established with the very publication of the first two successful techniques in 1839. William Henry Fox Talbot foresaw at once that his "photogenic drawing process" could be used to record ancient buildings, to inventory collections of artifacts, to duplicate manuscripts, and to reproduce botanical specimens. The first critics of Daguerre's daguerreotype process saw it as a means of bringing to Paris "the most remarkable views of the world," to quote the title-page of the two-volume album of engravings, *Excursions daguerriennes*, publication of which began in 1841. The recognition of the power of photography to persuade as well as to inform, however, came somewhat later. The classic sociological study *London Labour and the London Poor*, by Henry Mayhew, John Binny, and others (1851–62), was illustrated with drawings partly credited to daguerreotypes taken by Antoine Claudet; a sequel, patterned upon it, appeared in 1877—*Street Life in London*, by Adolphe Smith and John Thomson. The photographs, taken by Thomson, were moving, straightforward, unretouched pictures of chimney sweeps, flower sellers, bargemen, and other tradesmen. They were reproduced by the woodburytype process, a technique now long obsolete, which gave almost exact facsimiles of the original prints. The intent of the publication was to show—as Charles Dickens had shown in his novels—the hardships and problems faced by the ever-growing underprivileged population of London. Each of the photographs was accompanied by a detailed explicative text by Smith. Oscar G. Rejlander photographed orphan children in the streets of London performing such humble tasks as cleaning boots and opening carriage doors.

Thomson's London scenes

To Jacob A. Riis, a police reporter in New York City in the 1880s, the camera became the ally of his pen in the personal crusade he was waging to better the lot of the immigrants who then lived and worked in wretched conditions in teeming tenements in Manhattan's lower East Side. Himself an immigrant—he arrived in New York from Denmark in 1870—he knew at first hand the conditions he was seeking to eradicate. To supplement his written descriptions, he turned to photography. When the cameraman he employed proved unsatisfactory, he learned the process himself and was one of the first to use flash powder, a German invention recently introduced to America. His photographs, published in crude facsimile in newspapers and in his now-famous book *How the Other Half Lives* (1890), were instrumental in legislative reform.

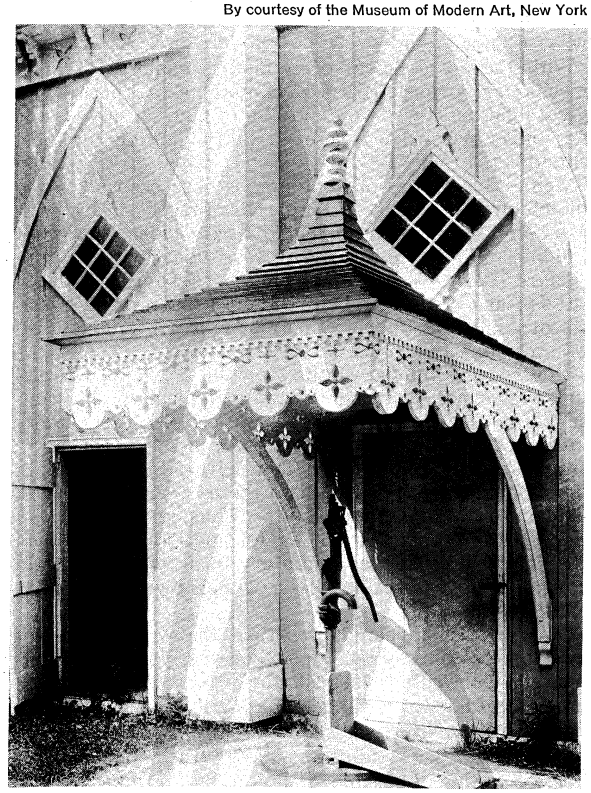
Beginning in 1905, Lewis W. Hine, a teacher at the Ethical Culture School in New York and a trained sociologist, began to make a pictorial record of immigrants passing through Ellis Island. He followed them in New York City, photographing them in their living quarters, at work, and in the streets. Later Hine travelled to textile mills, mines, and other places where young children were employed; largely through the evidence of his photographs, legislation was eventually passed against child-labour abuses.

This use of photography came to be called documentary in the 1920s by a group of motion-picture producers in Great Britain, headed by John Grierson. They saw the great potential of the photographic image as believable evidence. But the simple record photograph is not enough

"Migrant Mother, Nipomo, California" by Dorothea Lange, 1936.
By courtesy of the Library of Congress, Washington, D.C.

in itself; it must be endowed, as were those of Thomson, Riis, and Hine, with compassion for the subject and a sense of beauty. Seemingly, the use of photography as a tool for the betterment of mankind would belong more properly in a discussion of sociology rather than art, but some of the greatest examples of the art of photography have been produced under the banner of the "documentary movement."

Documenting the Depression in America



This is especially true of the body of photographs produced in America during the Great Depression by a group of dedicated photographers, under the direction of Roy E. Stryker, for the Farm Security Administration. The pictures covered the period from 1935 until the outbreak of World War II. Stryker, a professor of economics at Columbia University who had used photography in his studies, was invited by the Secretary of Agriculture to form a historical section of a newly formed division of the department that was concerned with the plight of farmers driven from their land in the dust bowl and who were migrating to the West. This at once took the form of a photographic project. The first photographer to be hired was Arthur Rothstein, a student of Stryker's. From California came Dorothea Lange, who had photographed migratory workers there. Her photographs are notable for their compassionate attitude toward people. In her "Migratory Pea Picker," a destitute young mother, surrounded by her children, peers at the camera with determination and courage. Walker Evans, with a direct uncompromising sense of environment and the beauty of everyday architecture, contributed a notable series. With the writer James Agee he documented the lives of sharecroppers in the book *Let Us Now Praise Famous Men* (1941). Others were documenting America at this time: Berenice Abbott produced a notable series of photographs of New York City, and Margaret Bourke-White with her husband Erskine Caldwell did a sensitive survey of the South, which appeared in book form as *You Have Seen Their Faces* (1937).

Photojournalism. From the outset, photography has served the press. Within weeks after the French government's announcement of the process in 1839, a daguerreotype was reproduced in the magazine *Le Lithographe*, and soon the by-line "from a photograph" appeared with increasing frequency in the captions of wood engravings in the popular illustrated newspapers and magazines. These reproductions were generally crude and carried little of the conviction of the original photograph. Regular use of photographs began with the perfection of the half-tone process for facsimile reproduction in the late 1880s. Magazines and newspapers now turned to photography for reporting topical events, and the profession of illustrator, which so many noted artists in Europe and America had followed, gradually became obsolete. With a few notable exceptions, such as William Warneke titled "Shooting of Mayor William J. Gaynor of New York," which appeared in the New York *World* in 1910, these early news photographs were unimaginative and dull.

After World War I, two of the largest picture magazines in Europe, the *Münchner Illustrierte Zeitung* and the *Berliner Illustrirte Zeitung*, began to develop a new approach to pictorial journalism. Using miniature cameras fitted with wide-aperture lenses—at first the Ermanox and then the Leica—Erich Salomon and Felix Man (pseudonym of Hans Baumann) took photographs indoors by available light, without flash. This technique led to informality of pose and a sense of presence that was remarkable. Stefan Lorant, editor of the *Münchner Illustrierte*, encouraged Man to take sequences of photographs, which he then laid out in imaginative picture essays. The example of the German picture magazines was followed in other parts of Europe and in America. One was the short-lived *Vu*, published in Paris. An issue of *Vu* devoted entirely to the Spanish Civil War contained memorable photographs by Robert Capa. In 1936 both *Life* and *Look* were conceived in America, and a formula was evolved in which the picture editor, photographer, researcher, and writer constituted a team. The result was the creation of a definite photographic style. *Life*'s first photographers were Margaret Bourke-White, already famous for her industrial photographs made largely for the magazine *Fortune*; Alfred Eisenstaedt, an experienced photo reporter for the German illustrated weeklies; Peter Stackpole, whose photographs of the Golden Gate Bridge in San Francisco attracted much attention; and Thomas D. McAvoy, a news photographer who had pioneered in photographing interior scenes by available light. The concept of *Life* from the start was summed up in the words of the founder, Henry Luce, who proposed to replace haphazard picture taking and editing with the

Life's first photographers

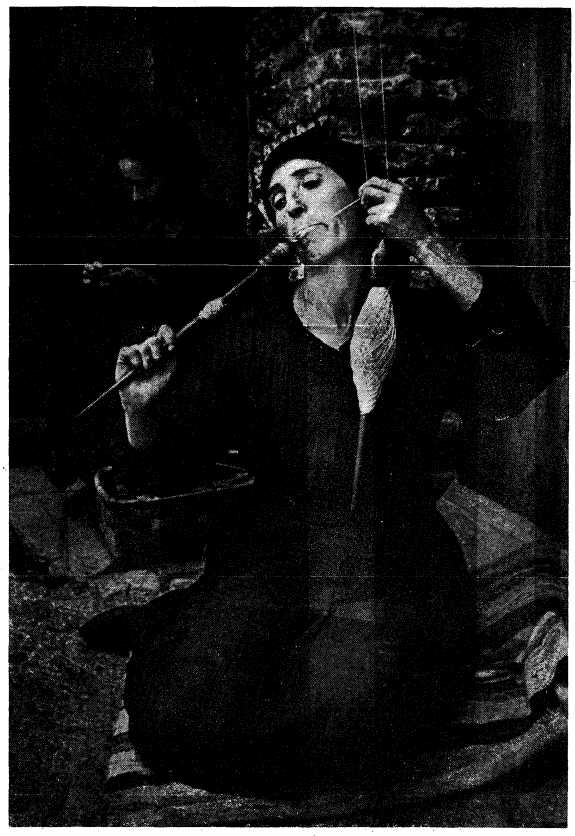
"Maine Pump" by Walker Evans, 1933.

"mind-guided camera." Photographers were briefed for their assignments and encouraged to take great quantities of photographs, in order that the editors might have a large selection. The visual organization of the picture story was carefully planned for maximum reader impact. The opening photograph of the picture essay, as this type of reportage came to be known, established the situation, and like written narration there was a visual climax and a definite conclusion. Usually the photographs were chosen and arranged on the pages before the accompanying text was written. Unlike the illustrated article, the picture essay quite logically is based upon the photographs, and the text is devoted to information that cannot be expressed visually: names, dates, places.

In the early days of *Life* and *Look*, photographers made great use of so-called synchroflash; *i.e.*, flash that was synchronized with the camera shutter, as distinct from open flash, which obliged the photographer to open the shutter, fire the flash, and close the shutter manually. The next step was the multiple flash, which made possible more sophisticated and pleasing lighting effects. The aim of *Life* and *Look* was to stress the human aspects of each situation as much as possible. By duplicating the existing illumination with the synchroflash lighting, photographers could await the moment when people were at their most natural and then make the exposure without the need for posing. This style was used brilliantly by Bourke-White. She wrote:

> Frequently I have set up a camera with remote control in the corner of a room, seated myself at a table some little distance away, and released the flash, possibly an hour later, when everybody had forgotten about the camera.

This way of photographing was soon challenged. Stefan Lorant, formerly editor of the *Münchner Illustrierte Zeitung*, left Germany during the Third Reich for London and established *Picture Post* in 1938. Working with him was Felix Man, who had pioneered with Erich Salomon in the use of the miniature camera. Lorant encouraged Man and other *Picture Post* photographers to develop the technique and pictorial style of available-light photographs so brilliantly begun in the 1920s. Their pictures, though lacking in sharpness and depth, had a remarkable naturalness that brought great reader appeal—so much so that *Life* began to publish similar photographs and hired a former *Picture Post* photographer, Leonard McCombe, with an extraordinary clause in his contract: he was forbidden to use flash.



Available-light photography

With the development of miniature cameras of great mechanical precision, lenses combining sharpness with great light-passing power, and film of high sensitivity, it is no longer necessary to use auxiliary lighting for most situations.

Memorable groups of photographs have been taken for the picture magazines. Examples are Man's "A Day with Mussolini," first published in the *Münchner Illustrierte Zeitung* (1931), and then, with a brilliant new layout, in *Picture Post;* W. Eugene Smith's "Spanish Village" (1951) and "Nurse Midwife" (1951) in *Life;* and Eisenstaedt's informal, penetrating portraits of famous Britons, also in *Life*.

Photographic books. Following the trend of the picture magazines, publishers began to replace the illustrated book, in which photographs were often haphazardly introduced to illustrate the text, with layouts designed to emphasize the photographs themselves. In these books the emphasis was reversed, and the text served rather to explain or illuminate the pictures. Thus, in *An American Exodus* (1939), by Paul S. Taylor and Dorothea Lange, striking photographs of migratory farm workers are accompanied by short quotations of their own words spoken at the time.

Other works appeared, in which the writing did not explain the photographs nor did the photographs illustrate the writing. Instead, the images and text were used together to produce what Wilson Hicks, *Life's* first picture editor, called the "third effect." Recently some magazine publishers have turned to book production, using the same techniques of group journalism in layout, writing, and production that had proved so successful in their magazines. To many photographers, books have become a chief method of the presentation of their work. In 1960 the Sierra Club began publication of handsome folio size books with *This is the American Earth* by Ansel Adams and Nancy Newhall. This book was followed by other publications, notably a series by Eliot F. Porter, entirely in colour.

Recent trends. Throughout its history, there have been two complementary yet distinct aesthetic approaches to photography. On the one hand, there has been the recognition of the basic qualities of photography and the desire to make use of them in a functional way. On the other hand, there have been those who believe that the most aesthetic use of photography is to relate it to other mediums. Since 1950 these trends have been pursued with equal vigour. To them has been added a third approach, which may be summed up in the word Alfred Stieglitz used to describe his late work: "the equivalent." To him photographs could be an equivalent of his thoughts and emotions.

In the United States, Minor White, through his long and distinguished career, his writing, his teaching, and his founding and editing of the influential magazine *Aperture,* has developed the Stieglitz approach to a highly sophisticated level. Metamorphosis to him is one of the paradoxes and virtues of photography. Its very reality and believability allow the sensitive artist to endow his photographs with overtones that may verge upon the mystical. The photograph must be transformed in such a manner that the viewer can read an inner message, which is not visible upon the surface, but which is carried by it. White's book *Mirrors, Messages, Manifestations* (1970) is a collection of superb photographs that present his spiritual biography.

Influence of Minor White on photography

To Aaron Siskind, who has worked with wall scrawls, weathered wood and plaster, torn billboards, and what he calls "the detritus of our world," the photograph must communicate more than the subject itself. The photographs of Harry Callahan express his highly developed sense of linear form, often by means of sharp contrasts of black and white and multiple images.

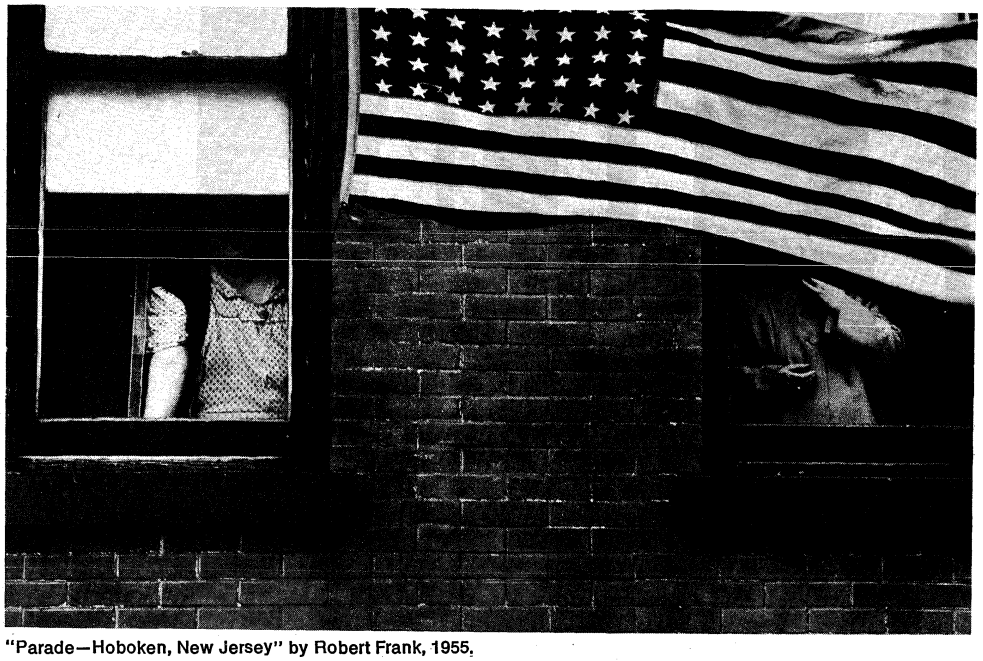
The American scene has been a subject of much interest to photographers: often called the "Social Landscape," the work of such photographers as Robert Frank, Bruce Davidson, and Lee Friedlander takes the form of penetrating sociological observations, somewhat reminiscent of the documentary photography of the 1930s. The approach differs in that rather than presenting problems faced by a certain level of American society, emphasis is placed on the effects of the urban environment upon people.

Colour photography has become increasingly popular within the ranks of the amateur. Statistics on home processing, however, show a reverse trend, a reflection in part of the more difficult techniques demanded by existing colour film and print material. Many professionals, however, prefer black and white to colour film for aesthetic, rather than technical reasons, and only a few have explored the artistic possibilities of colour photography. Among professional colour photographers, Eliot F. Porter and Marie Cosindas are the leaders in America: both prefer a somewhat realistic approach.



In England and Europe, trends closely parallel those in the United States. Bill Brandt, whose documentation of London began with the book *The English at Home* (1936) and continued during World War II with trenchant photographs of the bombing of that city, changed his style during the 1950s: with the use of an extremely wide-angle lens he created highly abstract studies of nudes. The "social landscape" school is well represented in the work of Tony Ray-Jones, who studied and worked in the United States before returning to Great Britain in 1966.

On the Continent, the most imaginative photographs are mostly made for publication, rather than for exhibition or hanging in galleries and homes. Europeans, in general, do not consider the photographic print as an end in it-

self, but as a step toward reproduction in periodicals and books. Brassaï (the pseudonym of Gyulas Halász), made his name in photography with the publication of *Paris de Nuit* (1933), intimate and sympathetic photographs of night life in the more humble quarters of Paris. Recently, like Aaron Siskind, he has been fascinated with wall scrawls and *graffiti;* a selection of them was published in 1960. Robert Doisneau is a master of humour, catching moments of absurdity in everyday life. Lucien Clergue has turned to the natural scene, and to the nude in surf. The tradition of the cameraless abstraction has been enriched by the Belgian Pierre Cordier with the introduction in 1958 of his "chimigrammes"—images made, not by light, but chemical action on photographic paper.

In Germany, the greatest influence has been the teaching of Otto Steinert at Saarbrücken and, since 1959, at the Folkwangschule in Essen. Almost single-handedly he brought back to Germany that spirit of experimentation and boldness of concept which had been suppressed during the Third Reich. An excellent photographer, Steinert was the founder in 1951, together with the art historian J.A. Schmoll gennant Eisenweth, of a movement they named "Subjective Photography." Chargesheimer, who made extraordinary abstractions, showed a different approach in his book *Cologne Before 5:30 A.M.:* a hard, almost brutal look at the skeleton of a city, with not a human to be seen. Horst Baumann specialized in illustration, particularly in colour. The Austrian, Ernst Haas is a master of colour photography, turning toward the abstract in his remarkable photographs of blurred action and bold compositions. A member of the Magnum group, a cooperative formed by Cartier-Bresson and others, Haas has produced work that is international in scope. The leading Swiss photographer is Emil Schulthess. In Italy the photographer's concern is chiefly centred upon the recording of the social scene: Mario Giacomelli's series of photographs of nuns and village life is typical and outstanding.

In Japan the extraordinary photographs of the landscape, particularly of Fuji-yama (Mt. Fuji) by Hiroshi Hamaya, parallel the straight photographic approach. Superb photographs have also been produced by Takayuki Ogawa, the social realist.

A lively interest in expanding the medium of photography beyond the straight approach is characteristic of much recent work. The experimentation takes many forms, including the revival of long-obsolete printing techniques such as the gum bichromate process and the platinotype. Perhaps the most startling change that has come about since 1960 is an interchange of mediums between photographers and painters. Many photographers make liberal use of manual techniques, such as negative and print retouching and the addition of colour. Simultaneously, painters, who have long utilized photographs as tools for observation, boldly imitate the very quality of photographic vision and sometimes introduce unaltered photographs by collage techniques or silk-screen reproduction directly into their canvases.

Interchange of mediums between photographers and painters

Collections. With the general acceptance of photography as an artistic medium, most museums today house collections of fine prints. The Metropolitan Museum of Art in New York City has long considered photography a branch of the graphic arts and has a notable collection in its Department of Prints and Photographs, including originals of the photographs reproduced by Stieglitz in *Camera Work*. The Museum of Modern Art, also in New York City, pioneered through the formation in 1940 of a separate Department of Photography. The International Museum of Photography at George Eastman House in Rochester, New York, is the largest museum of photography in the world; its rich collection covers production since the days of Daguerre. Photographs are also to be found in the Art Institute of Chicago, the San Francisco Museum of Art, the Oakland (California) Museum, and the Amon Carter Museum of Western Art in Fort Worth, Texas. The collection formed by the historians Helmut and Alison Gernsheim is now in the University of Texas at Austin. Both the Smithsonian Institution and the Library of Congress, Washington, D.C., have large collections of fine photographs.

In Great Britain the largest collections are those of the Royal Photographic Society, the Science Museum, and the Victoria and Albert Museum, all in London, and the Kodak Museum in Harrow, Middlesex. The Société Française de Photographie in Paris has a superb collection, dating from the formation of the society in 1854, and the Cabinet des Estampes of the Bibliothèque Nationale possesses large quantities of photographs. The largest collection in Germany, based on materials collected by the historian Erich Stenger, is owned by Agfa-Gevaert A.G., the photographic-materials manufacturers in Leverkusen. Collections are also in the Folkwang Museum, Essen, and the Staatliche Landesbildstelle in Hamburg. In Italy the Museo del Cinema in Turin, in addition to material on the history of motion pictures, has a collection of photographs.

BIBLIOGRAPHY. ALBERT BONI (ed.), *Photographic Literature,* 2 vol. (1962–72), an exhaustive and valuable bibliog-

raphy, listing books and articles, with detailed references to bibliographies.

General works: *The Encyclopedia of Photography*, ed. by WILLIARD D. MORGAN, 20 vol. (1963–64), richly illustrated, with contributions by world leaders in the art, science, and technique of photography; *Focal Encyclopedia of Photography*, rev. ed., 2 vol. (1965), especially strong on technique and scientific theory; *Life Library of Photography*, 17 vol. (1970–72), an indispensable series of well-illustrated books, covering all aspects of photography, with special emphasis on its use as a medium of communication and expression, unique in that the history of the medium is integrated with technical exposition.

Equipment, materials, and techniques: ANSEL ADAMS, *Camera and Lens: The Creative Approach*, rev. ed. (1970), vol. 1 of the series "Basic Photo," gives a detailed description of the aesthetic capabilities of the medium with precise technological instructions and illustrations. See also the earlier volumes in the series: *The Negative; The Print; Natural-Light Photography; Artificial-Light Photography* (1948–56); and ANDREAS FEININGER, *Total Picture Control* (1961), a textbook of advanced photographic technique. (*Colour photography*): E.J. WALL, *The History of Three-Color Photography* (1925, reprinted 1970), a basic technological survey of all known methods of synthesizing colours by recording the red, green, and blue rays photographically; J.S. FRIEDMAN, *History of Color Photography*, 2nd ed. (1968), a continuation of Wall's *History;* RALPH M. EVANS, W.T. HANSON, JR., and W. LYLE BREWSTER, *Principles of Color Photography* (1953), a detailed discussion of the visual perception of colour and the various systems by which it can be recorded photographically; LEWIS WALTON SIPLEY, *A Half Century of Color* (1951), a good survey of the medium, less technical than the encyclopaedic works of Wall and Friedman, discussing the use of colour photography, especially in the graphic arts.

Stylistic and historical development: JOSEF MARIA EDER, *Geschichte der Photographie*, 4th ed. (1932; Eng. trans., *History of Photography*, 1945), a pioneer Austrian work that deals primarily with the scientific and technological development of photography, but also discusses the work of artist-photographers (most useful for detailed citations of original sources); NATHAN LYONS (ed.), *Photographers on Photography* (1966), anthology of essays by photographers from H.P. Robinson (1892) to Wynn Bullock (1962); BEAUMONT NEWHALL (ed.), *On Photography* (1956), anthology of the inventors' own accounts of various processes, photographers' opinions of their art, and criticism; BEAUMONT and NANCY NEWHALL (eds.), *Masters of Photography* (1958), short, yet detailed, biographical sketches of 19 photographers, from David Octavious Hill to the present, with representative photographs of each; BEAUMONT NEWHALL, *The History of Photography from 1839 to the Present Day*, rev. ed. (1964), the stylistic development of the art of photography as related to the technological and scientific characteristics of the medium; and *Latent Image: The Discovery of Photography* (1967), although written from a scientific point of view, helpful for the understanding of the establishment of the medium; PETER POLLACK, *The Picture History of Photography*, rev. and enl. ed. (1969), especially valuable for its wealth of illustrations; *French Primitive Photography* (1969), a catalog of an exhibition, mainly from the collection of Andre Jammes and George Eastman House, with superb reproductions; HELMUT and ALISON GERNSHEIM, *The History of Photography from the Camera Obscura to the Beginning of the Modern Era*, 2nd rev. ed. (1969), an encyclopaedic general history of picture making by photography, with particular emphasis on European work; HELMUT GERNSHEIM, *Creative Photography: Aesthetic Trends, 1839–1960* (1962), complements the Gernsheim's *History* by bringing aesthetic developments up to 1960; GEORGES POTONNIEE, *Histoire de la decouverte de la photographie* (1925; Eng. trans., *History of the Discovery of Photography*, 1936), the first detailed account of the early days of photography; JOHN SZARKOWSKI, *The Photographer's Eye* (1966), a penetrating examination of photographic aesthetics covering photography's development; ROBERT TAFT, *Photography and the American Scene* (1938, reprinted 1964), the first history of photography in America in the 19th century. (*English pioneers*): D.B. THOMAS, *The First Negatives: An Account of the Discovery and Early Use of the Negative-Positive Photographic Process* (1964), a well-documented account of William Henry Fox Talbot's photographic work; WILLIAM HENRY FOX TALBOT, *The Pencil of Nature* (1844–46, reprinted 1969), the inventor's account, illustrated with 24 actual calotypes; see also BEAUMONT NEWHALL, *Latent Image* (1967). (*The Daguerreotype process*): BEAUMONT NEWHALL, *The Daguerreotype in America*, rev. ed. (1968), a study of the industry as well as the art of daguerreotyping, with a biographical index, a detailed discussion of the technique, and bibliography; RICHARD RUDISILL, *Mirror Image: The Influence of the Daguerreotype on American Society* (1971), a thorough survey, with emphasis upon the impact of the daguerreotype on American culture. (*The Collodion process*): FREDERICK SCOTT ARCHER, "On the Use of Collodion in Photography," *The Chemist*, Series 2, 2:257–258 (1851), the inventor's account, reprinted in BEAUMONT NEWHALL, *On Photography*, pp. 79–80 (1956); JOHN TOWLER, *The Silver Sunbeam* (1864, reprinted 1969), the most complete and popular textbook on photography during the collodion era. (*Pictorial effect and combination printing*): HENRY PEACH ROBINSON, *Pictorial Effect in Photography*, 3rd ed. (1886), the first book to provide directions for the production of photographs in the manner of paintings. (*Combat photography*): FRANCIS TREVELYAN MILLER (ed.), *The Photographic History of the Civil War*, 10 vol. (1911; reprinted in 5 vol., 1957), the first major publication of the immense photographic documentation of the Civil War by M.B. Brady, Alexander Gardner, and others. (*Stereoscopic photography*): WILLIAM CULP DARRAH, *Stereo Views: A History of Stereographs in America and Their Collection* (1964), a collector's account of the development of the industry, with useful checklists of photographs and publishers of views in all the U.S. states and considerable information on European production; BEAUMONT NEWHALL, "Looking Back at Stereo," in WILLIARD D. MORGAN and HENRY M. LESTER, *Stereo Realist Manual*, pp. 375–394 (1954), a comprehensive essay on the invention of the stereoscope; DAVID BREWSTER, *The Stereoscope: Its History, Theory and Construction* (1856), the first book on the application of stereo vision to photography, by the inventor of the lenticular, box-form stereoscope. (*The dry plate*): WILLIAM JEROME HARRISON, *A History of Photography* (1887), a detailed account of the perfection of the gelatino-silver-bromide process, with a letter from the inventor, R.L. Maddox; C.E. KENNETH MEES, *From Dry Plates to Ektachrome Film* (1961), the former director of research at Eastman Kodak recounts the invention of the dry plate and subsequent improvements, for many of which he was responsible; BEAUMONT NEWHALL, "Muybridge and the First Motion Picture," *Image*, 5:4–11 (1956), a biographical essay.

The Linked Ring and the Photo-Secession: JOSEPH T. KEILEY, "The Linked Ring: Its Position and Origin, and What It Stands for in the Photographic World," *Camera Notes*, 5:111–120 (1901), an account of the establishment of this influential society, its membership, and its exhibitions; *Camera Work: A Photographic Quarterly*, published and edited by ALFRED STIEGLITZ, 50 vol. (1903–17, reprinted 1969) magnificently illustrated quarterly essential for the understanding of the contribution of Stieglitz to photography and the introduction of modern art to America (for excellent reproductions of a selection of the plates, see *Life Library of Photography: The Print*, pp. 25–49); ROBERT DOTY, *Photo Secession: Photography As a Fine Art* (1960), an account of events leading up to the founding by Alfred Stieglitz of the society, with a detailed chronicle and interpretation of its activities.

Photojournalism: KEN BAYNES (ed.), *Scoop, Scandal and Strife: A Study of Photography in Newspapers* (1971), the first history of news photography to discuss the perceptual and editorial aspects as well as the technical; WILSON HICKS, *Words and Pictures: An Introduction to Photojournalism* (1952), basic description by the pioneer picture editor of *Life* magazine of problems and solutions of the photographic essay; see also, NANCY NEWHALL, "The Caption," *Aperture*, 1:17–29 (1952), a study of the mutual relationship of words and photographs; STANLEY RAYFIELD, *How Life Gets the Story* (1955), field experience of photographers of *Life*, presented in the format and photographic essay style of the magazine; NATHAN LYONS (ed.), *Toward a Social Landscape: Bruce Davidson, Lee Friedlander, Garry Winogrand, Danny Lyon, Duane Michals* (1966), photojournalistic techniques applied to observation of the urban scene; *The Persistence of Vision: Donald Blumberg, Charles Gill, Robert Heinecken, Ray K. Metzker, Jerry N. Uelsmann, John Wood* (1967), mixed media, biographical and bibliographical data on each photographer; *Vision and Expression* (1969), catalog of an exhibition; JERRY N. UELSMANN (1970), chronology, bibliography, and list of exhibitions.

Collections: LOUIS WALTON SIPLEY, "Museums and Collections of Photographs," in *Encyclopedia of Photography*, vol. 13, pp. 2468–2477 (1963); JACOB DESCHIN'S article "Historic Photo Collections on the Move," *Popular Photography*, 69:102–105, 138–139 (1971), brings Sipley's report up to date. See also "Museums and Collections," in the *Focal Encyclopedia.*

(Be.N.)

Photography, Technology of

Photography is the recording of visible images by light action on light-sensitive materials. The name is derived from the Greek *photos* (light) and *graphos* (writing). Usually photography refers to the formation of optical images projected by a lens in a camera onto a film or other material carrying a layer of light-sensitive silver salts; in an extended sense, the term also covers images formed by certain invisible radiations (ultraviolet and infrared rays) and images recorded in other sensitive materials not containing silver by means of chemical or physical processes or both. Related to photography is image recording by X-rays, electron beams, and nuclear radiations (radiography) and the recording and transmission of light images in the form of electromagnetic signals (television and video tape).

Photography is either still photography or motion-picture photography. Still photography records single self-contained images on separate sheets of film or other sensitized material. For convenience in camera use, the film may be a short strip carrying a number of such images. In cinematography or motion-picture photography a continuous strip of film records sequences of images representing successive movement phases of a subject in motion. Suitable projection then re-creates the illusion of movement (see MOTION PICTURES, TECHNOLOGY OF).

Still photography covers principally the recording of optical images formed by a lens in a camera and the duplication and reproduction of such images by light action (printing) to yield final pictures for various purposes. Generally, still photography is considered under two aspects: (1) pictorial and record photography, the aim of which is to yield a more or less accurate representation of an object photographed as an end in itself and (2) applied photography, in which the photographic image is an intermediate stage of, or serves as a tool for, other processes and procedures. Examples of applied photography are photomechanical reproduction for the graphic-arts field, making printed circuits, photographic templates, and the use of photography in measurements. Such uses often overlap applications that concern techniques of photographing special objects or objects under special conditions —*e.g.*, high-speed photography and photomicrography.

I. History and basic technology

HISTORY

Early discoveries. The forerunner of the camera was the camera obscura, a dark chamber or room with a hole (later a lens) in one wall through which images of objects outside the room were projected on the opposite wall. The principle was probably known 1,000 years ago and was described in the manuscripts of Leonardo da Vinci. The Italian scientist and writer Giovanni Battista della Porta, late in the 16th century, demonstrated a camera obscura with a lens. Various types of camera obscura were in use by artists in the 17th century. Although the blackening of silver salts was known in the 16th century, and possibly earlier, it was not until the early 18th century that it was recognized that the darkening was caused by light and not heat. The first photograph made in a camera was achieved in 1826 by Joseph-Nicéphore Niépce, a French lithographer–inventor. He used the action of light on an asphalt solution to make his picture.

Daguerreotype and calotype

Louis-Jacques-Mandé Daguerre, a French scenic painter, in 1839 published a detailed description of the procedures of his daguerreotype process. He treated a silver-plated sheet of copper with iodine vapour to form light-sensitive silver iodide and exposed it in the camera. The image was developed by mercury vapour at 60° C (140° F) and fixed with sodium thiosulfate solution (originally sodium chloride) to remove unexposed silver iodide. The image highlights consisted of milky white mercury amalgam against a plain silver background. The daguerreotype process yielded single laterally reversed pictures and became the first commercially utilized photographic process. The original plates were 6½ × 8½ inches in size; the still current (in England) "whole plate" negative and paper formats are directly derived from Daguerre. The first daguerreotypes required exposures of about 15 to 20 minutes in bright sunlight. The daguerreotype with its unique positive images proved to be a dead end in the development of photographic technology.

The negative–positive photographic system now in use was the contribution of William Henry Fox Talbot, a British amateur scientist. In the final form (1840) of Talbot's calotype (later talbotype) process, silver iodide paper was exposed in the camera, developed in a silver nitrate and gallic acid solution, and fixed with sodium thiosulphate. Talbot printed the resulting paper negatives on a silver chloride material to yield positive pictures.

The wet-collodion process. Introduced in 1851 by the English sculptor F. Scott Archer, wet collodion was the first sensitized material of sufficient speed for instantaneous exposures in good light. A glass plate coated with a nitrocellulose (collodion) solution containing potassium iodide was immersed in the dark in a silver nitrate solution, exposed in the camera while still wet, and immediately developed (originally in ferrous sulfate or oxalate, later in pyrogallic acid) and fixed. Photographers working away from their studio had to take portable darkrooms with them for this chemical treatment. The wet-collodion plate became the principal photographic process during the following 20 years and was used by the first news and feature photographers (*e.g.*, the American Civil War records by Mathew Brady and the Crimean War coverage by Roger Fenton). Its high-quality, fine-grain negatives kept the wet-collodion process in use in the graphic-arts field until the middle of the 20th century.

Dry plates and further improvements. The invention of the dry plate carrying a silver halide emulsion in gelatin (1871) initiated sensitized-materials manufacture. With such plates the photographer was no longer obliged to coat and sensitize his own material. Dry plates could be made and stored for months and, eventually, years before use. Ready prepared emulsions were on sale by 1873 and coated plates by 1876. The first orthochromatic (green-sensitive) plates were marketed in 1884, following the discovery of spectral sensitization with dyes. Panchromatic sensitizers followed in 1904 and infrared sensitizers in 1919.

Introduction of flexible supports

With the introduction of the wet-plate process, glass became the main support for negative materials. Hannibal Goodwin, a U.S. clergyman, in 1887 proposed the use of celluloid film carrying a silver bromide emulsion; this was marketed both as roll film and as sheet film from 1889 onward by the Eastman Kodak Company and was later replaced by the less flammable acetate film (safety film). By the 1950s and 1960s, sheet films coated on high-stability supports, such as polyester, had virtually displaced glass even in special fields.

Talbot first used silver chloride printing-out papers (*i.e.*, papers that gave an image without development), while albumen printing-out paper was suggested in 1850 and development papers in 1851. Developable silver bromide gelatin papers were manufactured from 1873 onward. Various other photographic printing processes appeared after 1842—among the most recent, transfer-diffusion process (1939), xerography (1938–48), and the Polaroid one-step process (1947).

Colour photography. Alexandre Becquerel, a French physicist, and Niépce de Saint-Victor (cousin of Joseph

Niépce) between 1848 and 1860 obtained colour images in specially treated silver chloride coatings; these images could not, however, be fixed. Gabriel Lippmann, a French physicist, in 1891 produced the first permanent colour photographs based on this principle, but the procedure was too complex for general application.

James Clerk Maxwell, in Britain, demonstrated in 1859 the reproduction of colours by combining red, green, and blue light in various proportions. (Colour screen plates based on this additive principle of colour reproduction were first marketed in 1907.) In 1868 the Frenchmen L. Ducos du Hauron and C. Clos suggested subtractive colour synthesis (the superimposition of dye images) as a means of forming colour pictures; this method provided the basis of assembly colour-print processes from the 1890s onward. In 1912 chromogenic development (converting a latent silver image directly into a colour image) was proposed; the first commercial colour film with three emulsion layers, Kodachrome, based on this principle, appeared in 1935.

Camera evolution. Daguerre's camera consisted of two boxes sliding inside each other; it weighed about 50 pounds, but smaller models soon appeared. For transportability some large cameras had bellows to connect the front and rear sections; these eventually evolved into the present-day view or technical camera of the studio photographer.

Studio cameras were scaled down to hand-camera size and were fitted with improved lenses (particularly the lens designed by an Hungarian mathematician, József Miksa Petzval, in 1840) and with more versatile shutters (the first leaf-type dating from about 1887). The large-size press cameras and single-lens reflexes in use from the 1890s onward were derived from this type of hand camera.

Development of roll-film cameras

In 1875 the first roll-film camera was proposed; it used a roll of paper coated with emulsion that was stripped off after exposure. The Eastman Kodak box camera of 1888—with its handy roll of negative paper (later negative film) and with Eastman's widely available processing and printing service—gave impetus to the development of amateur photography as a hobby on a mass scale. Roll films in more or less their present form followed in 1891. Roll-film cameras, at first converted plate-type hand cameras, evolved into various folding and rigid designs.

Numerous small camera designs existed from the very beginning of photography. In 1924 the Leitz optical works in Germany introduced the Leica, the first commercially successful miniature camera taking perforated 35-mm (millimetre) film. Originally designed in 1913 by Oskar Barnack, head of the Leitz experimental department, this camera became the prototype for a large number of similar cameras and the starting point of 35-mm photographic technique, including comprehensive camera and accessory systems for general and scientific photography.

Lighting and light sources. Daylight was the photographer's only source of light until his materials became sensitive enough to permit reasonable exposures by such artificial sources as gaslight and tungsten-filament lamps. Limelight, in which a dish of lime was heated by a flaming jet of oxygen and hydrogen gases, was already in use for photography in 1840. In the 1850s it was discovered that burning magnesium wire produced an intense light. Flash powder, a mixture of magnesium powder and potassium chlorate, appeared in the 1880s, and the first prototype flash bulb in 1925.

The first high-speed flash photograph was made in 1851 by Talbot, who used the spark discharge of a Leyden jar battery. Ernst Mach, the Austrian physicist, in 1885 used sparks to take high-speed photographs of bullets in flight. Experiments with gas discharge flash tubes at the Massachusetts Institute of Technology in the early 1930s led to the present-day electronic, or speed, flash (first marketed in 1940).

BASIC TECHNOLOGY

Black-and-white photography. The most widely used photographic process is the black-and-white negative–positive system (Figure 1). In the camera, the lens projects an image of the scene being photographed onto a film coated with light-sensitive silver salts, such as silver bromide. A shutter built into the lens admits light reflected from the scene for a given time to produce an invisible but developable image in the sensitized layer, thus exposing the film.

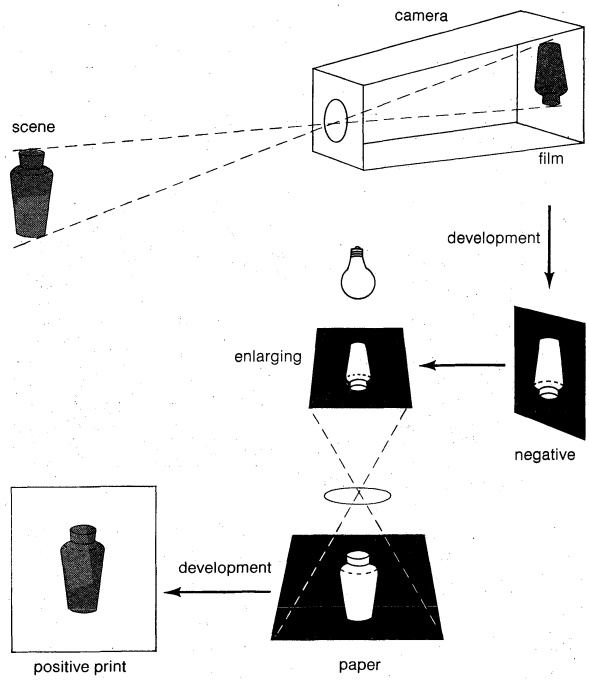

Figure 1: Sequence of negative–positive process, from photography of the original scene to enlarged print (see text).

During development (in a darkroom) the silver salt crystals that have been struck by the light are converted into metallic silver, forming a visible deposit or density. The more light that reaches a given area of the film, the more silver salt is rendered developable and the denser the silver deposit that is formed there. An image of various brightness levels thus yields a picture in which these brightnesses are tonally reversed—a negative. Bright subject details record as dark or dense areas in the developed film; dark parts of the subject record as areas of low density; *i.e.*, they have little silver. After development, the film is treated with a fixing bath that dissolves away all undeveloped silver salt and so prevents subsequent darkening of such unexposed areas. Finally, a wash removes all soluble salts from the film emulsion, leaving a permanent negative silver image within the gelatin layer.

Creation of a negative image

A positive picture is obtained by repeating this process. The usual procedure is enlargement: the negative is projected onto a sensitive paper carrying a silver halide emulsion similar to that used for the film. Exposure by the enlarger light source again yields a latent image of the negative. After a development and processing sequence the paper then bears a positive silver image. In contact printing, the negative film and the paper are placed face to face in intimate contact and exposed by diffused light shining through the negative. The dense (black) portions of the negative image result in little exposure of the paper and, hence, yield light image areas; thin portions of the negative let through more light and yield dark areas in the print, thus recording the light values of the original scene.

Colour photography. Present-day colour photographic processes rely on the fact that the eye sees colours in terms of primary stimuli of red, green, and blue to which corresponding receptors in the eye are believed to be selectively sensitive. Any colour sensation can thus be produced by a mixture of red, green and blue light in suitable proportions. Colour films record the proportion of the red, green, and blue components of colours and colour mixtures in nature by means of three sensitive layers that respond respectively to the three primary col-

ours. The images formed in the three layers are converted into coloured dye images, which in turn control the amount of red, green, and blue light left in a white light beam reflected from a colour print or shining through a colour transparency (see below *Colour photography*).

Basic camera functions. In its simplest form (Figure 2), the camera is a light-tight container carrying a lens, a

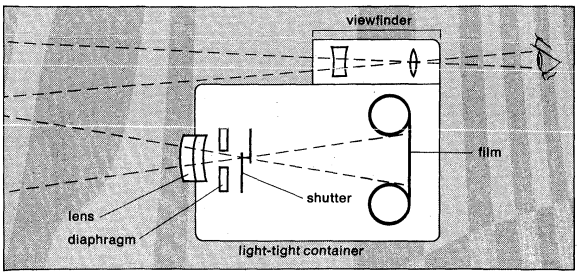

Figure 2: Basic camera elements.

shutter, a diaphragm, a device for holding (and changing) the film in the correct image plane, and a viewfinder to allow the camera to be aimed at the desired scene.

The lens projects an inverted image of the scene in front of the camera onto the film in the image plane. The image is sharp only if the film is located at a specific distance behind the lens. This distance depends on the focal length of the lens (see below *Photographic lenses*) and the distance in front of the lens of the object. As a camera is expected to be able to photograph near and far subjects, a focussing adjustment is embodied in all but the simplest cameras. Usually this adjustment functions by altering the distance between the lens and the film plane (typically, by moving the lens forward or back in the camera) to make objects at the selected distance produce a sharp image on the film. In some cameras focussing adjustment is achieved by moving only the front element of the lens, image sharpness resulting from modifying the focal length of the lens.

The two basic elements of exposure

The shutter consists of a set of metallic leaves mounted in or behind the lens or a system of blinds positioned in front of the film. It can be made to open for a predetermined time to expose the film to the image formed by the lens. The time of this exposure is one of the two factors controlling the amount of light reaching the film. The other factor is the lens diaphragm or aperture, an opening with an adjustable diameter. The combination of the diaphragm opening and exposure time is the photographic exposure, which can be expressed in terms of shutter speed and lens opening. To obtain a film image that faithfully records all the tone gradation of the object, this exposure must be matched to the brightness (luminance) of the subject and to the sensitivity or speed of the film. Many modern cameras incorporate light meters that measure the subject's luminance and indicate the required combination of shutter and diaphragm to yield a correctly exposed image. In automatic cameras the light meter may directly set the lens diaphragm or shutter or both in response to the subject luminance.

II. Cameras and lenses

CAMERA TECHNOLOGY

Principal camera types. The simplest camera type, much used by casual amateurs, has most of the features listed in the previous section—lens, shutter, viewfinder, and film-holding system. The light-tight container traditionally had a box shape. Such box cameras were usually intended for roll films; present-day compact versions frequently take instant-loading cartridges. Typically, a fixed shutter setting gives about $\frac{1}{40}$-second exposure; the aperture is fixed; and the lens is permanently set to record sharply all objects more than about six feet (two metres) from the camera. Box cameras are simple to handle, but their use is restricted to pictures of stationary or slow-moving subjects in bright daylight. More advanced versions may incorporate a fitting for flash bulbs or flash cubes for indoor picture taking or a light meter or both.

The 35-mm miniature camera. Perforated 35-mm film (originally standard motion-picture film) in cartridges holding 20 or 36 exposures with a nominal picture format of 24 × 36 mm is employed in miniature cameras. Smaller image formats—such as 24 × 24 mm, 24 × 32 mm, and 18× 24 mm (half frame)—also are available. The 35-mm camera has a comparatively fast lens (*i.e.*, with a large maximum aperture), a shutter with exposure times typically from 1 second to $\frac{1}{500}$ or $\frac{1}{1,000}$ second, and can focus on subject distances from infinity down to about three or four feet. A winding mechanism (usually a lever) advances the film from one frame to the next and, at the same time, cocks (tensions) the shutter for each exposure. An interlock prevents the shutter from being released until the film has been advanced and the film from being advanced until after an exposure. At the end of the film load, the film is rewound into the cartridge for removal from the camera in daylight.

Usually a 35-mm camera has a direct vision viewfinder, often combined with a rangefinder for accurate distance measurement. Advanced 35-mm cameras may have interchangeable lenses and a variety of other accessories. Many 35-mm cameras are single-lens reflex types (see below). Its instant readiness for action and fast shooting make the 35-mm camera popular for unobtrusive candid and news photography. In the early 1970s the 35-mm camera generally incorporated a light meter coupled with the exposure settings of the camera.

Advantages of the 35-mm camera

The ultraminiature or subminiature. This type takes roll film in widths narrower than 35 mm, either 16 mm or 9.5 mm, in special cartridges or chargers. The picture size may range from 8 × 11 mm to 12 × 17 mm. The ultraminiature is usually between matchbox and cigarette-pack size, permitting almost unobtrusive use. It has many of the features, suitably scaled down, of a 35-mm camera.

The view or technical camera. For studio and commercial photography the view or technical camera takes single exposures on sheet films (formerly plates) usually between 4 × 5 inches and 8 × 10 inches. A front standard carries interchangeable lenses and shutters; a rear standard takes a ground-glass screen (for viewing and focussing) and sheet-film holders. The standards move independently on a rail or set of rails and are connected by bellows. Both standards can also be displaced laterally and vertically relative to each other's centre and swung or tilted about horizontal and vertical axes. These features provide versatility in image control (sharpness distribution, subject distance, and perspective), though not speed in use. The view camera is nearly always mounted on a tripod or other support.

The press camera. Press cameras are loaded with sheet film (typical formats from 2½ × 3½ inches to 4 × 5 inches) for fast, hand-held shooting; they are traditionally of folding-bellows design with a lens standard on an extendable baseboard. In addition to sheet-film holders, press cameras take various types of roll film and 70-mm film magazines and often have coupled rangefinders. Modern modular designs have a rigid body with interchangeable front and rear units.

The folding roll-film camera. Obsolescence has overtaken the folding roll-film camera. Its design resembles the 35-mm miniature camera in shutter and viewfinder equipment, but such a camera has bellows and folds up to pocketable size when not in use. Generally it takes roll films holding eight to 16 exposures; typical picture sizes are 2¼ × 2¼, 2¼ × 3¼ or 1¾ × 2¼ inches. Some 35-mm cameras were also produced with bellows.

The single-lens reflex. The ground-glass screen at the back of the studio, or view, camera slows down picture taking because the screen must be replaced by the film for an exposure. The single-lens reflex camera (Figure 3) has a screen, but the film remains constantly in position. A 45° mirror reflects the image-forming rays from the lens onto a screen in the camera top. The mirror moves out of the way during the exposure and back again afterwards for viewing and focussing the next picture. The image on the screen therefore temporarily disappears from view during the exposure. Present-day single-lens reflexes are either 35-mm cameras or advanced roll-film models.

Reflecting the image through the lens

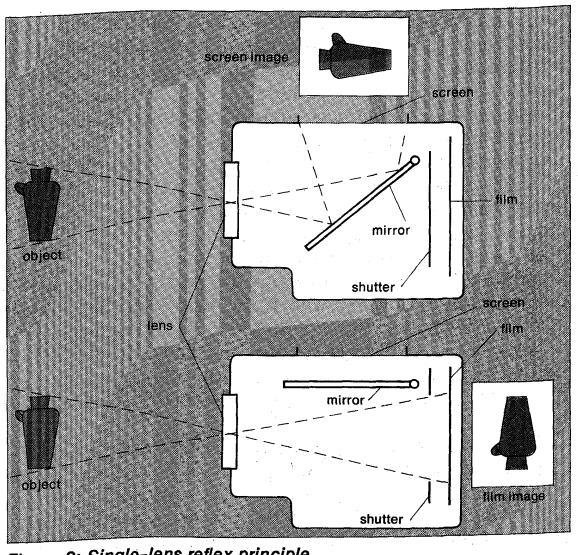

Figure 3: *Single-lens reflex principle.* (Top) Before exposure, upright but laterally reversed image is visible on top screen. (Bottom) During exposure, with mirror up and shutter open, an upside down but laterally correct image is projected on the film.

Most 35-mm reflexes have optical prism systems for eye-level viewing of the screen, built-in light meters, and numerous other refinements. Often the camera is part of an extensive accessory system.

The twin-lens reflex. The twin-lens reflex is a comparatively bulky dual camera (Figure 4) with a fixed-mirror

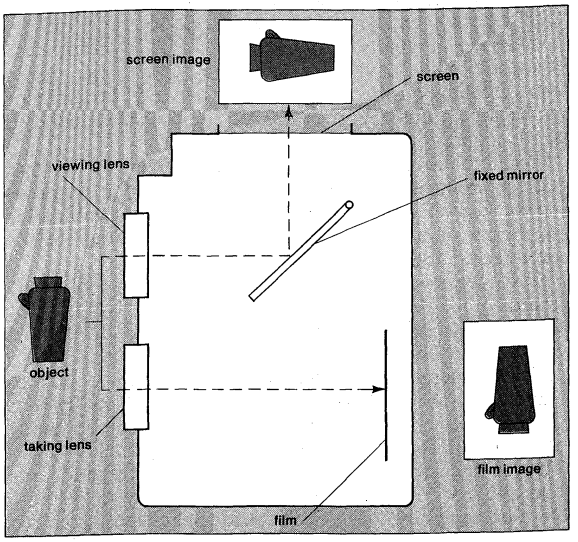

Figure 4: *Principles of the twin-lens reflex camera.* The fixed mirror deflects light rays coming through the viewing lens to a top screen, which shows the image upright but laterally reversed. Light from the object also goes through the taking lens, which is mounted on a common panel with the viewing lens, and is projected on the film.

reflex housing and top screen mounted above a roll-film box camera. Its two lenses focus in unison so that the top screen shows the image sharpness and framing as recorded on the film in the lower section. The viewing image remains visible all the time, but the viewpoint difference (parallax) of the two lenses means the framing on the top screen is not exactly identical with that on the film.

Shutter and diaphragm systems. Principal present-day shutters are the leaf shutter and the focal-plane shutter.

The leaf shutter. The leaf, or diaphragm, shutter consists of a series of blades or leaves fitted inside or just behind the lens. The shutter opens by swinging the leaves simultaneously outward to uncover the lens opening. The leaves stay open for a fixed time—the exposure time—and then close again. A spring drives the mechanism while an adjustable escapement controls the open time—typically between one and $\frac{1}{500}$ second. For longer exposures (time exposures) a special setting holds the shutter open as long as the exposure button (release) is held down; the shutter closes on letting go of the release. The mechanical escapement mechanism can be replaced by an electromagnet and an electronic circuit to control the length of time the shutter remains open.

The control of exposure time

Focal-plane shutter. The focal-plane shutter consists of two light-tight fabric blinds or a combination of metal blinds (Figure 5) moving in succession across the film

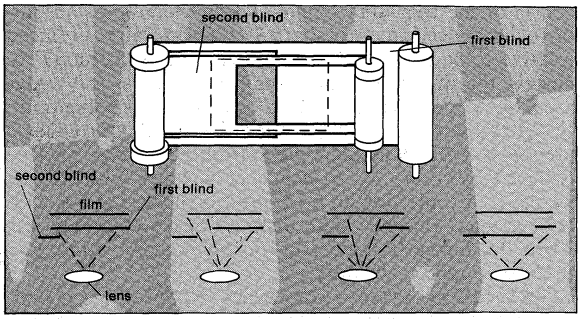

Figure 5: Focal-plane shutter consisting essentially of (top) two blinds that, moving in sequence (bottom), form a travelling slit (see text).

immediately in front of the image plane. The first blind uncovers the film and the second blind covers it up again, the two blinds forming a travelling slit the width of which determines the exposure time: the narrower the slit, the shorter the time. The actual travel time is fairly constant for all exposure times. A mechanism triggers the release of the second blind. Focal-plane shutters are usually adjustable for exposure times between one and $\frac{1}{1.000}$ second.

Diaphragm and shutter settings. In the lens diaphragm, a series of leaves increases or decreases the opening to control the light passing through the lens to the film. The diaphragm control ring carries a scale of so-called *f*-numbers, or stop numbers, in a series: such as 1.4, 2, 2.8, 4, 5.6, 8, 11, 16, 22, and 32. The *f*-numbers are inversely proportional to the square of the amount of light admitted. In the above series, each setting admits twice as much light as the next higher *f*-number, or stop (giving twice as much exposure), and half as much as the next lower value.

The series of *f*-numbers

Shutter settings on present-day cameras also follow a standard double-or-half sequence—*e.g.*, 1, ½, ¼, ⅛, $\frac{1}{15}$, $\frac{1}{30}$, $\frac{1}{60}$, $\frac{1}{125}$, $\frac{1}{250}$, $\frac{1}{500}$, and $\frac{1}{1.000}$ second. The shorter the exposure time, the "faster" the shutter speed.

Exposure values. The diaphragm and shutter control the amount of light reaching the film by adjusting the light intensity and the time during which it acts. Different aperture–shutter speed combinations may thus yield the same exposure—*e.g.*, diaphragm *f*/2.8 with $\frac{1}{250}$ second, *f*/4 with $\frac{1}{125}$ second, and *f*/5.6 with $\frac{1}{60}$ second. All such equivalent combinations can be assigned a single exposure value. Some cameras carry a scale of exposure values and have coupled aperture and shutter-speed settings. At a given exposure-value setting in such cameras, selecting various shutter speeds automatically adjusts the aperture to compensate and vice versa.

Exposure values run in a simple whole-numbered series, each step (EV interval) doubling or halving the effective exposure. The lower the EV number, the greater the exposure. Thus, EV 10 gives twice as much exposure as EV 11 or half as much as EV 9.

Automatic-diaphragm systems. On a camera with a ground-glass screen, such as a single-lens camera, a view camera, or reflex camera, viewing and focussing are carried out with the lens diaphragm fully open, but the exposure is often made at a smaller aperture. With a view camera the aperture must be reduced manually; but with many reflex cameras the lens aperture is semi-automatically or automatically reduced (stopped down) to the working aperture immediately before exposure. Typically, this is accomplished by an internal link between the release button and the lens.

Methods of focussing and framing. The ground-glass (sometimes grained plastic) screen is the most direct way of viewing the image for framing and for sharpness control. The screen localizes the image plane for observation. The image is also visible without a screen, but then the eye can locate the image plane of maximum sharpness only with a precisely focussed high-power magnifier. This aerial focussing method avoids interference of the ground-glass structure with sharpness assessment.

Focussing aids. The split-image wedge or wedge rangefinder consists of a pair of prism wedges fitted in the centre of the focussing screen. This system splits an out-of-focus image into two sharp halves laterally displaced relative to each other. When the camera is correctly focussed, the image becomes continuous across the wedge area. Since the eye can recognize slight image discontinuity better than it does slight unsharpness, this provides a precise way of focussing. The split-image wedge may be replaced by a ¼- to ½-inch spot covered with minute wedges. This microprism grid shows a blurred image with very ragged outlines and distinct microprism texture; when the image becomes sharp, the ragged outline and texture disappear abruptly.

Microprism grid of multiple wedges

The focussing screen is sometimes overlaid by a pattern of fine concentric lens sections. Called a Fresnel screen, it redirects the light from the screen corners toward the observer's eye and makes the image evenly bright.

Cameras without a screen generally are equipped with a distance scale, the lens being set to the estimated object distance. More advanced cameras have an optical rangefinder (Figure 6) as a distance-measuring aid; it consists

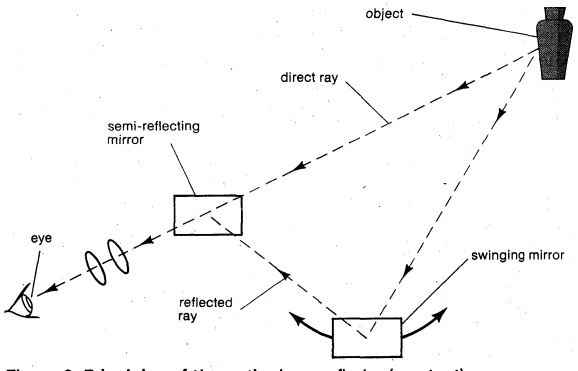

Figure 6: Principles of the optical rangefinder (see text).

of a viewfinder (see below) and a swinging mirror a few inches to one side of the viewfinder axis. As the eye views an image of the object, the mirror superimposes a second image from a second viewpoint. On turning the mirror through the correct angle, which depends on the object distance, the two images are made to coincide. The mirror movement can be linked with a distance scale, or coupled with the lens focussing adjustment. When the lens is incorrectly focussed, the rangefinder shows a double or split image. In place of a rotating mirror, the rangefinder may use swinging or rotating optical wedges (prisms).

Fully automatic focussing systems rely on photoelectric-cell circuits, which detect the contrast difference between a sharp and an unsharp image, thus eliminating visual judgment of image sharpness or continuity. The signal output from such a photocell system can power a small motor that automatically adjusts the lens setting to maximum sharpness. So far, such systems have been used only in professional motion-picture cameras. Another approach to automatic rangefinding employs extremely short laser pulses as a kind of optical radar—a system that requires considerable auxiliary equipment.

Viewfinders. The sighting devices in cameras lacking screens are called viewfinders; they show how much of the scene will appear on the film. The simplest viewfinder is a wire frame above the camera front, with a second frame near the back to aid the eye in correct centring. Most present-day finders are built into the camera and are compact lens systems. Bright-frame finders show a white frame reflected into the view to outline the field recorded on the film. An alternative form is the reflecting viewfinder in which the photographer looks down into a field lens on top of the camera. The upper section of a twin-lens reflex camera is such a reflecting finder, with provision for sharpness control (see above).

As the viewfinder axis in a camera other than a single-lens reflex does not usually coincide with the lens axis, the finder's and the lens's views do not exactly match. This parallax error is insignificant with distant subjects; with near ones it is responsible for the familiar fault of a portrait shot of a head that appears partly cut off in the picture even though it was fully visible in the finder. Camera viewfinders come with various parallax-compensating devices, such as correction marks to show the limits of the view at near range, or embody a system that moves the finder frame in unison with the distance settings.

Parallax problems with close-at-hand subjects

The optical finder gives a direct upright and right-reading view of the subject with the camera held at eye level. The traditional reflex camera, held at waist level, showed a laterally reversed view. Modern reflexes have a pentaprism arrangement that permits upright, right-reading, eye-level viewing by redirecting the image from the horizontal screen on top of the camera.

Exposure-metering systems. Exposure meters or light meters measure the light in a scene to establish optimum camera settings for correct exposures. A light-sensitive cell generates or controls an electric current according to the amount of light reaching the cell. A microammeter measures this current to indicate exposure settings. The two main types, the selenium cell and the cadmium sulfide cell, differ in that light falling on a selenium cell generates a current, while light falling on a cadmium sulfide cell changes its electrical resistance.

On separate exposure meters the values read off are transferred manually to the camera. Many modern cameras have built-in, coupled exposure meters; the operation of lining up the needle of the meter with an index at the same time sets aperture or shutter speed controls of the camera, or both.

In automatic exposure systems, the meter on its own sets the lens aperture or exposure time, or both. Or, pressing the shutter release may set the exposure combination by means of a selector mechanism immediately before the exposure itself.

On cameras with electronic shutter control, often a cadmium sulfide cell measures the light cumulatively during the exposure and closes the shutter as soon as the cell has registered a sufficient amount of light.

Measurements of the screen image brightness in a reflex camera can also provide exposure readings. Usually such through-the-lens meter systems cover the screen image with one or two photocells in the pentaprism housing. The readings depend on the light coming through the lens and so allow for the lens's angle of view, any light filters, close-up exposure corrections, stray light, and other factors.

Through-the-lens meter systems

In other systems, some of the light from the lens is diverted to a photocell before it reaches the screen (*e.g.*, by beam-splitting arrangements or through the use of a photocell behind an only partly reflecting mirror). Alternatively, with a focal-plane shutter camera a photocell may be mounted on an arm in front of the image plane and be swung out of the way while the picture is being taken.

Flash systems. Flash is a widely used artificial light source for photography, providing a reproducible light of high intensity and short duration. It can be synchronized with an instantaneous exposure. Being battery powered, small flash units are self-contained. The two main systems are flash bulbs and electronic flash.

Flash bulbs. The flash bulb consists of a small, oxygen-filled glass envelope containing two sealed-in wires with a filament, a firing paste, and a specific amount of aluminum or zirconium wire. A pulse of current through the lead-in wires fires the flash, making the filling wire burn away virtually instantaneously. The firing system is built into a flash gun, which consists of a small casing

holding a battery circuit, a reflector, and the fitting to take the bulb. Flash bulbs come in various sizes, from about ½ × 1¼ inches to the size of a 60-watt tungsten bulb.

So-called flash cubes consist of four miniature flash bulbs mounted in small reflectors on four sides of a one-inch cube. They plug into a rotating fitting in the camera, which has the necessary firing circuit and battery built-in. After every shot, the cube rotates to point a fresh bulb at the subject. Some flash cubes are triggered mechanically and need no batteries.

Rotating flash cubes

Electronic flash. Electronic flash is a high-voltage discharge through a gas-filled tube; but, unlike a flash bulb, it can flash any number of times. A capacitor charged up to several hundred volts (by a step-up circuit from low-voltage batteries or from the line voltage supply) provides the discharge energy. The flash is triggered by a low-voltage circuit generating a high-voltage pulse. The light output of an electronic flash is comparable with that of a flash bulb, but its duration is much shorter (typically, $\frac{1}{1,000}$ second compared with $\frac{1}{50}$ second for a bulb), while the maximum flash intensity is correspondingly higher. The smallest electronic flash units clip onto the camera and are about cigarette-pack size. Large units with flood and spotlight fittings are used in professional studio photography and often have adjustable power levels to provide different flash intensities.

Special electronic flash units with ring-shaped tubes mounted around the camera lens are used for shadowless lighting on small objects in close-up photography, particularly for medical and forensic purposes.

Firing and synchronization. Flash guns and units have a firing button for the triggering circuit but are usually fired by a switch in the camera shutter to synchronize the flash with the shutter action. A flash lead or a contact in the camera's accessory shoe connects the gun with this shutter switch.

Usually the shutter contact closes the instant the shutter is fully open. The shutter must then stay open while the flash reaches its peak brightness—$\frac{1}{60}$ to $\frac{1}{50}$ second with flash bulbs or 15 to 20 microseconds (millionths of a second) with electronic flash. Those limits determine the fastest usable shutter speed. On some shutters the flash is fired before the shutter opens, to allow for the firing delay of flash bulbs. With focal-plane shutters the transport time of the blinds affects the synchronizable shutter speeds.

System cameras. From the development of the 35-mm miniature camera in the 1930s evolved the concept of the system camera that could be adapted to numerous jobs with a range of interchangeable components and specialized accessories. Today, most moderately advanced 35-mm miniatures take interchangeable lenses, close-up and photomicrographic attachments, filters, flash units and other accessories. The most elaborate camera systems also include such accessories as alternative finder systems; interchangeable reflex screens, film backs, and magazines; and remote-control and motor-drive systems. Modular professional roll-film and view cameras are built up from a selection of alternative camera bodies, film backs, bellows units, lenses, and shutters. This is the nearest approach to the universal camera, assembled as required to deal with practically every type of photography.

Modular systems

PHOTOGRAPHIC LENSES

Characteristics and parameters. The lens forming an image in the camera is a converging lens, the simplest form of which is a single biconvex (lentil-shaped) element. (The word lens is derived from the Latin name of the lentil.) In theory, such a lens makes a light beam of parallel rays converge to a point (the focus) behind the lens. The distance of this focus from the lens itself is the focal length, which depends on the curvature of the lens surfaces and the optical properties of the lens glass. An object at a very long distance (optically regarded as at "infinity") in front of the lens forms an inverted image in a plane (the focal plane) going through the focus. Light rays from nearer objects form an image in a plane behind the focal plane. The nearer the object, the farther behind the lens the corresponding image plane is located—which is why a lens has to be focussed to get sharp images of objects at different distances.

Focal length and image scale. The image scale or scale of reproduction is the ratio of the image size to the object size; it is often quoted as a magnification. When the image is smaller than the object, the magnification of the object is less than one. If the image is $\frac{1}{20}$ the size of the object, for example, the magnification may be expressed either as 0.05 or as 1:20.

For an object at a given distance, the scale of the image depends on the focal length of the lens (Figure 7). A

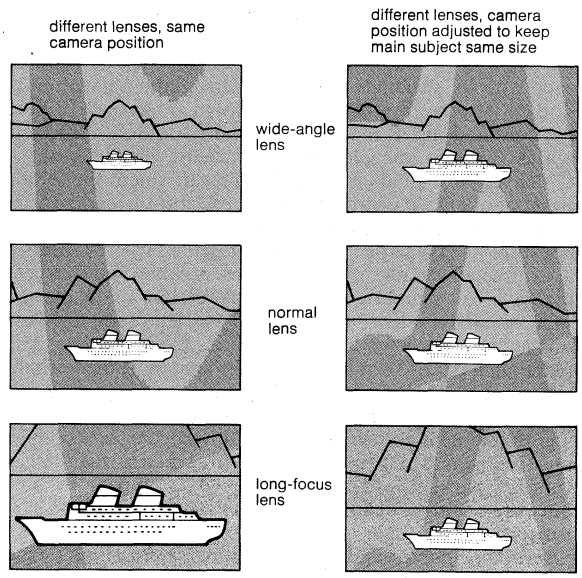

Figure 7: Effects of using lenses of different focal lengths.

normal camera lens usually has a focal length approximately equal to the diagonal of the picture format covered. A lens of longer focal length will give a larger scale image, but necessarily covers less of the scene in front of the camera. Conversely, a lens of shorter focal length yields an image on a smaller scale but—provided the angle of coverage is sufficient (see below)—takes in more of the scene. Many cameras, therefore, can be fitted with interchangeable lenses of different focal lengths to allow varying the image scale and field covered: long-focus lenses for magnified views of distant detail and short-focus, wide-angle lenses to cover wider views from nearer distances. The focal length of a lens in millimetres (sometimes in inches) is generally engraved on the lens mount.

Aperture. The aperture, or *f*-number, is the ratio of the focal length to the diameter of an incident light beam as it reaches the lens. For instance, if the focal length is 50 mm and the diameter of the incident light beam is 25 mm, the *f*-number is 2. This incident beam diameter is often roughly the lens-diaphragm diameter, but with some lens systems it may be appreciably larger or smaller. The maximum aperture (*f*-number at the largest diaphragm opening) is also marked on the lens, usually in the form *f*:2, *f*/2, or 1:2.

Angle of coverage. A lens must cover the area of a camera's film format to yield an image adequately sharp and with reasonably even brightness from the centre to the corners of the film. A normal lens should cover an angle of at least 60°. A wide-angle lens covers a greater angle—about 70° to 90° or more for an ultrawide-angle lens. A long-focus lens covers a smaller angle; for instance, the diagonal of a 24 × 36 mm picture format only subtends a 28° angle with a 135-mm lens.

The angle of coverage depends on the lens design. Designations like "wide angle" or "narrow angle" are not necessarily synonymous with "short focus" and "long focus," as the latter terms refer to the focal length of the lens relative to the picture format.

Optical performance. A simple lens produces a very imperfect image, which is usually blurred away from the centre. The image may have colour fringes around object outlines, and straight lines may be distorted. Such defects, called aberrations, can be eliminated—and even then not completely—only by replacing the single lens element by a group of elements of appropriate shape and separation. Aberrations arising from some of the lens elements then counteract opposite aberrations produced by other elements. The larger the maximum aperture, the greater the angle of coverage and the higher the degree of correction aimed at, the more complex camera lenses become. Lens design for relative freedom from aberrations nowadays involves advanced computer programming to calculate the necessary geometrical parameters of every lens element.

Groups of lens elements for correcting aberrations

Aberrations. There are a number of lens aberrations, each with its own characteristics. Chromatic aberration is said to be present when the lens forms images by different-coloured light in different planes and at different scales. Colour-corrected lenses largely eliminate these faults. Spherical aberration is present when the outer parts of a lens do not bring light rays into the same focus as the central part. Images formed by the lens at large aperture are therefore unsharp but get sharper at smaller apertures. Curvature of field is present when the sharpest image is formed not on a flat plane but on a curved surface. Astigmatism occurs when the lens fails to focus image lines running in different directions in the same plane; in a picture of a rail fence, for instance, the vertical posts are sharp at a focus setting different from the horizontal rails. Another aberration, called coma, makes image points near the edges of the film appear as irregular unsharp shapes. Distortion is present when straight lines running parallel with the picture edges appear to bow outwards (barrel distortion) or inwards (pincushion distortion).

Resolving power and contrast transfer function. One way of testing lens performance is to observe the image it forms of patterns of increasingly closely spaced black lines separated by white spaces of line width. The closest spacing still recognizable in the image gives a resolving power value, expressed in lines per millimetre. Photographs of such line patterns or test targets show resolving power of the lens and film combination. For example, a resolution of 80–100 lines per millimetre on a fine-grain film represents very good performance for a normal miniature camera lens.

The visual sharpness of an image depends also on its contrast. Opticians, therefore, often plot the contrast with which the image is reproduced against the line spacing of that image. The resulting contrast transfer curve, or function, gives a more reliable indication of the lens performance under practical picture-taking conditions.

Special lens types. Apart from general purpose camera lenses of various focal lengths, there are lenses of special characteristics or design.

Telephoto lenses. Long-focus lenses are bulky, because they comprise not only the lens itself but also a mount or tube to hold it at the appropriate focal distance from the film. Telephoto lenses are more compact; their combinations of lens groups make the back focus (the distance from the rear lens element to the film) as well as the length of the whole lens appreciably shorter than the focal length. Telephoto lenses are therefore popular for interchangeable-lens cameras. Strictly, the term telephoto applies only to a lens of this optically reduced length; in practice, long-focus lenses of all types tend to be called indiscriminately telephoto or "tele" lenses.

Tele-converter lenses

If a camera lens is interchangeable, an accessory teleconverter lens group can be positioned between the prime lens and the camera. This turns a normal lens into an even more compact telephoto system, which is less costly than a telephoto lens but which greatly reduces the speed of the prime lens and usually impairs sharpness performance.

Wide-angle and retrofocus lenses. Short-focus, wide-angle lenses are usually mounted close to the film. Single-lens reflex cameras need a certain minimum lens-to-film distance to accommodate the swinging mirror. Wide-angle (and sometimes normal-focus) lenses for such cameras therefore use so-called retrofocus designs—in effect, inverted telephoto systems. In these, the back focus is appreciably longer than the focal length. In practice, both a telephoto and a retrofocus lens must be specially designed for its particular use to ensure optimum image performance.

Fish-eye lenses. For image angles greater than 110°, it becomes difficult to bring the lens close enough to the film to allow the rays between lens and film to diverge sufficiently. The fish-eye lens overcomes this difficulty by making the rays diverge less behind the lens than they do in front. The resulting image shows appreciable distortion with image details near the edges and corners progressively compressed. Fish-eye lenses usually cover angles between 140° and 210° and are used for unusual wide-angle effects where the distortion becomes a deliberate pictorial element. They also have certain scientific applications, for instance, to cover a horizon-to-horizon view of the sky in recording cloud formations.

Mirror lenses. Images can also be formed by light reflected from curved mirrors. This method, long used in astronomical telescopes, is applied to long-focus lens systems of short overall length by folding the light path back onto itself. A mirror lens or catadioptric system has no chromatic aberrations. Other aberrations are corrected by incorporating one or more appropriate lens elements. The arrangement of the system, with a central opening in the primary mirror, makes stopping down with a customary diaphragm difficult. Catadioptric systems therefore generally use neutral-density filters to control light transmission.

Variable-focus lenses. In variable-focus lenses, the focal length can be varied by movement of some of the elements or groups within the lens system. One lens can thus replace a range of interchangeable lenses. Such a lens also allows instant assessment of the pictorial effect of using different focal lengths.

The variable-focus, or zoom, lens was originally developed for motion-picture photography, in which adjustment of the focal length during a shot produced a zooming-in or zooming-out effect (hence the name). It is increasingly used in still cameras, especially 35-mm single-lens reflexes since the reflex finder permits accurate continuous assessment of image coverage. During zooming, the image changes in scale but not in sharpness. To ensure reasonably constant performance over their focal-length ranges, zoom lenses are complex systems containing from a dozen to 20 elements. Zoom lenses for still cameras usually have focal-length ratios of 2:1 to 3:1 (*e.g.*, 40–120 mm for a 35-mm reflex), occasionally up to 6:1.

Lens-changing systems. Miniature and roll-film cameras hold interchangeable lenses in screw or quick-change bayonet mounts. In a focal-plane shutter camera the usable range of focal lengths is practically unlimited. In cameras with leaf shutters, the lens is either mounted in front of the shutter or the lens is changed complete with shutter. Some designs use convertible lenses with the rear components built into the camera together with the shutter; interchangeable front groups then provide different focal lengths in combination with the fixed rear group. View-camera lenses—usually with their own shutters—are mounted on lens boards that clip into and out of the front camera standard.

Convertible lens with fixed rear component

Afocal attachments provide the effect of alternative focal lengths with a fixed camera lens. They are magnifying or reducing telescopes without a focal length (hence afocal), yielding a virtual image that the camera lens projects onto the film. Their designated magnification factor indicates the effect on the image scale; *e.g.*, a 1.5× tele attachment magnifies the image on the film 1½ times, while a 0.7× wide-angle attachment reduces the image scale to 0.7 times that of the prime camera lens. There are also afocal zoom and afocal fish-eye attachments.

Lens coating. When light passes from one optical medium to another (especially from air to glass and vice versa in a lens), about 4 to 8 percent of it is lost by

reflection at the interface. This light loss builds up appreciably in complex multi-element lenses. Some of the reflected light still reaches the film as ghost images or light spots or as general contrast-reducing scattered light.

To reduce such losses, the air to glass surfaces of modern lenses typically carry a microscopically thin coating of metallic fluorides. The coating eliminates most reflected rays. Complete elimination can occur only for light of one wavelength if the coating thickness and refractive index are exactly right. In practice, a coated lens surface reflects about 0.5 percent of incident white light—1/10 of the light lost by an uncoated lens. Multiple coatings can reduce reflections over a wider wavelength range.

Lens coating has made possible modern optical designs of a dozen or so lens groups (20 or more air–glass surfaces); with uncoated lenses the limit was around ten surfaces, which cost a light loss of nearly 60 percent.

III. The photographic process

BLACK-AND-WHITE FILMS

The latent image. The sensitive surface of ordinary film is a layer of gelatin carrying minute suspended silver halide crystals or grains (the emulsion)—typically silver bromide with some silver iodide. Exposure to light in a camera produces an invisible change yielding a latent image, distinguishable from unexposed silver halide only by its ability to be reduced to metallic silver by certain developing agents.

Formation of the latent image

Current theories postulate that silver halide crystals carry minute specks of metallic silver—so-called sensitivity specks—which amount in mass to about 1/100,000,000 part of the silver halide crystal. A silver halide is a compound of silver with fluorine, chlorine, bromine, or iodine, but only the last three are light sensitive. When light action releases electrons from the silver halide crystal, they migrate to the sensitivity specks. The resulting electric charge on the specks attracts silver ions from the neighbouring silver halide; and as the silver ions accumulate, they become metallic silver, causing the speck to grow. Halide (*e.g.*, bromide) ions at the same time migrate to the surface of the silver halide crystal and are there absorbed by the gelatin of the emulsion. When the sensitivity speck is large enough, it provides a point of attack for the developer, which can then reduce the whole silver halide crystal to silver. Developers are selective organic reducing agents that attack only silver halide crystals that have sufficiently large sensitivity specks. The halide grains carrying a developable sensitivity speck make up the latent image.

Sensitometry and speed. The sensitivity or speed of a film determines how much light it needs to produce a given amount of silver on development. Sensitometry is the science of measuring this sensitivity, which is determined by giving the material a series of graduated exposures in an appropriate instrument (the sensitometer). After development under specified conditions, the density of the silver deposit produced by each exposure is measured and the densities are plotted on a graph against the logarithm of the exposure. The resulting characteristic curve, or $D/\log E$ curve (see below, *Contrast*), shows how the film reacts to exposure changes. A specified point on the curve also serves as a criterion for calculating film speed by methods laid down in various national and international standards.

The most widely used speed scale is ASA speed. It is arithmetic, with the speed number directly proportional to the sensitivity. A film of 200 ASA is twice as fast (and for a given subject requires half as much exposure) as a film of 100 ASA. Some speed scales, such as the DIN system used on the European continent, are logarithmic. Every increase of three in the DIN speed number doubles the actual speed. A 50 ASA film is equivalent to 18 DIN, 100 ASA to 21 DIN, and so on.

All-around films for outdoor and some indoor photography have speeds between 80 and 160 ASA; fine-grain films for maximum image definition between 20 and 64 ASA; high-speed films for poor light and indoor photography between 200 and 500 ASA; and ultraspeed films for very low light conditions from 650 ASA up.

Colour sensitivity. Initially, the silver halide emulsion is sensitive to ultraviolet radiation and to violet and blue light. Most films contain sensitizing dyes to extend their colour sensitivity through the whole visible spectrum. Such films (called panchromatic films) record subject colour values as gray tones largely corresponding to the visual brightness of the colours. Some high-speed panchromatic films are extra red-sensitive for photography by red-rich tungsten lighting.

Non-colour-sensitized or blue-sensitive emulsions (without sensitizing dyes) are used for copying monochrome originals and similar applications needing no extended colour sensitivity. At one time, orthochromatic films—sensitive to violet, blue, green, and yellow but not to red—were also used for general photography; nowadays they are employed mainly for photographing of phosphor screens, such as cathode-ray tubes, and for other purposes requiring green but not red sensitivity. Both non-colour-sensitized and orthochromatic films can be handled in the light of appropriately coloured darkroom safelights.

Use of orthochromatic films

Infrared films are sensitized to invisible infrared wavelengths. They are used in aerial photography to cut through atmospheric haze (which scatters blue light but not infrared rays) and for special purposes in scientific and forensic photography.

Filters. Filters can modify the way in which a film records colours as monochrome tone values. They are disks of coloured glass or gelatin with controlled transmission characteristics. Placed in front of the camera lens, they preferentially transmit light of their own colour and hold back light in other colours. A yellow or yellow-green filter is often used in landscape photography to prevent overexposure of the blue sky and to bring out detail in cloud formations. Orange and red filters make the sky still darker and cut through haze by absorbing scattered blue light.

Contrast filters differentiate between the gray values of objects of different colour but of similar brightness. For instance, a red flower and green foliage record in similar shades of midgray. A red filter holds back green light to darken the green foliage, making the flower lighter; a green filter absorbs red light, thus darkening the flower. Such deliberate tone distortion is widely used in photomicrography and other fields.

Other filter types used in photography include ultraviolet, infrared, and polarizing filters. Ultraviolet-absorbing filters screen out ultraviolet rays at high altitudes (*e.g.*, in mountain photography). Since camera lenses are not normally corrected for such rays, they can reduce image sharpness, even though the lenses allow only a small amount of ultraviolet to be transmitted. Infrared filters are used with infrared film to hold back visible light. Polarizing filters polarize light and can absorb polarized light if suitably oriented. Light reflected at certain angles from shiny surfaces of nonmetallic media (glass, water, varnish) is polarized; a properly oriented polarizing filter subdues such reflections in a picture. Such filters are also employed in scientific photography.

Since a filter screens out part of the light, its use calls for extra exposure, the amount of which is indicated by a filter factor—*e.g.*, 2×, which means the exposure time must be multiplied by 2. For cameras with an exposure-value scale, a filter may specify an exposure value reduction (−1, −1½, etc.; *i.e.*, the indicated exposure value must be reduced by this amount). The correct filter factor depends—apart from the filter colour—on the spectral sensitivity of the film, the colour quality of the lighting, the type of subject and effect aimed at, and other exposure conditions. Factors published by filter manufacturers usually apply to average daylight conditions and panchromatic films.

Filter factors for proper exposure

Other film characteristics. Of practical interest to the photographer are the graininess, resolving power, and contrast of a film. Although they are characteristics of the film itself, they are influenced by the conditions of development (see below *Processing and printing*).

Grain. The image derived from minute silver halide crystals is discontinuous in structure. This gives an ap-

pearance of graininess in big enlargements. The effect is most prominent with fast films, which have comparatively large silver halide crystals; slower, fine-grain emulsions are therefore preferable for miniature and ultraminiature negatives intended for considerable enlargement.

Resolving power and acutance. The fineness of detail that a film can resolve depends not only on its graininess but also on the light scatter or irradiation within the emulsion (which tends to spread image details) and on the contrast with which the film reproduces fine detail. These effects can be measured physically to give an acutance value—today preferred to resolving power as a criterion of a film's sharpness performance. Fine-grain films with thin emulsions yield the highest acutance.

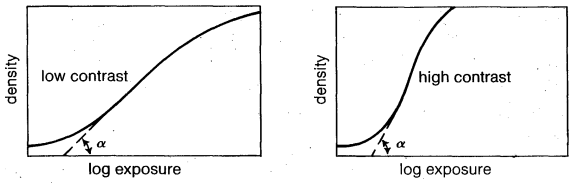

Figure 8: Characteristic curves of low-contrast and high-contrast film (see text).

Contrast. High-contrast films reproduce tone differences in the subject as great density differences in the image; low-contrast films translate tone differences into small density differences. The characteristic curve of a film obtained by plotting the density against the logarithm of the exposure (mentioned earlier under *Sensitometry and speed*) can be used to express a film's contrast (see Figure 8). The slope of the straight-line section of the curve (sometimes called the gamma, actually the tangent of the angle α) indicates contrast: the steeper the slope, the higher the contrast rendering. General-purpose films yield medium contrast (gamma 0.7 to 1). High-contrast films (gamma 1.5 to 10) are used for copying line originals and other specialized purposes; low-contrast films for continuous-tone reproduction. Gamma is also used to indicate degree of development, since increased development, with a given emulsion, results in a higher gamma.

Film structure and forms. Viewed in magnified section (Figure 9), a film consists of a number of layers and

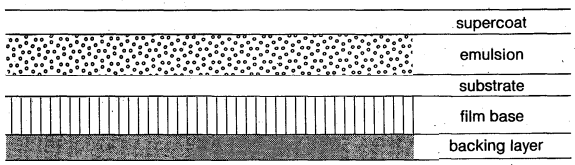

Figure 9: Structure of a modern black-and-white film (see text; thicknesses not to scale).

components: (1) A supercoat of gelatin, a few microns (one micron is 0.001 millimetre) thick, protects the emulsion from scratches and abrasion marks. (Pressure and rubbing can produce developable silver densities.) (2) The emulsion layer (silver halide suspended in gelatin) is usually nine to 12 microns (up to $\frac{1}{2,000}$ inch) thick but may sometimes reach 25 microns. (3) A substrate or subbing layer promotes adhesion of the emulsion to the film base. (4) The film base or support is usually cellulose triacetate or a related polymer. The thickness may range from 0.08 to 0.2 millimetre (0.003 to 0.008 inch). Films for graphic arts and scientific purposes are often coated on a polyethylene terephthalate or other polyester support of high dimensional stability. Glass plates—once the commonest support for negative materials—are now used only for applications requiring extreme emulsion flatness. (5) A backing layer on the rear of the film base counteracts curling. Usually it contains also a nearly opaque dye to suppress light reflection on the rear support surface. Such reflection (halation) reduces definition by causing halolike effects around very bright image points. Some film bases (especially in 35-mm films) are tinted gray to absorb light that has passed through the emulsion layer.

Use of anti-halation dye

Sheet film. Press and studio cameras generally take sheet film—single sheets (typical sizes range between 2½ × 3½ and 8 × 10 inches) loaded in the darkroom into light-tight film holders for subsequent insertion in the camera.

Perforated film. Some film is perforated along its edges and rolled up on its own inside a light-tight cartridge, which can be loaded into the camera in daylight. Once the camera is closed, a transport sprocket engaging the edge perforations draws the film from the cartridge onto a spool and advances it from picture to picture. The commonest film width is 35 mm (for 35-mm miniature cameras), and its cartridge typically holds enough film for 36 or 20 exposures. A 70-mm-wide film for larger cameras and 16-mm-wide strips for ultraminiatures are packed and used in a similar way.

Roll film. The term roll film is usually reserved for film wound up on a spool with an interleaving light-tight backing paper to protect the wound-up film. The spool is loaded into the camera in daylight, the backing paper leader threaded to a second spool, and the film wound from picture to picture once the camera is closed. This is the classical roll film of roll-film cameras. Common current film widths are 62 mm ($2\frac{7}{16}$ inches) and 45 mm ($1\frac{13}{16}$ inches). The rear of the backing paper carries sets of consecutive numbers spaced at frame intervals for different image formats. In some roll-film cameras these numbers are visible through a window in the camera back and show how far the film must be wound from one picture to the next. Instant-loading cartridges also use paper-backed roll film.

PICTURE-TAKING TECHNIQUE

The main areas of practical camera handling in photography concern sharpness control, exposure, and lighting.

Sharpness control. The image on the film is sharpest when the lens is focussed to the exact object distance. Usually, however, a scene includes objects at varying distances from the camera. Various factors affect the sharpness distribution in a picture of such a scene.

Depth of field. The sharpness in the image of objects in front of and behind the focussed distance falls off gradually. Within a certain range of object distances this sharpness loss is still comparatively unnoticeable. This range is the depth of field and depends on: (1) the amount of sharpness loss regarded as acceptable: miniature negatives requiring big enlargement must be sharper than larger-format negatives, which are enlarged less; (2) the lens aperture used: stopping down the lens (higher *f*-numbers) increases the depth of field; (3) the object distance: the depth of field is smaller for near objects than for more distant ones; and (4) the focal length of the lens: depth of field is reduced with longer focus lenses (and with larger picture formats requiring lenses of longer focal length); the depth increases with shorter focus lenses. A depth of field indicator, often included on the focussing mounts of lenses, shows on the distance scale how far in front of and behind the focussed distance objects will be in focus at different diaphragm openings.

Factors influencing depth of field

Subject and camera movement. Movement of the subject while the camera shutter is open for the exposure leads to a blurred image. The exposure time must therefore be short enough to keep the blur within acceptable limits. The shutter speed required depends on the movement speed of the object, the scale of the image (movement blur gets greater the nearer the subject or the longer the focal length of the lens used) and the movement direction; movement across the direction of view produces more blurring than movement receding from or approaching the camera.

Movement blur can be reduced, even with comparatively slow shutter speeds, by moving the camera (panning) to follow the subject during the exposure. This records the moving object comparatively sharply against a blurred background and emphasizes the impression of speed. Deliberate movement blur is sometimes aimed at for pictorial effect.

Camera shake through unsteady support during the ex-

posure also creates image blur—over the whole picture in such cases. Hand-held shots generally demand shutter speeds of $^1/_{30}$ second or shorter. For longer times a firm camera support—such as a tripod—is essential.

Exposure technique. The correct exposure (aperture and shutter settings) can be derived from tables or calculators or by direct measurement of the subject luminance with a light meter.

Meter readings. Straightforward readings with the meter cell pointed at the scene measure average reflected-light intensity, and they are reliable for subjects of average contrast and brightness distribution. Abnormal subjects of extreme contrast, or large highlight or shadow areas, need overriding exposure corrections. Spot readings taken with a meter covering a narrow angle measure selected subject details; *e.g.*, a medium tone for correct exposure irrespective of brightness distribution. This is practical with certain through-the-lens meter systems. Readings of the light reflected from the brightest scene highlight or of the light falling on the scene (incident light readings) measure the lighting level. This method is suitable for reversal processes (including colour) in which the exposure must be accurately matched to the lightest subject detail.

The selection of the appropriate aperture and shutter speed among combinations of equivalent camera exposures depends on the requirements of depth of field and of subject movement.

Lens aperture as the key to flash exposure

Flash exposures. The lens aperture controls flash exposure, since the flash duration is generally shorter than the open time of the camera shutter. The light intensity on a scene is, by basic illumination laws, inversely proportional to the square of the distance between light source and subject. The light intensity reaching the film is also inversely proportional to the square of the diaphragm *f*-number. For a given flash source and film speed, increased flash distance can therefore be compensated by corresponding *f*-number adjustment; the exposure is constant as long as the product of distance and *f*-number is constant. Flash and film manufacturers quote this product as a guide number for various flash–film combinations. For rapid exposure calculation, dividing the guide number by the flash to subject distance gives the required *f*-number; dividing the guide number by the *f*-number gives the distance at which the flash must be arranged. Different guide numbers are needed for shutter times shorter than the flash duration.

Special meters can measure flash light quantity on a scene during a test firing of the flashes. This is a practical procedure with studio setups using electronic flash units, but it is wasteful with flash bulbs. Cadmium sulfide cells of automatic cameras control an electronic shutter to allow for the light from flash bulbs (but not electronic flash) in their exposure-control functions.

There are two types of flash exposure automation. In one type, coupled focus settings and lens diaphragms stop down the lens when focussing on nearer distances to keep the flash exposure constant. The coupling is usually adjustable for different flash guide numbers. In the other type, used with computer electronic flash units, a photocell monitors the light intensity reflected from the subject and controls the flash duration and hence the exposure accordingly. The control range may typically cover $^1/_{50,000}$ to $^1/_{1,000}$ second in flash duration and 1½ to 20 feet (½ to six metres) in subject distances.

Exposure latitude. The ideal negative exposure records the darkest subject shadows as a just visible density. More exposure yields a denser negative, which, however, can still give an acceptable print by appropriate print-exposure adjustment. This range of usable negative exposures, the exposure latitude, depends on the film and the subject. This latitude is greater, the lower the subject contrast and the greater the film's exposure range (and, generally, the lower the film contrast). Thanks to exposure latitude, simple cameras with limited exposure adjustability can still yield acceptable pictures under differing light conditions.

Lighting technique. The kind of lighting on the scene governs the way in which the picture reproduces the subject. Orientation of the subject—as in taking a portrait—with respect to the light direction can often control the effect. Lighting from behind the camera gives flat effects, light from one side yields depth and modelling, while the principal light from behind the subject produces dramatic against-the-light effects of high contrast. Artificial light setups in the studio, with tungsten lamps or electronic flash, offer the greatest flexibility. Under such conditions, the photographer can arrange two or more lamps for various lighting effects.

Flexibility with studio lighting

Directional lighting improves detail contrast and brilliance. Excessive subject contrast, however, makes accurate exposure settings difficult and may lead to loss of picture detail in the highlights or shadows. Fill-in lighting, by a flash or other light source on or near the camera, can illuminate heavy shadows facing the camera.

PROCESSING AND PRINTING

Negative development. Amateurs usually process films in developing tanks. In this type of development, a roll or miniature film is wound around a reel with a spiral groove, which keeps adjacent turns separated and allows access by the processing solutions. Once the tank is loaded (in the dark), processing takes place in normal light, the processing baths (developer, intermediate rinse, fixer) being poured into the tank at the appropriate intervals. Sheet films are similarly treated in small tanks or held in hangers and immersed sequentially in the different processing solutions. Large-scale commercial processing laboratories use machines that automatically feed the films through the solutions in proper sequence.

Developers and their characteristics. The developer consists typically of one or more developing agents, a preservative (such as sodium sulfite) to prevent oxidation by the air, an alkali (such as sodium carbonate) to activate the developer, and a restrainer or antifoggant to ensure that the developer acts only on exposed silver halide crystals. A developer's main characteristics are activity, development speed, and effect on film gradation, graininess, and sharpness. Developers may be prepared on the basis of published formulas or bought as ready-mixed powders or concentrates for dilution with water.

The developer is allowed to act for a specific time to build up the image to the required density and contrast. This time depends on the developer, the temperature, the degree of agitation, and the film—as indicated by film and developer manufacturers' recommendations.

Fixing. The fixing bath contains a chemical (sodium thiosulfate) that converts the silver halide into soluble, complex silver salts that dissolve in the fixer. During this process the film loses its original silver halide milkiness overlaying the image and becomes clear. The fixer also contains a weak acid (to halt the development process) and a hardening agent to reduce gelatin swelling.

Washing and drying. Washing removes all residual soluble chemicals from the emulsion and must be thorough for image performance. Films are hung up to dry after removal from the tank.

High-speed processing. Greatly reduced processing times are possible with high-activity developers at elevated temperatures and with fast-acting fixing agents, such as ammonium thiosulfate. Such processes can cut access time to the negative down to less than a minute. One-bath (monobath) processing in a solution containing both fast-acting developing agent and fixing chemicals also reduces processing time. In special rapid-access processing equipment, films pass through chambers spraying the processing solutions onto the film surface or run in contact with monobath-soaked webs.

Monobath processing with developer and fixer

Printing. The simplest printing equipment is the contact printing frame in which the negative and printing paper are held together behind a glass plate during exposure to a suitable lamp. A printing box is essentially a printing frame with built-in light source. Contact printing gives a positive of the same size as the negative.

Enlargers. Usually negatives are enlarged to prints of the desired final size. The enlarger is a projection system on a vertical column mounted on a horizontal baseboard (Figure 10). It has a lens, a film holder (negative car-

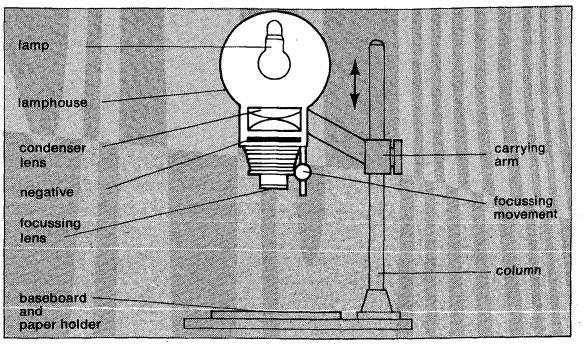

Figure 10: Basic enlarger features.

rier), and a lighting system (typically a lamp and condenser lens) for illuminating the negative. Raising or lowering the enlarger head on the column controls the image magnification; adjustment of the lens to negative distance focusses the image on the enlarging paper on the baseboard. In automatically focussing enlargers, these two adjustments are linked mechanically to keep the image sharp all the time. Enlargers are made in various sizes to take different maximum negative formats.

Printing papers. Papers for enlarging and contact printing are produced in grades of differing exposure range—*i.e.*, ratios of shortest to longest exposure to produce the lightest tone and a full black, respectively. The various grades yield prints of a normal tone range from negatives of different contrasts: a soft paper grade for a high-contrast negative, a normal paper for a normal negative, a hard paper for soft negatives, and so on. Paper grades are also numbered—typically from 0 to 5—in ascending order of contrast. Variable-contrast papers use a mixture of two emulsions of a different contrast and colour sensitivity; the contribution of each is controlled by filters in the path of the exposing light.

Paper grades in order of contrast

Other paper characteristics are the speed (slower for contact papers, faster for enlarging papers), image colour (blue black to warm brown), surface texture (glossy, velvet, mat), and base thickness (single or double weight). Some printing materials are coated on a white opaque plastic base or on plastic-laminated paper; these papers absorb no water during processing, allowing prints to dry more rapidly.

Printing exposures. Correct printing exposures are determined by trial and error or by test strips given a series of progressively increasing exposures. More sophisticated exposure control systems measure either the brightness of selected image portions projected on the enlarger baseboard or the average light intensity reaching the paper during the exposure. Printing papers are exposed and processed in a darkroom lit by an olive green or orange safelight. Printing papers are sensitive to violet, blue, and sometimes green light.

Print processing. The processing of prints consists of development, an intermediate rinse or stop bath, fixing, and washing. The developer and fixer are similar in principle to those used for negative films. In the normal method, dish or tray processing, prints are immersed successively in the solutions in dishes laid out side by side. Development is checked visually, the print remaining in the developer until the image has reached its full density. For drying, the prints may be clipped to a line, placed in a heated print dryer, or squeegeed onto a mirror-finished plate for a high-gloss surface.

Stabilization processing. Certain rapid processing papers incorporate developing agents in their emulsions and are processed on a roller processor. This processor runs the paper through an activating bath for instant development and then through a stabilizing bath, followed by a pair of squeegeeing rollers from which the print emerges merely damp. This process takes about ten to 15 seconds; the prints, however, do not keep quite as well as conventional prints, since unexposed silver salts are not removed from the emulsion but only converted into moderately light-stable compounds. Such prints can be made more permanent by subsequent fixing and washing.

Disadvantage of prints finished by stabilization processing

Dry processing. Processing baths can be completely eliminated by incorporating in the emulsion of the paper development and stabilization chemicals that become active on heating. One method is to disperse the processing chemicals in the emulsion in microscopic capsules containing the solution and a blowing agent. On passing the exposed paper over a heated roller, the blowing agent bursts the capsules, and the liberated processing solutions act on the silver halide immediately around each capsule. The liquid solvent instantly evaporates, leaving a dry print. Such encapsulation materials are used for such purposes as making proof prints of negatives and re-enlarging microfilm images. Certain nonsilver processes in photocopying systems also offer dry processing.

COLOUR PHOTOGRAPHY

Colour reproduction. Present-day colour photographic processes are tricolour systems, reproducing different colours that occur in nature by suitable combinations of three primary coloured stimuli. Each of these primary colours—blue-violet, green, and red—covers roughly one-third of the visible spectrum. Tricolour impressions can be produced by (1) combining coloured lights (additive synthesis) or (2) by passing white light through combinations of complementary filters each of which holds back one of the primary colours (subtractive synthesis).

In additive synthesis, a combination of red and blue-violet light (*e.g.*, light beams of the two colours directed on the same spot of a white screen) gives a purplish pink (magenta); equal parts of red and green produce yellow, and equal parts of green and blue violet produce bluish green (cyan). Superimposition of all three light beams on a screen yields white; combinations of varying proportions of two or three of the colours produce virtually all the other hues.

In subtractive synthesis, yellow, magenta, and cyan filters or dye layers subtract varying proportions of the primary colours from white light. The yellow filter absorbs the blue component of white light and so controls the amount of blue present in a white light beam that has passed through the filter. Similarly, the magenta filter controls the amount of green light left, and the cyan controls the amount of the red component. A cyan and magenta filter superimposed in a white-light beam holds back both the red and the green component, making the emerging beam blue. Similarly a cyan and yellow filter together yield green, and a yellow and magenta filter together yield red. Superimposing such filters or dye images of different densities in a white-light beam can therefore re-create any colour impression in the same way as superimposing light beams of the primary colours.

Subtraction of primary colours by filters or dye layers

The difference between additive and subtractive synthesis is the approach: in additive synthesis colours are built up by combining different intensities of primary-coloured light and in subtractive synthesis, by removing different proportions of primary-coloured light from white light. All modern colour films are based on subtractive synthesis. In theory either method of colour synthesis should be capable of reproducing every existing colour in nature. In practice, the reproduction is imperfect. No filter dyes meet the required ideal specifications. Nevertheless, for most purposes, reproduction is adequate.

Colour films. *Reversal colour films.* To reproduce colour by subtractive three-colour synthesis (Figure 11),

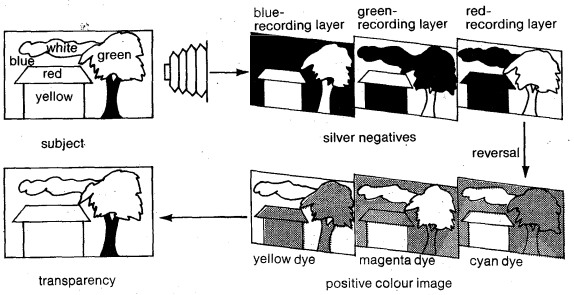

Figure 11: Colour reproduction sequence with subtractive reversal film (see text).

colour films first break down the colours of an image into their primary components by means of three separate sensitized layers, each of which responds exclusively to blue, green, or red light. The image in each layer is reversal-processed to yield a positive dye image in a colour complementary to the layer's spectral sensitivity. Thus, the blue-sensitive layer first yields a negative image of everything blue in the original scene (*e.g.*, the blue sky) and then a positive image of everything that is not blue. This positive image is coloured yellow. Similarly, the green-recording layer yields a magenta positive image of everything that is not green, and the red-recording layer a positive cyan image of everything that is not red. Blue sky, for instance, does not figure in the yellow positive image, but does figure in the magenta positive image (not being green) and in the cyan positive image (not being red). The magenta and cyan dyes in the areas that were blue sky are superimposed; white light passing through the resulting transparency loses its green and red, but not its blue, component; thus, the sky appears blue. Similarly, green subject components end up as positive yellow image density in the blue-recording and positive cyan density in the red-recording layer, combining to green in the transparency. Yellow records as a negative image in the green-recording and red-recording layers, hence leaving a positive yellow image only in the blue-recording layer. All other colours are formed by similar combinations of different densities of the dye images.

Negative colour films. Negative colour materials work in a similar way but yield a negative dye image by direct development. Blue subject tones record in the blue-sensitive film layer to produce a yellow negative image. Green colour components yield a magenta dye image in the green-responding layer, and red components yield a cyan dye image in the red-recording layer. With respect to the subject, the colour negative therefore reverses the tones in brightness as well as in colour. Printing the colour negative on a colour paper with three differentially responding layers reverses the process once more, reconstituting the original subject colours in a positive print.

Colour-film structure. In a magnified section (Figure 12) a reversal colour film has these components:

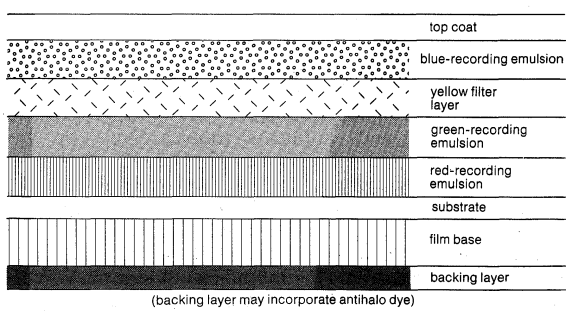

Figure 12: Structure of reversal colour film (see text; thicknesses not to scale).

1. A top layer of plain gelatin, which protects the underlying layers against abrasion and damage.
2. The first emulsion layer, which contains blue-sensitive silver halide plus a yellow-forming colour coupler. This is a colourless substance that reacts with the decomposition products of the developing agent to generate dye in all areas where a silver image is produced and in proportion to the density of that silver image.
3. A yellow filter layer of finely divided (colloidal) silver, which holds back blue light from the subsequent emulsion layers. It disappears during the bleaching stage of processing.
4. The second emulsion layer, which contains blue-and-green sensitive silver halide plus a magenta-forming colour coupler. The blue sensitivity is suppressed by the yellow filter layer.
5. The next emulsion, which is blue-and-red sensitive (blue again being suppressed) and contains a cyan-forming colour coupler.
6. A substrate, which ensures optimum adhesion of the emulsion layers to the film base and may also contain light-absorbing silver to prevent the scattering of light by reflection from the support surface (halation).
7. The film base or support of clear cellulose acetate derivative (or sometimes polyester), typically about 0.005 inch thick.
8. The back of the support, which carries a light-absorbing layer (an alternative to the antihalation layer in the substrate); on roll films this also acts as an anticurl layer.

Variations in reversal colour films

The above scheme is subject to variations. Some reversal colour films do not incorporate colour couplers in the emulsions but introduce them in the processing solutions. Processing such nonsubstantive colour films is more complex than processing substantive-coupler films containing couplers in the emulsions.

Negative colour films are similar, but the couplers are themselves often already coloured yellow or red or both. The unreacted couplers remain as positive images, which compensate for some deviations of the image dyes from the colour characteristics of ideal dyes. Such negatives are characterized by an apparently overall reddish or orange tint.

Some colour films come with different combinations of colour sensitivity and dye colour formed in the individual layers for deliberately falsified colour rendering (false-colour films) in special applications.

Colour positive (print) materials have a paper or white, opaque film base instead of transparent film and have no antihalation layer. The emulsion sequence may be different from the above scheme, as may be their spectral sensitivities. The latter may be keyed to the transmission characteristics of the negative dyes for better colour reproduction.

The dye images are reasonably lightfast, but fade on prolonged exposure to ultraviolet-rich radiation. Colour transparencies and prints intended for continuous display may be protected by ultraviolet-absorbing coatings or filter layers.

Colour balance. Colour film reacts to all hue and tone differences including the prevailing light colour. A film recording approximately natural colours in daylight reproduces scenes photographed by tungsten light with a reddish overall tint—because this lighting is richer in red rays than is daylight. This spectral balance of different "white" light sources may be rated numerically by the colour temperature—a concept of theoretical physics that, with tungsten lighting, corresponds roughly to the absolute lamp-filament temperature. Such absolute temperatures are expressed in degrees Kelvin (°K). The higher the colour temperature the richer the light is in bluish and the poorer it is in reddish rays and vice versa. Average daylight is rated at about 5,500° K, the light from an overcast sky from 6,500° K up; the colour temperature of tungsten lamps ranges between 2,600° K and 3,400° K.

To ensure correct "white light" colour reproduction with different types of lighting, the sensitivities of the three film layers must be matched to the colour temperature of the light. Reversal colour films are therefore made in different versions. Daylight films are balanced for faithful colour rendering with 5,500° to 6,000° K light (average daylight, blue-coated flash bulbs, electronic flash). Type A films are balanced for 3,400° K light (high-temperature tungsten filament and photoflood lamps). Type B films and tungsten films are balanced for around 3,200° K to match tungsten studio lamps.

"Universal" colour films

Such accurate film balance matching is less vital with negative colour films since the colour rendering of the print can be modified during colour printing. "Universal" amateur negative colour films are usable with any light, from tungsten to daylight. For high quality, professional negative colour films are still preferentially balanced to either daylight or tungsten sources.

Strongly coloured filters are suitable only for special effects; they overlay the colour image with the filter colour. Pale correction filters can match a film to a light source other than that for which it is balanced—*e.g.*, pale blue, with a daylight-type film used in tungsten lighting,

to raise in effect the colour temperature. Pale pink or amber filters similarly reduce the colour temperature for using artificial-light-balanced films in daylight. Colour-film manufacturers publish detailed recommendations of actual filters required for such conversion.

In outdoor photography, especially involving distant views, an ultraviolet-absorbing filter is often required, as ultraviolet radiation records in the blue-sensitive layer of the film, producing an overall blue cast in the transparency. A pale pink skylight filter for outdoor subjects lit only by skylight counteracts the cold bluish colour rendering resulting from such illumination.

Colour-film processing. The processing sequence for colour materials is longer than for black-and-white films and requires more solutions. Development needs very precise timing and temperature control. Colour films can be processed in amateur developing tanks; professionals use sets of tanks in temperature-controlled water jackets with provision for standardized solution agitation.

Reversal colour processing. Each make and type of colour film requires its own individual chemicals (often available in kits) and sequence for processing. A typical sequence for a substantive (couplers in the film) colour film is (1) first development, to form a negative silver image in each emulsion layer; (2) stop bath or hardening or both, to arrest negative development and harden the emulsion layers; (3) fogging, to render the remaining silver halide in each emulsion layer developable (in this step, the film is either exposed uniformly to white light or treated with fogging chemicals); (4) colour development, to produce a positive silver image in the remaining silver halide plus a coincident dye image by reaction with the colour couplers; (5) bleaching, to reconvert the negative and positive silver images into silver halide; (6) fixing, to dissolve all silver halide out of the emulsion, leaving only the three dye images; (7) the final wash, to remove all soluble chemicals (rinsing and washing are also done after each of the above processing stages); and (8) stabilization and drying (the stabilization bath in some colour processing sequences improves the lightfastness of the dyes).

Processing of colour films lacking couplers

Processing of nonsubstantive colour films, in which the couplers are in the colour developer, is more complex because each emulsion layer is re-exposed by appropriately coloured light and colour-developed separately. This operation requires automated processing machinery.

Negative colour processing. Negative colour films are practically all of the substantive-coupler type. In a typical processing sequence, colour development is done first; it forms a negative silver image in each emulsion layer, together with a corresponding dye image. Next, a stop bath stops the development process and may or may not include hardening. Bleaching then converts the silver image into silver halide. In the fourth step, fixing dissolves the silver halide out of the emulsions, leaving the negative dye images. Finally comes washing, stabilizing, and drying. Washing or rinsing also follow each of the first three stages.

Substantially the same procedure is followed for processing positive colour papers. The bleaching and fixing stages may be combined in one bleach-fix stage.

Colour printing. Colour print processing can be done in dishes or trays, but professional colour laboratories use either tank sets of suitable size to take larger print formats or drum processors, with the print attached to the circumference of a rotating drum that dips into a trough of processing solution. The liquid in the trough is changed at time intervals appropriate to the processing sequence; in automatic systems the solution change is program controlled. Various processes are in current use.

Methods of obtaining colour control

Positive prints from colour negatives. Positive prints are obtainable from colour negatives by enlarging them onto a positive colour paper. Colour control consists of modifying the colour of the printing light by yellow, magenta, and cyan filters of various densities—singly or in combination—to obtain a print of correct or desired colour balance. In simple colour enlargers such filters are placed in a filter drawer between the negative and light source. Advanced colour enlargers use variable-density cyan, magenta, and yellow filters in front of the light source; the light is then thoroughly mixed in a diffusing globe or box before reaching the negative. Alternatively, high-density filters may be inserted to varying degrees into the light path.

The above method of subtractive or white-light printing depends on subtracting or holding back colour components of white light. In additive printing the prints are given successive exposures through high-density red, green, and blue filters. Each of these exposures forms the image in one of the emulsion layers of the paper; colour balance depends on the proportions of the individual exposure times. The red, green, and blue filters are mounted in a turret in front of the enlarger lens or interposed by a relay mechanism between the lamp and the negative. In automatic colour printing systems these relays are controlled by photocells that evaluate the red, green, and blue components of light transmitted by the negative.

An alternative method of additive printing starts with a white light exposure (equivalent to simultaneous blue, green, and red light) and then interposes high-density yellow, magenta, and cyan filters in the light path to terminate the exposure to blue, green, and red light, respectively.

Reversal colour printing. Colour transparencies can be printed on a reversal colour paper similar to a reversal film and processed in an analogous way. The same kind of colour control with filters is again possible, but the colour effect of the subtractive filters or of the additive filter exposures is reversed.

Dye-destruction processes. Dye-destruction processes differ from chromogenic colour materials (where colour images are produced during development) in starting off with emulsion layers containing the final dyes. During processing these are bleached in proportion to the silver image formed. Straightforward processing of a dye-destruction or dye-bleach material yields a positive image from a positive original and consists of: development to form a silver image; stop-fixing to arrest development and remove unexposed silver halide; dye bleaching to bleach the dye in the areas containing a silver image; silver bleaching to convert the silver image into silver halide; and fixing, to remove residual silver halide. Washing is done between all the processing stages.

Obtaining a positive image from a negative requires a more elaborate processing sequence, analogous to reversal processing in a chromogenic system. Dye-bleach materials use far more light-stable dyes than those produced by colour-coupling development. The positive–positive procedure also yields duplicate transparencies on dye bleach materials with a transparent film base.

Assembly colour prints. The original method of producing colour prints was based on separation negatives obtained by photographing the original scene on separate black-and-white plates or films through a blue, green, and red filter, respectively. This method analyzes the subject in terms of its tricolour components in the same way as the initial negative images in a three-layer colour film. Positive prints from the separation negatives, converted into colour images (*e.g.*, by toning) and superimposed on top of each other, yield a subtractive tricolour print.

Prints by the dye transfer process

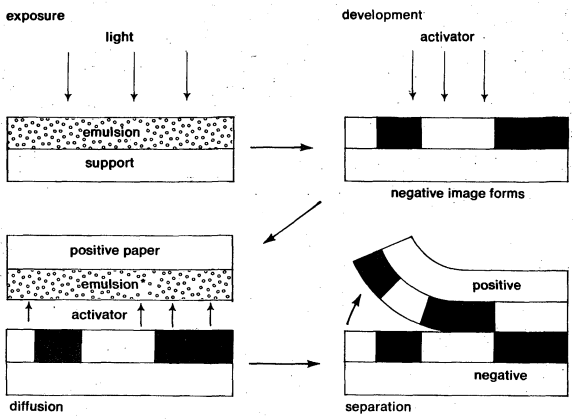
The main surviving assembly print process, dye transfer, uses a set of separation positives on a panchromatic matrix film made either from separation negatives of a colour transparency or by separation (three filtered exposures) from a colour negative. Appropriate processing converts the matrix film into a gelatin relief image whose depth is proportional to the positive silver density. Each matrix is soaked in dye solution (yellow for the matrix derived from the blue-filter negative and so on), and the dyes from the matrices are transferred in succession to a single sheet of gelatin-coated paper. Elaborate care is required to ensure accurate superimposition (registration) of the dye images; the result is a positive colour print.

Transparency projection. Many amateur colour pictures are in the form of transparencies, particularly on 35-mm film. These are usually mounted in plastic or card frames or bound between glass for projection on a screen

in a darkened room. The projector consists of a lens, a holder for the slide, and a lighting system (lamp, reflector, and condenser lenses to concentrate the light onto the slide). Modern slide projectors take the slides in magazines or trays holding 30 to 50 or more slides. An automatic slide transport feeds each slide from the tray into the light path of the projector and may be operated from a remote control unit or by pulses from a tape recorder, which can also record a commentary to the complete slide series. Some projectors feature remote-controlled or automatic focussing to keep each successive slide image sharp on the screen.

The standard miniature slide size is 2 × 2 inches for transparencies up to 1⅝ × 1⅝ inches; the most usual transparency format in such slides is 24 × 36 millimetres. Projectors for larger slides (*e.g.*, 2¾ × 2¾ inches for transparencies up to 2¼ × 2¼ inches) and ultraminiature projectors (*e.g.*, 10 × 14 millimetre transparencies in 3 × 3 centimetre slide frames) are suitably scaled up or scaled down versions of the standard models.

The size of the projected image depends on the distance of the projector from the screen and the focal length of the projection lens. Projectors may also project from the back onto a translucent screen; such rear projection setups are more compact, and the image is often bright enough for viewing in daylight. The rear-projection system is used in schools and for commercial displays. Elaborate slide shows are produced by linking two or more projectors aimed at the same or adjacent screen areas. With a suitably assembled slide set, the pictures can be made to change, overlap, and assemble, according to a predetermined program.



IV. Special techniques

POLAROID PHOTOGRAPHY

History and evolution. The diffusion-transfer process, the basis of the Polaroid system, was invented almost simultaneously in 1939 in Belgium and Germany. It relies on a silver halide negative material with a special processing procedure to produce positives in one stage. The process was initially used in office copying systems, and it is still in use in such systems.

Land's adaption of process for camera use

In 1947 Edwin Land, a U.S. inventor, introduced a version of the process adapted for camera use in which the processing takes place in the camera and yields a positive print within a minute or less of exposure. The original Polaroid material was a dual roll of negative and positive paper. Later, film packs and sheet films appeared, for use in special cameras or in camera backs to fit professional cameras taking interchangeable film holders or magazines. Present-day Polaroid films include high-speed emulsions, high-contrast process, transparency, and scientific materials based on the same process. Early in 1963 a diffusion-transfer colour material appeared for positive colour prints; similar materials for positive transparencies and for colour negatives are in preparation.

*emulsion with development nuclei

Figure 13: Steps in the production of a positive print by the diffusion-transfer process.

Black-and-white diffusion transfer. The negative material—paper or film—carries a silver halide emulsion incorporating developing agents. After exposure (Figure 13), soaking in an alkaline solution containing a silver halide solvent activates the developer to yield an almost instant negative image. The negative is brought into contact with an unsensitized print material containing development nuclei. The silver salts from the unexposed image areas diffuse into the positive layer and deposit metallic silver on the development nuclei. The whole process takes one-half to one minute, after which the negative and positive sheets can be peeled apart. The positive is the finished print; the negative is usually discarded or, if on film, it may be washed and treated to give a conventional negative for normal enlarging.

In the Polaroid instant-picture process the negative emulsion is fast enough for camera exposure. The positive material carries pods of jellied processing solution. After exposure, the negative and positive sheets pass between pressure rollers built into the camera or camera back; the pressure ruptures the reagent pod and the processing jelly is spread between the two surfaces. After the requisite processing time the finished print is again peeled off the negative material.

The Polacolor process. The colour version of the Polaroid material uses six active layers: a blue-sensitive silver halide emulsion backed by a layer consisting of a yellow dye and developer compound, a green-sensitive layer backed by a layer of magenta dye and developer, and a red-sensitive layer backed by a cyan dye and developer. The dye-developer in each case consists of dye molecules (not colour couplers) chemically linked to developing agent molecules.

After exposure and activation by the alkaline jelly, the dye-developer molecules in each layer migrate into the adjacent silver halide layer and there develop any exposed silver halide to a negative image. This at the same time anchors the dye component of the dye-developer molecule in position. Dye-developer molecules in unexposed image areas are not used up by development but migrate into the receiving layer of the positive material. Here they are immobilized, remaining as dye images corresponding to a positive of each silver halide layer in the negative film. The dyes thus re-create a full-colour positive image. The process depends on the controlled diffusion of the dye-developer molecules, achieved by spacing layers and balanced exposure and development time. Developing takes about one minute. Like the black-and-white Polaroid material, Polacolor film is available in rolls, film packs, and sheets.

Applications. The Polaroid process has an advantage in applications that need quick access to a finished print, provided that the limited print size (3¼ × 4¼ inches in the film pack and roll film, or 4 × 5 inches in sheet film) is not too serious a drawback. The initial field for the process was amateur snapshooting and instant portraits, from which evolved the taking of identification pictures for work and security passes. Such passes are made with special cameras that record a portrait together with personal details on a composite print, which is then laminated to form a tamperproof identity card of a standard size. In studio photography, Polaroid prints provide a quick method of making exposure tests, and checking the effects of lighting arrays. Polaroid prints have found some use in press photography. Commercial applications are numerous and include progress pictures on a building site and shots of properties for real-estate advertisements. In the laboratory, Polaroid prints yield instant records of experimental setups and are used for photomicrography, infrared photography (with a special infrared material), and for recording oscilloscope traces and other data from instruments. Polaroid prints of close-ups are also used in forensic and medical photography.

Limitations of the Polaroid process

Instant diffusion-transfer prints are not suitable for rapid-sequence photography, for applications requiring high image definition, or for applications in which a number of duplicate prints are required. Nor is the Polaroid process applicable under conditions precluding immediate

processing of the picture (*e.g.*, in underwater or space photography).

Key patents have largely reserved the use of this type of instant photography to materials and equipment of the Polaroid Corporation. As these patents are expiring, other major manufacturers are patenting their own versions of instant-picture cameras and processors. Proposed modifications of the process include negative films loaded in standard spools or cartridges in normal cameras, which are then fed—in a daylight processor—through an activating bath together with a separate positive material. The pictures are not available singly after each exposure, but the processing procedure at the end of a roll is virtually as rapid and convenient as Polaroid-camera processing. Polaroid has demonstrated a movie-film system based on this idea.

SPECIAL PHOTOSENSITIVE SYSTEMS

The high working speed (efficiency of converting light into permanent images) of silver halides makes them almost the only materials suitable for camera use. Numerous light-sensitive systems not using silver have been known since the beginning of photography. In view of an increasing silver shortage and its consequent high price, a number of substitute systems have grown in importance, and new ones have appeared during recent years. Most of them are limited to office copying, microfilming, the graphic arts, and other applications in which flat copy is reproduced.

Electrophotography. Electrophotography covers a number of processes that rely on photoconductive substances whose electrical resistance decreases when light falls on them. A layer of such a substance with a grounded backing plate is given a uniform electrostatic charge in the dark. When a light image is projected onto the surface, the photoconductor allows the electrostatic charge to leak away in proportion to the exposure. This leaves an "image" charge that can be converted, in various ways, into a visible image.

Principles of xerography

In xerography, the photoconductive layer is selenium, and the image is made visible by dusting the plate with an electrostatically charged powder (toner) having a charge that is the opposite of that of the electrostatic image. The powder adheres to the image portions only and is then transferred to a sheet of plain paper also under the influence of electrostatic fields. A final heat treatment fuses the powder into the paper for a permanent picture. The process usually makes a positive from a positive original. In office copying machines (the main application of xerography) the whole operating sequence is programmed and automated. A zinc oxide coated paper may replace the selenium plate; if so, the pigment powder deposit is fused directly into the paper surface.

The process is used mainly for line images without intermediate tones between black and white. Modified procedures permit continuous-tone reproduction and—with coloured pigments—also colour printing.

In the electroplastic process, a transparent thermoplastic serves as the photoconductive layer. After charging and exposure, the residual electrostatic charge forms stresses in the thermoplastic. Controlled heating deforms the surface in the image areas into a grain pattern, which is frozen into the plastic on cooling. The resulting image is light scattering and is viewed by reflection or in special projection systems. The electroplastic image can be erased by reheating the plastic layer, which then becomes reusable.

Colloid and photopolymer processes. A comparatively early nonsilver process depended on organic colloid (gum or gelatin) treated with a bichromate. Exposure to light hardened the gelatin, rendering it insoluble, while unexposed portions could be washed away with warm water, leaving a relief image.

Photopolymer systems substitute a plastic precursor in place of the gelatin. The plastic precursor polymerizes to an insoluble plastic when exposed to light, and the unexposed soluble material is washed out by a suitable solvent. Photopolymer processes have been adapted for forming resists (protective coatings) for etching, as, for instance, in the manufacture of printed circuits. In indirect photopolymer systems a light-sensitive substance is mixed with a plastic precursor and on exposure decomposes into compounds that initiate polymerization of the plastic. The polymerizable layer may include a pigment for a final coloured image. Superimposing colour images derived from separation negatives can yield positives; systems of this type are used for quick colour proofing in photomechanical reproduction.

Diazonium processes. A diazo or dyeline process depends on the decomposition by light of organic diazonium salts. These salts can also couple with certain other compounds to form dyes. After exposure, only the exposed (and decomposed) diazonium salt forms dye, producing a positive image from a positive original.

The materials are usually papers or transparent supports impregnated with the required chemicals. They are mainly sensitive to ultraviolet rays and can therefore be handled by normal tungsten lighting.

The light-decomposition of diazonium compounds also produces gaseous nitrogen. This phenomenon is utilized in vesicular processes that incorporate the diazonium compound in a thermoplastic layer. The nitrogen slowly diffuses out of this layer, but if heat is added immediately after exposure, the expanding nitrogen gas forms minute light-scattering bubbles visible as an image. The scattering power corresponds to the exposure. Further general exposure, after the plastic has cooled, decomposes the residual diazonium compound with gradual diffusion of the nitrogen out of the layer, destroying the latter's light sensitivity. This process and thermal dyeline systems are dry-processing instant-access systems and are used for making microfilm duplicates.

Photochromic systems. Certain dyelike substances can exist in a colourless and a coloured state. They are called photochromic compounds. The coloured state is formed by exposure to radiations of a certain wavelength. The compound reverts to its colourless state either in the dark or on treatment with radiation of a different wavelength. This reversibility is a primary characteristic of photochromism, and it is an instant-image system involving no processing.

Reversibility of the photochromic systems

Photochromic systems are used in microrecording (see below *Microfilming and micro-reproduction*). As the change of state takes place on a molecular level, the images are practically grain free and resolution is limited only by the resolving power of the optical system. Photochromic materials can be negative or positive working. With some photochromic compounds the dye image can be rendered permanent by optical, gas, or solution treatment.

Glasses containing certain metal compounds also act as photochromic materials. Exposure to light breaks down the compounds into metal that forms a visible (and permanent) image in the glass. Another type of photochromic glass contains silver halide crystals dispersed in the glass melt. The action of light decomposes the silver halide, forming a visible silver deposit. The halogen cannot escape from the glass, so it recombines with the silver in the dark and the image fades. Such photochromic glasses are incorporated in automatic light-control devices; light transmission decreases as the intensity of the light reaching the glass rises. Such glass has found use in certain types of sun glasses.

SPECIAL TECHNIQUES AND APPLIED PHOTOGRAPHY

High-speed and stroboscopic photography. High-speed photography is generally concerned with exposure times shorter than about $\frac{1}{1,000}$ second (one millisecond) and often exposures shorter than $\frac{1}{1,000,000}$ second (one microsecond). This field partly overlaps that of high-speed cinematography—sequences of very short exposures. Exposure times can be reduced by high-speed shutter systems or by short duration flash sources.

High-speed photography, together with high-speed cinematography, aids in the study of missiles, explosions, nuclear reactions, and other phenomena of military and scientific interest. In industry, high-speed pictures show up movement phases of machinery, relays, and switches;

dynamic fractures of materials or insulation breakdown; and, in natural science studies, flight movement of birds and insects.

High-speed shutters. The shortest exposure with mechanical shutters is about $\frac{1}{3,000}$ second. Special high-speed shutter systems are magneto-optical, electro-optical, or electronic.

A magneto-optical shutter (Faraday shutter) consists of a glass cylinder placed inside a magnetic coil between two crossed polarizing filters; so long as the filters remain crossed, virtually no light can pass through. A brief current pulse through the coil generates a magnetic field that rotates the light's plane of polarization in the cylinder so that during the pulse some light passes through the second polarizing filter.

Principle of the Kerr cell

The electro-optical shutter (Kerr cell) is made up of a liquid cell of nitrobenzene fitted with electrodes and again placed between two crossed polarizers. An electric pulse applied to the electrodes changes the polarization properties of the nitrobenzene so that this arrangement again transmits light. Minimum exposure time is around five nanoseconds (5×10^{-9} second).

Image converter tubes electronically transmit and amplify an optical image focussed on one end of a tube onto a phosphorescent screen at the other end. Electrons flow in the tube only in the presence of an electric field, which can be controlled by short-time pulses down to a few nanoseconds.

High-speed light sources. The shortest electronic-flash duration is around one microsecond. Spark discharges in air between electrodes yield still shorter exposures; discharge voltage may go up to tens or hundreds of thousands of volts. Short-duration pulses applied to X-ray tubes produce X-ray flashes for high-speed radiography. The shortest exposures are between 20 and 50 nanoseconds. Special switching modes turn lasers into high-speed sources with durations down to a fraction of a nanosecond.

Synchronization. Generally the event photographed is made to trigger the exposure (the current pulse to operate the shutter or flash or spark source) to ensure correct synchronization. Examples are bullets interrupting a light beam to a photocell, or self-luminous phenomena (explosions) triggering the system via a photocell circuit. The event and the exposure may be also triggered together by a signal from a common source.

Stroboscopic photography. Electronic-flash units designed to flash in rapid succession (up to several hundred times a second) can photograph a moving subject in front of a stationary camera with its shutter open to yield multiple images of successive movement phases. The technique has been used in pictorial and sports photography (*e.g.*, recording the movement of dancers or golfers) and for analyzing movement cycles without a motion-picture camera. With very rapid cyclic movement (*i.e.*, rotating machine components) illumination by the stroboscopic flash synchronized with the movement cycle makes the moving component appear stationary.

Aerial photography. Photographs from airborne or spaceborne vehicles either provide information on ground features for military and other purposes (reconnaissance) or record the dimensional disposition of such features (surveying).

Reconnaissance photography for capturing detail

Reconnaissance photographs call for maximum sharpness and detail rendering. Infrared films are often used to bring out details not discernible visually. In nonmilitary applications such photographs may reveal ecological factors (tree diseases, crop variations) and traces of archaeological sites not visible from the ground. Such shots are generally taken with cameras using five- or 9½-inch roll film in large magazines, built into the aircraft and operated electrically by the pilot or other crew member, or automatically at set intervals. Some systems incorporate a shutterless technique; the film runs continuously past a slit at a rate matched exactly to the image movement in the camera's focal plane as the aircraft flies over the ground (image motion compensation).

Aerial survey is a systematic procedure of photographing the ground for map production; exposures are made at intervals to partly overlap the view of successive pictures. The aircraft must fly on a steady course at a constant height, which, together with the focal length of the lens, determines the image scale. Larger areas are covered by successive adjacent tracks. The individual photographs are enlarged to the same degree and then assembled in a precise mosaic.

For vertical aerial surveys the camera points directly down. Oblique surveys, with the camera pointed at an angle, reveal more perspective detail but need optical rectification when subsequently used in map making. Aerial photographs taken under precisely specified conditions can serve for accurate measurements of ground details by stereoscopic evaluation (see below *Photogrammetry*).

Underwater photography. Underwater photography requires either special watertight cameras or pressure-resistant housings for normal cameras. In both cases, camera functions are controlled through pressure-tight glands. A flat glass or plastic window is usually in front of the camera lens. Light sources are battery-powered tungsten or tungsten-halogen lamps or electronic flash units (again in self-contained pressure-proof housings) or flash bulbs in suitable guns. For comfortable handling the weight of the housing with camera is adjusted to slight negative buoyancy. Complete camera and lighting outfits may be built into sledgelike or torpedolike units with an electric or compressed-air motor for self-propulsion through the water.

Since the refractive index ratio of glass to water is lower than for glass to air, the light-bending power of a glass lens is less in water than in air. This factor reduces the lens's angle of view and makes objects appear at about three-fourths of their actual distance. This difference must be allowed for in focussing—possibly by a suitably calibrated distance scale or by fitting the housing with a compensating porthole, which acts as a diverging lens.

Underwater cameras

Underwater cameras with lenses designed for direct contact with the water eliminate the air space between the lens and the porthole. Such lenses can cover wider angles of view without distortion, but they do not give sharp images outside the water.

As light absorption by the water—depending as it does not only on depth but also on water clarity—is difficult to estimate visually, exposure meters (in watertight cases) are needed. The red and yellow absorption of the water more than a few feet below the surface turns colour photographs taken by daylight into virtually monochrome shots; hence artificial light is essential to show up the full colour range of fish and other underwater subjects.

Close-range and large-scale photography. Near photography to reveal fine texture and detail covers several ranges: (1) close-up photography at image scales between 0.1 and 1 (one-tenth to full natural size); (2) macrophotography between natural size and 10–20× magnification, using the camera lens on its own; (3) photomicrography at magnifications above about 20×, combining the camera with a microscope; and (4) electron micrography with an electron microscope at magnifications of 10,000 to 1,000,000×, which involves photography of the electron microscope's phosphor screen or placing a photographic emulsion inside the vacuum chamber of the electron microscope to record directly the image formed by the electron beams.

Close-up and macrophotography. Supplementary close-up lenses or extension tubes (placed between the lens and camera body) allow the camera to focus on near distances for large scales of reproduction. Special close-up rangefinders or distance gauges establish exactly the correct camera-to-subject distance and precise framing of the subject field. Special simple close-up cameras, as in fingerprint recording and certain fields of medical photography, are permanently set to a fixed near distance and have a distance gauge or similar device built in. Screen-focussing cameras (view and single-lens reflex) need no such aids, as the finder screen shows the precise focus and framing.

Extension tubes or extension bellows or both or "macro" lenses of extended focussing range are used for the macro

range of distances. For optimum image quality, macrophotographic lenses specially corrected for large image scales may be used or the camera lens reversed back to front.

Photomicrography. There are two principal methods of photographing through a microscope. In the first, the camera, with its lens focussed at infinity, is lined up in the optical axis of the microscope, which is also focussed visually on infinity. In the other method, the camera without lens is positioned behind the microscope eyepiece, which is focussed to project the microscope image directly onto the film.

Special photomicrographic cameras generally employ the second method. Microscope adapters to provide a light-tight and rigid connection between the camera and microscope are available for both systems. Such microadaptors may incorporate their own shutter and a beam splitter system for viewing and focussing of the microscope image through a focussing telescope. Photomicrographs are the essential adjunct to all microscopy to record biological, bacteriological, physical, and other observations in black-and-white or colour.

Basis of depth perception

Stereoscopic and three-dimensional photography. Visual three-dimensional depth is perceived partly because of the fact that the human eyes see a scene from two viewpoints separated laterally by about 2½ inches (six centimetres). The two views show slightly different spatial relationships between near and distant objects (parallax); the visual process fuses these stereoscopic views into a three-dimensional impression. A similar impression is obtained by viewing a pair of stereoscopic photographs taken with two cameras or a twin camera with lenses 2½ inches apart, so that the left eye sees only the picture taken by the left-hand lens and the right eye only that of the right-hand lens. Binocular viewers or stereo-selective projection systems permit such viewing.

Stereo photographs can also be combined in a single picture by splitting up the images into narrow vertical strips and interlacing them. On superimposing a carefully aligned lenticular grid on the composite picture, an observer directly sees all the strips belonging to the left-eye picture with his left eye, and all the strips belonging to the right-eye picture with his right eye. Such parallax stereograms are seen in display advertising in shop windows or showcases. They also can be reproduced in print, overlayed by a lenticular pattern embossed in a plastic covering layer.

Photogrammetry makes use of stereo photography in measuring dimensions and shapes of ground objects in depth, as from successive exposure pairs made during an aerial survey flight. If all exposure parameters, including flying height, ground separation between exposures, and focal length of the aerial camera lens are known, the height of each ground feature can be measured. Photogrammetric plotting instruments do this and draw height contour curves of all features for aerial maps.

Similar photogrammetric evaluation of stereo photographs of nearby subjects can also be made. For instance, it is possible to reconstruct accurately the scene of a highway accident. In industry, a photogrammetric plot of an automobile model can be fed into a computer to program the machine tools that will shape the full-scale motor body components.

Infrared photography. Images formed by infrared and heat radiations can be recorded either directly, on films sensitive to them, or indirectly, by photographing the image produced by some other system registering infrared radiation.

Silver halide emulsions can be sensitized to infrared rays with wavelengths up to around 1,200 nanometres (one nanometre is $\frac{1}{1,000,000}$ of a millimetre). The usual sensitivity range is 800 to 1,000 nanometres. Direct infrared-recording aerial photography shows up ground features of differential infrared reflection but similar light reflection (*e.g.*, different types of foliage) and cuts through haze and mist. Special colour films with an infrared-sensitive layer and processed to colours different from the natural rendering (false-colour films) show up such differences still more clearly. In forensic photography, infrared pictures reveal ink alterations in forgeries, differentiate stains, and help to identify specific textiles and other materials. In medicine, infrared photographs show subcutaneous blood vessels, as the skin is transparent to infrared.

Applications of direct infrared photography

With suitable equipment, it is possible to convert an infrared image into one visible on a fluorescent screen, where it can be photographed. In infrared scanner systems a moving mirror scans the object or scene and focusses the radiation onto an infrared-sensitive cell. The cell generates electric signals to modulate a light source, which, in turn, scans a photographic film or paper synchronously with the mirror. The resulting image records hotter and colder parts of the object as lighter and darker areas and can establish actual temperatures of subject details—sometimes to within a fraction of a degree. This system has been used to record temperature variations in the skin for the diagnosis of cancer.

Ultraviolet photography. Invisible shortwave ultraviolet radiations can be recorded directly or used in fluorescence photography (see Figure 14).

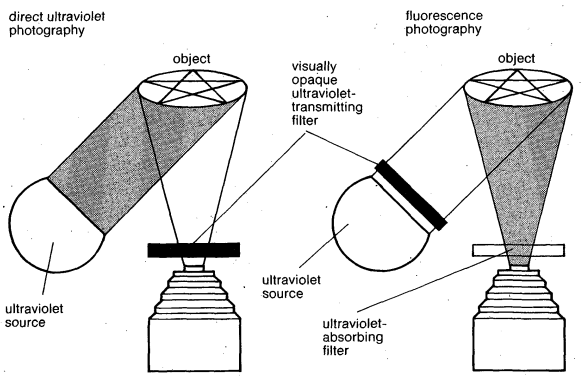


Figure 14: Arrangements for ultraviolet photography.

For direct ultraviolet recording, the photographically useful wavelength range lies between 400 nanometres (visible violet) and about 200 nanometres and needs special optical systems transparent to ultraviolet rays (quartz, silica, or fluoride elements or combinations thereof). Light sources rich in ultraviolet such as mercury vapour lamps—with an ultraviolet-transmitting, but visually opaque, filter in front of the camera lens—ensure that the photograph records only the ultraviolet-reflecting characteristics of the subject.

Fluorescence photography records the glow or visible light given off by certain substances when they are irradiated by ultraviolet rays. The object is illuminated only by ultraviolet rays by screening out the visible light with a filter that transmits only ultraviolet radiation, and another filter that absorbs the ultraviolet rays is placed over the camera lens, permitting only the visible light (fluorescence) to be recorded on the film. Normal lenses and panchromatic or colour materials are used.

Applications of ultraviolet photography

Ultraviolet photography can identify or separate pigments and fabrics and can detect forgeries of documents. Fluorescence photography can identify dyes, stains, and markings, specific chemical substances, and fluorescent components in microscope specimens. Ultraviolet microscopy offers increased resolution through the shorter wavelength radiations employed. Aerial and satellite photography by ultraviolet can show up ultraviolet-reflective ground features.

Radiography and other radiation recording techniques. Silver halide emulsions are sensitive to X-rays, gamma rays, and charged particles emitted by radioactive substances. Some of these rays penetrate visually opaque materials to varying degrees to show up internal structures. Radiography covers techniques of recording the subsurface features of objects.

X-ray radiography. X-rays (wavelengths between $\frac{1}{100}$ and $\frac{1}{100,000}$ that of visible light) are produced by high-voltage electron streams bombarding an electrode in a vacuum tube. For radiography the object to be

recorded is placed between an X-ray tube and the film; the film registers the differential absorption of the X-rays by the object's internal structure as a projection shadowgraph.

The most familiar application is in medicine for diagnosis and recording, including dental radiography. Industrial radiography permits nondestructive inspection of castings, welds, and engineering structures.

Gamma radiography. This technique of gamma-ray radiography is similar to that of X-ray radiography but relies on rays emitted by radioactive substances (*e.g.*, artificial isotopes like cobalt-60). Gamma rays have wavelengths from 100 to 1,000 times shorter than X-rays and correspondingly greater penetrating power. Small gamma-ray sources are placed in areas inaccessible to X-ray tubes such as inside pipelines. In all radiographic applications, the exposure occurs under conditions of normal light, from which the radiographic film is protected by a light-tight (but radiation-transparent) wrapping.

Autoradiography. Autoradiography records the distribution of radioactive materials in botanical and histological specimens placed in contact with a photographic emulsion. This technique has been applied to the study of metabolism of plants and animals; it records the activity of organic compounds of radioactive isotopes introduced into the system of the plant or animal. In engineering studies, autoradiography can be used to follow the transfer of radioactive substances from one surface to another in lubrication. The technique also has applications in machining and other metal-treatment processes.

Nuclear-track recording. Tracks of elementary particles, such as protons, electrons, and mesons, produced by nuclear reactions, can be recorded by photographic means. The most common technique is to photograph the visible traces of such tracks in bubble or spark chambers with special camera and lens arrangements. Different arrangements can provide for coverage of large fields or the recording of tracks simultaneously from several directions for three-dimensional reconstruction.

Particle tracks can be recorded directly in thick (up to one millimetre) emulsion layers or in emulsion stacks (up to 20 inches) carried in high-altitude balloons and in spacecraft and satellites. Special processing procedures are required to deal with these emulsion thicknesses.

Astronomical photography. By the cumulative effect of light received over a long period, a photographic emulsion can record celestial objects too faint to be visible. Before radio telescopes (see TELESCOPE), photography was the only way of detecting many such objects.

Astronomical cameras as units of telescopes

Astronomical cameras are film- or plate-holding units built onto high-power telescopes, typically reflecting systems. The telescopes run on precision, clock-driven mounts to keep the optical axis stationary with respect to the sky area as the Earth rotates during an exposure time, which can run into several hours. For increased recording sensitivity, the telescope image may be intensified electronically.

Astronomical photographs taken through narrow-band colour filters—including infrared or ultraviolet transmitting filters—show selective emission characteristics of stars. In the case of the Sun and of planets, such photographs can reveal some surface details not observable by white light. Colour photographs reveal colours not directly visible because the intensity of starlight is too low to stimulate the eye's colour-vision mechanism.

Spectrography records the composition of light emitted by stars and other objects, the star image of the telescope being photographed through a diffraction grating, a device that disperses white light into constituent wavelengths. Elements present in the star or the gas mantle surrounding it can be identified from their characteristic spectral lines. Displacement of such lines from their known wavelength position can indicate the velocity with which the distant stellar systems recede from or approach the Earth.

Microfilming and micro-reproduction. Microfilming is the copying of documents, drawings, and other such matter at a reduced scale—typically 1:15 to 1:25—for compact storage. Complete micro-reproduction systems include methods of filing the film copies for easy retrieval and re-enlargement.

Documents, periodicals, and other printed matter are usually microfilmed on 16-mm film with an image size between 10 × 14 and 14 × 20 mm in a copying camera taking 100-foot lengths of film. Engineering drawings of high information content are microfilmed on 35-mm unperforated film with a standard image size of 32 × 45 mm. Films of up to 105 mm in width are also used. Automated microfilm cameras run continuously, documents being fed onto a moving band carried past the camera at a steady speed while the film runs past a slit at a matched rate.

Readers and reader printers are desk-top projectors that display the frames re-enlarged to about natural size on a back projection screen. In a reader printer the image may also be projected on sensitized paper for full-size enlargements. Advanced readers have elaborate retrieval systems based on frame coding and run the microfilm rolls through at high speed until a specific searched image is reached.

Aperture cards or standard-size transparent jackets store microfilm images as single frames or groups of frames. Such unitized microfilms permit easier indexing and retrieval by classical or punched card indexing systems. Certain 35-mm microfilm cameras photograph the original document directly on film premounted in an aperture card and processed on the spot.

Microfiche system

A unitized system called microfiche carries up to 70 frames each about 11 × 16 mm on a 4 × 6-inch sheet of film—the equivalent of a 70-page document. The microfiche camera repositions the film frame by frame after every exposure. Microfiche can also be produced by mounting strips of 16-mm microfilm on self-adhesive 4 × 6-inch film sheets or jacketing such strips in multichannel plastic jackets of the same format.

Various duplication methods allow microfilm records to be extensively distributed.

For still greater space saving, microfilm images may be reduced beyond 1:100 on high-resolution photochromic image materials. Extreme fine-grain silver copies then hold 3,000 to 4,000 individual frames on a single 4 × 6-inch film. This method, proposed for complex catalogues and like purposes, offers easy retrieval of individual frames but requires a high-magnification reader.

V. The photography industry

Equipment manufacture

Present-day manufacture of cameras and other photographic equipment is concentrated in mass-production plants that make most of the components (camera bodies, lenses, shutters, and other parts) on more or less automated machines; the components are then assembled by semiskilled or skilled labour. Smaller manufacturers of low- and medium-priced cameras obtain components for assembly from such specialist suppliers as shutter manufacturers (about half a dozen leading firms in the world) and lens producers. High-quality precision cameras are produced on a smaller scale with automated fabrication of the engineering components but much more extensive manual assembly by highly skilled technicians. Components and functions of every camera are tested at every production stage; less expensive cameras are usually batch tested by a sampling procedure.

The raw material for lens manufacture covers a range of optical glasses of different optical characteristics. About ten major worldwide glass producers supply the several dozen optical firms offering lenses of well-known brands. The glass is cast into blanks for specific lens elements, ground and polished to the required exact specifications, and the elements assembled in metal (sometimes plastic) mounts. Extensive production tests and optical performance checks safeguard quality standards.

Silver halide emulsions are made by mixing silver nitrate with a solution of alkali halide—typically potassium bromide and iodide—in gelatin. The silver halide then precipitates out as fine crystals. After cooling to a jelly, shredding, and washing, the emulsion is remelted and treated to increase speed and contrast. Colour sensitizers and additives are introduced, and the gelatin emulsion is machine coated on wide continuous webs of paper or film. Gen-

erally several coatings are applied. Operations from emulsion mixing onward are carried on in total darkness. After cooling and drying, the material is batch tested for consistent characteristics then cut and packed.

Film base is produced either by coating a solution of the base material on large drums where it solidifies (film casting) or by extrusion of plastics, such as polyester, in film extruders. For print materials, paper of suitable purity is coated with a barium sulfate emulsion in gelatin, to provide a smooth white surface, and then with the silver halide emulsion.

Photofinishing laboratories process most amateur and some professional photographers' films and prints. In 1969, the total volume of business of the 2,000 to 3,000 laboratories in the United States was estimated at $850,000,000, of which $750,000,000 was colour processing.

Continuous processing of films

Photofinishing laboratories use machines that carry the films in spliced-together lengths or on racks through successive tanks of the processing solutions. Prints are usually made to standard formats on automatic enlargers, taking both the negatives and the paper in continuous rolls. The paper rolls of 250 or 500 feet are processed in continuous-strip processors, which deliver prints dry and with a glossy surface ready for automatic cutting. Many printers have automatic exposure measurement based on overall negative density, with automatic controlled colour correction for colour negatives. High-capacity colour printers of this type can produce 2,000 to 3,000 prints per hour. Coding systems identify individual films and corresponding prints by customer or order number for final re-sorting. More exacting processing services grade colour negatives before printing by light transmission measurements through different colour filters; the resulting exposure data may be punched as edge codes in the film itself or programmed on perforated paper tape. When the tape is run through the printer together with the film, the perforations directly control the colour exposures and corrections.

Enlargements to special sizes and colour printing for professional photographers require individual enlarging by skilled personnel on conventional enlargers with advanced automation features of focussing, exposure measurement, and colour control.

Other processing services include duplication of transparencies, various types of photocopying (partly on coin-operated copiers set up in public places), microfilming, and microfilm processing.

Industry economics

The world's largest producer of photographic goods is the United States, followed by Japan, West Germany, Great Britain, and France. The photo industry in the United States employs some 112,000 persons; the German and Japanese industries about as many again between them.

The world's major photo exporters are the United States, followed by Japan and West Germany. Principal foreign markets of United States photo products are Canada, Japan, West Germany, and Great Britain. The United States is also the largest photo importer, its main suppliers being Japan, West Germany, Belgium, and Great Britain.

In the United States the ratio of photo- (including movie) equipment production to photo-chemical production (films, papers, chemicals, etc.) is about 3:4; the corresponding ratio in Germany is 3:2, in Japan nearly 2:1 and in Great Britain about 1:2. Approximately 35 to 40 percent of sensitized materials production is bought by amateurs, the remainder for professional purposes, including applied photography and industrial recording. This ratio is changing in favour of professional uses.

Photometry, Astronomical

Astronomical photometry is a branch of astronomy dealing with the measurement and study of the brightness of celestial objects. In astronomy, the term photometry is most commonly applied to measurements of brightness that extend, in any one observation, over a limited band

of wavelengths only, rather than over all wavelengths of light. The relationship of the dominant, or effective, wavelength (represented by λ_0) to the bandwidth being observed (represented by $\Delta\lambda$) is a ratio ($\Delta\lambda/\lambda_0$) that is typically between one-third and one-three-hundredth. In contrast, the terms radiometry and bolometry, in astronomical usage, are applied to brightness measurements comprising all wavelengths, while the term spectrophotometry is generally used when only a very narrow band of wavelengths is measured at one time; *i.e.*, when the ratio $\Delta\lambda/\lambda_0$ is chosen close to zero. (For the related study of the electromagnetic spectra produced by celestial objects, see SPECTROSCOPY, PRINCIPLES OF.)

Originally, the role of photometry was to help identify stars in the compilation of star catalogs and charts. As photometric methods became more sophisticated, photometry became a developed branch of astronomy aimed toward the determination of the physical properties of stars; it is also used extensively in studies of most other classes of celestial objects, each of which requires special consideration and treatment or, in some instances, a special technique.

Historical survey. Photometry is one of the earliest branches of astronomy, the variety of brightnesses of the stars and planets having been obvious from time immemorial. Originally, it sufficed to arrange these celestial objects subjectively in sequence from the brightest to the faintest, as was done by Hipparchus around 130 BC. His work was expanded by Ptolemy about 300 years later to include about 1,000 stars. Both men used a system of "magnitudes," in which the brightest stars were ranked first magnitude and the faintest perceptible to the naked eye sixth. Further classification of the naked-eye stars by magnitudes was done in the late 16th and early 17th centuries by Tycho Brahe and Johann Bayer. After the telescope was invented, classification was rapidly extended to fainter stars by Galileo and others. All these early observers employed subjective estimates of stellar magnitude (sometimes using their own terminology and units, such as grades). As a result, there was little homogeneity to their systems.

The need for a comprehensive and consistent set of visually estimated stellar magnitudes was first met by Friedrich W.A. Argelander in several works, culminating with his great *Bonner Durchmusterung* ("Bonn Survey"), a catalog that gave magnitudes for about a third of a million stars in the northern half of the sky, down to about the tenth magnitude. The magnitude intervals were subdivided into ten subclasses, corresponding closely to the least perceptible differences in brightness as judged by eye; thus, Argelander's magnitude estimates appear in decimal form. For example, 4.3 designates a stellar brightness three subclasses fainter than fourth magnitude. Argelander fitted his magnitude scale to the traditional one of six magnitude classes for the naked-eye stars. This system of magnitudes, while convenient and useful, was entirely subjective in nature and lacked a physical or quantitative definition.

Early in the 19th century, astronomers began to intercompare quantitatively the brightness of stellar images with visual photometers, devices with which the observer matches two star images, one of which may be that of an artificial star, in the field of view of a telescope. Gustav Fechner, a German scientist, observed that the response of the eye was characterized by approximately equal sensation for equal ratios of brightness, while others found that the old magnitude intervals corresponded to brightness ratios of between 2.2 and 2.8—or, in other words, stars of the second magnitude, for example, were from 2.2 to 2.8 times brighter than stars of the third magnitude. The English astronomer Norman Robert Pogson proposed in 1856 the adoption of 2.512 (the fifth root of 100) as the formal basis of a physically defined magnitude scale. This, the Pogson scale, is now universally adopted by astronomers and may be stated conveniently: the difference in magnitude between two stars is given by 2.5 times the logarithm (to base 10) of the brightness ratio. If the ratio is obtained from measurements at a specific wavelength, the result is a monochromatic (one-colour) magnitude; if the ratio is obtained in terms of the response of a particular light receiver to a specific band of wavelengths, the result is a heterochromatic (more than one colour) magnitude in what is called a natural system characteristic of that photometric instrument and technique.

Pogson scale of magnitude

Adopting the Pogson scale, astronomers made use of visual photometers toward the end of the 19th century to re-establish the magnitude system on a physical basis, while they fixed the magnitudes in the range from fourth to sixth to agree with the ancient and the *Durchmusterung* values. Several new catalogs achieved improved accuracy because of the physically defined scale. The most important of these were the *Potsdamer Photometrische Durchmusterung,* which included 14,199 stars brighter than 7.5 magnitude in the Northern Hemisphere, and the *Revised Harvard Photometry,* which included 9,110 stars brighter than 6.5 magnitude over the entire sky as well as 36,682 fainter stars to about ninth magnitude.

In the last decade of the 19th century, bright stars were found to produce photographic images larger and denser than those of faint stars, so that measures of these image properties could be used to establish magnitudes. It is notable, however, that the dimensions of the optical images of stars in the focal plane of a telescope are substantially identical for all stars, bright and faint. The form and dimensions of the image are determined chiefly by the disturbing influences of atmospheric turbulence upon the diffraction pattern formed by the objective. The optical images from bright and faint stars differ only in energy flux. On the other hand, photographic images of bright stars are larger because of the turbidity and halation (a blurring caused by reflection) characteristics of the photographic emulsion; in particular, the size of a stellar photographic image is not a manifestation of the star's diameter.

Photographic photometry, despite calibration difficulties, soon largely displaced visual photometry. The photographic method not only determined photographic magnitudes in the blue spectral region, to which it was primarily sensitive, but, with suitable colour filters and orthochromatic emulsions, established photovisual magnitudes that closely matched the colour characteristics of the visual system of magnitudes. The photographic and photovisual magnitudes were adopted as the International System and served until about the middle of the 20th century, when photoelectric techniques were adopted because of their greater accuracy.

The International System of photometry

The earliest efforts to measure stellar brightness by means of the photoelectric effect, the conversion of light to electric current, were made in 1913. The technique was restricted to the brightest stars, however, because of inadequate sensitivity, although its inherent accuracy surpassed that of all other photometric methods. One of the chief difficulties was the accurate measurement of the feeble current produced by photocells. Until electronic amplifiers displaced the more primitive electrometers, photoelectric photometry remained severely handicapped. In 1932 in the United States Albert Edward Whitford made use of an electronic amplifier for the first time in astronomy. A second major advance took place when practical photomultipliers (see below *Principles of photometric methods: General techniques*) became available after World War II. Photoelectric methods now surpass all others in reliability, accuracy, and sensitivity.

The UBV system. What is called the UBV system of stellar magnitudes has been widely adopted as a successor to the International System. It is based on photoelectric photometry in three broad bands: the ultraviolet (U), blue (B), and visual (V) spectral regions; the latter two are similar to those of the old photographic and visual magnitudes. The additional U band includes the important spectral region that includes the Balmer discontinuity, in which light intensity drops suddenly owing to absorption by ionized hydrogen.

Apart from the Balmer discontinuity and the spectral lines, the distribution of stellar radiation with wavelength is known to approximate roughly the distribution of radiation from what the physicist calls blackbodies (*i.e.*,

bodies emitting radiation freely at all wavelengths) with temperatures ranging from about 2,000° to 50,000° K (0° K equals −273° C or −460° F). The relative strengths of the B and V magnitudes vary with stellar temperature and consequently with spectral type. For a given star, the quantity B–V, termed a colour index, expresses in magnitude form the ratio of brightnesses in two different wavelength bands. It might be expected, therefore, that a star's spectral type could be inferred from its B–V colour index; but this inference is valid only when the starlight has not passed through regions of interstellar dust. The dust scatters light more strongly at short wavelengths; and for every three magnitudes lost in the V band there are about four lost in B, resulting in an apparent reddening of the B–V colour index by about one magnitude. The apparent B–V of a star must therefore be corrected for this reddening, called colour excess, before any inference of the star's spectral type can be made. It is here that a third band in the ultraviolet plays a role, as it makes possible the determination of colour excess, total absorption, and spectral type for many stars. This kind of information about stars can be obtained more certainly when the UBV photometric data are supplemented by spectroscopic data, but UBV photometry can be carried out on stars far too faint for spectroscopic studies.

The colour index

Many more stars have been measured in the UBV than in any other photoelectric system. Such measurements are available to observers as standards of reference over the entire sky. Included are stars of most spectral types, luminosities, and degrees of reddening. The magnitudes have been made to coincide closely with the historical magnitudes for the bright stars; that is, the zero point for the V magnitudes has been fitted to selected stars in the North Polar Sequence, which in turn had been fitted to the old *Durchmusterung* values. The B–V and U–B colour indices are defined as zero for A0 stars of normal luminosity, thus conforming to the earlier zero-point convention. On the whole, the UBV bands are readily duplicated to a sufficient accuracy by appropriate combinations of photomultipliers and standard filters as well as standard photographic emulsions whenever photographic photometry is desired.

Principles of photometric methods. *General techniques.* In astronomical photometry, the process starts at the focal plane of a telescope, and from the start the principal methods differ greatly.

In photoelectric photometry, the image of a single star is passed through a small diaphragm in the focal plane and falls upon a photoelectric detector; all other images in the focal plane are blocked off and wasted. Photographic photometry, on the other hand, has the advantage of recording simultaneously all the images to which the plate is exposed. An additional advantage of the photographic method is that the plate becomes a permanent record, useful also for purposes other than photometry. Unfortunately, these advantages can be gained only at the cost of considerably reduced accuracy, for the complex relationships between the size and density of photographic images of stars and the brightness of the optical images are not subject to full control or accurate calibration. Nonuniform sensitivity or development over the surface of the emulsion, other photographic effects, the atmospheric dispersion and turbulence as they affect the chromatic form of the images, and field errors caused in the telescope optics all act to introduce large accidental and systematic errors.

Advantages and disadvantages of photography

Photoelectric photometry owes its accuracy primarily to two factors: the highly linear relation between the amount of incoming radiation and the electric current it produces and the use of precise electrical measurement techniques. In contrast, the photochemical processes and densitometric techniques (measuring the degree of darkening of photographic film) used in photographic calibration are relatively crude. For this reason, virtually all modern magnitude scales are established with photoelectric photometers, whereas the photographic methods are used only where their advantages may be exploited and deficiencies minimized. For example, after photoelectric measurements have been made, in a small area of the sky, of a select few individual stars that embrace an adequate range of magnitude and colour index, a photograph of the same area offers a means of determining the magnitudes of many more stars by interpolation. This simultaneously eliminates some of the chief shortcomings of the photographic method and provides much data with little telescope observing time.

The two chief stellar photometric instruments in current use are the photoelectric photometer, which attaches directly to the telescope, and the iris photometer, a device used to measure the degree of darkening of images on a photographic plate. As noted above, a diaphragm in the photoelectric photometer's focal plane serves to isolate the single image to be measured. Large diaphragms admit images of extended objects such as nebulae or planets; small ones isolate a star from a close companion or reduce the amount of background light from the sky when the star to be measured is very faint.

Two principal photometric instruments

The light comprising the stellar image passes through the diaphragm, an appropriate filter, a field lens, and into a photomultiplier, a device that produces a relatively strong electric current from a weak light input. The purpose of the field lens is to focus a small image of the telescope's entrance pupil onto the input of the photomultiplier. Typical output currents for stellar measurement lie in the range from 10^{-5} to 10^{-11} ampere, despite the large amplification factor achieved within the photomultiplier, typically around 10^6. The output current may be measured in a variety of ways.

A photoelectric photometer has some viewing eyepieces to allow selection of and alignment on the object to be measured or to permit guiding on a separate stellar image. There may also be provisions for simultaneous observing of several colours or multiple images or for scanning across an image.

In order to retain the highest accuracy in photoelectric photometry, all of the instrumentation must be stable, accurately calibrated, and free from effects that are dependent on such extraneous influences as temperature or orientation in the Earth's magnetic and gravitational fields. But even when these effects are minimized, there remain limitations to accuracy imposed by the atmosphere.

Limitation on accuracy

Because the transparency of the Earth's atmosphere is neither perfect nor constant and may not be uniform around the sky, it is usually necessary to compare photoelectric measurements of stars quickly and repeatedly, using nights of the greatest clarity. (Exceptions to this rule are sometimes permissible; for example, when the instrument is equipped to compare two nearby images simultaneously.) Reference stars of known magnitude as near the program stars as possible are customarily chosen to facilitate rapid manipulation of the telescope and to minimize the influence of differences in atmospheric conditions. The atmosphere's extinction of starlight is dependent on both the path length traversed by the light and the transparency of the air; it also depends on colour, being more pronounced at shorter wavelengths. Accordingly, all photoelectric measurements require slight corrections, since seldom will the stars be observed through identical lengths of air path. It is customary to apply these corrections to convert the magnitudes into what they would be in the absence of an atmosphere.

In the iris photometer, a beam of light is made to pass through the photographic plate, and the diameter of the beam is adjusted by means of an iris diaphragm to always pass a constant amount of light around and through a stellar image. The iris diameter thus adjusted will usually be found to be approximately proportional to the magnitudes of the imaged stars, over a range of several magnitudes. The stars of the calibrated sequence provide the link between arbitrary iris diameters and the magnitudes and permit the magnitudes of the program stars to be determined by interpolation. Another method of calibrating the image properties with magnitudes, believed by some to be superior in accuracy and range, consists of studying the image profiles with a microdensitometer; *i.e.*, by passing through them a very fine pencil beam of light.

Use of the iris photometer

Visual photometry continues in use in a few special areas of research. For extremely close visual binary stars, no other method has proved successful in measuring the magnitude of each component separately or in obtaining a difference in magnitude, Δm. Experienced observers of double stars attempt to estimate Δm directly, but the reliability varies with the seeing quality and proximity and Δm of the pair. Some observers of double stars make use of a double-image polarizing eyepiece that provides for equalizing the brightnesses in calibrated fashion; accuracies of about 0.05 magnitude can be obtained, although the measures are difficult.

Visual estimates of stellar brightness are also made by dedicated hobbyists, a particularly valuable pastime for those who observe the long-period variable stars whose slow variation few major observatories can follow thoroughly or economically. Although such visual estimates of magnitude seldom are more accurate than 0.1 magnitude, the amplitudes of variation of the long-period variables are so large that this accuracy is sufficient for most purposes.

From photographs of wider double stars, estimates of the difference in magnitude can also be made profitably by visual inspection, particularly when an objective grating has been used to limit the apparent difference in magnitude to 0.5 magnitude or less.

Selected areas; transfer photometry. At one time, the magnitudes of stars in one region of the sky were determined by making a photograph of the desired region and superimposing on it a second exposure of a region containing stars of known magnitude. In this process, termed transfer photometry, both the magnitude scale and the zero point of one region were effectively transferred to another. The reference regions were set up in several places in the sky, known as selected areas. Because one of the regions was centred about the north celestial pole and was therefore observable at all seasons in the Northern Hemisphere, it became the standard reference region. The photometrically calibrated stars in it make up the North Polar Sequence. The accuracy of the photographically determined magnitudes in this and other selected areas is insufficient to warrant their continued use; indeed, systematic errors of scale amount to as much as 30 percent at the 18th magnitude. All modern transfer work is therefore done with photoelectric photometers.

North Polar Sequence of stars

Broad-band photometry. If all stars were of identical colour—that is, of identical spectral energy distribution—their apparent magnitudes would be independent of the wavelength chosen for measurement and of the bandwidth used. In this idealized situation, any detector could be employed without spectral restrictions; and consequently, an observer would exploit the full spectral response of his most sensitive detectors in order to measure the magnitudes of the faintest objects in the most efficient way. In fact, however, the stars do have a wide variety of spectral energy distributions, and this imposes the necessity of determining magnitudes in restricted bands of colour.

From the definition given earlier of the Pogson magnitude scale, it would appear that monochromatic magnitudes pertaining to a specific wavelength are best suited to physical interpretation, because comparing the brightnesses of stars at wavelengths that might differ among stars of different energy distribution would have little physical meaning. But in order to study the most distant stars, whose apparent intensity is inherently so feeble, moderately broad bands are needed to provide sufficient energy to be detectable by even the most sensitive light receivers. Thus, the astronomer is compelled to make a compromise between a clear physical definition and the need to use sufficiently broad bands to examine stars in a consistent fashion, from the brightest to the faintest. In this discussion of the way in which broad-band magnitudes may be used and interpreted, it will simplify matters to exclude from consideration peculiar stars, novae, emission nebulae, and other sources of nonthermal radiation whose spectral energy distribution may be entirely dissimilar to that of most stars.

With any broad spectral band there can be associated a representative wavelength, λ_r, at which a monochromatic band of arbitrary narrowness would produce the same system of magnitudes for stars of a given spectral energy distribution when measured with the same telescope and detector system. Accordingly, the representative wavelength, λ_r, can be defined by an equation that includes variables for photometer response and for stars of differing spectral energy distribution. In comparing the values that the representative wavelength takes for the hottest and coolest stars, it is found that its range of variation depends on both the width and symmetry of the band in question. As a typical example, the V and B bands of the UBV system have values of representative wavelength that vary by about 2 or 3 percent over the normal range of stellar energy distributions. Experience has shown that this departure from monochromaticity is quite tolerable in the context of many applications, some of which will be mentioned presently, but that it is unacceptable for certain more critical applications, which will be taken up in the following section.

Representative wavelength of a broad spectral band

In practice, a broad-band-magnitude system is readily defined by (1) a set of magnitudes for specified stars as measured with a particular photometric apparatus and (2) a specification of the chief components of the apparatus, such as colour filters and type of detector, or, alternatively a specification of the instrument's response function. Although exact duplication of the apparatus response function cannot be expected in other photometers, sufficiently close approximation can usually be achieved, and small corrective transformations can be applied to produce results virtually consistent with those of the original equipment. It can be shown that broad-band magnitudes are in many instances adequate approximations of monochromatic magnitudes when the wavelength of the latter is defined by an equation that is somewhat different, though analogous, to that for λ_r. This is designated as the effective wavelength, λ_0, and it lies within the range through which λ_r varies over the range of stellar energy distribution encountered among stars and can be thought of simply as a kind of mean value of λ_r.

Some examples of applications to which broad bands are suited have been mentioned earlier: estimating the spectral types of stars as well as measuring the amount of reddening and absorption influencing their apparent colour indices and magnitudes. (In instances of extreme reddening, small corrections may be required if λ_r differs significantly from λ_0.) Other examples are stellar distances derived photometrically and absolute magnitudes.

Distances of remote stars can be deduced from their apparent brightnesses. In principle, it suffices to compare the apparent brightness of a star of unknown distance with that of one of the same spectral type and luminosity class at a known distance, since the ratio of apparent brightnesses (due allowance being made for any absorption) is simply the ratio of the square of their distances. A more customary way of treating this problem involves the concept of absolute magnitude, which is taken to be the apparent magnitude that a star would have if it were to be viewed from a standard distance of ten parsecs (about 32.6 light-years). The relation between the absolute and apparent magnitudes, M, m, and the distance, d, expressed in parsecs can be derived from the inverse-square law of diminishing brightness in magnitude form; and it states that the absolute magnitude is equal to the apparent magnitude minus a logarithmic value of the distance:

The concept of absolute magnitude

$$M = m - 5 \log \frac{d}{10}.$$

If there is any interstellar absorption, A, then it is also subtracted from the apparent magnitude:

$$M = m - A - 5 \log \frac{d}{10}.$$

These relationships serve to define a set of absolute magnitudes for stars of known distance, so that the relative intrinsic brightnesses and total energy outputs of different types of stars can be determined. A profoundly important relationship between the absolute magnitudes and spectral types of stars was established in this way by Ejnar Hertz-

sprung and Henry Norris Russell early in the 20th century and elaborated upon by numerous subsequent investigators. The relationship, commonly referred to as the Hertzsprung-Russell diagram from the form in which it is usually displayed, has played a fundamental role in studies of the constitution and evolution of the stars.

Conversely, the absolute magnitude of a star can be inferred from its spectral type and luminosity class, and this inference together with its apparent magnitude permits a determination of its distance.

Broad-band systems, such as the UBV system and its predecessors, have been of immense value in providing information about the stars in the Galaxy, extragalactic distances, and other important basic and statistical data. For this kind of application, monochromatic magnitudes would not have been significantly better.

Narrow-band photometry. Several types of investigation require narrow bands even at the cost of limiting sensitivity and thereby excluding application to the faintest stars. In general, the narrower and more numerous the bands are within a spectral range, the more may the photometric methods approach the spectroscopic in terms of the number of independent parameters that can be determined. In addition, the narrowing of a band toward monochromaticity aids in physical interpretation, particularly in relating the photometric data to theoretical stellar models and to spectrophotometry.

Two general types of narrow-band photometry have been profitably applied to stellar problems: one in which the strength of a stellar absorption line is measured, the other in which selected regions of the continuum are measured. In the former, the bandwidth is typically very narrow, ten to 30 Å (angstroms) wide, while in the second the bands are of intermediate width, typically 150 to 300 Å (one angstrom equals 10^{-10} metre).

The hydrogen-beta system

As an example of the former, the Hβ (hydrogen-beta) system introduced by Bengt Strömgren is based on measures of the strength of the Balmer Hβ line, a hydrogen absorption line at 4861 Å, which, for the stars of spectral type O9 to B9, is well correlated with luminosity. When UBV photometry is supplemented by Hβ photometry, the colour indices B–V and U–B (corrected for reddening) show spectral type, while the Hβ strength shows the luminosity. Despite the narrow band required for the Hβ measure, the efficiency of the photometric method, in terms of the time needed to reach a given faint star, is higher than that of the traditional spectroscopic method. Stars of other spectral types may be studied in an analogous way, making use of other appropriate spectral-absorption features.

In a different approach to obtaining two-dimensional classification of stars through photometry, several investigators have used four or more bands of intermediate width that, being less wasteful of light, allow the study of fainter stars. A number of general characteristics of stellar spectral energy distribution may be selected as criteria: a colour index based on the region at shorter wavelengths than the Balmer discontinuity (see above *The UBV system*), the depth of the Balmer discontinuity, a colour index in the region between 3800 and 4600 Å that is generally characterized by a different colour temperature than that at longer wavelengths than 4600 Å, or various combinations of these. In some instances it is possible to form compound colour indices that are insensitive to interstellar reddening but that remain sensitive to some inherent property of the star. In general, it has not been possible to accomplish two-dimensional classification over the entire range of spectral types; instead, particular systems are devised for use within restricted spectral ranges.

Spectrophotometry. In spectrophotometry, photometric methods are employed to study in great detail the spectral energy distribution of stars, generally with emphasis on the continuum rather than the spectral lines. Spectrophotometry has been done both photographically, by the scanning of a spectrogram and its calibration images with a microphotometer, and photoelectrically, by the direct scanning of a spectrum at the telescope. The scanning can be continuous or may consist of discrete measures made at selected places along a spectrum. If at selected places, the spectral regions may be isolated by filters; it is more customary, however, to use a spectrograph as a dispersing instrument with one or more slits located in the focal plane that admit restricted and well-defined bands of wavelengths into the light receivers. The bandwidth is generally so restricted that the measures are essentially monochromatic.

As in broad-band photometry, the photographic method is less wasteful of light, since the entire spectrum is photographed; photoelectric direct scanning wastes most of the light but is capable of very high precision. Spectrophotometry, at least with high resolution, is applicable only to the brightest stars and requires large telescopes for maximum light collection. Fortunately, among the bright stars there are examples of most types of normal stars, so that a large body of fundamental knowledge on stellar radiation can be obtained.

An important application of spectrophotometry is the study of interstellar absorption, particularly how the absorption varies with wavelength. For this purpose, two stars of the same spectral type, one reddened, the other unreddened, are compared spectrophotometrically. Another important result of spectrophotometry is the absolute calibration of stellar energy output through direct comparison with artificial standards of radiation. From such measurements, it is known, for example, that the radiation received at the Earth from an A0 star of 0 magnitude at 5560 Å (close to the effective wavelength of the V magnitude) is 3.8×10^{-9} erg per second per square centimetre per angstrom.

Surface photometry. Many celestial objects extend over an appreciable angle and present an apparent surface in the field of view. Examples are galaxies, nebulae, the Sun, the Moon, and most planets. Photometric studies of such objects can be made in two ways: in detail over the surface, as a function of position, or in whole, whereby the integrated light of the entire surface is taken.

The results of detailed surface photometry of an object are conveniently displayed in an isophotal map, a map in which contours of constant brightness are drawn much in the same fashion as altitudes in a terrestrial contour map. Customarily, isophotometric mapping is done by an instrument that follows contours of constant density on a photograph. This technique of isophotometry can be applied in the study of galaxies. If photographs have been made at different effective wavelengths, it is possible to distinguish regions containing the older and redder objects from those regions containing young stars and stellar associations.

Isophotometry of galaxies

A more recent technique consists of the superposition of a positive photograph taken in one colour onto a negative taken in another colour. By appropriate control of the balance of photographic densities, the images of selected types of stars will cancel, leaving the regions containing extreme blue and red objects showing up boldly as dark or light areas. This is an example of the use of photometric techniques in a qualitative rather than quantitative fashion.

While furnishing less information than detailed surface photometry, integrated magnitudes based on the entire surface of an extended object provide a convenient measure of the total radiation emitted. The ratio of the total luminosity to the total mass of a galaxy is an important parameter in the study of these objects. Moreover, for the most remote galaxies, integrated magnitudes provide a means of estimating their approximate distances.

In the study of emission nebulae, measures of the strength of various emission lines provide information about the constitution, density, and temperature of the nebulae. Recently developed techniques employing pressure-modulated Fabry–Pérot interferometers provide, in addition, details about the mass motions of the nebular gases.

Variation of light from astronomical objects. A considerable number of celestial objects vary in brightness, some being highly regular and repetitive in behaviour, others quite irregular. Many of these objects have provided important clues to astronomical problems.

Among the variable stars are some, such as the RR Lyrae variables and the Cepheids, whose light variation is caused by physical pulsation. Since early in the 20th century the Cepheids have played a vital role as astronomical distance indicators. Because those stars possess easily recognized light-variation characteristics in terms of the shapes, amplitudes, and periods of their light curves, they have been studied intensively. In particular, those Cepheid variables located in the neighbouring galaxies called the Magellanic Clouds show that their average brightnesses are highly correlated with their periods. Since all stars in the Magellanic Clouds are roughly at the same distance, the correlation must apply to their average absolute magnitudes also. Once their mean absolute magnitudes are known, it is sufficient to observe the period of any other Cepheid variable to infer its mean absolute magnitude and from this (and its mean apparent magnitude) its distance. This process, stated here in an oversimplified form, is used to determine the distances of the nearest galaxies. Although the RR Lyrae variables are not as intrinsically luminous and cannot be seen as individual stars at such distances, they serve a similar purpose in aiding the astronomer to deduce the distances of some star clusters within the Galaxy.

Pulsating stars, in some instances, also provide knowledge of stellar diameters. Their brightnesses are known to vary as a consequence of a pulsation process in which both diameter and surface temperature vary cyclically. If at two times during the cycle the colour indices and, thus, surface temperatures are the same, then the ratio of brightnesses must be proportional to the square of the radii at these times. If radial velocities are also known, the varying rate at which the stellar surface moves throughout the cycle is known; and, when the rate is integrated, the distance traversed between any two instants can be deduced. Thus, the difference between, as well as the ratio of, the two radii is available, and thus the radii can be determined. By carrying out such a process for many pairs of instants of common colour index, detailed knowledge of the star's pulsation in diameter can be obtained.

Eclipsing binary stars

An important group of stars is the eclipsing binaries, double stars too remote and too close together to be resolved, and whose orbital plane is oriented in space to pass through or very near the Earth. The combined light of an eclipsing binary, viewed of necessity in a single image, diminishes whenever one star eclipses the other; thus, there are two times per period when the apparent brightness reaches a minimum. From an analysis of the geometrical shape of the light curve, it is possible to infer important properties of the stars and their orbits. If radial-velocity curves are also available for the two components, it is possible to determine the stars' masses and diameters.

In the solar system, the rotational characteristics of many minor planets have become known from cyclic variation in their brightnesses, as has the rotational period of the planet Pluto. Observations of the occultation of stars by the Moon have provided important new information on the diameters of stars. Very fast photometry is required to follow the rapid extinction of light as the Moon's edge cuts the star from view; the shape of the extinction curve requires resolution in time on the order of milliseconds.

Two new types of objects discovered in recent years show characteristic variations in energy output, sometimes including the optical spectral region. They are pulsars and quasi-stellar sources, which are treated in detail in separate articles. In one pulsar, near the centre of the Crab Nebula, the optical brightness varies with the same periodicity (33 milliseconds) as its radio emission. Irregular brightness variations occurring in quasi-stellar sources over times of only months imply that their sizes must be no larger than the distance traversed by light in such times, and thus they must be many times smaller than galaxies.

Limits of observations. There are practical limitations to both the accuracy and dynamic range of astronomical photometry. The factors determining the limits are to be found in the statistical character of the detection of small numbers of photons, the irreducible units of light; in the nature of the photometric instrumentation; and in the behaviour of the terrestrial atmosphere.

The spectral transmission of the atmosphere is characterized by numerous wavelength regions called windows (regions of relative clarity) separated by regions of high opacity. Even within the windows, the atmosphere not only absorbs light and disturbs the images formed by telescopes; it also emits light, so that even a moonless sky is not totally dark. In addition, there is a background of scattered light from interplanetary dust and distant unresolved stars, nebulae, and galaxies. On a dark, clear night, the surface brightness of the sky is equivalent to about one star of 22nd visual magnitude in every square second of arc. Ultimately, this background light limits the extent to which faint stars can be detected on a fully exposed photograph.

23rd-magnitude stars

The faintest stars that have been photographed thus far by traditional methods are at about the 23rd magnitude, approximately one-third as bright as the sky background. This limit, 23rd magnitude, also represents the extent to which photoelectric photometry has been carried, because, in the absence of photographic star charts, the positions of any fainter stars remain unknown. If photoelectric photometry of a 23rd-magnitude star is carried out with a 5″-of-arc diaphragm, the light from the star would represent only about 2 percent of all the sky light admitted. At this faint level, only about two photons of visual light arrive per hour per square centimetre at the Earth from the star. Thus, quite apart from the brighter sky background, a very large telescope aperture and a very long observing time are necessary to collect a statistically significant quantity of light. Similar statistical considerations may limit the speed with which even bright objects may be observed, as in the case of rapid-scanning devices or observations of occultations of stars.

At the faintest levels, it appears that electronographic techniques, as developed by André Lallemand and Gerald E. Kron, will make possible the measurement of fainter stars beyond the reach of either conventional photoelectric or photographic methods. Kron has extended photometry in this fashion almost to the 24th magnitude. The essential principle employed is the replacement of the photographic plate by a photoelectric imaging device. In the latter, an image is produced on a photographic plate by highly accelerated electrons emitted by a photocathode placed at the optical focal plane of the telescope. The advantage over conventional photography lies in the much higher efficiency and sensitivity, while the advantage over conventional photoelectric photometry lies in the fact that a feeble star does not have to compete for detection with all the light from the surrounding sky background as admitted by a diaphragm, but only with that sky light arising from the small area occupied by the image itself.

There are also limitations on the working range of photometric processes. A photoelectric photometer, for example, typically is restricted to a range of less than 15 magnitudes because of factors such as saturation and fatigue of instrumental components at the brightest levels and electrical or statistical limitations at the faintest levels. Much wider ranges are possible by means of calibrated optical attenuation and overlapping intervals of measurement. The full range of photoelectrically measured astronomical objects is now about 50 magnitudes, extending from the Sun at an apparent magnitude of −26.8 to the faintest star at about 23rd magnitude.

In terms of accuracy, photometric measures in principle can be carried out over sufficiently long time intervals or can be repeated indefinitely to reduce the residual uncertainty inherent in the averaged results. Even this procedure, however, reaches practical limits imposed by systematic errors caused by imperfect calibration or observational procedures, the approximate character of transformations to standard systems, residual errors in the known magnitudes of standard stars, and unrecognized sources of error. In practice, the best photoelectric magnitudes of bright stars are typically accurate within about

1 percent, while, for certain forms of differential photometry, accuracies about 50 times greater can be achieved. On the other hand, photographically interpolated magnitudes are seldom more accurate than about 4 percent.

Photoperiodism

Photoperiodism is the functional or behavioral response of an organism to changes of duration in daily, seasonal, or yearly periods of light and darkness. Flowering in plants, breeding in animals, and migration in birds are among the many well-known photoperiodic responses that have received intensive study. Though such reactions are genetically determined, temperature, nutrition, and other environmental factors modify the responses.

Modifying factors

Plants. Photoperiodism was first reported in 1920 when the flowering of certain plants was demonstrated to be controlled by the daily duration of light. Investigators established the existence of three types of plants on the basis of day lengths favourable to flowering: short-day plants, which fail to flower when days exceed a certain duration called the critical day length; long-day ones, which fail to flower unless the days exceed a critical day length; and indeterminate ones, which flower about equally well regardless of day length. Critical day lengths for both long- and short-day plants differ widely from species to species and even among varieties of a single species.

Other responses that are influenced by the photoperiod include the formation of bulbs, tubers, roots, and runners; the coloration of stems and leaves; the falling of leaves; and the development of certain anatomical features.

The photoperiodic response of plants actually depends on the duration of the darkness, and not on light, a fact that was not understood at the time the phenomenon was named. Thus, a short-day plant flowers when nights are long and a long-day one when nights are short or absent. A brief period of artificial light in the middle of a long dark period divides it into two short ones and thus promotes the flowering of long-day plants and inhibits that of short-day ones. The dark reactions are, therefore, the time-measuring reactions.

Control of flowering

Growers of chrysanthemums can produce these highly seasonal flowers throughout the year by proper control of night length and other cultural conditions for adapted varieties. Increasing the length of day by artificial light keeps the plants from blooming until they attain sufficient size or until the desired date is reached. The light is then discontinued, or in some times of the year the plants are covered with black cloth during part of the day, thereby increasing the night length adequately to bring them into bloom.

Artificial control of day length is also used to regulate the time of flowering of orchids, China asters, feverfew, and tuberous-rooted begonias. Experiments show that the growth of some kinds of woody nursery plants can be maintained in the greenhouse during the winter by the use of artificial light. The uses of artificial light to improve production of various kinds of plants are constantly increasing.

The photoperiodic reaction occurs in the leaf, but the response generally occurs elsewhere. Thus, a product generated in the leaves evidently moves to the growing points, where it controls flower-bud formation. The product is a flower-promoting substance produced during dark periods. It may be a special flower-forming hormone, florigen, but such a substance had not been identified by the mid-1970s. Other growth substances, especially a group called gibberellins, are known to play a key role in flower formation.

Knowledge of the initial photochemical step in photoperiodism was obtained by studies of the way in which light acts. Red light is more effective than any other kind in preventing flowering of short-day plants and promoting flowering of long-day ones. A second but far less effective region occurs in the blue area of the light spectrum. Flowering is controlled in both kinds of plants by light of the same wavelength ranges, indicating that the basic photochemical reactions are identical, although in one type they suppress, and in the other promote, flowering.

The inhibition of flowering of some short-day plants by exposure to red light can be prevented by exposing them immediately afterward to light of somewhat longer wavelength, namely, far-red light. A similar cancellation of the action of red by far-red radiation occurs in the germination of light-sensitive seeds and in the control of growth of the stem and other parts of dark-grown seedlings, indicating that the same initial photoreaction is present in all these phenomena. Many of these responses can be reversed repeatedly by successive alternating exposures to red and far-red light. The ultimate response to such a series of exposures is dependent on the kind of light last given.

Reversibility arises from the photochemical interconversion of two forms of a photoreceptive pigment called phytochrome. Thus, a red-absorbing form is converted by red light to the far-red-absorbing form and this in turn is reconverted by far-red light to the red-absorbing form. The far-red-absorbing form of phytochrome is believed to be biologically active, probably an enzyme; but the action it catalyzes is not yet known. The red-absorbing form is thought to be inactive.

Animals. The most conspicuous activities of animals closely correlated with certain seasons of the year, and hence with changes in day length, are bird migration, reproduction, and changes in coat and plumage. Each of these occurs with marked regularity at a particular time each year. By retaining animals in captivity and subjecting them to artificial increases and decreases in day length, bird migration, reproduction, and other activities have been induced out of season. It has been concluded, therefore, that in nature the changing daily periods of light and darkness determine to a great extent when many seasonal activities occur.

Before their northward migration to breeding grounds in the spring, birds undergo a marked change in their physiological state. The change is shown by increased activity of the reproductive organs and deposition of large amounts of fat. When these same changes were induced experimentally in winter by exposing captive birds to artificial increases in day length, the birds migrated northward in winter when released. By employing different schedules of day length at various seasons of the year, it has been demonstrated that the rate of change in physiological state depends on the daily amount of illumination. As little as nine hours of light per day is stimulating. The response is rapid under long days and slow

under short days. A gradual increase in the amount of light per day is not necessary. Constant day lengths are effective, as are decreasing day lengths, provided that the daily amount of light is stimulating. Therefore, migratory birds that winter on or near the Equator, where the day lengths are constant, or in the Southern Hemisphere, where the day lengths decrease after December 21, could have the onset of their spring migration regulated by day length. Prerequisite to the response to light that occurs in winter and spring is exposure to short days or long nights in autumn. This phase of the annual cycle is called the preparatory phase, since failure to complete it precludes the subsequent response. Under experimental conditions completion occurs uniformly and more rapidly with longer nights. Day lengths in autumn wind the "clock" within the bird, so to speak, while the day lengths of winter and spring make it run and determine how fast it runs.

Regulation of reproduction

In most birds, mammals, and other vertebrates, breeding is seasonal. By experimental manipulation of day length, reproductive activity has been induced out of season. For the species that normally breed beginning in autumn (*e.g.*, brook trout, deer, sheep, and goats), decreasing daylight or short days following long days will be effective. For species that breed in the spring (*e.g.*, starling, junco, ferret, and mink), increasing daylight or long days following short days will be effective. Changes in breeding season occur in some birds and mammals when they are transported from the Southern to the Northern Hemisphere or from the region of the Equator to temperate latitudes. Although day lengths are constant on the Equator and change but little in the tropics, there is some evidence that day length does regulate the breeding and plumage cycles of tropical birds. Experimental modification of the breeding cycle of invertebrate animals (*e.g.*, snails, crustaceans, and insects) by means of day length has also been demonstrated.

Attempts to discover how the length of daylight affects the breeding cycle have shown that the light stimulates the eye or part of the brain near the eye. The light stimulates the release of special hormones from the brain, which eventually reach the pituitary gland (the master endocrine gland located at the base of the brain). The pituitary, in turn, secretes the hormones that, among other functions, control the growth of the reproductive organs. There is good evidence that the length of the dark period and the ratio of light to darkness are important factors in determining the reproductive response. The effects of day length on the migratory response seem to apply as well to the reproductive response in some birds. Response to light can be modified by temperature, nutrition, and inherent internal factors. Important among the last is a daily rhythm of about 24 hours' duration (termed circadian), which makes it appear as though the organism were keeping track of each day. The response to light-dark cycles seems to depend in part on the time that the light and dark periods occur within these 24-hour periods. A few species of birds and mammals studied did not show any influence of light on the reproductive cycle.

The most conspicuous seasonal change in coat and plumage occurs in those mammals and birds that are white in autumn and winter and brown in spring and summer (*e.g.*, varying hare, ermine, and ptarmigan). By experimental manipulation of light, either of these colours can be produced out of season. Molt into white plumage or coat can be induced by short days. Temperature is not a factor. Day length also influences the time of annual molt in birds, growth of wool in sheep, and production of the winter coat in mink and ferret.

A number of less obvious seasonal activities also occur in response to day lengths. In some aphids, the production of winged individuals (as opposed to wingless individuals) normally occurs in autumn and is dependent on a period of darkness of 12 to 14 hours. In certain other insects the occurrence of sexually reproducing individuals, which occurs normally in autumn, can be produced out of season by shortening the days.

Practical applications of knowledge of photoperiodism are common in poultry management, for the length of daylight affects laying, sperm production, and body weight of the fowl.

(A.Wo.)

Photoreception

Photoreception is the activation of a biological process by means of illumination. Most organisms, including man, respond to visible light; some react to wavelengths of light not seen by man; and still others can react to properties of light not detectable by man, such as polarization (vibration of light waves in a definite pattern). This article is concerned with the sensory processes by which animals detect information carried by light.

Light energy is necessary for life on Earth. Green plants require light for photosynthesis, the process by which water and carbon dioxide are transformed into carbohydrates; plants also show adaptive responses (*e.g.*, germination and flowering) to annual changes in daily light periods. Animals depend on plants for food and thus are indirectly dependent upon photosynthesis. In some animals, response to variations in day length is of great importance in the regulation of annual reproductive cycles. (For additional information about the above responses to light, see PHOTOSYNTHESIS; PHOTOPERIODISM; STEREOTYPED RESPONSE.)

Light, the name given to the mediator of the sensation of sight in higher animals, including man, and the equivalent of this sensation in lower animals, is the part of the electromagnetic spectrum that is visible to animals; it includes the range of wavelengths from about 300 nanometres (1 nm = 10^{-6} millimetre) in the near ultraviolet to about 700 nanometres in the deep red (300 nanometres is beyond violet and does not evoke sensation in the human eye).

The entire cell of a unicellular animal such as *Amoeba* may be sensitive to light so that the cell moves toward or away from it. Some unicellular animals (*e.g.*, *Euglena*) have developed a light-sensitive receptor, or eyespot—a region with a lower threshold for light stimulation than occurs in the rest of the cell. Some multicellular animals have photoreceptive cells, or eyespots, scattered in various parts of or throughout the body; those in the outer covering of the earthworm (*Lumbricus*) serve in directional orientation, which involves comparison of light intensities at different directions. Most animals

have localized photoreceptors of varying complexity—*e.g.*, the ocellus of certain mollusks and arthropods; the compound eyes of arthropods; and the camera eyes of cephalopods and vertebrates.

Evidence indicates that the eyes of certain insects can make use of the information carried by near ultraviolet wavelengths of light as well as that carried by visible wavelengths; both carry information related to the sensation of colour. The eyes of many invertebrates, such as certain arthropods and mollusks, have evolved in such a way that they can detect polarized light; *i.e.*, it evokes a sensation and provides information used for navigation. Visual sensation in higher organisms is primarily a complex response to the intensity and the spatial and temporal distribution of light on the photosensitive retina (the innermost layer of nervous tissue within the eye). Different eyes, different specialized parts of the same eye, and even the same parts of the same eye vary in their responses to illumination. Both the properties of light and those of the eye are thus important determinants of visual sensation. The great differences in the light-analyzing capacities of animals are reflected in the great diversity of gross structural organization involved in photoreception. The fundamental mechanism of photoreception—photochemical activation of a light-receptive pigment and the primary excitation-initiating process—seems to be similar among most animals, however.

This article deals with the optical properties of eyes, including the basic arrangements for image formation and light detection and the morphology of photoreceptors; the photochemistry of light detection; and the physiological functioning of the receptor cells that initiate nervous activity. These initial processes of photoreception provide information for the neural centres of the retina and higher nervous centres. The neural events involving the higher centres lead to visual perception.

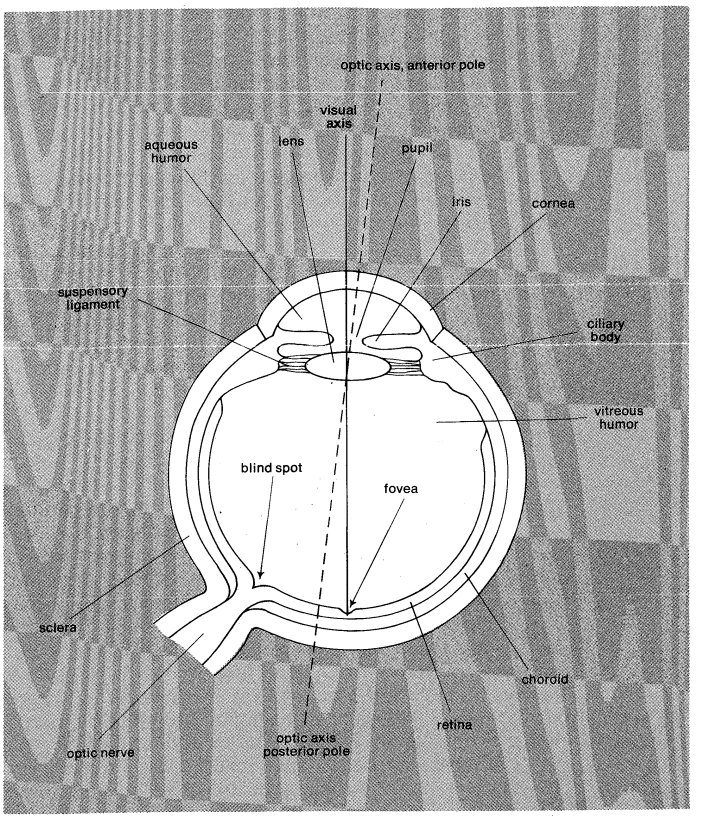

Figure 1: General structure of the mammalian eye.

THE OPTICAL PROPERTIES OF EYES

The first active step in vision is the absorption of light by a photosensitive substance, a visual pigment. Various devices within the eye assist vision by directing incoming light to this pigment; *i.e.*, they act as light guides by refracting (bending), reflecting (turning back), or guiding light. The arrangement of the optical structures influences the resolving capability and other basic properties of visual sensation.

Camera eyes. *In vertebrates.* The mammalian eye (Figure 1), somewhat like a camera, has a cornea (a transparent, anterior portion) and a lens; it functions as a dioptric system—*i.e.*, a system in which light rays are refracted so as to focus on the retina; the image projected on the retina is inverted. In the retina the light first passes through several layers of nerve cells before impinging on the photoreceptor cells, called rods and cones. The dimensions and refractive powers of all the optical parts of the human eye are known, making it one of the best understood vertebrate eyes (see EYE AND VISION, HUMAN).

The large size of the camera-like vertebrate eye makes it potentially the most efficient of all eyes because it can project a large image on a large surface area containing a high density of receptors. Both vertebrate and invertebrate eyes reflect the influence of the animal's environment. The optical arrangement of the eyes of animals active during the night (*i.e.*, nocturnal) suggests that resolution is sacrificed for light-gathering power (see Figure 2). The opossum lens, for example, is so large that it almost touches the retina—*i.e.*, it has a short focal length, the distance from the centre of the dioptric system to the place at which the image of distant objects is focussed (retina). The short focal length combined with a wide aperture results in a low focal ratio, or f-number

The influence of environment on vertebrate eyes

$$\left(\frac{\text{focal length}}{\text{aperture diameter}}\right),$$

and ensures high light-gathering ability. In the eyes of animals active during the day (diurnal), the lens is smaller; as a result, the optical centre is closer to the front of the eye, and its front surface is flatter. Thus, the focal length of the system is longer, the f-number is higher, and the image on the retina is larger and dimmer than in the nocturnal eye. Assuming that the large image can be detected by the photoreceptors, resolution is improved at the expense of the speed of the lens system.

From G.L. Walls, *The Vertebrate Eye*, Cranbrook Institute of Science

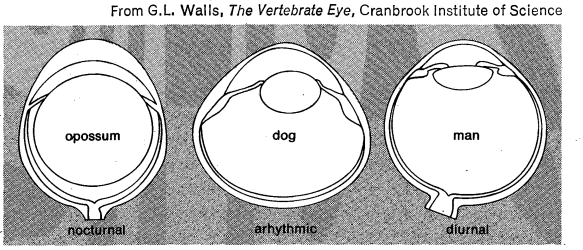

Figure 2: Influence of the environment on the optical arrangements of animal eyes (see text).

In order to utilize efficiently a large image, the retinas of diurnal animals have localized areas with many photoreceptors; *i.e.*, a higher receptor density. The receptors in this area, called the area centralis, are usually cones, the receptors of daylight and colour vision. These areas for sharp vision, often circular, are seldom located exactly in the optic axis (an imaginary line drawn through the centre of the cornea and the central point of the eye, see figure 1). The eyes of most birds have two such areas, the centre of each of which is specialized by a thinning of the retina to include only the receptors. This gives rise to a depression called the fovea, also found in teleost fishes, certain reptiles, and man. When the area centralis contains a yellow pigment, it is called the macula lutea. The macula lutea is found in higher primates (simians) and possibly chameleon lizards. This pigment filters out the shorter wavelengths of light and improves the sharpness of the image by reducing the chromatic aberration (variation of the focal length with different wavelengths of light) that would be caused by the inability of the lens to bring the long and short wavelengths to the same focus.

Distant objects are in focus on the retina of the normal human eye. In order for objects closer than about six

Accommodation in the eyes of vertebrates

metres (20 feet) to be in focus, however, an adjustment called accommodation is necessary; otherwise, the image would fall in back of the retina, and the object would appear fuzzy. In mammals, birds, and reptiles other than snakes, the accommodative adjustment consists of sharpening the curvature of the lens so as to shorten its focal length. In snakes, elasmobranchs (*e.g.*, sharks), and amphibians, accommodation is achieved by moving the lens —hence its focal plane—forward. In lampreys and teleost fishes the eye is adjusted for near objects, and accommodation for distant vision is carried out by a backward movement of the lens. Some species have evolved anatomical adaptations that make accommodation unnecessary. The retina of the fruit bat (*Pteropus medius*), is in folds, ensuring that some part of it will intercept an image at any location. The ray *Raja batis* and the horse have so-called ramp retinas, in which a continuous and gradual change occurs in the distance between the lens and retina in certain parts of the eye. Specific areas in these animals' eyes are presumably used to view objects at varying distances much as the human eye directs the image for detailed vision onto the fovea.

Because vertebrate species are adapted to almost every aquatic and terrestrial environment, they have evolved equally diverse eyes. In air, for instance, the front surface of the cornea can function effectively for image formation; in underwater eyes, however, the refractive index (the ratio of the speed of light in air to that in a given medium) of water and the cornea are almost identical, and the corneal front surface does not refract light. In these eyes the lens does much of the image formation.

Vertebrates have two types of photosensitive cells, rod cells and cone cells. The rod cells, which are long and fat, contain large amounts of visual pigment; they are the photosensitive cells for vision under conditions of dim illumination (scotopic vision). The cone cells, which are relatively small, mediate daylight vision (photopic vision) and colour sensation in many animals. The photosensitive photoreceptor outer segments of rods and cones are stacks of disks, or lamellae, with the planes of the disks at right angles to the long axis of the rod and cone cells. The retinas of animals active both day and night, as are those of humans, contain both rods (for night vision) and cones. In parts of the human retina the rods and cones are intermingled; elements of the nervous system provide the switching mechanism that permits adjustment for light conditions. The specialized fovea contains only cone cells; in the fovea the switching function is accomplished by eye muscles that change the direction of the field of vision in order to bring the image to the fovea.

The amount of light reaching the photoreceptor cells is controlled to some extent by the pupil, the opening of the eye through which light passes. The iris, the coloured portion of the eye surrounding the pupil, constitutes a diaphragm. Its muscles cause the pupil to change in diameter, decreasing the size of the pupil when light enters and increasing it when little or no light enters. The area of the pupil increases about 15 times in going from one millimetre to four millimetres in diameter, a relatively small increase in comparison with the range of light intensities under which the eye effectively operates. Since the amount of light entering the eye is proportional to the size of the pupil, it can be seen that changes in pupil size modify the amount of light only over a small range. Changes in pupil size are important in the human eye because they allow the lens to be used most effectively for visual acuity. When the whole lens is used, as in dim light when the pupil is large, the image formed by the lens is rather poor, chiefly because of chromatic aberration. The neural image on the retina is already poor, however, because the responses of thousands of rods must be pooled to obtain maximum sensitivity. Use of the whole lens is beneficial because it adds further light without reducing the image quality. When illumination is bright, the pupil is small, and only the aberration-free central part of the lens is used. This high-quality image is used effectively by the cone receptors of the fovea. There, no pooling of receptor responses occurs.

Pupils that form a circle when closed cannot greatly change in area; however, a pupil that forms a slit when closed can close almost completely. When nocturnally active animals find themselves in bright sunlight, they need additional protection for their sensitive rod-containing retinas; such animals have evolved pupils that close to form a slit. Many nocturnal vertebrates also show eyeshine (*e.g.*, the glow of a cat's eyes reflecting light at night). Eyeshine, which is caused by a mirror-like reflection from either the retina or choroid (a layer of blood vessels and connective tissue), enhances the sensitivity of the eye. The reflection of the light outward means that it passes the receptors a second time, giving them a chance to absorb light that was not absorbed during the inward passage through the receptors. Some animals thus have smaller rod receptors than they would otherwise need.

Adaptations of the eyes of nocturnally active animals

In cephalopods. The eyes of the invertebrate cephalopods—octopus, squid, and cuttlefish—are usually cited as examples of convergent evolution because they have independently evolved large camera-like eyes similar to those of vertebrates. The cephalopod eye lies within a cartilaginous cup. It consists of a cornea, lens, iris, and retina with the same basic relations to one another as are found in vertebrate eyes. Iris muscles can enlarge and narrow the pupil. Many details, of course, are different; for example, although the maximum density of photoreceptors in cephalopods is high—about 50,000 per square millimetre in *Loligo* and 100,000 per square millimetre in *Sepia*—the retinal structure otherwise bears little resemblance to that of the vertebrate. The photosensitive cells are of two types and are organized to detect polarized light (see below *Morphological features*). In addition, unlike vertebrate receptors, those of the cephalopod are the first element of the retina to be illuminated (rather than the last, as in vertebrates), and the optic ganglion (a mass of nerve tissue) is separate from the retina (rather than an intimate component, as in vertebrates). Both vertebrate and cephalopod retinas show pigment migration and movement of the receptors in response to adaptation for conditions of light and dark.

The cephalopod cornea does not have any focussing function. Image formation is accomplished entirely by the lens, which is forced forward for viewing nearby objects. The pupil is round in deep-sea cephalopods, such as *Loligo*, and slit-shaped in shallow-water dwellers, such as the octopus. Cephalopod photoreceptors are very long, an adaptation for nocturnal or deep-sea and low-light level conditions. The length allows for the presence of more visual pigment and hence greater absorption of light by each receptor cell.

Eyespots. Eyespots, the most primitive eyes, are found in the protozoan flagellates (unicellular animals with a flagellum, or whiplike structure, used for locomotion), flatworms (Platyhelminthes), and segmented worms (Annelida). An eyespot may be a specialized part of a cell as in protozoans, a single photoreceptor cell, or a small cluster of receptors with few or no accessory optical and neural structures. The entire epithelium (skin) of the annelid earthworm *Lumbricus* contains isolated light-sensitive cells that are eyespots. These photoreceptor cells are rather spherical in shape. A rhabdomere—a structure containing photosensitive pigment—lines a vacuole, or internal cavity, of the photoreceptor cell. The function of the vacuole may be to gather light.

Eyespots in planarians and amphioxus

The flatworm *Planaria* has a more highly developed eyespot. A number of photoreceptor cells are clustered under the epidermis. All of the rhabdomeres, which occur together within a cup-shaped collection of pigment cells, are located on slender filaments some distance from a cell that also gives rise to a nerve fibre.

A third type of eyespot is found in the nerve cord of the cephalochordate amphioxus. Each of a small cluster of photoreceptors, the Hesse cells, has a rhabdomere along the edge that faces a pigmented cell.

Ocelli. The ocellus, which is recognized as a true eye, is similar to a camera in that it usually projects an inverted image onto a light-sensitive layer. The ocellus is distinguished from the compound eye, which has many lenses, and from the more highly developed camera-like eye of the mollusks and vertebrates.

In mollusks. In a simple ocellus, that of *Nautilus*, the photoreceptor cells are bipolar—*i.e.*, the rhabdomere is at one end, the nerve fibre at the other—and arranged in a cup-shaped sheet. There is no lens or cornea, only a pinhole opening.

The more complex ocellus of the slug *Agriolimax reticulatus* is located at the tip of the tentacle (see Figure 3); there is a cornea under the epithelium, a vitreous body (a mass of clear jellylike material), and a lens, as well as a main retina and an accessory retina. The accessory retina is believed to function as an infrared receptor. As the tentacle is withdrawn, the accessory retina is rotated so that it is exposed to incoming radiation. The few photoreceptor cells are surrounded by pigment-containing cells. The ovoid eye is about 0.18 millimetre (0.01 inch) in its longest diameter. Distant objects appear in focus in the photoreceptor cells of *Agriolimax*, and the shape of the eye changes as the state of retraction of the tentacle varies. The change in shape may provide a mechanism for accommodation, although accommodation may not be particularly useful, because indications are that this ocellus does not clearly distinguish form.

The molluscan ocelli described above resemble a miniature simple camera, in which an inverted image is projected onto a photosensitive retina. The optics of other ocelli, however, are more sophisticated; for example, the scallop *Pecten* (Figure 4) and related genera have about 100 eyes located along the fringe of the mantle, the lining of the inner surface of the shell. The eyes are one millimetre in diameter and have a double retina; one is called a distal retina, the other a proximal retina. The nerve fibres of the distal (*i.e.*, farthest from the body axis) retina respond only to decreases in light intensity; the nerve fibres of the proximal (*i.e.*, closest to the body axis) retina, on the other hand, respond only to increases in light intensity. Because the photoreceptors in the proximal retina are inverted, light passes through all parts of them before reaching the light-sensitive pigment, and the photoreceptors just touch a reflecting structure, the tapetum lucidum. The scallop tapetum contains about 35 layers of thin crystals; the thickness of and the degree of separation between crystals are precise. The crystals and the intervening spaces function as an interference filter. The small reflection from each crystal interface adds to give a large net reflection from the surface of the tapetum. The fact that the photoreceptors just touch the tapetum ensures that they are illuminated on the second pass (after tapetal reflection) by the same light that passed through them the first time. The tapetum in the scallop eye acts as a concave (*i.e.*, depressed toward the centre) mirror, projecting light through the proximal retina and focussing an image of a distant object on the photoreceptors of the distal retina. The combination of tapetum lucidum and inverted photoreceptors in the proximal retina may thus enhance sensitivity without sacrificing resolution. The structural details of the tapetum lucidum have been described not only for the eye of the scallop *Pecten* but also for several arthropod and vertebrate eyes.

The tapetum lucidum

In arthropods. Among arthropods, ocelli are the main organs of sight in arachnids such as spiders and in insect larvae that undergo complete metamorphosis (*i.e.*, a radical physical change during development). Insects that undergo incomplete metamorphosis have three ocelli arranged in a triangle on the dorsal, or top, part of the head; these are subsidiary, however, to the main organs of sight, the compound eyes.

Spiders have two kinds of ocelli, the principal, or antereo-median, eyes and the lateral eyes. The principal eyes of jumping spiders are used when stalking prey and in courtship; the photoreceptors are arranged in four layers in the optic axis (see Figure 5). The two deepest layers cover the entire retina; the two most superficial layers are confined to the retina's central region. The rhabdomeres of the three deepest layers are rod shaped. Those of the most superficial layer are ovoid and oriented in the direction of propagation of light through the eye. Because the receptors are layered, the images of objects at different distances from the eye appear in different layers; it is possible that this type of retinal system is used for depth perception. It appears more likely, however, that the arrangement is used for colour vision. Images of distant red objects appear in the first retinal layer, blue-green images appear in the second layer, and ultraviolet images in the third layer, because the primitive lens system shows considerable chromatic aberration.

No image for visible light appears in the most superficial ovoid rhabdomeres of the principal eyes of spiders, and it has been postulated that they function to detect polarized light. The principal eyes also have a set of six muscles that produce eye movements when an image falls on the retina. The eye follows the image, which remains centrally fixed.

The lateral ocellus of the caterpillar, which has a group of five or six ocelli on each side of the head, resembles one ommatidium, or unit, of a compound eye. The optical apparatus includes a lens, or cornea; a crystalline cone, which is the principal focussing device; and two layers of photoreceptors (distal and proximal) in the optic axis, each of which is radially arranged like sections of an orange. The rhabdomeres of both cell types are in close apposition over much of their length. Objects at different distances project images at different vertical locations in the rhabdom—*i.e.*, a group of rhabdomeres in physical contact with one another. The proximal and distal

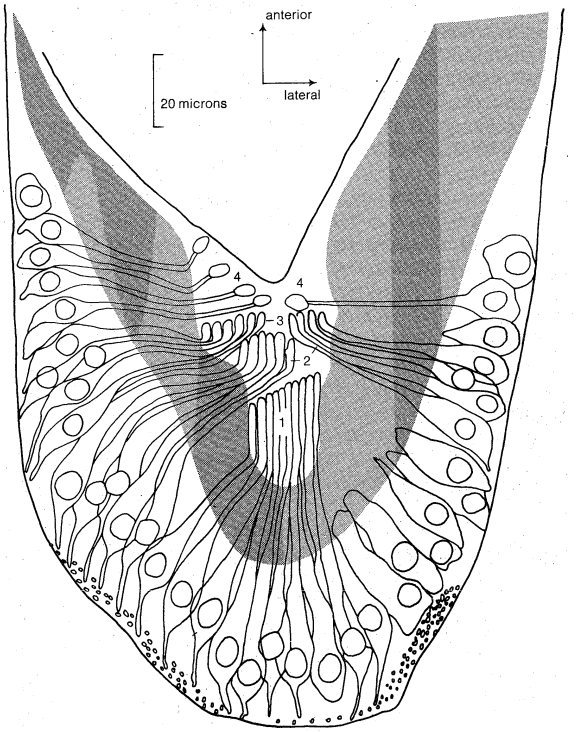

Figure 5: Frontal (horizontal) section close to the centre of the retina of the spider *Metaphiddipus aeneolus*, with the layers of receptor endings numbered 1 to 4. In layers 1, 2, and 3 the presumed receptive part of each receptor is the straight terminal portion; in layer 4 it is the terminal ovoid swelling.
From M.F. Land, *Journal of Experimental Biology* vol. 51 (1969)

rhabdoms form an optically continuous structure, a light guide. The optical information in this structure depends on the light accepted at the distal part of the rhabdom, rather than on the locations in the rhabdom at which images are projected, because the rhabdoms actually touch one another and effectively form one optical structure (see *Optical properties of photoreceptors* below).

Spatial resolution in ocelli and camera eyes

No optical system can form a point image of a distant luminous point, such as a star; because of diffraction (a modulation in which a redistribution of energy occurs), the image is instead a small spot, the Airy disk, with a bright centre enclosed in concentric, alternately bright and dim rings. The radius of the first dark ring indicates the size of the diffraction pattern. The smaller the aperture and the longer the wavelength, the bigger the Airy disk and the poorer the resolution.

The degree to which images can be detected is determined both by the size of the Airy disk and the size, separation, and density of packing of photoreceptors. Compared with the eyes of most invertebrates, a relatively large number of photoreceptors occurs in the principal eye of the jumping spider. This suggests that the image is good, that its quality is primarily determined by the size of the lens, and that the mosaic of receptor units makes maximal use of the image quality. By comparison, the theoretical resolution of the human eye is ten times better than that of the spider. This difference results solely from the difference in the size of the eye. In both the human eye and that of the spider, the focal length is adjusted to transmit the image onto a retina containing about the same density of photoreceptors. Actual resolution, however, is complex and depends on other factors, such as the nature of the target, properties of the illumination, the form of measurement, and neural processing in the eye and brain.

In the lateral ocellus of insect larvae, the size and density of the receptors are probably the limiting factors in resolution. In addition to poor spatial resolution, the light-gathering power of the lateral ocellus is also inferior to that of the spider eye.

Compound eyes. Aggregations of ocelli are found in several lower animals—in polychaete worms, for example. True compound eyes are found only in the arthropods, however. The compound eye of insects is composed of hexagonal or rectangular-shaped, closely packed optical units called ommatidia (small eyes); each ommatidium is virtually a single eye. In different species the size, number, and structure of ommatidia vary. An ommatidium (Figure 6) is composed of a corneal lens, or facet, which consists of a modified extension of the cuticle (the hard outer covering of arthropods) on the surface of the eye; four cells called Semper's cells or cone cells, which form the crystalline cone; and a sensory region called the retinula (small retina). In primitive insects (*e.g.*, the springtail *Lepisma*), in which the transparent cone cells are not specialized, the ommatidia are called acone ommatidia. In the more common eucone ommatidium, which occurs in moths and butterflies, the cone cells have a more complicated structure and contain granules of glycogen, or animal starch; because the granules are packed at various distances from each other, the refractive index varies in different positions in the cell. In certain beetles (*e.g.*, *Lampyris*) and in the horseshoe crab *Limulus*, the crystalline cone is an extension of the cornea.

Components of the ommatidium

The sensory part of the ommatidium, the retinula, consists of several radially arranged cells (retinular cells); each has a photoreceptor component, or rhabdomere (see Figure 6). The rhabdomeres of neighbouring retinular

(C) Cross sections through the retinula at the levels of two neighbouring layers, rhabdomeres from retinular cells 1, 4, and 5 constituting one layer (upper figure); 2, 3, 6, and 7 constituting the next layer (lower figure); 1, 4, and 5 the third; and so on alternately.

cells may be either in contact (forming a rhabdom) or completely separate. The optical isolation of each ommatidium is enhanced by its being surrounded by light-screening, pigment-containing cells. During adaptation to light and dark conditions, migration of pigment in cells around the crystalline cone, the corneal process, the proximal part of the ommatidium, and within the retinular cells has been reported to occur in most types of compound eyes.

The apposition eye. In the compound eyes of diurnal arthropods, each ommatidium is separated from its neighbours by pigmented, or iris, cells under all conditions of illumination. As a result, the rhabdom of each ommatidium receives light only through its own corneal lens; light from the lenses of other ommatidia is blocked by the pigment. This is the basic structure of the apposition eye (Figure 7). There are, however, variations in structure.

In the honeybee *Apis mellifera*, the cornea is layered, each layer having a different refractive index. It has been shown that the corneal lens projects a small inverted image of a distant object in the crystalline cone some distance short of the rhabdom of an ommatidium. If the image were focussed exactly on the rhabdom, it might effectively transmit image-location information by means

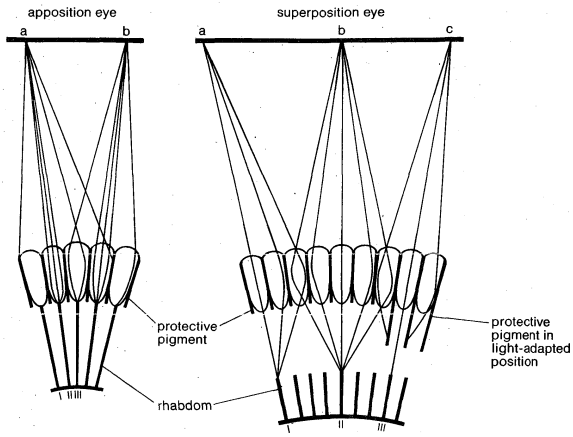

Figure 7: Image formation in apposition and superposition eyes: I, II, III represent different ommatidia; a, b, c represent point objects (see text).
From G.A. Mazohkin-Porshnyakov, *Insect Vision* (copyright 1969); Plenum Press

of differing responses of the individual retinular cells within an ommatidium. Because the image is focussed in front of the rhabdom, however, individual retinular cells within an ommatidium do not respond to image location. The defocussing also has the effect of broadening the field of view of the ommatidium. As the image moves, it can still be guided into the rhabdom by the crystalline cone, which is considerably wider than the rhabdom.

Specialization of the butterfly eye

It is not possible to generalize from the known optics of the compound eye of the bee to other apposition eyes as, for example, those of the butterfly, which superficially resemble the bee's in having a cylindrical rhabdom. Certain features of the butterfly eye are known, however (see Figure 8). Under the rhabdom of each ommatidium, the

From N. Yagi and N. Koyama, *The Compound Eye of Lepidoptera: Approach from Organic Evolution* (1963); Maruzen Co., Ltd.

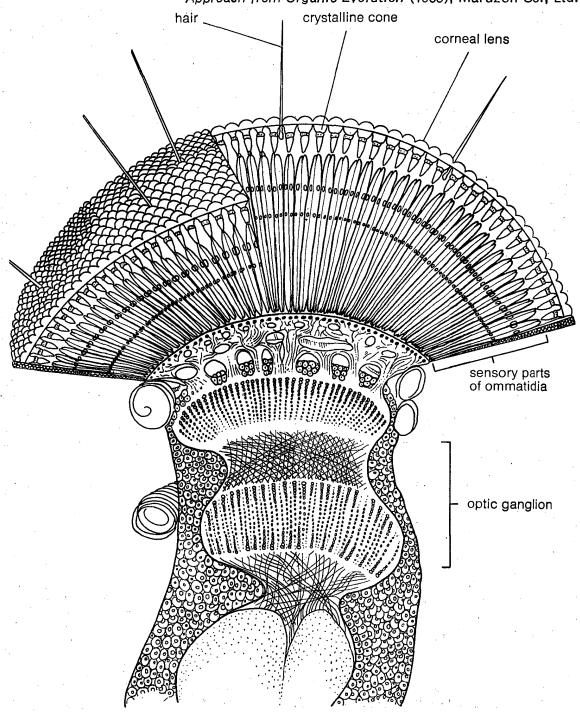

Figure 8: Section through the compound eye and optic lobe of a butterfly.

tracheole, or respiratory tubule, which supplies air to the ommatidium, has become specialized to form a tapetal filter comparable with that of the *Pecten* eye; it reflects highly saturated colours, usually blue colours in the dorsal ommatidia and more reddish colours in the ventral part of the eye. Each ommatidium thus has its own mirror. (The swallowtails, *Papilio*, are the only butterflies lacking this adaptation.) The light in the rhabdom of an ommatidium is tinted by the coloured light reflected from the mirror, and can be seen only with the aid of an ophthalmoscope—an instrument for viewing the interior of the eye. This filter system probably aids vision by enhancing contrast between objects of certain colours.

Butterflies with a tapetal filter, as well as nocturnal species (with a tapetum of different structure), have a corneal surface structure that acts as an anti-reflector. It consists of minute conical corneal "nipples" that provide a gradual transition between the refractive index of air and that of the cornea, effectively eliminating front-surface reflection for many wavelengths of light. One of the functions of this coating may be to minimize reflection of images from the tapetum lucidum back into the eye.

The rhabdomeres within an ommatidium in the compound eyes of flies (Diptera) have a microvillar structure (*i.e.*, one involving minute hairlike projections; see below *Morphological features*) and are completely separate from one another, in contrast to the apposition eyes above, in which the rhabdomeres are in contact. Each ommatidium contains eight retinular cells and eight rhabdomeres.

From any relatively distant point in space, a small cluster of ommatidia in a fly's eye appears darker than other areas because these ommatidia are the ones that are best aligned to absorb light coming from the direction in which the ommatidia are pointed. This cluster, called the pseudopupil, is often found in insect eyes; it moves, appearing to follow an observer viewing different parts of the compound eye. In the compound eye of the butterfly it is the pseudopupil that lights up with colours when observed and viewed from the same direction as the illumination with the ophthalmoscope. The pseudopupil of flies usually consists of seven ommatidia. In this apposition eye a distant point forms an image on the distal end of the rhabdomere, not within the crystalline cone as in the apposition eye of the bee. From any distant point in space only one rhabdomere in each ommatidium of the pseudopupil is illuminated by a point source; *i.e.*, one rhabdomere in each ommatidium of the pseudopupil is directed toward the same point.

Spatial resolution in the apposition eye

Experimental results suggest that the resolution of the compound eye (*i.e.*, the capability of the eye to distinguish between two separate but adjacent objects) is determined by the divergence angle between the ommatidia. If a compound eye views a pattern of alternating black and white bars in which the angle formed by one bar is the same as that between the ommatidia, the image of one black bar falls on one ommatidium, and the image of the flanking white bars falls on its nearest neighbours. This defines the limit of resolution; if the image of more than one bar falls in an ommatidium, the bars are not resolved.

The image is out of focus at the rhabdom in the bee eye. The angle between fly rhabdomeres is the same as the angle between ommatidia. The fused rhabdom of the bee and the separate rhabdomeres of the fly probably convey polarization and colour information rather than spatial information.

The array of corneal lenses on the surface of the eye can be considered as sources of light that interfere deep within the eye to give high-order diffraction images. The structure of the eye suggests that this effect is not detectable by the photoreceptors. Substantial shielding pigment between the ommatidia reduces the intensity of such patterns, which thus should be relatively ineffective in exciting the rhabdom.

The superposition eye. In the compound eyes of nocturnal arthropods, the rhabdoms are deep within the eye, far from the cornea and crystalline cone. In 1891 Sigmund Exner, an Austrian physiologist, reported experiments that showed how these eyes function. He demonstrated that there is pronounced pigment migration within the iris cells. In eyes adapted to darkness, the pigment of these cells migrates upward and into spaces between the crystalline cones of neighbouring ommatidia. In the light-adapted eye, on the other hand, the pigment migrates into the region between the cones and the rhabdom, in effect isolating each ommatidium by surrounding it with a light-absorbing tubular pigmented structure.

The pigment migration has the effect of changing the sensitivity of the eye. When a light-adapted eye is placed in the dark, there is an initial increase in sensitivity of about ten times with no accompanying pigment movement. In the following 25 minutes in the dark, the sensitivity increases about 100 times, as the pigment gradually withdraws from between the cones.

Exner found that the corneal process of the firefly *Lampyris*, a structure that resembles the crystalline cone of butterflies and other nocturnal insects, has a higher refractive index at the centre than near the periphery and effectively bends incoming light. When the eye is dark-adapted, light from many facets converges in the rhabdoms of many ommatidia forming a so-called superposition image (Figure 8). This eye differs from the apposition eye in that light from many facets is involved in forming an image in the rhabdom of an ommatidium; in the apposition eye, on the other hand, light from its own corneal lens reaches the rhabdom within a particular ommatidium. The mosaic image of the superposition eye, although less sharply defined than that of the apposition eye, is brighter and thus a valuable adaptation for nocturnal insects. In the light-adapted condition, inward migration of pigment in the iris cells effectively prevents the spread of light to adjacent ommatidia, and the superposition eye acts somewhat like the apposition eye; *i.e.*, only the light from one facet reaches the rhabdom within an ommatidium.

Important differences between apposition and superposition eyes

THE PROPERTIES OF PHOTORECEPTORS

The photoreceptor cell absorbs light energy and transforms it into a nervous response. The actual photoreceptor component, or organelle, of the photoreceptor cell contains a coloured substance (visual pigment) that absorbs light and initiates the chain of chemical reactions leading to nervous excitation. The vertebrate photoreceptor cells, the rods and cones, are so called because of the shape of their photoreceptors, which are found in the outer segments of the cells. Invertebrate photoreceptor cells, the photoreceptors of which are the rhabdomeres, show greater diversity of structure than do those of vertebrates.

The function of photoreceptors is dependent on the visual pigment they contain; the identification of photoreceptors ultimately depends, therefore, on correlating the light-absorbing properties of the pigments within them and the physiological response of the receptor cells. Such evidence exists for a number of invertebrates and vertebrates; the identity of some vertebrate and many invertebrate photoreceptors, however, has been inferred from their location, colour, and structure after comparison with known photoreceptors.

When viewed with the light microscope, the outer segments of vertebrate receptors and the rhabdomeres of invertebrates can be recognized by their shape, location, and high refractive index. In the electron microscope, all photoreceptors are seen to consist of a dense collection of membranes. The outer segments of vertebrate photoreceptors are lamellate (layered). Invertebrate rhabdomeres usually consist of microvilli (minute projections of the receptor cell membrane) and resemble a tiny honeycomb in three dimensions. In certain invertebrates, however, the rhabdomeres are lamellate, resembling those of vertebrates. Some features of photoreceptors from various animal groups are discussed below.

Morphological features. *Invertebrate photoreceptors.* The photoreceptor of the jellyfish *Polyorchis penicillatus* (Figure 9) is a modified cilium, or hairlike structure, as are the photoreceptors of many higher animals. Cilia are found in the cells of most animals; their motion is used either to move the animal or to move materials within or outside the body. As seen in the electron microscope, a cilium characteristically consists of nine double, peripherally arranged filaments (very fine threadlike structures) and a central pair of filaments in a so-called 9 + 2 pattern. A cilium arises from a cell structure known as a centriole, near which is often found a second centriole; ciliary rootlets extend from the centrioles to deep within the cell. In sensory cells a cilium often develops into a

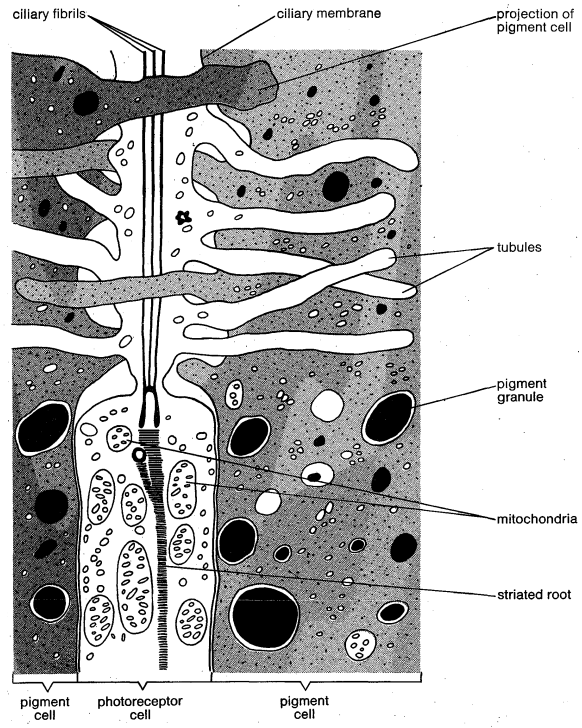

Figure 9: The distal part of a photoreceptor cell and two adjacent pigment cells in the ocellus of the hydromedusan *Polyorchis penicillatus*.

From *Proceedings of the U.S. Academy of Sciences* (1962) in D. Mazia and A. Tyler, *General Physiology of Cell Specialization*, Copyright 1963; used by permission of McGraw-Hill Book Company

sensory organelle. Sensory cilia invariably lack the central pair of filaments, having what is called a 9 + 0 pattern. The sensory cilium of *Polyorchis* contains numerous coarse microvilli, which constitute the sensory portion; centrioles and a ciliary rootlet are also present. Near the base of the photoreceptors are frequently found large numbers of cell components called mitochondria. Mitochondria manufacture the compound adenosine triphosphate, which seems necessary for the photoreception process.

The microvilli found in the primitive photoreceptor of *Polyorchis* are atypical in two respects: first, it is unusual for the microvilli of rhabdomeres to be derived from cilia; second, the microvilli of the rhabdomere, which are usually packed together very densely (hexagonal packing), are, in the jellyfish, mingled with the microvilli of the pigment-containing cells that envelop the rhabdomere. Migration of pigment into or out of the pigment-cell microvilli provides a mechanism for regulating the amount of light absorbed by the receptor. The identification of photoreceptor cells in the jellyfish has been based on anatomical and behavioral evidence. The cells are located in ocelli, the removal of which renders the jellyfish incapable of responding to illumination.

Although the ctenophorans (comb jellies) usually have been assumed to lack both a response to light and photoreceptor cells, recent evidence has raised some doubt about such a conclusion. Electron microscopic examination of *Pleurobrachia pileus* has revealed a radial arrangement of four groups of lamellate bodies; the lamellae are composed of membranes of about 12 sensory cilia (*i.e.*, 9 + 0 type). The sensory cilia, instead of developing microvilli as in *Polyorchis*, become individual platelets. These lamellate structures, which are located in infolded regions of the presumed photoreceptor cell, resemble similar lamellate structures in certain molluscan and vertebrate photoreceptors; it is presumed by some investigators, therefore, that the lamellate structures of *Pleurobrachia* may be photoreceptors.

The planarian flatworm *Dendrocoelum lacteum* (phylum Platyhelminthes) has photoreceptor cells with well-developed rhabdomeres (see Figure 10). The cytoplasm of the receptor cell, which has a tubular extension, contains many mitochondria; the surface membrane, which

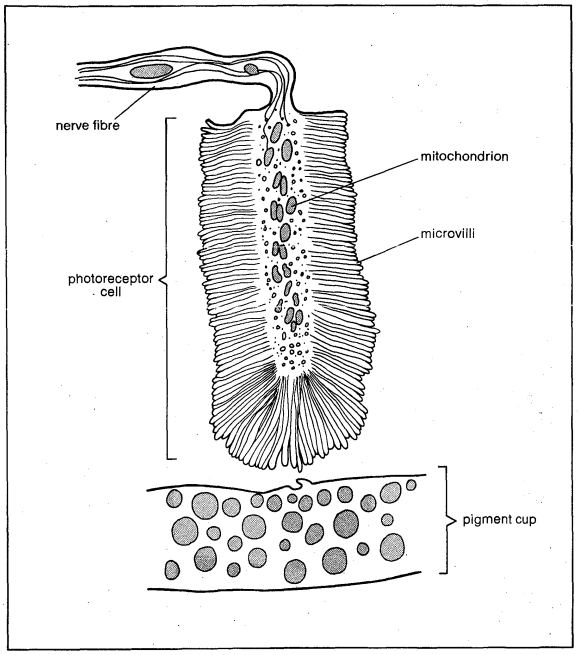

Figure 10: The photoreceptor cell in the flatworm *Dendrocoelum lacteum.*

From *Zeitschrift fur Zellforschung und mikroskopische Anatomie* (1961) in D. Mazia and A. Tyler (ed.), *General Physiology of Cell Specialization* (Copyright 1963); used by permission of McGraw-Hill Book Company

forms the tightly packed microvilli that constitute the photoreceptor organelle, is presumed to be the site of the visual pigment. No evidence has been found that either this photoreceptor or those of other flatworms are derived from cilia.

The nemertine worms (phylum Nemertea) have photoreceptor cells that resemble those of planarians when viewed with the light microscope. The photoreceptor cells on the eye of *Lineus ruber* resemble those of planarians in the electron microscope in that both have a rhabdomere consisting of microvilli. An important difference exists, however: the photoreceptors of *L. ruber* possess a filament that resembles a ciliary rootlet, even though no evidence exists that the rhabdomere is derived from cilia; in fact, cilia have not been observed in this cell. The function of the filament is not yet known.

Photoreceptors in the eye of the rotifer *Asplanchna brightwelli* (phylum Aschelminthes) are lamellate. Thin lamellae, arranged as leaves of a cabbage, apparently are folds of the receptor membrane. There is no evidence that the receptor is derived from cilia.

The photoreceptor cells in the eyes of the arrowworm *Sagitta scrippsae* (phylum Chaetognatha) have rhabdomeres consisting of structures of ciliary derivation that are called microtubules. The microtubules arise from a cone-shaped body filled with granules and cordlike structures. The cone-shaped body is derived from a sensory cilium. The microtubules comprising the rhabdomere are 50 nanometres in diameter and 20 long.

Photoreceptors of annelid worms

The segmented worms (Annelida) are the first invertebrate animal group in which the photoreceptors of a considerable number of species have been investigated. Studies indicate that annelids generally have rhabdomeres consisting of microvilli and are not of ciliary origin; however, at least one exception (*Branchiomma*) to this pattern has been observed.

The photoreceptor cell of the earthworm *Lumbricus terrestris* is an example of a rhabdomere comprised of microvilli; as mentioned previously, the microvilli of the membrane of the rhabdomere border on a vacuole within the receptor cell rather than on its outer surface. A number of sensory cilia are mixed with the microvilli and extend from the cell cytoplasm into the vacuole. The microvilli are not derived from cilia, and their function is as yet unknown. Although rhabdomeres consisting of microvilli have been found in several other annelids, no evidence of cilia has been reported. In the polychaete worm *Nereis vexillosa,* however, the microvillar rhabdomere arises from a tubular extension of the cell containing a centriole and a small fibre (fibril) with the structure of a ciliary rootlet; no direct evidence has been found thus far to link these ciliary vestiges to the rhabdomere.

The photoreceptor of the polychaete *Branchiomma vesiculosum* is a well-documented example of an annelid photoreceptor derived from cilia. The photoreceptor cell has a large invaginated (inpocketed) cavity filled with about 450 flattened lamellar sacs, which are the expanded flattened membranes of cilia having the 9 + 0 configuration. A collection of mitochondria and the nucleus of the receptor cell are displaced from the light path.

The Onychophora represent a transitional group that combines features of both the annelids and the arthropods. The photoreceptor cells of several species of onychophorans have been studied with the electron microscope. The photoreceptor cell of *Peripatus* closely resembles that of some annelids. The rhabdomere, which consists of microvilli, has a sensory cilium near its base. In studies of the *Peripatus* eye during development, no connection has been found between the sensory cilium and the developing microvilli. The function of the sensory cilium in this and in other photoreceptors in which no clear developmental relationship exists between the two is obscure.

Arthropods have few cilia, although they do occur in a few organs and provide the developmental basis for one type of arthropod ear, the chordotonal organ. Cilia have not been found in association with arthropod photoreceptors, however. The photoreceptor cells of all arthropods studied thus far are generally similar. Part of the cell surface forms densely packed microvilli, which is the photoreceptor containing the visual pigment.

The presumed photoreceptor in echinoderms is a collection of loosely packed microvilli extending from each receptor cell into the central cavity of the ocellus. In some species, each receptor cell has at least one cilium with the 9 + 0 pattern; this pattern is presumed to exist in other species. No relationship exists between the cilia and the microvilli; thus, the same condition prevails as in certain mollusks, annelids, and *Peripatus.* The echinoderms studied thus far appear to have a rhabdomere composed of microvilli and in close association with a sensory cilium.

Photoreceptor cells in mollusks and cephalopods

The mollusks (*e.g.,* scallops, clams, squid) have two morphologically distinct types of photoreceptor cells. One contains microvilli; of these, some photoreceptors have rudimentary cilia and fibrils such as those of certain annelids. Most mollusks appear to have this type of photoreceptor. The other type contains cilia; about 100 cilia on one surface of the cell develop into flattened sacs that are either packed tightly, like slices of bread, or curl on one another, like cabbage leaves. The ciliary type of rhabdomere is found in *Onchidium verruculatum* and in *Cardium edule.* The eyes of the bivalves *Pecten, Chlamys, Spondylus,* and *Amussium* contain double retinas, each with one of the types of photoreceptor. Evidence indicates that both types are photoreceptors and that they have different functions. The distal retina, with a ciliary photoreceptor, responds to a decrease in illumination; the proximal retina, with a microvillar photoreceptor, responds to increasing illumination.

The cephalopod retina has long cylindrical photoreceptor cells with rhabdomeres consisting of microvilli. In some cells the long axes of the microvilli are horizontal. The other type has vertical microvilli. The axes of both types of microvilli are parallel to a plane that is tangent to the retinal surface. This orthogonal arrangement of the microvilli in different cells—*i.e.,* in which they are perpendicularly disposed to one another—forms the physical basis for polarized light detection in the cephalopods.

Vertebrate photoreceptors. The photoreceptor of such primitive chordates as the urochordate ascidian tadpole is a modified cilium with the 9 + 0 pattern; the cilium

has developed into numerous lamellae. The cephalochordate *Branchiostoma californiense* may have both microvillar and ciliary photoreceptors. The Hesse cells, shown experimentally to be photoreceptor cells, have typical microvillar rhabdomeres with no cilia. Two other types of cells that may have a photoreceptor function are the dorsal ependymal cells (*i.e.*, special cells lining the cavities of the brain) and cells of the infundibulum, a ventral portion of the brain. Both cells have appendages containing cilia that form lamellae.

Other vertebrates have the two types of photoreceptor cells mentioned before: rods and cones. The rods are the photoreceptors for vision under conditions of dim illumination; the cones mediate daylight vision and colour sensation in many animals. The photoreceptors in both the rods and cones are composed of stacks of disks derived from cilia; the lamellae are stacked at right angles to the long axis of the cell and constitute the outer segments of rod and cone cells.

Most of the lamellae of the outer segment of the rod consist of free-floating disks within the limiting membrane of the outer segment (see Figure 11). The free-floating disks are formed at the base of the outer segment by a process of continuous infolding of the membrane of the outer segment. The process of new disk generation proceeds continuously during the life of the animal, and the entire outer segment of the rod is replaced in about one week. As new disks are being formed at the base of the rod, disks at the other end of the outer segment are being broken off and ingested by pigment cells; the rod length thus remains constant. As infolded regions of the membrane at the base of the rod move outward, they are pinched off to form free-floating disks. The outer segments of the cones, sometimes conical, or cone-shaped, and shorter than the outer segments of the rods, do not have free-floating disks. The process of infolding stops just after formation of the outer segments of the cones; infoldings occur along the entire length of the cones (see Figure 11). Because the membrane of the outer segments of the cones is not formed continuously during life, membrane components are continuously replaced. It has been shown that renewal takes place continuously along the entire surface of the membrane in cones. In rods, on the other hand, the renewal occurs only at the base, as new disks form.

Structural differences between rods and cones

The terms rod and cone are misleading, because these receptors cannot always be identified by shape; considerable variation exists between species. There are, nevertheless, a number of morphological differences between the rods and cones. The outer segments of the rods of many species are deeply incised—*i.e.*, lengthwise clefts in the disks give the outer segment a scalloped appearance in cross section. Both the rods and cones contain dense aggregations of mitochondria in the inner segment, or ellipsoid (see Figure 12). In the same region the cones of many species have an oil droplet, sometimes coloured, that filters the light before it reaches the receptor. An important difference between the photoreceptors of vertebrates and those of most invertebrates is that the latter give rise to nerve fibres that synapse either with cells in the central nervous system or with cells in a nerve ganglion within the eye; the vertebrate receptors, on the other hand, end in a region called a foot piece, into which nerve cells of the retina send synaptic projections.

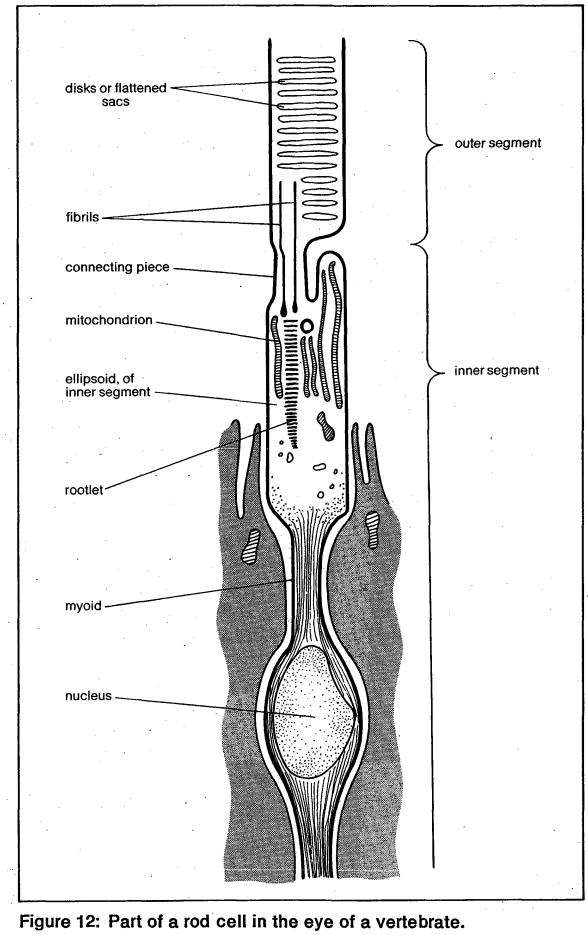

Figure 12: Part of a rod cell in the eye of a vertebrate.

Embryology and evolution of photoreceptors. There are two types of vertebrate eyes. The more familiar is the highly developed lateral eye. The other is the primitive median, or pineal, eye (in the top of the head). Only cyclostomes, reptiles, and amphibians have a median eye. It is best developed in lizards, in which the cornea is translucent and the number of receptors is small. The photoreceptor cells of the pineal eye are homologous (*i.e.*, structurally or developmentally related) with those of the lateral eye. They are, in fact, cones, the outer segments showing the characteristic infoldings along their entire length. In the median eye, the ends of the outer segments face the lens and light; in the lateral eye the retina is inverted, so that the ends of the outer segments face away from the light and toward the back of the eye.

The vertebrate retina is literally a part of the brain. The photoreceptor cells are derived from cells that line the neural tube, a hollow, dorsal structure that appears early in the embryo. The median eye develops from an outpocketing of the neural tube, and the cilia that develop into outer segments face the lens.

Invertebrates lack a neural tube; their photoreceptor cells develop from embryonic epithelial cells that send

out axons—threadlike extensions—that grow into the central nervous system. Often the epithelial cells contain cilia, and the photoreceptors develop from the cilia. The ciliary photoreceptors of invertebrates do not appear to be homologous with those of vertebrates. As mentioned above, it is of particular interest that photoreceptors of diverse structure and in many different phyla develop either from cilia or in close association with them. Still unknown is the developmental and functional role of the sensory cilia that are frequently found in association with photoreceptors of apparently nonciliary origin.

Optical properties of photoreceptors. *Rhabdomeres and outer segments as light guides.* The densely packed membranous structures of photoreceptors have a higher refractive index than the surrounding substances. The refractive index of the rhabdomere of the blowfly (*Calliphora*), for example, is 1.349, and that for the surrounding substance is 1.336; any light reflected from the inside surface of the rhabdomere is called dense to rare reflection. When the angle at which the light strikes the inside surface (angle of incidence) is such that the change of the angle of the light when entering the photoreceptor (*i.e.*, the angle of refraction) is 90°, all of the light is reflected back into the rhabdomere. The angle of incidence at which total internal reflection occurs is called the critical angle. The rhabdomere and outer segment trap the light entering it at angles equal to or greater than the critical angle and propagate it, essentially without loss of energy. The rhabdomere and outer segment thus act as an optical wave guide, or light pipe (see OPTICS, PRINCIPLES OF). Although all light entering the photoreceptor organelle—*i.e.*, all light incident at angles equal to or less than the critical angle—is propagated by successive internal reflection, only certain angles of reflection occur; these are determined by various physical characteristics of the organelle. As a result, the light within the photoreceptor light guides is propagated in modes, or patterns, of energy. This is important for the photoreceptive function of the rhabdomere and outer segment because the amount of information the organelle can carry is related to the number of modes propagated. The thinnest photoreceptor organelles, such as those of certain fly rhabdomeres with a diameter of 0.5 nanometre, can, for example, support only one mode, called the lowest order mode. The amount of energy propagated in the rhabdomere in this mode depends on the wavelength of light, so that the shorter wavelengths are best propagated. Thus reddish light is not made available to the rhabdomere's visual pigment as readily as bluish light; the light guide properties of the organelle, therefore, can influence the physiological response of the photoreceptor. The light guide also profoundly affects the amount of image information transmitted because the greater the number of modes, the more image information. This last consideration is of particular importance for fused rhabdoms, in which image information apparently is not transmitted (although the question is not yet entirely settled). These light guide properties are of importance for still another reason. A small amount of the modal energy propagated by a light guide is actually outside the structure. Thus when, as described in the next section, pigment granules come near the photoreceptor organelle, they control the amount of light in the organelle by absorbing the energy propagating outside, so that it can no longer be transmitted by the photoreceptor. Such pigment granules may exert an even more profound effect by raising the refractive index outside the organelle, thus destroying its guiding properties and causing the light to spread into adjoining structures where it is absorbed, but not by visual pigment; absorption thus does not result in sensation.

Migration of pigment granules

Photomechanical light and dark adaptation. A mechanism that may partly control the amount of light within the photoreceptor under widely different illumination conditions involves the migration of photoprotective pigment granules either within the receptor or within neighbouring cells so as to envelop the photoreceptor; it has been observed in both vertebrates and invertebrates. Pigment migration in response to illumination takes place in the retinas of most vertebrates except mammals. The most pronounced effects are found in fishes, frogs, and toads; they also occur in reptiles and in diurnal and nocturnal birds.

Pigment migration is combined with photomechanical movements of the photoreceptor cells of many lower vertebrates (Figure 13). In darkness the pigment granules

From Dr. Samuel R. Detwiller, *Vertebrate Photoreceptors* (1943); Macmillan & Co.

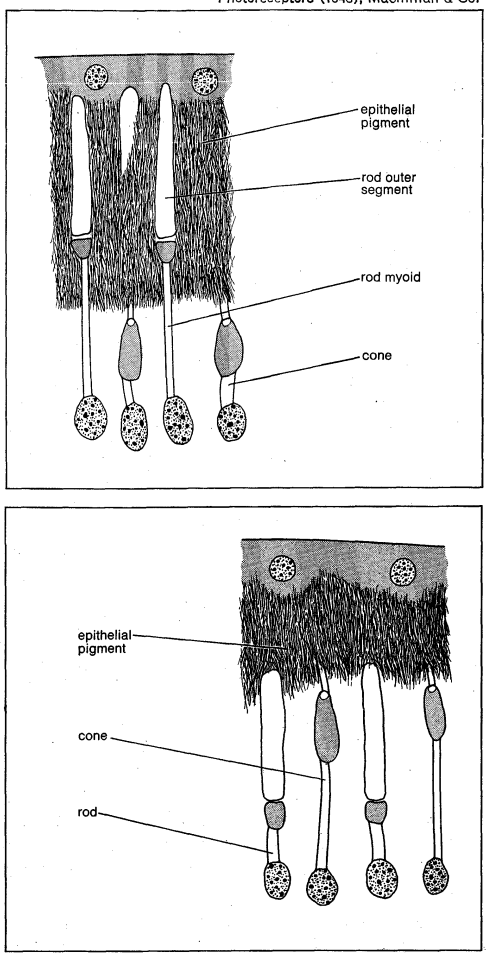

Figure 13: *Adaptation of retina.*
(Top) Theoretical light-adapted retina, showing migrated epithelial pigment, elongated rods, and contracted cones. (Bottom) Theoretical dark-adapted retina, showing contracted pigment, elongated cones, and contracted rods.

of the pigment epithelium are withdrawn, as shown in the figure. The rod myoids (contractile elements) are contracted in darkness so that the rod outer segments are withdrawn from the pigment and exposed fully to the available light. On the other hand, the cone myoids are extended, so that their outer segments are within the pigment, which functions effectively to reduce the amount of light in the outer segment, as explained in the previous section. The cone outer segments are enveloped by pigment, presumably to help suppress responses from the daylight receptors under conditions of dim illumination. Under the influence of light the rod myoids extend within several minutes, and the pigment envelops the rod myoids to help suppress the diurnal activity of the rod system (pigment surrounds only the rod myoids, not the outer segments [see Figure 13, top]). At the same time the myoids of the cones contract to withdraw the cone outer segments from the pigment. As mentioned above, neither photomechanical nor pigment movements occur in mammalian eyes; switching between rod and cone systems is accomplished neurally.

The envelopment of rhabdomeres by pigment migration is widespread in invertebrates. An example of this phenomenon occurs in the ommatidium of the amphipod *Gammarus ornatus*, in which the rhabdomeres of five radially arranged receptor cells form a star-shaped rhabdom. Extensions of the receptor cells are directed toward

the cornea next to the lenslike crystalline cone and away from the cornea to cell bodies beneath a so-called basement membrane. In the dark-adapted condition the pigment is located around the cone and in the cell body. The rhabdom functions as a light guide within which is the visual pigment, which absorbs light. In the light-adapted condition, the pigment migrates from the receptor cell body to surround the rhabdom completely. Similar cell pigment migrations occur within the receptors of many invertebrates. In the compound eye of the horseshoe crab *Limulus*, the rhabdom is also star-shaped in cross section, but the rays of the star are much longer than are those of *Gammarus*. In the eye of *Limulus* the pigment migrates radially within the receptor cell, completely enveloping the rays in a matter of minutes in bright light and requiring about one hour to withdraw entirely from the rhabdom area in darkness.

The rhabdom of the migratory locust (*Schistocerca*) shows an interesting variation. In the light-adapted retina, mitochondria migrate and become tightly packed around the rhabdom. This may be a device for providing energy for the rapidly metabolizing light-activated photoreceptor. There is physiological evidence, however, that, in the light-adapted condition, the mitochondria, which have a high refractive index, increase the critical angle by coming close to the rhabdom. They thereby cause loss of light from the rhabdom and a decrease in the "field of view" of the rhabdom. When the eye is dark-adapted, the space around the rhabdom is replaced by fluid-filled spaces, with a low refractive index; they return the rhabdom to an efficient light guide mode of operation.

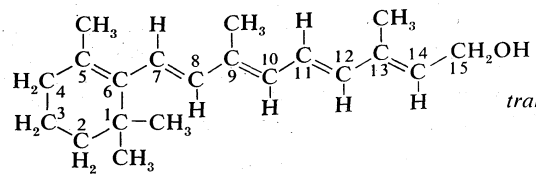
Birefringence and dichroism. The physical properties of certain crystals, glass, liquid, and gas, are the same regardless of the direction of the light propagated through them; for example, the speed and thus the refractive index of light are the same regardless of its direction of propagation. Such a medium is said to be isotropic. In other crystals, the atoms are arranged so the refractive index varies with the direction of propagation of light; such crystals are said to be anisotropic. If a medium has a crystalline arrangement that retards light in a particular direction, it is birefringent. In such an arrangement an entering ray of light is divided into two rays that are polarized in planes at right angles to one another.

When birefringence can be made to disappear by immersing a substance in a liquid with an appropriate refractive index, the birefringence is caused by an orderly arrangement of isotropic particles submicroscopic in size, such as the limiting membranes surrounding cells. Such birefringence is called form birefringence to distinguish it from the intrinsic molecular crystalline birefringence described above. Very small rods, lying parallel to each other, cause positive birefringence; parallel platelets cause negative birefringence. Studies have shown that rods in frogs have a negative form birefringence caused by the platelets and a positive intrinsic birefringence. These phenomena are thought to result from the ordered arrangement of a lipid (fat) layer two molecules thick in the platelet membranes.

Birefringence in the rods of frogs

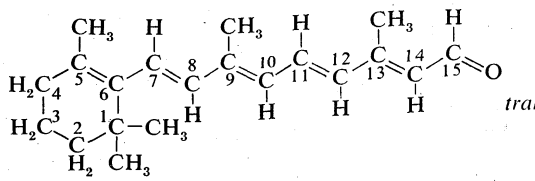
Variation in the colour of light absorbed dependent on the direction of polarization of the light is termed dichroism. This property is a sensitive indicator of the orientation of molecules in a structure; dichroism in photoreceptors, for example, results from the ordered arrangement of the visual pigment molecules. The visual pigment of outer segments is dichroic, as are the outer segments. Dichroism of the outer segment can be demonstrated only by measuring the absorption of polarized light shone through the side of the outer segment. Light that propagates in the usual direction, that is down the long axis of the outer segment, does not show different absorption properties that depend on the direction of polarization. The fact that there is not dichroism for light propagating along the long axis, but there is for light propagating perpendicular to the long axis, indicates that the visual pigment molecules are oriented at random but with the long axes in the plane of the disks.

Rhabdoms consisting of microvilli can detect the plane of polarization of polarized light. Invertebrates with such rhabdoms use polarization properties of the blue sky opposite the Sun for navigation. In animals with the ability, the rhabdomeres comprising a rhabdom show orthogonal orientation. It has been shown that the microvilli are dichroic and that the dichroism is caused by the visual pigment. The orientation of the microvilli provides the mechanism for sensation of polarized light. Vertebrates cannot detect polarized light because of the random orientation of visual molecules within the plane of the platelets.



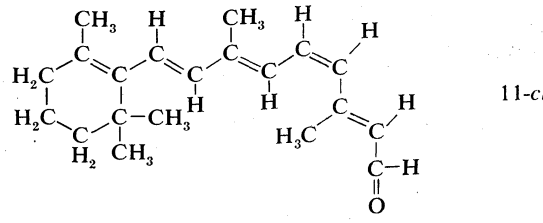
Stiles–Crawford effect. In the Stiles–Crawford effect, first observed in humans, the luminous efficiency of light has been shown to be greater when entering the centre than when entering the edge of the pupil. This effect may be considered an optical property of the cone receptor cells. The energy acceptance, or radiation, pattern of photoreceptors is a consequence of the optical wave guide properties resulting from the small size of the receptors. The Stiles–Crawford effect is not observed with dim illumination (rod vision), probably because the acceptance angle of the rods is wider, and it essentially fills the pupil (see also EYE AND VISION, HUMAN).

Visual pigments. As light propagates through the photoreceptor, the visual pigment absorbs photons (light particles). The absorption of one photon by a visual pigment molecule can initiate events that lead to nervous excitation. The photoreceptors in the eyes of both vertebrates and invertebrates consist of tightly packed membranes (lamellae), the function of which is to support the visual pigment and other molecules necessary for excitation. The photoreceptor membrane is a lipid layer two molecules thick, with protein either between the layers, coated over the layers, or both. The outer segment of the frog rod is 40 percent lipid and 60 percent protein; more than 80 percent of the protein is visual pigment.



Components. Visual pigment has two components: the light-absorbing chromophore (a chemical group that produces colour) and the protein moiety (opsin) to which it is chemically attached. The structure of the naturally occuring chromophore, retinal, is thought to be the same in all animals. Before it has been exposed to illumination, the chromophore is 11-*cis*-retinal, an alternate structure of vitamin A aldehyde. Upon exposure to light each chromophore molecule absorbs one photon of light. The absorption of a photon changes 11-*cis*-retinal to *trans*-retinal. (See structural formulas.) The resulting change in the shape of the molecule causes the separation of retinal from its protein component and gives rise to a number of coloured intermediates. In the dark, 11-*cis*-retinal combines spontaneously with the protein component to regenerate the visual pigment.

Characteristics of retinal



Hundreds of visual pigments have been identified and

trans-retinol

trans-retinal

11-*cis*-retinal

characterized by the wavelength of light that is best absorbed by them (absorption maximum, or λ max); the wavelength maxima range from 432 nanometres for the green rod of the frog to 625 nanometres for the red-absorbing cone of the goldfish. The reason for such a great range when the chromophore is the same in all visual pigments lies in part in properties of the chromophore; much of the variation, however, resides in the protein component. Variation in protein structure among different animals gives rise to different absorption maxima.

There are two forms of vitamin A: retinol A_1 and retinol A_2. The structure of A_1 differs only slightly from that of A_2. The effect of this slight structural difference is to increase the wavelength for maximum absorption by as much as 20 to 60 nanometres, depending on the pigment involved. The pigments with the shortest λ max are A_1 pigments; those with the longest are A_2. There is a broad area of overlap within the two groups, however. In general, marine fishes, land vertebrates, arthropods, and mollusks have A_1 pigments; freshwater fishes have A_2 pigments.

The protein components, or opsins, of visual pigments have not yet been fully characterized. The visual pigment of rods, a combination of retinal and opsin, is called rhodopsin, or visual purple. Estimates for the molecular weights of the opsins found in rods centre around 40,000. Squid opsin, however, has a molecular weight of about 70,000. Analyses of the visual pigments from the rods of squid and vertebrates suggest that the protein components are quite different. The nature of cone pigment proteins is thus far virtually unknown.

Important to an understanding of the photochemical reaction is the nature of the attachment of the chromophore to the opsin. Although controversy still exists on this point, it is clear that the visual pigment is part of the photoreceptor membrane and is very closely attached to its lipid and protein.

The role of visual pigments in vision. The sensitivity of the dark-adapted human eye can be measured as a function of wavelength of the stimulating light falling on that part of the retina in which the density of rods is greatest. When such a curve is compared with a curve of the absorption spectrum (the entire range of wavelengths of light absorbed) of human rhodopsin in the outer segments of the rods, the two curves correspond exactly. This is strong evidence that rhodopsin initiates the visual process for light absorbed in the outer segments.

The problem of cone pigments is an important one. More than 100 years have passed since it was concluded after a comparative study of retinas that the rods of vertebrate retinas mediate vision in dim light and the cones mediate daylight and colour vision. Recently, a method called microspectrophotometry has been developed for the study of cone pigments and other visual pigments. By projecting a minute beam of light onto a single photoreceptor, the absorption spectra of a variety of vertebrate and invertebrate photoreceptors have been measured. The absorption spectra of single human and other primate cones have thus been characterized. There are three types: a blue absorbing cone, a green absorbing one, and a yellow absorbing one. Originally suggested in 1802, these three cone types, now positively identified, can quantitatively explain human colour sensation.

Absorption spectra of photoreceptors

Such methods have been helpful in identifying receptors and their visual pigments in animals other than man; for example, in the retina of the frog *Rana pipiens*, a green rod and a red rod have been identified. A double cone with principal and accessory pigments and a single cone have also been characterized. Microspectrophotometry has been used to obtain evidence of visual pigments in rhabdomeres of the fly *Calliphora*.

PHYSIOLOGICAL RESPONSE OF PHOTORECEPTORS

The initial molecular events of photoreception can be summarized: after the absorption of a photon of light, 11-*cis*-retinal is converted into *trans*-retinal; the process disrupts the binding of retinal to opsin and results in the sequential formation of a number of coloured photoproducts.

The final physiological effects of photoreception have also been well defined. Excitation of visual pigments results in a change in certain properties (*i.e.*, permeability and potential) of the limiting membrane of the photoreceptor cell. Because the initial and final molecular events of photoreception are now understood, there is considerable hope that the entire chain of molecular events between the absorption of light by the visual pigment and the changes in potential of the cell membrane can eventually be reconstructed. This challenging problem has stimulated research concerned with the nature of the photoreceptor membrane and the chemistry of the photoproducts.

The internal environment of cells is generally different from that outside. The main cation (positively charged atom) inside cells is usually potassium; the main cation outside is sodium. In the resting, or unexcited, state, the cell membrane of most excitable cells (such as receptor, nerve, and muscle cells) is impermeable to sodium ions but permeable to potassium ions. A separation of charges occurs on either side of the membrane because the positively charged potassium ions diffuse outside of the cell, leaving a surplus of nondiffusing negatively charged atoms (anions) inside the cell. The result is a difference in potential across the cell membrane; this difference is proportional to the logarithm of the ratio of the concentration of potassium ions outside to that inside the cell. Photoreceptor cells are negative by some 30 to 60 millivolts (1 mV = 0.001 volt) inside relative to the outside, the exact value depending on the specific cell. This negative potential difference is termed the resting potential.

Receptor potential. The absorption of a single photon by the visual pigment in a photoreceptor may result in a physiological response of the receptor cell. Such a response of the cell can be measured as the receptor potential—that is, a change in the potential of the cell membrane caused by a change in the permeability of some part of the membrane to certain ions. The permeability change is in turn related to the absorption of light by the chromophore through a chain of molecular events as yet unknown. The receptor potentials of the eyes of animals from a number of phyla have been investigated. In certain photoreceptors the receptor potential is positive in sign, or depolarizing; in others it is negative, or hyperpolarizing.

Definition of receptor potential

Depolarizing receptor potentials. The depolarizing receptor potential, a change in potential response to illumination that is positive in sign, is characteristic of photoreceptor cells in many invertebrate phyla. One of the best known photoreceptors is the retinular cell in the compound eye and in the ventral eye of the horseshoe crab *Limulus*, an arthropod. The membrane potential of this cell is easily measured by means of a very small electrode (a device that can be placed inside a cell to measure the potential across the cell membrane). When the electrode penetrates the cell in the absence of light, the potential falls to some negative value, perhaps −40 millivolts, which is the resting potential. Even in complete darkness, however, variation in the resting potential occurs in the form of slow fluctuations. Although these spontaneously and randomly occurring fluctuations presumably seldom result in a physiological visual response, they are miniature receptor potentials. Each is accompanied by a decrease in the resistance of the membrane (*i.e.*, it becomes a better conductor) and an increase in the permeability of the membrane to sodium ions. When the receptor is illuminated with dim light, the slow potential fluctuations increase in frequency, and, with brighter light, they become briefer and higher in frequency, finally fusing to form a more or less steady depolarizing receptor potential. Thus, a short time after the cell is exposed to light, the membrane becomes depolarized; when the light is removed, the receptor potential decays, and the resting potential is restored. The extent of the receptor potential increases with increasingly stronger illumination; it has a linear relationship to the logarithm of the intensity of illumination. Whatever properties are responsible for this transformation are responsible for the photoreceptor's enormous dynamic range: despite the fact that the recep-

Relationship between receptor potential and illumination

tor potential can change at most on the order of 100 millivolts, the receptor can respond over a range of more than ten orders of magnitude, a range of intensities of over 100,000,000,000.

In all species with this depolarizing receptor potential, the fact that the resistance of the photoreceptor cell membrane decreases during the receptor potential suggests that it becomes more permeable to some ion or ions during this time. Evidence as to the nature of the permeability change suggests that it is principally an increase in permeability to sodium ions that causes the receptor potential. There is additional evidence for this conclusion (see *Bibliography*).

The depolarizing receptor potential is characteristic of the arthropod photoreceptor consisting of microvilli and the receptor cell. Species from most of the orders of Arthropoda have now been investigated, and exceptions have not been reported. Usually, the photoreceptor cell gives rise only to a receptor potential. The receptor potential is conducted passively a short distance to higher order nerve cells via a nerve fibre. The higher order nerve cells convert the receptor potential to propagated action potentials (nerve impulses) for transmission of the information over longer distances.

The proximal sense cell of the double retina of *Pecten* is similar to the above in that illumination gives rise to a depolarizing receptor potential and a decrease in resistance. The morphology of the proximal sense cell is also similar to that of the arthropod photoreceptors in that it has coarse microvilli. But the proximal sense cell of *Pecten* has a long nerve fibre that carries nerve impulses. The depolarizing receptor potential activates the mechanism that initiates an action potential, and steady depolarization of the axon gives rise to a series of nerve impulses; the stronger the intensity of illumination, the greater the extent of the receptor potential and the higher the frequency of nerve impulses. Nerve activity of this nature is rarely found in arthropod photoreceptor cells.

In addition to the arthropods and *Pecten*, a proximal sense cell in the leech (*Hirudo*), an annelid, has the depolarizing type of receptor potential.

Hyperpolarizing receptor potential with decrease in resistance. As noted above, the proximal sense cells of the *Pecten* eye have a depolarizing receptor potential, and the nerve responds to illumination with a series of nerve impulses. The distal sense cells, which also have nerve fibres, respond to a decrease in illumination with nerve impulses. This is called an off response. Recent studies indicate that the receptor potential of the distal sense cell is a hyperpolarizing potential, a potential change that is negative in sign. When the cell is depolarized, the extent of the receptor potential increases; when the cell is sufficiently hyperpolarized, the receptor potential reverses polarity and becomes depolarizing. The receptor potential of the distal sense cell is accompanied by a decrease in resistance. The hyperpolarizing potential is believed to be caused by an increase in permeability to potassium and perhaps to other ions.

The photoreceptor of the *Pecten* distal sense cell is a ciliary derivative. A primitive chordate, the tunicate *Salpa*, which has a microvillar photoreceptor, has the same type of hyperpolarizing photoreceptor potential. There thus does not seem to be any association of physiological potential types with structurally or embryologically similar photoreceptors.

Hyperpolarizing receptor potential with increase in resistance. The rod and cone photoreceptors of vertebrate eyes have a third type of receptor potential. In the dark, sodium ions flow steadily into the outer segment; light decreases this dark current—*i.e.*, the cell becomes hyperpolarized, and its resistance increases. If the cell is sufficiently hyperpolarized under experimental conditions, depolarization occurs; the receptor potential thus is reversed, as would be expected if the permeability change involves principally sodium ions.

Interpretation of the physiological response. As a nerve cell is depolarized, it discharges nerve impulses; as it becomes hyperpolarized, the membrane potential returns to the resting potential. The fact that certain photoreceptor cells are hyperpolarized by illumination is thus confusing and raises the possibility that light is inhibiting the receptors. In the generation and transmission of information about illumination, however, the sign of the response may actually be unimportant. It has been known for some time that there are several types of optic nerve fibres in vertebrate eyes; some discharge impulses during illumination, others discharge either only at the onset and cessation of illumination or merely at the cessation. In other words, information about the cessation of illumination is at least equal in importance to information about its onset and duration. Such observations of optic nerve activity prove that the hyperpolarizing response of the receptor, the only response of the receptor, is translated into a code that includes the discharge of nerve impulses both during and after illumination. Thus, the hyperpolarizing response of the receptor, although it may be important in emphasizing the off response, does not result in the loss of information about excitation. Because the hyperpolarizing response is definitely used to produce excitation at a later stage, it is misleading to consider it an inhibitory response. The same is true in reverse for the depolarizing response.

The way in which initial photoreception is processed by the retina and higher centres to cause visual perception is beyond the scope of this article. It may be mentioned, however, that the initial information used in this processing is the direct result of the physical and chemical properties of the photoreceptor.

Photosynthesis

Photosynthesis means putting together with light energy. During photosynthesis in green plants, light energy is captured and used to convert water, carbon dioxide, and minerals into oxygen and energy-rich organic compounds.

GENERAL CHARACTERISTICS

Importance. Without photosynthesis, the earth's atmosphere would be devoid of oxygen. All living cells convert food into energy and structural components necessary for life; if plant photosynthesis were to stop, most living things would disappear from the earth in a few years. Growth, repair, reproduction, and other dynamic processes performed by organisms require light energy that is absorbed by chlorophyll pigments in green plants and stored as chemical energy in organic products, especially carbohydrates. The chemical energy and electrical energy used by brain cells, for example, were once sunlight that was absorbed by the chlorophyll in green plants.

In the past, green plants, growing in warm climates in the presence of more carbon dioxide than the atmosphere contains now, increased in numbers faster than they were consumed; as a result, abundant supplies of "fossil fuels" (*i.e.*, coal, oil, and gas) were deposited in the earth's crust. The combustion of these fuels provides much of the energy now used in factories, in homes, and in transportation.

Increasing requirements for food in a world in which human population is increasing exponentially requires not only an increase in the amount of photosynthesis on earth but also an increase in the efficiency of converting photosynthetic products into food for man. The possibility of developing methods for synthesizing food commercially depends in part on the costs involved and on the population pressure. If the cost of energy were reduced, the synthesis of food from water, minerals, and carbon dioxide might become economically feasible. Food synthesis is a remote prospect, however, because the cost of power plants cannot compete with photosynthesis, in which the energy supply is free.

Overall reaction of photosynthesis. In many green plants, carbohydrates are the most important direct organic product of photosynthesis (see Figure 1). The formation of a simple carbohydrate, glucose, is indicated by a chemical equation,

$$6CO_2 + 12H_2O \xrightarrow[\text{green plants}]{\text{light}} C_6H_{12}O_6 + 6O_2 + 6H_2O$$

carbon dioxide — water — glucose — oxygen — water

Little free glucose is produced in plants; instead, glucose units are linked together to form starch, or are joined with fructose, another sugar, to form sucrose (see CARBOHYDRATE).

Not only carbohydrates, as was once thought, but also amino acids, proteins, lipids (or fats), pigments, and other organic components of green tissues are synthesized during photosynthesis. Minerals supply the elements (*e.g.*, nitrogen, N; phosphorus, P; sulfur, S) required to form these compounds. A generalized equation that expresses the total photosynthetic process is:

$$kCO_2 + lH_2O + mNO_3^- + nSO_4^= + \text{other materials} \xrightarrow[\text{green plants}]{\text{light}} \text{organic compounds} + xO_2$$

carbon dioxide — water — nitrate — sulfate — oxygen

The specific organic compounds formed and the quantities (k,l,m,n,x in the equation above) of minerals, water, and other necessary components required vary with the species, physiological state, and environment of a plant. In the overall reaction, chemical bonds are broken between oxygen (O), carbon (C), hydrogen (H), nitrogen, and sulfur, and new bonds are formed in products that include oxygen and organic compounds containing the elements. More energy is required to break bonds (*e.g.*, in water, sulfate) than is released when new bonds form in the products. This excess bond energy, provided by light, accounts for a large part of the light energy stored as chemical energy in the organic products formed during photosynthesis.

Evolution. Although life and the quality of the atmosphere today depend on photosynthesis, it is likely that green plants evolved long after the first living cells appeared on earth. When the earth was young, complex molecules probably were synthesized from hydrogen (both gaseous and combined, as hydrocarbons and water) and the action of ultraviolet radiation from the sun. The first living cells probably evolved from these molecules (see LIFE). The accidental joining together (condensation) of glycine, an amino acid, and acetate, a fatty acid, for example, may have formed complex organic molecules known as porphyrins; these molecules, in turn may have evolved further into coloured molecules called pigments; *e.g.*, chlorophylls of green plants, bacteriochlorophyll of photosynthetic bacteria, hemin (the red pigment of blood), and cytochromes, a group of pigment molecules essential in both photosynthesis and respiration.

Primitive coloured cells then had to evolve mechanisms for using the light energy absorbed by their pigments. At first, the energy may have been used only to initiate reactions useful to the cell. As the process for utilization of light energy continued to evolve, however, increasingly larger amounts of light energy probably were stored as chemical energy, to be used as required in the processes necessary to maintain life. Green plants, which have a mechanism for utilizing light energy in cell organelles called chloroplasts and are capable of storing up to 30 percent of absorbed light energy, are the culmination of the evolutionary process.

Bacterial photosynthesis

The evolutionary pathway that led to the photosynthetic bacteria is distinct from the one that resulted in green plants. Photosynthetic bacteria use absorbed light energy less efficiently than do green plants, although both can synthesize organic compounds from carbon dioxide and inorganic minerals. Bacterial photosynthesis always differs from photosynthesis in green plants in two important ways: first, no oxygen is produced; second, "far-red light" can be absorbed and used by bacterial chlorophylls. This light has a longer wavelength and less energy than the light used by green plants. Although bacterial photosynthesis is of little quantitative importance, its study and comparison with photosynthesis in green plants have been valuable in understanding both these processes.

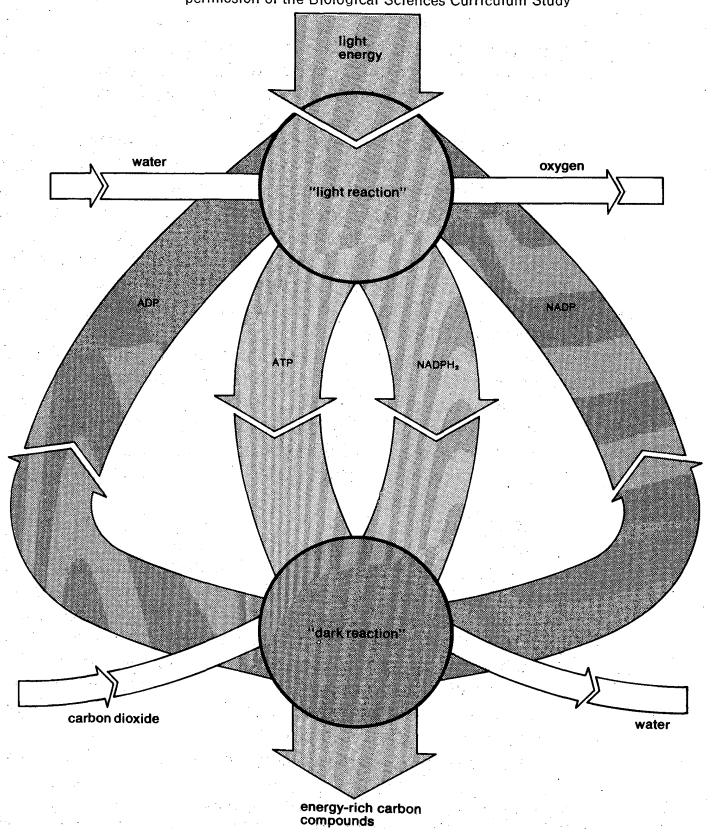

Figure 1: Summary of photosynthesis (see text).

FACTORS THAT INFLUENCE THE RATE OF PHOTOSYNTHESIS

The rate of photosynthesis is defined in terms of the rate of oxygen production either per unit mass (or area) of green plant tissues or per unit weight of total chlorophyll. Active, healthy plants growing in air, which contains 0.03–0.04 percent carbon dioxide, at 25° C are able to produce several litres of oxygen per hour for each gram of chlorophyll. This amount of chlorophyll is contained in about one kilogram (2.2 pounds) of wet tissue of an active sun-loving plant such as spinach. The single-celled alga *Chlorella pyrenoidosa* contains about four grams of chlorophyll per kilogram of wet tissue, or four times the amount in a kilogram of spinach. Oxygen production can be raised severalfold by increasing the carbon dioxide level to 1 percent and, sometimes, by raising the temperature to 35° C or more. The algae must be suspended in liquid 100 times their volume or spread as a thin film, however, so that the organisms obtain sufficient air and light. These requirements make more difficult the task of astronautical engineers who want to design spaceship systems that use photosynthesis to renew oxygen supplies to remove carbon dioxide, and to provide food during flights in outer space. For similar reasons, the culture of algae has not yet been developed as an economic process for large-scale food production on earth. As the human population increases, however, it is likely that methods will be developed for conversion of algae into foodstuffs for man.

Environmental factors

The amount of light, the carbon dioxide supply, and the temperature are the three most important environmental factors that directly affect the rate of photosynthesis; water and minerals in sufficient quantities also are necessary. The rate of photosynthesis in green plants is determined by the plant species and its physiological state; *e.g.*, health, maturity, whether or not it is in flower.

Light intensity and temperature. The complex mechanism of photosynthesis includes a photochemical, or light-dependent, stage and an enzymatic, or dark, stage that involves chemical reactions. These stages can be distinguished by studying the rates of photosynthesis at various degrees of light saturation (*i.e.*, intensity) and at different temperatures. Over a range of moderate temperatures and at low to medium light intensities (relative to the normal range of the plant species), the rate of photosynthesis increases as the intensity increases and is independent of temperature. As the light intensity increases to higher levels, however, the rate becomes increasingly dependent on temperature and less dependent on intensity; light "saturation" is achieved at a specific light intensity, and the rate then is dependent only on temperature if all other factors are constant. In the light-dependent range before saturation, therefore, the rate of photosynthesis is determined by the rates of photochemical steps (*i.e.*, light absorption by chlorophyll, energy transfer between pigments, and the conversion of the energy of excited pigments to chemical energy). At high light intensities, some of the chemical reactions of the dark stage become rate-limiting. At light saturation, rate increases with temperature until a point is reached beyond which no further rate increase can occur.

Carbon dioxide. Included among the rate-limiting steps of photosynthesis are the chemical reactions by which organic compounds are formed using carbon dioxide as a carbon source. The rates of these carboxylation reactions can be increased slightly by increasing the carbon dioxide concentration. An increase in carbon dioxide concentration of 100 times (from 0.03 to 3.0 percent), however, results only in a two to fivefold increase in the rate of photosynthesis in algae such as *Chlorella pyrenoidosa* at light saturation.

Internal factors. Each plant species has become adapted to a range of environmental factors. Complex regulatory mechanisms within a plant's chloroplasts automatically adjust the activities of enzymes (*i.e.*, organic catalysts) involved in important photosynthetic reactions; these adjustments maintain a balance in the overall photosynthetic process. When light intensity, temperature, or some other factor varies beyond the normal environmental range of a plant, therefore, the regulatory mechanisms no longer can compensate adequately, and the overall rate of photosynthesis decreases.

ENERGY EFFICIENCY OF PHOTOSYNTHESIS

The energy efficiency of photosynthesis is defined as the ratio of energy stored (as organic compounds) to the energy of light absorbed. The chemical energy stored during photosynthesis is difficult to calculate precisely because many products are formed, and the amount of energy stored varies with the plant species and environmental conditions. If the equation for glucose formation given above is used to approximate the actual storage process, each mole (*i.e.*, 6.02×10^{23} molecules) of oxygen produced (equal to one-sixth mole of glucose formed) results in the storage of a large quantity (about 117 kilocalories) of chemical energy.

Light is thought to consist of a wave of particles known as photons; these are units of energy, or light quanta. The light energy, or number of photons, in one mole of light is called an einstein. The energy of a light quantum varies inversely with the length of the photon waves; *i.e.*, the shorter the wavelength, the greater the energy content. Blue light has a shorter wavelength and therefore more energy than red light; the same number of einsteins of both blue light and red light, however, are required in photosynthesis per mole of oxygen formed. Because this "quantum requirement" of photosynthesis is about the same for any wavelength of light absorbed, the excess energy must be discarded as heat before conversion of light to chemical energy occurs. In this way, only one mechanism for energy conversion is required in the chloroplast, regardless of the wavelength of light absorbed.

Quantum requirement

After years of study and controversy, the quantum requirement for photosynthesis has been reliably established as about nine einsteins absorbed per mole of oxygen formed. The energy efficiency for glucose production with red light is 31%; this value coincides with the theoretical one calculated from the mechanism of photosynthesis, as the product of the efficiencies of the "light stage" (38%) and the "dark stage" (83%).

The so-called "light stage" includes not only the photochemical steps but also some dark reactions that occur in or on chloroplast membranes. These dark reactions involve breaking the bonds of the water molecule (*i.e.*, the oxidation of water), forming oxygen gas, transferring hydrogen (as electrons and protons), and storing chemical energy in the energy-rich molecule adenosine triphosphate (ATP). The maximum efficiency of the photochemical steps, which have an upper limit imposed by the second law of thermodynamics, is about 75%. The remaining steps of the light stage have an overall efficiency of about 54%.

The optimal efficiency of the light stage of photosynthesis has been measured only under carefully selected laboratory conditions, usually with algae such as *Chlorella pyrenoidosa* or *Scenedesmus*. These aquatic single-celled plants have fewer energy-requiring functions and can be supplied with the most desirable conditions more easily than can higher plants. The energy efficiency of the light stage in higher plants generally is much less than 54% for several reasons: the variation in the amount of light that reaches the leaves, the possibility of low concentrations of carbon dioxide in regions with many growing plants, the energy requirements for synthesizing non-photosynthetic tissues (*e.g.*, stems, roots, fruit), and the other physiological functions that require energy. If agricultural products (*e.g.*, fruit) alone are considered as the end product of the energy conversion process of photosynthesis, the efficiency may decrease to 1% or less.

THE STUDY OF PHOTOSYNTHESIS

Early studies. The study of photosynthesis began in 1771, when it was observed that mint produced some substance (later recognized as oxygen) that supported combustion. The requirement for light was recognized in 1779. In 1782 it was demonstrated that the combustion-supporting gas (oxygen) was formed at the expense of another gas, or "fixed air," which had been identified the year before as carbon dioxide. Gas-exchange experiments

in 1804 showed that the gain in weight of a plant growing in a carefully weighed pot was the sum of carbon, which came entirely from absorbed carbon dioxide, and water taken up by plant roots. Almost half a century passed before the concept of chemical energy developed sufficiently to permit the discovery (in 1845) that light energy from the sun is stored as chemical energy in products formed during photosynthesis.

Recent studies. *Sulfur bacteria.* Comparisons between photosynthetic processes in green plants and in certain photosynthetic sulfur bacteria provided important information about the photosynthetic mechanism. Sulfur bacteria, which use hydrogen sulfide as a source of hydrogen atoms instead of water, produce sulfur instead of oxygen during photosynthesis. In the 1930s, a Dutch biologist, Cornelis van Niel, recognized that the utilization of carbon dioxide to form organic compounds was similar in the two types of photosynthetic organisms. Suggesting that differences existed in the light-dependent stage and in the nature of the compounds used as a source of hydrogen atoms, he proposed that hydrogen was transferred from hydrogen sulfide (in bacteria) or water (in green plants) to an unknown acceptor (called A), which was reduced to AH_2. During the dark reactions, which are similar in both bacteria and green plants, the reduced acceptor (AH_2) reacted with carbon dioxide (CO_2) to form carbohydrate (CH_2O) and to oxidize the unknown acceptor to A. Van Niel's proposal was important because the popular (but incorrect) theory had been that oxygen was removed from carbon dioxide (rather than hydrogen from water) and that carbon then combined with water to form carbohydrate (rather than the hydrogen from water combining with CO_2 to form CH_2O).

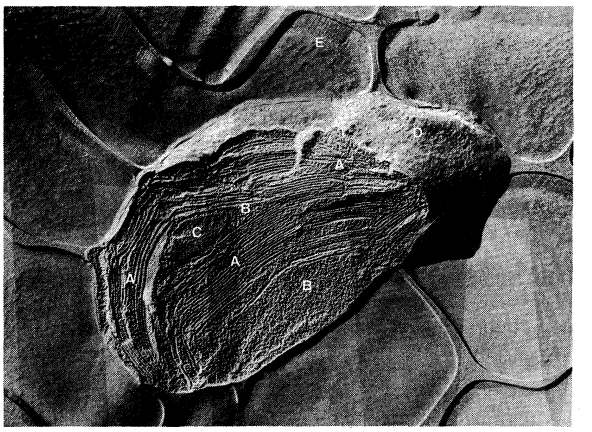
Importance of isotopes of oxygen

Isotope studies. By 1940 chemists were using radioactive isotopes of the elements as markers to follow the reactions of photosynthesis. Water marked with an isotope of oxygen (^{18}O) was used in early experiments. Plants that photosynthesized in the presence of water containing $H_2{}^{18}O$ produced oxygen gas containing oxygen-18; those that photosynthesized in the presence of radioactive carbon dioxide and normal water, however, produced normal oxygen gas. These results provided strong support for van Niel's theory that the oxygen gas produced during photosynthesis is derived from water.

Radioactive isotopes of carbon (^{14}C) and phosphorus (^{32}P) have been valuable in identifying the products of photosynthesis. A photosynthesizing plant uses the radioactive carbon (^{14}C) from radioactive carbon dioxide ($^{14}CO_2$) to synthesize complex organic compounds. If green plants photosynthesize in the presence of radioactive carbon dioxide, the compounds formed early in the pathway by which the carbon is reduced, or "fixed" into organic compounds, become labelled with radioactive carbon. The amount of radioactivity in each of the intermediate compounds in the pathway indicates its concentration under conditions of continuous (or steady-state) photosynthesis. If, on the other hand, algae photosynthesizing in the presence of radioactive carbon dioxide are subjected suddenly to some change in environment (*e.g.*, removal of light and, therefore, cessation of the light dependent reactions), changes occur in the concentrations of certain intermediates, compared with their concentrations during steady-state photosynthesis. When light is removed, for example, reactions that require chemical energy originating with light energy stop; reactions that do not require this chemical energy, however, continue. As a result, intermediate compounds that require light energy to undergo further change "pile up" (or increase in concentration), while intermediates that can undergo further change in the dark decrease in concentration. The reactions that require converted light energy were established in this way, as was the step in which carbon dioxide enters the pathway for fixation into organic compounds. This technique also has aided in identification of enzymes that function in regulating the reactions of the carbon dioxide fixation (or reduction) pathway. Radioactive phosphorus has been used to study this pathway because many of the intermediates are sugar phosphates (see below *The carbon reduction cycle*).

Electron flow studies. The earliest stages of light absorption by the chlorophyll pigments have been studied with fluorescence techniques. The ability of the chlorophyll molecule to absorb light resides in its molecular structure. The light energy aborbed by a chlorophyll molecule excites some electrons (negatively charged particles) within the structure of the molecule to higher energy levels. In the case of one type of chlorophyll molecule, called chlorophyll *a*, an excited state is created when the molecule absorbs red light. The return of an excited chlorophyll *a* molecule to its original low energy state (called the ground level) is accompanied by the release of the light energy originally absorbed by the electrons. Part of the energy is released by the re-emission of red light (called fluorescence), and the remainder is converted into chemical energy. Anything that blocks the photosynthetic conversion of light to chemical energy, therefore, causes an increase in fluorescence. If the temperature, for example, is lowered so that enzymatic reactions no longer can occur, fluorescence increases.

When a high-energy electron in an excited chlorophyll molecule leaves chlorophyll during photosynthesis, it is transferred through a series of molecules, called electron carriers, which can gain electrons (be reduced) or lose them (be oxidized). As a result, the chlorophyll molecule returns to the ground state, and the carrier molecule, also called an electron acceptor, is reduced. The electron then is passed successively to other carriers in the electron transport chain. If specific chemical inhibitors are added to green plant tissue to block the transfer of electrons between known pairs of electron carriers, one carrier will be more reduced than the other. Information about the sequence of electron carriers in the electron transport chain has been obtained in this way; in addition, the relationship of each carrier to other carriers and to the site of the photochemical steps has been determined.



Mutants

Algae whose genetic material has been changed (*i.e.*, algal mutants) have been used to follow electron flow during photosynthesis. Certain algae can be subjected to treatment (*e.g.*, high-energy radiation or specific chemicals) that induce genetic alterations (*i.e.*, mutations). Single mutations in the photosynthetic apparatus may occur. Such mutants, which frequently cannot synthesize one of the key electron carrier molecules of the photosynthetic apparatus, no longer can carry out normal photosynthesis. These algal mutants, which can survive in a growth medium that contains certain necessary organic substances, can be tested for their ability to photosynthesize in the presence and absence of selected electron carrier molecules. Algae are grown, for example, in the presence of light and in a growth medium with or without added plastoquinone, one type of organic molecule involved in electron transfer. If the algae can photosynthesize only if plastoquinone is present, the mutant (assumed to be incapable of synthesizing this molecule) is used to determine whether or not any other electron carrier is more oxidized (*i.e.*, has fewer electrons) in the absence of plastoquinone than in its presence; *i.e.*, algae containing a sequence of carriers lacking plastoquinone molecules cannot transfer electrons past the plastoquinone site in the electron chain. Such carriers presumably would follow plastoquinone in the sequence of carriers in the electron transport chain.

Electron-flow studies have revealed that hydrogen is not transferred directly from water to carbon, nitrogen, and sulfur. Instead, as bonds in the water molecule are broken by the chemical energy generated from light in the photochemical reactions, electrons and hydrogen ions (also called protons) move separately through complex membrane structures called lamellae in the photosynthetic apparatus, or chloroplast. The electrons, which eventually are transferred to electron acceptors (also called coenzymes), are used during the reduction of carbon dioxide to organic products such as glucose. As carbon is reduced, therefore, the protons that result from breaking the bonds of the water molecule are used to balance the chemical reactions involved in the pathway in which organic products are formed.

Chloroplasts. Isolation of the entire photosynthetic apparatus, called the chloroplast, and fractionation of this

cell organelle into its component parts also have provided information about photosynthesis. Around 1940 a British biochemist, Robert Hill, discovered that green particles obtained from broken cells could produce oxygen from water in the presence of light and an electron acceptor compound (*e.g.*, ferric oxalate). This reaction, commonly known as the Hill reaction, provided additional support for the van Niel theory that water provides the oxygen that forms oxygen gas during photosynthesis in green plants. During the 1950s Daniel Arnon and other American biochemists prepared plant cell fragments in which not only the Hill reaction but also the synthesis of the energy storage compound ATP (adenosine triphosphate) occurred. In addition, the coenzyme NADP (nicotine adenine dinucleotide phosphate), the electron acceptor in the carbon dioxide fixation pathway in intact chloroplasts, was used as the final acceptor of electrons, replacing other electron acceptors (*e.g.*, the ferric oxalate used by Hill). Hill's procedures were refined further so that individual small pieces of isolated chloroplast membranes, or lamellae, could perform the Hill reaction. These small pieces of lamellae were then fragmented into pieces so small that they performed only the two light reactions (see below *The light reactions*) of the photosynthetic process. It is now possible also to isolate the entire chloroplast so that it can carry out the complete process of photosynthesis, from light absorption, oxygen formation, and the reduction of carbon dioxide to the formation of glucose and other products.

Electron micrograph of an isolated spinach chloroplast prepared by the freeze-etching method. (A) Lamellae, which are layers of lipid and protein with chlorophyll, other pigments, and enzymes, are the sites of light absorption and splitting of the water to give oxygen and hydrogen. (B) Stroma, containing soluble enzymes, is the site of conversion of carbon dioxide and hydrogen to carbohydrates. (C) Starch granule is a storage product of photosynthesis. CHLOROPLASTS, THE PHOTOSYNTHETIC UNITS OF GREEN PLANTS

General features. Intricate structural organization of the photosynthetic apparatus is essential for the efficient performance of a complex process such as photosynthesis. In addition, regulation of the rates of formation of the various organic products (*e.g.*, amino acids, fatty acids, simple carbohydrates such as glucose) is dependent on organization with the chloroplast.

Structural features

The chloroplast is enclosed in a double membrane, and its size approximates a spheroid about 2.5μ thick and 5μ long (1μ = 0.001 millimetre). Some single-celled algae have one chloroplast that occupies more than half the cell volume. Higher plants (*e.g.*, spinach) contain many chloroplasts, each approximately the size of the one in some algal cells.

When thin sections of a chloroplast are examined under the electron microscope, several separate regions are apparent. The stroma area contains a few membranes and also soluble—*i.e.*, dissolved—enzymes, including those involved in the conversion of carbon dioxide to glucose and other organic compounds. A lamella, which contains all the photosynthetic pigments, is approximately 0.010–0.015μ thick and can extend throughout the chloroplast. Examination of cross sections of lamellae under the electron microscope shows that their edges are joined to form closed hollow discs that are called thylakoids ("sacklike"). It is probable that the spaces within the thylakoids are separate and that the spaces outside are continuous with the stroma regions.

The chloroplasts of some higher plants have another interesting feature. In chloroplasts such as those from spinach, there are certain regions, called grana, in which the thylakoids are very tightly stacked. Since the lamellae contain chlorophyll and all the other pigments involved in photosynthesis, grana regions are highly coloured; when viewed through a light microscope, therefore, grana appear as tiny green bodies within the chloroplasts. The function of grana is not yet known with certainty.

Chemical composition. *Proteins.* Both the structure and the chemical composition of lamellae are complex. Lamellae consist of approximately equal amounts of lipids and proteins. The proteins include structural proteins, enzymes, and protein-containing coenzymes. Enzymes are required as organic catalysts for specific reactions within the lamellae. Structural proteins either bind together or provide a matrix for the other components of the lamellae. Protein coenzymes, also called cofactors, include important electron carrier molecules called cytochromes, which are iron-containing pigments; the pigment portions of cytochromes are attached to protein molecules. During electron transfer, an electron is accepted by an iron atom in the pigment portion of a cytochrome molecule, which thus is reduced; then the electron is transferred to the iron atom in the next cytochrome carrier in the electron transfer chain, thus oxidizing the first cytochrome and reducing the next one in the chain. The cytochrome cofactors of importance in photosynthesis are called cytochrome f, cytochrome b_6, and cytochrome b_3.

In addition to the metal atoms found in the pigment portions of cytochrome molecules, metal atoms also are found in other protein molecules of the lamellae. In proteins with a total molecular weight of 900,000 (based on the weight of hydrogen as one), there are two atoms of manganese, ten atoms of iron, and six atoms of copper. These metal atoms are required for the catalytic activity of some of the enzymes important in photosynthesis. The manganese atoms may be involved in oxygen formation. Both copper- and iron-containing proteins may be involved in electron transport between water and the final electron acceptor molecule of the light stage of photosynthesis, (an iron-containing protein called ferredoxin); this molecule is in part firmly fixed in the lamallae but also occurs as a soluble component in the chloroplasts. The electrons accepted by ferredoxin may be passed to the electron acceptor coenzyme NADP, which is the carrier of electrons required to reduce carbon dioxide in the pathway that culminates in the formation of glucose.

Lipids. About one-fourth of the lipid portion of the lamellae consists of pigments and coenzymes; the remainder consists of various lipids, including phosphate-containing ones called phospholipids. Although the functions of lipids in the photosynthetic process are not yet fully understood, lipids in the lamellar membranes can function as electrical insulating material and permit a charge, or potential difference, to develop across the membrane. The charge is a source of either chemical or electrical energy. The lipids in lamellar membranes also serve as solvents for certain small organic molecules that do not dissolve in water (*i.e.*, hydrophobic molecules) and are necessary for the various photochemical reactions that occur during photosynthesis. Lamellar phospholipid molecules provide stability for the intricate structural arrangement of the lamellae.

Pigments

The most prominent pigment molecules of the lamellae are the chlorophyll molecules. Approximately one-fifth of the lamellar lipids are chlorophyll; one type, chlorophyll *a*, is more abundant than the second type, called chlorophyll *b*. Although chlorophylls are the main light-absorbing molecules in green plants, other pigments such as carotenes and carotenoids (which are responsible for the

yellow-orange colour of carrots) also can absorb light and may supplement or replace chlorophyll as the light-absorbing molecules in some plant cells; the light energy absorbed by these pigments, however, must be passed to chlorophyll before conversion to chemical energy can occur. Various plastoquinone compounds found in the lamellae are involved, as are the cytochromes, in the electron-transport process.

Lamellae. Although the detailed structure of the lamellae is not yet known with certainty, it is known that structural organization is required for their proper function. Intact thylakoids (*i.e.*, lamellar discs) apparently are necessary for the formation of the energy-rich storage compound adenosine triphosphate (ATP). Lamellae that have been broken down to small units can no longer form ATP as the conversion of light into chemical energy occurs during the electron transport process. Lamellae can be disrupted mechanically under carefully controlled conditions into small fragments that absorb light energy and break the bonds of water molecules (*i.e.*, oxidize water) to produce oxygen, as electrons are transferred to ferredoxin, the final electron acceptor of the light stage. Further disruption of mechanically broken lamellae, however, results in complete loss of photosynthetic activity.

Lamellae that are treated with certain detergents can be broken down into two types of small particles. One type can absorb light energy, oxidize water, and produce oxygen, as electrons are accepted by a dye (which thus is reduced) that is added to the particles; these particles use light energy to generate "oxidizing power," which is necessary for the production of oxygen. This type of particle contains one or more of the photochemical units from the lamellae (see light reaction II in Figure 2), which are composed of pigment molecules and enzymes necessary for using light energy to oxidize water and to produce oxygen. A large number of chlorophyll molecules, probably several hundred, in this photochemical unit are arranged around a reaction centre in which the actual conversion of light to chemical energy occurs. Chlorophyll molecules found in this reaction centre can either lose electrons (*i.e.*, be oxidized) or gain electrons (*i.e.*, be reduced) and are known to be associated intimately with the following electron carrying cofactors: cytochrome b, cytochrome f, and plastoquinone. The chlorophyll molecules that do not function at the reaction centre trap light energy that otherwise might not be absorbed. The light energy absorbed by one of these chlorophyll molecules is transferred from one pigment molecule to another until it reaches the reaction centre; there it is converted to chemical energy. In this energy conversion centre a cofactor that has lost an electron during the photochemical step reacts with enzymes and water to produce oxygen. Another cofactor, reduced during the light reaction, transfers an electron to one of a series of electron carriers.

In the presence of electron donors, such as the reduced dye added to the unit above, and ferredoxin (an electron acceptor), the second type of lamellar particle, obtained by treating lamellae with detergents, can absorb light and transfer electrons from the electron donor (*i.e.*, the reduced dye) to ferredoxin; these particles utilize light energy to generate "reducing power," which is necessary for the reduction of carbon dioxide. This type of particle may contain the second type of photochemical reaction centre (see light reaction I, Figure 2), in which a photochemically oxidized cofactor (from the energy conversion centre described above), reduced when it accepts an electron from an electron carrier, is reoxidized as it transfers an electron to ferredoxin, the final electron acceptor of the light stage of photosynthesis. The two types of photochemical reaction centres found in the lamellae of green plants generate sufficient chemical energy from light to carry out all the reactions of photosynthesis, including the transfer of electrons from water through a series of electron carrier molecules to carbon dioxide.

Importance of lamellar particles

THE PROCESS OF PHOTOSYNTHESIS

The role of light energy in electron transfer. The general features of a widely accepted mechanism for photoelectron transfer, in which two light reactions occur during the transfer of electrons from water to carbon dioxide, were proposed by Robert Hill and F. Bendall, in 1960. A scheme for this mechanism is shown in Figure 2. In this figure the vertical scale represents the relative ability (in volts) of various cofactors of the electron-transfer chain to be oxidized or reduced. Molecules with the strongest affinity for electrons (*i.e.*, strong oxidizing agents) are near the bottom of the scale. Molecules that readily give up electrons (*i.e.*, strong reducing agents) are near the top of the scale. The zero point indicates the tendency for hydrogen ions (H^+) to gain electrons (*i.e.*, be reduced) to form hydrogen gas (H_2).

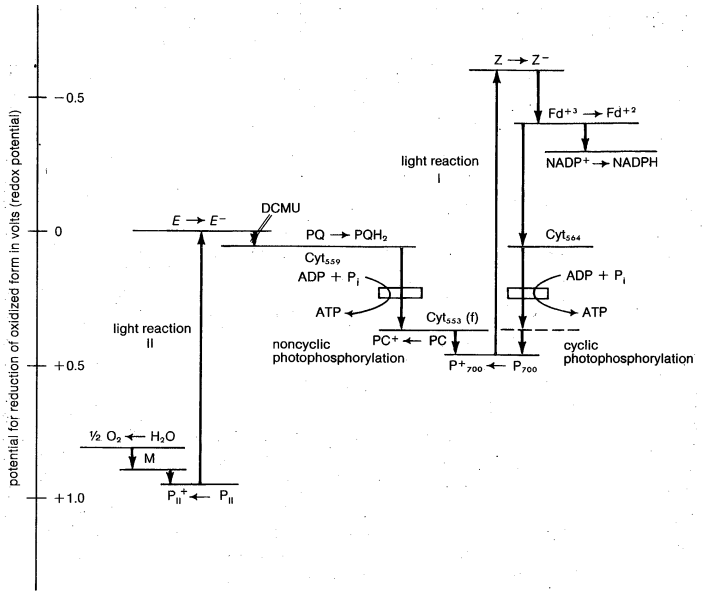

Figure 2: Flow of electrons during the light stage of photosynthesis. Upward pointing arrows represent light reactions that increase the chemical potential; downward pointing arrows represent the flow of electrons in the membrane, in which the release of energy is coupled with the storage of energy in the formation of ATP (see text).

The light reactions. In light reaction II (Figure 2), the energy of an absorbed photon of light is used during the enzyme-catalyzed transfer of an electron from an unknown molecule (designated M) to a carrier (called E). The electron added to carrier E (thus reduced to E^-) is transferred to the next carrier, plastoquinone (PQ), which is reduced to PQH_2. An electron from reduced PQ is transferred through a series of electron carrier molecules to cytochrome f. The energy released during the flow of two electrons from plastoquinone to cytochrome f is used to form at least one molecule of the energy-rich storage compound ATP. In another reaction, electrons are removed from water (thus oxidizing it) and transferred to the unknown molecule M (very easily reduced; *i.e.*, a strong oxidizing agent), thereby reducing M once again; as a result of this reaction, oxygen gas is formed.

In light reaction I (Figure 2) an electron is transferred from a pigment molecule (possibly a molecule of chlorophyll *a*), discovered in 1961 and called P_{700}, to an unknown acceptor molecule (designated Z). P_{700} oxidizes reduced cytochrome f (from light reaction II) and a copper-containing protein molecule (called plastocyanin, or PC). An electron is transferred from the reduced acceptor molecule (Z^-) to the iron-containing protein molecule, ferredoxin (Fd). The reducing power in reduced ferredoxin (Fd^{+3}) either can be used to reduce NADP (the initial step in carbon fixation) or nitrate (to ammonium ion) or sulfate (to sulfide).

Evidence to support the existence of two light reactions. Evidence in support of the above scheme of two light reactions during the light stage of photosynthesis (Figure 2) has been obtained. Using *Chlorella*, the American biochemist Robert Emerson increased the quantum efficiency (*i.e.*, ratio of light absorbed to oxygen formed)

of light with a wavelength longer than .68μ by using it in the presence of light with a shorter wavelength (.58μ). The addition of light of shorter wavelength resulted in oxygen production that exceeded the sum of oxygen produced when each wavelength of light was used alone.

Accessory pigments in algae

In some algae, with coloured molecules (called accessory pigments) in addition to chlorophyll, the effect of light absorbed by accessory pigments is different from that absorbed by chlorophyll *a*. Light absorbed by the accessory pigments in these algae is involved more directly in the oxidation of water and the production of oxygen (reaction II in Figure 2); on the other hand, light absorbed by chlorophyll *a* is used in the transfer of electrons that are used during the reduction of carbon dioxide (reaction I in Figure 2).

When ferredoxin and NADP are added to broken spinach chloroplasts in the presence of light, the following events take place: electrons are transferred from water to NADP, NADP is reduced, and oxygen is formed. None of these events occurs if the plant killer dichlorophenylmethylurea (DCMU; see Figure 2) is present. Since the addition of certain reduced dyes (*i.e.*, electron donors), however, results in the reduction of NADP (light reaction I) without production of oxygen (light reaction II), it is known that DCMU blocks light reaction II. During light reaction I, electrons are transferred from the donor to NADP by way of reduced carrier Z and ferredoxin (Fd).

Quantum requirement. The quantum requirements of the individual light reactions of photosynthesis are based on the theory that one photon of light is absorbed for each electron transferred in each of the two light reactions. The total number of quanta required, therefore, to transfer four electrons that result in the formation of one molecule of oxygen should be four times two, or eight. It appears, however, that additional light is absorbed and used to form ATP by a cyclic photophosphorylation pathway (see next section). The actual quantum requirement, therefore, probably is nine to ten.

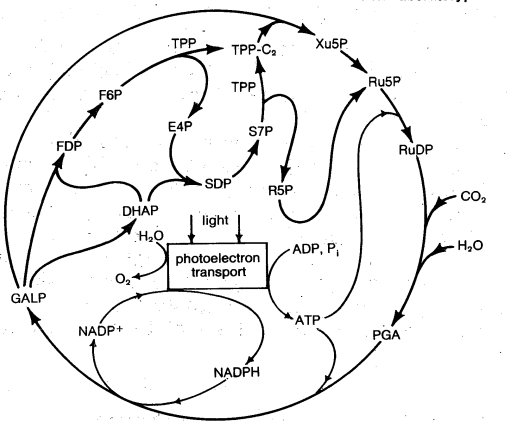
The conversion of light energy to ATP: Photophosphorylation. In contrast to electron transfer in light reactions I and II, in which transfer can occur with small particles of chloroplasts or membrane fragments, intact thylakoids are required for photophosphorylation. Enzymes, attached to the outer surface of the thylakoids and shaped like spherical particles, catalyze the final reaction in the formation of ATP from ADP and inorganic phosphate (abbreviated P_i). When these enzymes are removed by chemical agents, electron flow occurs without phosphorylation; photophosphorylation then is said to be uncoupled from electron transfer.

Photophosphorylation in chloroplasts occurs either by a cyclic or a noncyclic process. During noncyclic photophosphorylation, the transfer of each pair of electrons from water to NADP during light reactions I and II (see Figure 2) results in the formation of at least one molecule of ATP. During cyclic photophosphorylation, electrons, which have been transferred to the primary electron acceptor (Z) of light reaction I, are returned through a phosphorylation site to the donor of electrons (P_{700}) in light reaction I. The number of molecules of ATP formed during the transfer of a pair of electrons through this pathway for each light activation step has not yet been established with certainty.

The mechanism by which energy is used to form ATP during electron transfer is not yet known with certainty. One theory is that energy liberated during electron transfer is used to form some energy-rich compound (called X~I), which then reacts with inorganic phosphate (P_i) to form an energy-rich compound, called X~P. An enzyme-catalyzed reaction would result in the formation of ATP and X. An alternative mechanism is that electron flow is accompanied by a flow of hydrogen ions (H^+), also called protons, through the lamellar membrane. In this way, a gradient of protons, which is a form of energy, could be built up across the membrane. Two protons from a specific gradient could provide the energy necessary to form one molecule of ATP. In this mechanism the proton gradient replaces X~I above. The membrane itself could contain the structures and molecules necessary to convert the energy of the proton gradient to either X~P or ATP.

The carbon reduction cycle. The reduction cycle in which carbon dioxide is fixed, reduced, and utilized involves the formation of intermediate compounds, called sugar phosphates; the sequence in which the intermediates are formed has been determined. During the reduction cycle, the energy-rich compounds formed during the light reactions (*i.e.*, ATP and reduced NADP) are utilized.

From the University of California, Lawrence Radiation Laboratory, Berkeley



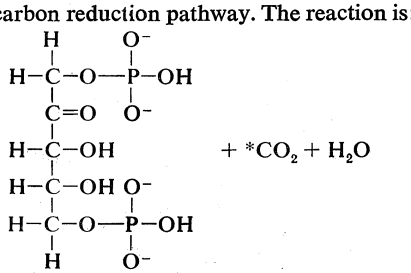


Figure 3: Pathway of carbon reduction in photosynthesis, the reductive pentose phosphate cycle. Thick arrows indicate steps catalyzed by regulated enzymes; the box labelled photoelectron transport represents the reactions shown in Figure 2 (see text).

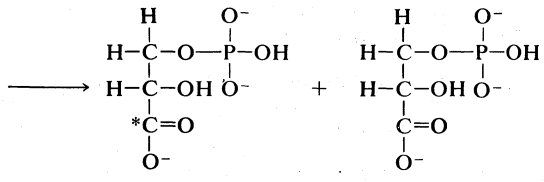
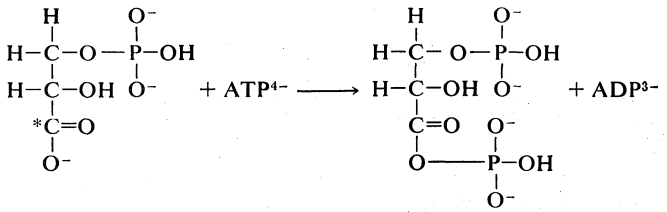
The fixation of carbon dioxide. Early investigations of the photosynthetic process showed that the first radioactive products formed from carbon dioxide labelled with radioactive carbon included organic acids known as carboxylic acids.



Identification of the first compound formed

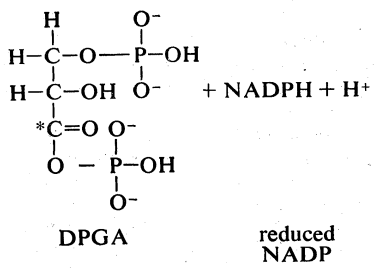
Melvin Calvin, a Nobel Prize recipient for his work on the carbon reduction cycle, allowed green plants to photosynthesize in the presence of radioactive carbon dioxide for a few seconds under various experimental conditions. Products labelled with radioactive carbon included a three-carbon compound called 3-phosphoglyceric acid (abbreviated PGA, see Figure 3), sugar phosphates, amino acids, sucrose, and carboxylic acids. When photosynthesis was stopped after two seconds, the principal radioactive compound was PGA, which therefore was identified as the first compound formed during carbon dioxide fixation in green plants. Some plants, however, including many tropical grasses have a different pattern (see below *Carbon fixation in tropical grasses*).

If light is removed from plants photosynthesizing in the presence of radioactive carbon dioxide, the amount of PGA formed increases rapidly; simultaneously, however, the amount of another sugar, called ribulose-1,5,-diphosphate (RuDP), declines rapidly. Energy-rich compounds derived from the light reactions, therefore, are utilized in converting PGA to other products and in forming RuDP. If the carbon dioxide level is decreased suddenly in the presence of light, there is a simultaneous increase in the amount of RuDP and a decrease in PGA formation; in other words, RuDP reacts with radioactive carbon dioxide (indicated below as $*CO_2$) to form PGA; this is the first step in the carbon reduction pathway. The reaction is:



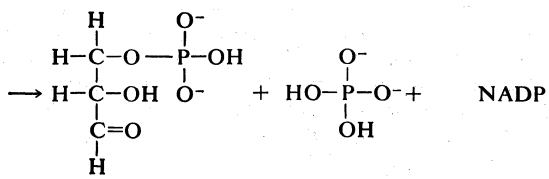
RuDP
(ribulose-1.5-diphosphate)

PGA (labelled 3-phosphoglyceric acid) PGA (3-phosphoglyceric acid)



The carboxylation enzyme (*i.e.*, the enzyme that catalyzes the addition of carbon dioxide to RuDP), called ribulose diphosphate carboxylase, has been purified from spinach leaves.

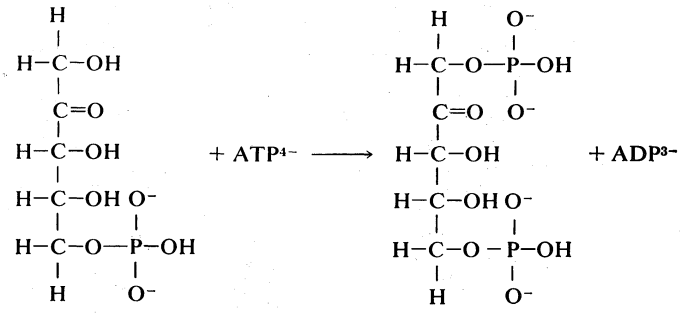
The reduction of carbon. During the formation of ATP in the light stage of photosynthesis, about 13 kilocalories (or one-third of the energy available in the photons contained in one mole—an einstein—of red light) of chemical energy are stored in this energy-rich molecule. An enzyme (3-phosphoglycerate kinase) catalyzes the transfer of the terminal phosphate of an ATP molecule, as well as a large part of the chemical energy stored in it, to the carboxyl carbon (labelled * below) of PGA. The reaction is:



PGA DPGA (diphosphoglyceric acid)

The unstable energy-rich compound formed in this reaction (called phosphoryl-PGA, and abbreviated to DPGA) immediately accepts two electrons from reduced NADP to form a stable three-carbon compound called glyceraldehyde-3-phosphate (GALP; see Figure 3). The reaction (presented below), catalyzed by the enzyme glyceraldehyde phosphate dehydrogenase, is the step in which carbon is reduced.

DPGA reduced NADP

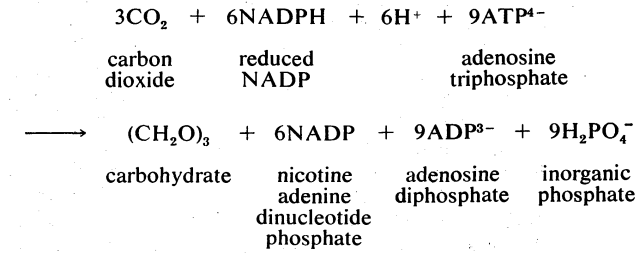


GALP (glyceraldehyde-3-phosphate) inorganic phosphate (oxidized NADP)

Two reactions (*i.e.*, those in which DPGA and GALP are formed) are the reverse of reactions that occur in the Embden-Meyerhof-Parnas (EMP), or glycolytic pathway by which sugars are converted to a three-carbon compound called pyruvate (see METABOLISM).

The reductive pentose phosphate cycle. Many reactions (in addition to the two cited above) of both the EMP pathway, in which oxygen is not utilized, and an oxidative (*i.e.*, oxygen-requiring) five-carbon sugar phosphate cycle known as the HMP shunt, also are involved in the cycle known as the reductive pentose phosphate cycle in photosynthesis. Several of the enzymes (*i.e.*, triose phosphate isomerase, pentose phosphate isomerase, aldolase, transketolase, and ribulose phosphate 3-epimerase) that catalyze the reactions, therefore, also are important in the photosynthetic reductive cycle (shown in Figure 3). Two additional enzymes, fructose diphosphatase and sedoheptulose diphosphatase, however, are important only in the photosynthetic reductive cycle; each removes a phosphate group, from fructose diphosphate (FDP, a six-carbon phosphate-containing sugar) and sedoheptulose diphosphate (SDP, a seven-carbon phosphate-containing sugar), respectively. The net result of the reactions catalyzed by the enzymes in the photosynthetic reductive cycle is the conversion of five molecules of the three-carbon sugar phosphate, glyceraldehyde-3-phosphate (GALP), to three molecules of the five-carbon sugar phosphate, ribulose-5- phosphate (Ru5P; see Figure 3).

ATP formed during the light stage also is used to convert Ru5P to RuDP, the compound involved in carbon dioxide fixation. The reaction, catalyzed by the enzyme ribulose phosphate kinase, is:



Ru5P ribulose-5-phosphate RuDP (ribulose-1,5-diphosphate)

Utilization of the products of the cycle. During a complete carbon reduction cycle, three molecules of carbon dioxide are added to three molecules of ribulose-1,5-diphosphate (RuDP); *i.e.*, RuDP is carboxylated, and six molecules of phosphoglyceric acid (PGA) are formed. If the carbon reduction cycle is to be self-sustaining (*i.e.*, require no carbon source other than carbon dioxide), five PGA molecules must be reduced to five triose phosphate molecules (*i.e.*, glyceraldehyde-3-phosphate, GALP); these molecules then must be converted to three molecules of RuDP, which are required to continue the carboxylation reaction, in which carbon dioxide is fixed. The sixth molecule of PGA is used in the synthesis of other products; *e.g.*, carbohydrates such as starch (see below *Regulation of the cycle*).

Summary of the energy requirements of the cycle

During the carbon reduction cycle, six molecules of PGA are reduced; this reduction requires the converted light energy contained in six molecules of ATP and six molecules of reduced NADP. The phosphorylation (*i.e.* addition of phosphate) of three molecules of ribulose-5-phosphate requires an additional three molecules of energy-rich ATP. The overall reaction of the cycle can be represented as:

carbon dioxide; reduced NADP; adenosine triphosphate

carbohydrate; nicotine adenine dinucleotide phosphate; adenosine diphosphate; inorganic phosphate

The reduction of one molecule of carbon dioxide to a sugar, therefore, requires the energy contained in three molecules of ATP and two molecules of reduced NADP.

Regulation of the cycle. For every three molecules of carbon dioxide fixed in the carboxylation reaction and then reduced, one three-carbon compound (*e.g.*, phos-

phoglyceric acid, glyceraldehyde-3-phosphate) can be utilized in the synthesis of products such as carbohydrates, fats, and proteins. Three-carbon compounds usually are utilized in the synthesis of fats and proteins; these compounds include phosphoglyceric acid and the triose phosphates (that is, glyceraldehyde-3-phosphate, GALP, and a derivative, dihydroxyacetone phosphate, DHAP; see Figure 3).

During the synthesis of carbohydrates, however, two triose phosphate molecules must combine to form a six-carbon compound called fructose diphosphate (FDP); this molecule then loses one phosphate group and forms fructose-6-phosphate (F6P; Figure 3). The fructose diphosphatase enzyme that catalyzes this reaction is called a regulatory enzyme because its activity can be increased or decreased by certain factors; for example, the activity of the enzyme is regulated not only by the presence or absence of light but also during photosynthesis in light. This enzyme controls the rate of the reaction in which three-carbon compounds that form fats and proteins are changed into the six-carbon compound required to form carbohydrates (*e.g.*, sucrose, starch, cellulose). Fructose diphosphatase, therefore, is a very important enzyme in regulating the fate of the sixth sugar phosphate molecule, formed during the photosynthetic cycle, as it enters the biosynthetic pathways of metabolism. For additional information about regulation of metabolic pathways, see METABOLISM.

Another important regulatory enzyme, ribulose diphosphate carboxylase, controls the rate of carbon dioxide fixation. By limiting the rate of fixation and thus the amount of carbon dioxide reduced, this enzyme provides a mechanism by which ATP and reduced NADP, which otherwise would be used in the carbon reduction cycle, can be used in the biosynthetic pathways that result in the formation of carbohydrates, proteins, and fats. By means of the regulatory effects of this enzyme, the reduction of carbon dioxide is balanced with the conversion of reduced carbon to organic products.

A third regulatory mechanism involves four enzymes of the carbon reduction cycle: ribulose diphosphate carboxylase, phosphoribulokinase, fructose diphosphatase, and sedoheptulose diphosphatase; these enzymes are not active in the absence of light. The dependence of these enzymes on light for activity is part of a regulatory mechanism by which the chloroplasts can change from photosynthetic to oxidative metabolism at night.

Carbon dioxide fixation in tropical grasses. When some tropical grasses (and certain other plants) photosynthesize for a few seconds in the presence of carbon dioxide labelled with radioactive carbon, the important radioactive compounds formed are malate (a carboxylic acid) and aspartate (an amino acid). The plants contain an enzyme that catalyzes the formation of phosphoenolpyruvate (PEPA) from pyruvate, an important intermediate in the EMP or glycolytic pathway. A mechanism has been proposed for the incorporation of carbon dioxide in these photosynthetic plants. It is postulated that phosphate first is added to pyruvate to form PEPA; carbon dioxide is incorporated into PEPA (*i.e.*, PEPA is carboxylated) to form a four-carbon acid called oxaloacetic acid (OAA). Oxaloacetic acid can be converted either into aspartate or malate. By some mechanism not yet known with certainty, the carbon atom incorporated into the four-carbon acids may be transferred to some acceptor (perhaps ribulose-1, 5-diphosphate); 3-phosphoglyceric acid eventually is formed and reduced by way of the carbon reduction cycle.

An explanation for this unusual pathway may be that the plants store carbon, and perhaps transport it from one kind of cell to another, as malic acid. Chloroplasts in cells around vesicles of the leaf called parenchyma cells contain enzymes that catalyze the reactions of the reduction cycle. Chloroplasts in a second type of green cells called mesophyll cells apparently contain the enzymes that catalyze the formation of PEPA and its carboxylation to oxaloacetic acid. The tropical grasses and other plants that utilize this pathway may have evolved under conditions of limited water supply and high light intensity; in this case, carbon dioxide would have been the limiting factor in photosynthesis (see above *Factors that influence the rate of photosynthesis*). It is possible that, in such circumstances, a special mechanism for the fixation of carbon dioxide might represent an evolutionary advantage, even though some chemical energy is sacrificed. The basic process of photosynthesis, therefore, may have been adapted or altered during the evolution of the process to allow certain plant species to survive under available ecological conditions.

Phthiraptera

Lice (order Phthiraptera) are small, wingless, parasitic insects divisible into two main groups: the Mallophaga, or chewing or biting lice, which are parasites of birds and mammals, and the Anoplura, or sucking lice, parasites of mammals only. One of the biting lice, the human louse, is the carrier of typhus and louse-borne relapsing fever; it thrives in conditions of filth and overcrowding. Outbreaks of louse-borne diseases were frequent by-products of famine, war, and other disasters before the advent of powerful insecticides (see INFECTIOUS DISEASES). Heavy infestations of lice may cause intense skin irritation, and scratching for relief may lead to secondary infections. In domestic animals rubbing and damage to hides and wool may also occur, and meat and egg production may be affected; in badly infested birds the feathers may be severely damaged. One of the dog lice is the intermediate host of the dog tapeworm, and a rat louse is a transmitter of murine typhus among rats.

General features. The flattened bodies of lice range from ⅓ millimetre to 11 millimetres in length and are whitish, yellow, brown, or black. Probably all species of birds have chewing lice, and most mammals have either chewing or sucking lice, or both. There are about 2,900 known species of Mallophaga, with many others still undescribed, and about 400 species of Anoplura. No lice have been taken from the duckbilled platypus or from anteaters and armadillos; and none are known from bats or whales. The size of louse populations varies enormously on different individuals, sometimes seasonally. Sick animals and especially birds with damaged bills, probably because of the absence of grooming and preening, may have abnormally large numbers: over 14,000 on a sick fox and over 7,000 on a cormorant with a damaged bill; the numbers found on healthy hosts are usually considerably smaller. Apart from grooming and preening by the host, lice and their eggs may be controlled by predatory mites, dust baths, intense sunlight, and continuous wetting.

Natural history. *Life cycle.* With the exception of the human body louse, lice spend their entire life cycle, from egg to adult, on the host. The females are usually larger than the males and often outnumber them on any one host; in some species males are rarely found, and reproduction is by unfertilized eggs (parthenogenetic). The eggs are laid singly or in clumps, usually cemented to a feather or hair; the human body louse lays its eggs on clothing next to the skin. The eggs may be simple ovoid structures glistening white among the feathers or hairs or may be heavily sculptured or ornamented with projections that assist in the attachment of the egg or serve in gas exchange. When the nymph within the egg is ready to hatch, it sucks in air through its mouth; this passes down the alimentary canal and accumulates behind the nymph until sufficient pressure is built up to force off the cap (operculum), helped by an armed, platelike structure, the hatching organ, at the upper end of the prelarval skin. The emergent nymph is similar to the adult but is

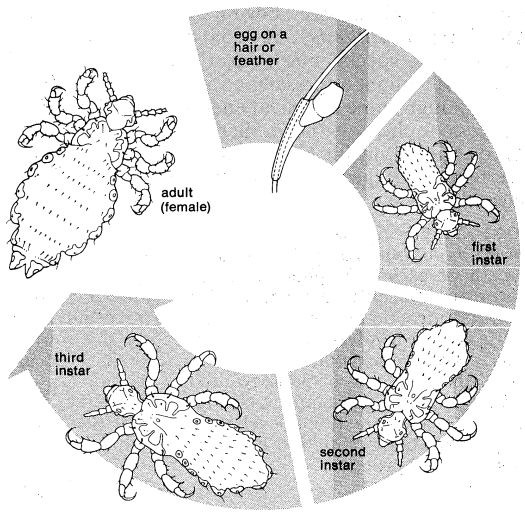

Figure 1: Life cycle of a typical louse.

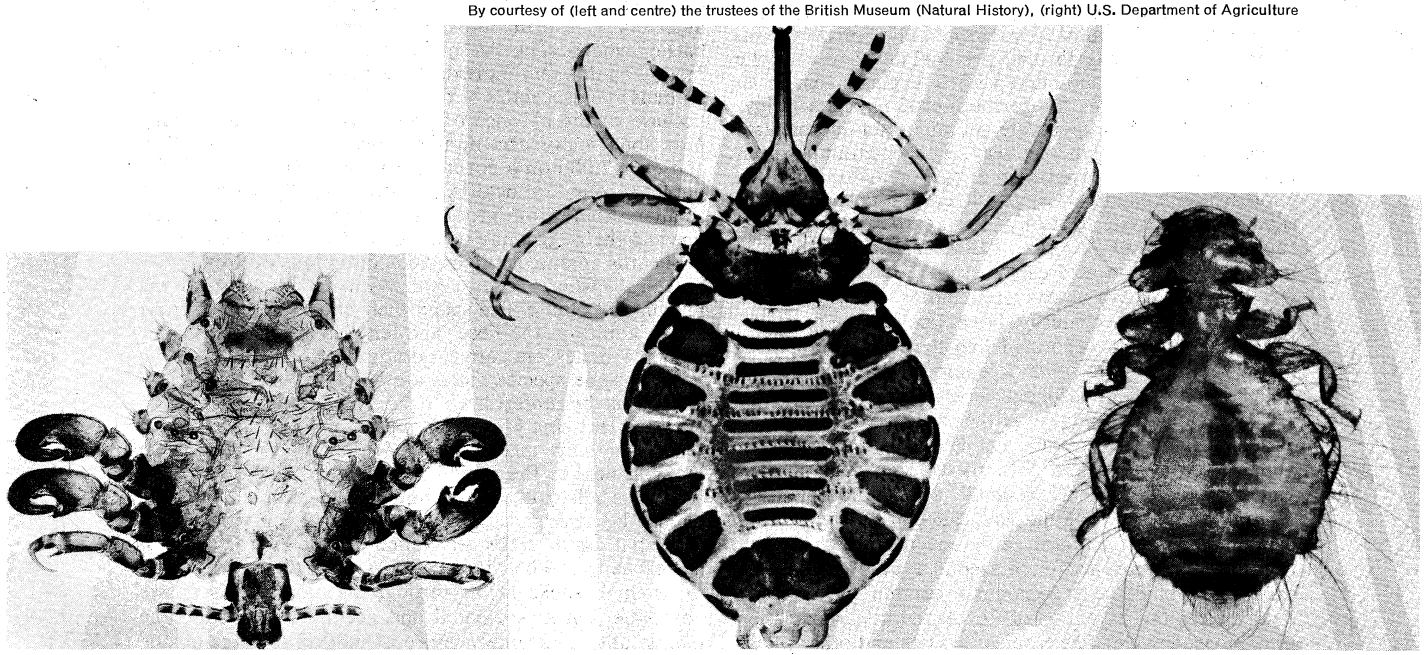
smaller and uncoloured, has fewer hairs, and differs in certain other morphological details.

Metamorphosis in the lice is simple, the nymphs molting three times, each of the three stages between molts (instars) becoming larger and more like the adult (see Figure 1). The duration of the different stages of development varies from species to species and within each species according to temperature. In the human louse the egg stage may last from six to 14 days and the stages from hatching to adult, eight to 16 days. The life cycle may be closely correlated with the particular habits of the host; *e.g.*, the louse of the elephant seal must complete its life cycle during the three to five weeks, twice a year, that the elephant seal spends on shore.



Ecology. Sucking lice live exclusively on blood, their mouthparts being well adapted for this purpose. The delicate stylets, retracted into the head when the louse is not feeding, are used to pierce the skin, and a salivary secretion is injected to prevent coagulation while the blood is sucked into the mouth. The chewing lice of birds feed on the feathers, or on feathers, blood, and tissue fluids, or on fluids only. The fluids are obtained either by gnawing the skin or, as in the poultry body louse, from the central pulp of a developing feather. The chewing lice of hummingbirds have delicate mandibles that can pierce the skin of the host and a modified eversible "throat" (hypopharynx). The feather-eating Mallophaga are able to digest the keratin of feathers. It is probable that the chewing lice of mammals do not feed on wool or hairs but on skin debris, secretions, and perhaps sometimes blood and tissue fluids.

Many birds and mammals are infested by more than one species of lice, most of the birds having at least four or five; these species may inhabit different parts of the body, with adaptations to the particular habitat. Among the avian chewing lice, some species occupy different regions for resting, feeding, and egg laying. A louse is unable to live for more than short periods away from its host, and adaptations serve to maintain its close contact: being attracted by body heat and repelled by light, the louse stays within the warmth and darkness of the host's plumage or pelage. It is also probably sensitive to the smell of its host and the peculiarities of feathers and hairs that help the louse orient itself. A louse may leave its host temporarily to pass to another host of the same species or to a host of another species, such as from prey to predator. Chewing lice have often been found attached to louse flies (Hippoboscidae), also parasitic on birds and mammals, and on other insects by which they may be transferred to a new host. They may not be able to establish themselves on the new host, however, perhaps because of chemical or physical incompatibility with the host as food or habitat; some mammalian lice, for example, can lay their eggs only on hairs of a suitable diameter.

The infrequency of transfer from one host species to another leads to host specificity, or host restriction, in which a species of louse is found only on one species of host or a group of closely related host species. It is probable that some host-specific species have developed through isolation because there is simply no opportunity for the transfer of lice. Domestic and zoo animals sometimes have established populations of lice from different hosts, and pheasants and partridges often have flourishing populations of chicken lice. *Heterodoxus spiniger*, which is parasitic on domestic dogs in tropical regions, was most likely acquired relatively recently from an Australian marsupial.

Form and function. The louse body is flattened dorsoventrally with the long axis of the head horizontal, enabling it to lie close along the feathers or hairs for attachment or feeding. The shape of the head and body varies considerably, especially in the avian chewing lice,

From H. Weber, *Grundriss der Insektenkunde* (1967); Gustav Fischer Verlag, Stuttgart

in adaptation to the different ecological niches on the body of the host. Birds with white plumage, such as swans, have a white body louse, while the dark-plumaged coot has an almost black body louse. The antennae are short, three- to five-segmented, sometimes modified in the male as clasping organs to hold the female during copulation; the eyes are compound; the mouthparts are biting (mandibulate) in the Mallophaga, strongly modified for sucking in the Anoplura. The Anoplura have three stylets enclosed in a sheath within the head, and a small proboscis armed with recurved toothlike processes, probably for holding the skin during feeding. The elephant louse, morphologically intermediate between the Mallophaga and Anoplura, has chewing mouthparts, with the modified mandibles borne on the end of a long proboscis. The thorax may have three visible segments, the mesothorax and metathorax fused, or all three fused into a single segment as in the Anoplura. The legs are well developed, the tarsus one- to two-segmented, with two claws in the avian Mallophaga and a single claw in some of the mammal-infesting families; the Anoplura have a single claw opposed to a tibial process forming a hair-clasping organ. The abdomen has eight to ten visible segments. There is one pair of thoracic breathing pores (spiracles) and a maximum of six abdominal pairs. The eversible male genitalia provide important characters for the classification of species. The female has no well-defined ovipositor, but various lobes present on the last two segments of some species may act as guides to the eggs during laying. The alimentary canal in the Mallophaga is composed of the esophagus, well-developed crop and midgut, a smaller hindgut, four malpighian tubules, and a rectum with six papillae. The crop is either a simple swelling between esophagus and midgut or a diverticulum from the esophagus. In the Anoplura the esophagus passes straight into the large midgut with or without a swelling forming a crop; there is also a strong pump for sucking up the blood. Members of the superfamily Amblycera have well-developed, comblike structures at the base of the crop, which prevent undigested feather parts or other particles from passing into the midgut; in the family Philopteridae these combs are smaller and lie at the anterior part of the crop; the Trichodectidae and Anoplura have no crop teeth. Apart from the eyes, which are sensitive to light, the other sensory structures are the tactile hairs and the sense organs in the mouth and on the antenna, some of which function as taste and smell organs.

Evolution and paleontology. It is generally accepted that the lice are derived from the book lice (order Psocoptera). It is also accepted that the Anoplura are related to the Mallophaga, some authorities believing that they evolved from an ancestral stock before the division into the Amblycera and Ischnocera, others that they diverged from those Ischnocera already parasitic on mammals. The origins of the elephant louse are obscure.

Apart from a louse egg found in Baltic amber, there are no fossils that might provide information on the evolution of the lice; however, their host distribution is in some ways analogous to a fossil history. Mallophagan genera frequently have a number of species that are restricted to one species of bird or to a group of closely related birds, suggesting that the stock ancestral to the bird order was parasitized by an ancestral mallophagan stock that diverged and evolved along with the divergence and evolution of its bird hosts. This relationship between host and parasite may throw some light on the relationships of the hosts themselves. The flamingos, which are usually placed with the storks, are parasitized by three genera of Mallophaga found elsewhere only on ducks, geese, and swans and may therefore be more closely related to those birds than to storks. The louse most nearly related to the human body louse, is that of the chimpanzee, and to the human pubic louse that of the gorilla. However, a number of factors have obscured the direct relationship between louse species and host species, the most important being secondary infestation, which is the establishment of a louse species on a new and unrelated host. This may have happened at any stage during the evolution of host or parasite so that subsequent divergence will have obscured all traces of the original change of host.

Classification. *Distinguishing taxonomic features.* The important characters used in classifying lice at the subordinal level are mainly based on the mouthparts. Features separating the lower categories are the special modifications of mouthparts, crop, antennae, sutures, and internal thickening of the head capsule; the number and form of claws; the segmentation of thorax and abdomen; the form of body plates; the number of spiracles; the pattern of bristles (or setae); and features of the male genitalia and terminal segments of the abdomen.

Annotated classification. Lice can be included in one order, the Phthiraptera, being separated by the characters of the mouthparts into three suborders: Mallophaga, Rhynchophthirina, and Anoplura.

ORDER PHTHIRAPTERA

Small dorso-ventrally flattened parasitic insects. Eyes reduced or absent, ocelli absent, antenna three- to five-segmented, mouthparts mandibulate or piercing. Obligate permanent ectoparasites of birds and mammals.

Suborder Mallophaga (chewing or biting lice)

Mandibulate mouthparts. Parasites of birds and mammals. About 2,900 species.

Superfamily Amblycera

Antenna four- to five-segmented, third segment pedunculate; articulation of mandibles horizontal; two- to five-segmented maxillary palpus; crop simple.

Family Menoponidae. Widespread parasites of birds, contained in about 60 genera.

Family Boopidae. Confined to marsupials of Australasia, except for one species found on domestic dogs.

Family Laemobothriidae. Contains some of the largest Mallophaga up to 11 millimetres in length. Parasites of birds of prey, rails, and some storks.

Family Ricinidae. Parasites of passerines and hummingbirds.

Family Trimenoponidae. Parasites of New World marsupials and rodents.

Family Gyropidae. New World, parasitic mainly on rodents, with one species on primates and one on peccaries.

Superfamily Ischnocera

Third antennal segment filiform; articulations of mandibles vertical; maxillary palpus absent; crop as diverticulum of esophagus; parasites of birds and mammals.

Family Philopteridae. Parasites of birds, except for one genus (*Trichophilopterus*) on lemurs; contains approximately 130 genera recorded from all orders of birds, except the swifts and hummingbirds.

Family Trichodectidae. Approximately 14 genera parasitic on mammals, rarely on primates, sloths, and rodents; more widespread on land carnivores, hyraxes, horses, donkeys, and artiodactyls, except pigs.

Suborder Rhynchophthirina

Modified mandibles borne at end of long proboscis; filiform five-segmented antennae; meso- and metanotum fused; thoracic spiracle ventral; single tarsal claw; crop absent; one genus with two species: *Haematomyzus elephantis* on the African and Indian elephants and *H. hopkinsi* on the African wart hog.

Suborder Anoplura (sucking lice)

Piercing mouthparts in the form of three fine eversible stylets; filiform four- to five-segmented antennae; all three segments of thorax fused together; thoracic spiracle dorsal; single tarsal claw, at least on second and third legs; crop absent, or if present is a simple enlargement; about 400 species.

Family Echinophthiriidae (seal lice). Parasitic on seals.

Family Haematopinidae (wrinkled sucking lice). Includes two genera parasitic on pigs, cattle, deer, and horses.

Family Hoplopleuridae (small mammal-sucking lice). A large family containing approximately 27 genera parasitic mainly on rodents but also on insectivores, primates, and one on an ungulate.

Family Linognathidae (smooth sucking lice). Parasitic on artiodactyls and hyraxes, except for two species parasitic on carnivores.

Family Neolinognathidae. Two species parasitic on insectivores.

Family Pediculidae (human lice). Two genera parasitic on man, the great apes, and on some of the New World monkeys, the last perhaps being secondarily acquired from man.

Critical appraisal. The classification given above is a currently accepted one. Other classifications rank the Anoplura and Mallophaga as separate orders, with the elephant louse placed in one or the other according to personal opinion. Some workers consider the Phthiraptera as comprising four suborders: the Amblycera and Ischnocera (both now included in the Mallophaga), Anoplura and Rhynchophthirina, dropping the name Mallophaga entirely. This represents the view that the Ischnocera, Anoplura, and Rhynchophthirina are more closely related to each other than are any of them to the Amblycera. There are considerable differences in the number and extent of the mallophagan families recognized and also on the generic limits within the families. In the Anoplura, controversy continues on the relations of the genera to each other and in which families they should be included.

The lice of man are referred to by various names, depending on whether the head louse is considered as a distinct species or as a variety or subspecies of the body louse. At present they are probably best referred to under one name, *Pediculus humanus,* but if separated subspecifically they must be called *Pediculus humanus humanus* (the body louse) and *Pediculus h. capitis* (the head louse).

Phylogeny

Phylogeny may be defined as the history of the evolution of a species or group. While the term can be applied to a particular species or limited group, it is commonly used to refer to lines of descent and relationships within the broader groups of plants or animals.

Phylogeny is, thus, clearly an evolutionary concept, for it is based upon the proposition that organisms of different species and higher groups are, in fact, related by descent from common ancestors. Unfortunately, however, judgments of relationships among organisms are almost always based upon incomplete evidence, for the plants and animals of today are merely the current stage in a continuing process of diversification that has been in progress for more than 3,000,000,000 years. The overwhelming majority of species that have ever lived have long since been extinct and with them the connecting links necessary for the direct demonstration of the descent of modern organisms from common ancestors. Phylogenetic judgments, therefore, are based largely upon indirect evidence and cautious speculation. Different biologists, using much the same data, may arrive at wholly different and sometimes conflicting phylogenies. Biologists are confident that the world of life is the product of organic descent from earlier ancestors and that the true relationships, in principle at least, are discoverable. The various systems of phylogeny are simply each author's best approximations of that true but unattainable phylogeny.

The speculative nature of phylogeny

Phylogeny is the foundation for taxonomy, the science of the classification of organisms. The necessity for classification into species, genera, families, and higher groups derives from the enormous number and variety of species and man's desire to find some convenient and orderly way of grouping them. Were it not possible to classify them into larger groups concerning which generalizations can be made, study of the world of life would be severely limited. The early systems of classification were purely empirical attempts to group organisms according to degree of similarity, without any theoretical basis. Since the publication of the *Origin of Species* by Charles Darwin in 1859, organic descent and relationship have been accepted as the basis for the taxonomic system, and a good taxonomy is one that expresses these relationships best (see CLASSIFICATION, BIOLOGICAL).

THE BASIS OF PHYLOGENY

In principle, every aspect of biology is a product of phylogeny and may shed some light upon phylogenetic relationships, but, in practice, some kinds of data are more useful than others. The more valuable kinds of evidence derive from paleontology, comparative anatomy, comparative embryology, and biochemistry; geographical distribution, study of ultrastructure (electron-microscopic structure of cells), and computer analysis of data may also be useful.

Fossils, the preserved remains of the life of the past, are usually contained in sedimentary rocks, with ancient fossils in the deeper layers and more recent fossils in the superficial layers. Most commonly, only the hard parts of the body (wood, skeleton, and teeth, for example) are preserved; soft parts are generally lost. As a result, the fossil record is often very helpful in determining the phylogeny of groups with extensive hard parts, such as corals, mollusks, starfishes, and vertebrates, but is generally of little help in the study of the numerous soft-bodied groups.

A closely graded series of fossils leading from an ancestral to a descendant group is conclusive evidence of relationship. One of the best known examples of such a series is that of the horses, the fossil record of which begins nearly 60,000,000 years ago with the four-toed *Hyracotherium* (or eohippus), less than a foot high at the shoulder and having low-crowned teeth adapted to browsing on

tender leaves and shoots. The series proceeds by moderate steps to the modern horses, *Equus*, which may stand five feet tall at the shoulder, have only a single toe, and have high-crowned teeth adapted to grazing on hard, gritty grasses. The evidence of direct relationship is clear. (The horse phylogeny also includes several lines of descent that became extinct.)

The importance of comparative studies

Comparative anatomy has been used more extensively than any other source of data for phylogenetic studies. A comparison of the skeletons of the forelimbs of a mole, a bat, and a seal shows that, in spite of their radically different uses, these limbs are all built on the same plan, with variations in size and proportions suited to the life habits of the animals. In each, there is a single, relatively long bone, the humerus ("upper arm"), which joins the shoulder at one end and connects at the other end with two parallel bones, the radius and ulna ("forearm"); next is a cluster of small bones, the carpals ("wrist bones"), which in turn connect with the metacarpals ("palm bones"), and these finally attach to the phalanges ("finger bones").

As it is difficult to believe that such different functions (burrowing, flying, and swimming) would coincidentally be subserved by such similar structures, the inference is strong that these animals are related by descent from a common ancestor. Such structures, in which the same materials have been used in much the same ways, are said to be homologous, and homology is considered to be strong evidence of relationship.

Comparative embryology is essentially the comparative anatomy of development, and it provides similar phylogenetic evidence. The embryos of all terrestrial vertebrates, for example, develop a typical, fishlike set of gill pouches, only to refashion them into such unlike structures as the ear tubes, various glands of the neck region, and the lungs. While this seemingly roundabout pattern is inexplicable on any other grounds, it follows quite logically if it is assumed that the higher vertebrates are descendants of ancient fishes.

Biochemical evidence of relationship originally dealt with such things as enzymes or hormones held in common by organisms of a series. Currently, however, detailed comparisons of the structures of proteins and of deoxyribonucleic acid (DNA, which carries hereditary information) are possible, and these are expected to contribute valuable phylogenetic data.

THE EARLY STAGES OF PHYLOGENY

The earliest stages of phylogeny are intertwined with the origin of life and its early diversification (see LIFE).

Chemical evolution. Fossil remnants of the origin of life are not and presumably never can be known, but much experimentation indicates that the earliest living things were probably products of a long chemical evolution, based upon random reactions of the chemicals of the crust of the earth and of the early atmosphere. As a result, the primeval seas must have become a thin "soup" of many compounds, including some of those characteristic of living organisms. Some of these probably formed complex aggregates, or protein-containing droplets, which, by binding molecules to their surface, could form a membrane, thus permitting the beginnings of individuality. If such a protein droplet with a limiting membrane were to produce more of its own substance—that is, to reproduce—it could rightly be called an elementary organism. In present-day organisms such a process is associated principally with the class of complex molecules called nucleic acids. For this reason, many investigators believe that the beginnings of life could not have preceded the association of nucleic acids (especially DNA) with proteins; others believe that this stage may have been preceded by one based upon self-reproducing proteins alone.

A strand of DNA with a protein sheath would be essentially a virus. Although all known viruses are parasitic, it is conceivable that a free-living virus system could have existed at a time when the waters of the world were rich in many organic compounds that are now found almost exclusively within organisms. As larger self-reproducing units were formed, mutations, or chance variations in DNA, could produce genetically still more complex units, whose increasing numbers would rapidly deplete the primitive stockpile of nutrients in the surrounding water. As each nutrient became scarce, natural selection would favour any units that had become able, by a mutation, to produce the scarce nutrient. Thus, an increasingly complex system of enzymes that could synthesize nutrients would be built up, and with it increasing cell size and structural complexity. The earliest organisms were heterotrophic—that is, they depended upon outside sources of nutrition, primarily by absorbing organic matter from the primitive seas—but later organisms acquired the ability to make their own food (*i.e.*, became autotrophic). These organisms were the earliest bacteria, complete cells with many enzymatic pathways of intermediary metabolism and the capability to store energy as food and release energy when needed by the burning of that food (respiration). The bacteria evolved several nutritional and respiratory systems. Many became heterotrophic, obtaining their nutrients from other organisms, usually by parasitism; others became saprophytic, absorbing dissolved organic matter from decomposing organisms; and still others became autotrophic, synthesizing some or all of their nutritive requirements. They evolved the ability to use several different energy sources, based upon the oxidation of compounds of sulfur, nitrogen, or iron (chemotrophic nutrition). Some of the "sulfur-eating" bacteria contain the green pigment chlorophyll, which absorbs sunlight and provides energy. Bacterial chlorophyll is chemically related to the chlorophyll of higher plants, and it is possible, but by no means certain, that it is genetically related. It differs markedly in that the bacterial chlorophyll is not contained in saclike plastids but is dissolved in the cellular fluid, or cytoplasm; and it does not evolve free oxygen during the energy-storing process. The next step probably was the appearance of the cyanophytes (blue-green algae), typically with a larger mass of cytoplasm than bacteria. Although single-celled, they may form colonies of considerable size. Their green pigment is true chlorophyll, and they show typical plantlike photosynthesis with the evolution of free oxygen (a reaction that stores energy at nearly three times the rate of the best of the chemotrophic reactions). The advent of these blue-green algae, some 2,000,000,000 or 3,000,000,000 years ago, began the increase of the world's free oxygen and paved the way for the development of the higher forms of life. Photosynthesis greatly increased the store of organic compounds and the energy available, while the oxygen atmosphere made possible the highly efficient oxidative metabolism of higher organisms.

Earliest organisms

After the blue-green algae there appeared an extensive array of algae, molds, protozoans, and higher plants and animals. Three groups of algae can be dismissed with passing mention, as they arose from uncertain ancestors and have given rise to no further groups. These groups are the chrysophytes (yellow-green and golden-brown algae, chiefly diatoms); the pyrrophytes (cryptomonads and dinoflagellates); and the rhodophytes, or red algae. Three more have greater phylogenetic importance: the chlorophytes (green algae), which almost certainly gave rise to the land plants—the bryophytes (mosses and liverworts) and the tracheophytes, or vascular plants (including all of the higher plants); the euglenoids (unicellular, flagellate organisms), which suggest a broad connection between plants and animals at this primitive level; and the phaeophytes (brown algae), which some biologists have considered to be a probable source of the animal kingdom. Two groups of molds may have arisen from bacterial ancestors, but they share many characteristics with the protozoans, and they may well have been derived from protozoan ancestors. Finally, the protozoans (unicellular or acellular animals) were derived from unknown, more primitive ancestors, and one or more groups of protozoans have given rise to metazoans, the higher animals.

Algae of phylogenetic importance

The probable main lines of descent. Traditionally, the basic taxonomy of the living world has been dominated by its most conspicuous members—the higher plants and

animals, which contrast obviously in many ways. This dichotomy was formalized by the recognition of two kingdoms, Plantae and Animalia, which were at first thought to encompass the entire world of living beings in two sharply separated groups. When the multicellular algae were studied, they were assigned to the plant kingdom, and many of the protozoans were readily assigned to the animal kingdom. Yet other protozoans and many of the unicellular algae seemed difficult to separate, and it strained the definitions of plant and animal rather severely to include bacteria or blue-green algae in either kingdom, although doubts were generally suppressed in favour of assignment of both groups to the plant kingdom. As to the viruses, it was commonly debated whether they were living at all, and, hence, no assignment to kingdom was made.

Because of these problems, various biologists have suggested that a taxonomy based upon three or four kingdoms would be truer to nature. In one four-kingdom system, the kingdom Mychota comprises the bacteria and the blue-green algae (viruses were excluded on the ground that they were not considered organisms); the kingdom Protoctista comprises the protozoans and all the higher algae except the green algae; the kingdom Plantae comprises the green algae, the bryophytes, and the tracheophytes; and the kingdom Animalia includes only the metazoans, the multicellular animals. In a three-kingdom system, the Mychota (or Monera of some authors) includes the same groups, but the protoctists are considered to have sufficiently clear relationships, some to higher plants and others to higher animals, that they are best assigned to these kingdoms. In another version of a three-kingdom system the kingdom Protista includes monerans, algae, fungi, and protozoans; the kingdom Animalia includes organisms from sponges to echinoderms and chordates; and the kingdom Plantae includes bryophytes and tracheophytes.

Such ideas have long had theoretical interest, but they did not begin to gain wide acceptance until the 1960s, when growing knowledge of the cell structure and genetics of micro-organisms made it clear that there is a marked discontinuity between the bacteria and blue-green algae on the one hand and the cells of all higher organisms on the other. Because of the contrast in structure and behaviour of the nucleus (Greek *karyon*), these most primitive organisms are designated as procaryotes; all higher organisms are designated as eucaryotes. The differences are many and profound. The nuclear material of the procaryotes is not separated from the cytoplasm by a membrane, and, when the cell divides, it does so by simple fission, without the complex division stages (mitosis) so striking in all eucaryote cells. The genetic material is represented by strands of DNA that, unlike the DNA of eucaryotes, is not combined with protein to form typical chromosomes. Genetic evidence, however, proves that the simple division is qualitatively equal; that is, complete sets of genes are passed to the two daughter cells. A sexual process does not occur in procaryotes, although there are several parasexual alternatives whereby genes are transferred from one cell to another. The cytoplasm is similarly very simple in procaryotes. The ribosomes, microscopic globules on which protein synthesis occurs, drift freely in the cytoplasm. There are no storage areas (vacuoles), cellular components such as mitochondria, or plastids for photosynthesis. Flowing, or streaming, of the cytoplasm does not seem to occur. Some bacteria have flagella, extremely fine, whiplike projections by which they can move, but the structure of these is usually much simpler than that of eucaryote flagella.

Procaryotes and eucaryotes

In contrast, all eucaryote cells have a nucleus separated from the cytoplasm by a membrane, and the DNA is bound with large amounts of protein to form chromosomes. They divide by mitosis, a complex division in which chromosomes are duplicated, condensed, arranged on a spindle-shaped temporary structure, then distributed to each of the two resulting nuclei, one member of each duplicated set going to each nucleus. The fusion of sex cells is not universal among eucaryotes, but it does occur in most groups. The cytoplasm of eucaryote cells is filled with fine membranes (the endoplasmic reticulum, visible only with the electron microscope) to which the ribosomes are attached. The cytoplasm also contains a series of components, or organelles, not found in procaryotes: mitochondria, in which respiratory enzymes are located; the basal granules and centrioles, structures upon which the locomotory hairs (cilia and flagella) and mitotic figures are based; and, in some cells, the plastids, which contain the photosynthetic pigment, chlorophyll. The fine structure of eucaryote cilia and flagella consists of a circlet of nine double filaments surrounding two central filaments.

Because of these extensive and fundamental differences, many biologists believe that the divergence between procaryotic and eucaryotic cells is the greatest single discontinuity among organisms. But how was this wide gap bridged? Surely, the eucaryotes must have been derived from procaryote ancestors. One theory of the origin of the eucaryote cell from the procaryote cell is based upon symbiosis, the invasion of one kind of cell by another to the mutual advantage of both cells, much as algae live within the cells of fungi in the lichen partnerships. Perhaps a primitive, heterotrophic procaryote, capable of anaerobic respiration (living without oxygen), ingested an aerobic procaryote, which required oxygen to live. As time passed, the partnership became obligatory, with the captured aerobes functioning as mitochondria, thus effectively conferring the advantages of aerobic respiration upon the host cell. Next, these protamoeba types of organism ingested flagellated procaryotes, which, in time, became flagella or cilia; in many lines of descent, only the basal bodies of the flagellated protozoan remained (with their DNA), and they became centrioles and centromeres, fundamental parts of the mitotic apparatus, the evolution of which thus became possible. Finally, such a cell ingested blue-green algae, which thus became plastids. The cell that was so constructed had effectively become a eucaryote.

The plausibility of such a sequence of symbioses is much enhanced by the fact that all of the organelles mentioned do, in fact, contain DNA, and they are self-reproducing within the eucaryote cell. Based upon this hypothesis of the origin of the eucaryotes, a basic phylogeny can be devised, with four kingdoms. The procaryotes comprise the kingdom Monera. Symbiotic modification of an anaerobic, heterotrophic procaryote would establish the eucaryote cell, the first members of the kingdom Protoctista. Some of these protoctists then formed symbiotic, multicellular associations with blue-green algae. In most of these, the cells of a colony all remained largely equivalent, thus giving rise to the several groups of algae. The green algae, however, showed a tendency to differentiate into specialized cells, and it seems very probable that the kingdom Plantae developed from such cells. Nonphotosynthetic eucaryotes (protamoebans) gave rise to the fungi (protoctists), to the protozoans (also protoctists), and, through one or another group of protozoans, to the kingdom Animalia, comprising all the multicellular animals with specialization of cells and division of labour among the cell types.

There has not been universal agreement on such a four-kingdom phylogeny. Some workers, using an array of biochemical data, derive the green algae and the red algae from the blue-greens by simple differentiation, and all higher plants they derive from the green algae. In such a scheme the single kingdom Plantae includes the procaryotes; by inference, all other organisms would belong to the kingdom Animalia, thus reaffirming the traditional two-kingdom system. A one-kingdom system, with all organisms assigned to the plant kingdom and animals deriving from the same phylogenetic stem as the brown algae, is also a possible arrangement. This interesting hypothesis has not received much support, because it separates widely some organisms that appear to be closely related on other grounds (as different groups of amoeboid protozoans), and it disregards the now well-established contrast between procaryotes and eucaryotes.

Perhaps a three-kingdom system represents a reasonable compromise and synthesis of present knowledge. Under one such system, the kingdom Mychota encom-

The three-kingdom system

passes the viruses, bacteria, and blue-green algae. (The viruses are here included because research has revealed a complex genetic system inconceivable except in an organism.) Viruses contrast with other procaryotes mainly by the absence of intermediary metabolism, for which they depend upon their hosts; however, it is quite usual for parasites to depend upon their hosts for some of the vital functions. The kingdom Plantae would include the eucaryote algae, all derived either directly or through an intermediate from the procaryotes via the symbiotic pathways described earlier; the fungi, which may be a connecting link to the animal kingdom, and the land plants—bryophytes and tracheophytes—both derived from the green algae. The kingdom Animalia would include the protozoans, with broad connections to the plant kingdom via the flagellate-euglenoid and flagellate-green-algan links, and the metazoans, the origin and relationships of which will be discussed below.

MAJOR TRENDS IN THE PHYLOGENY OF PLANTS

Algal predecessors. Whatever the origin of the eucaryote algae, all but the green algae were evolutionary blind alleys, having given rise to no further groups (Figure 1).

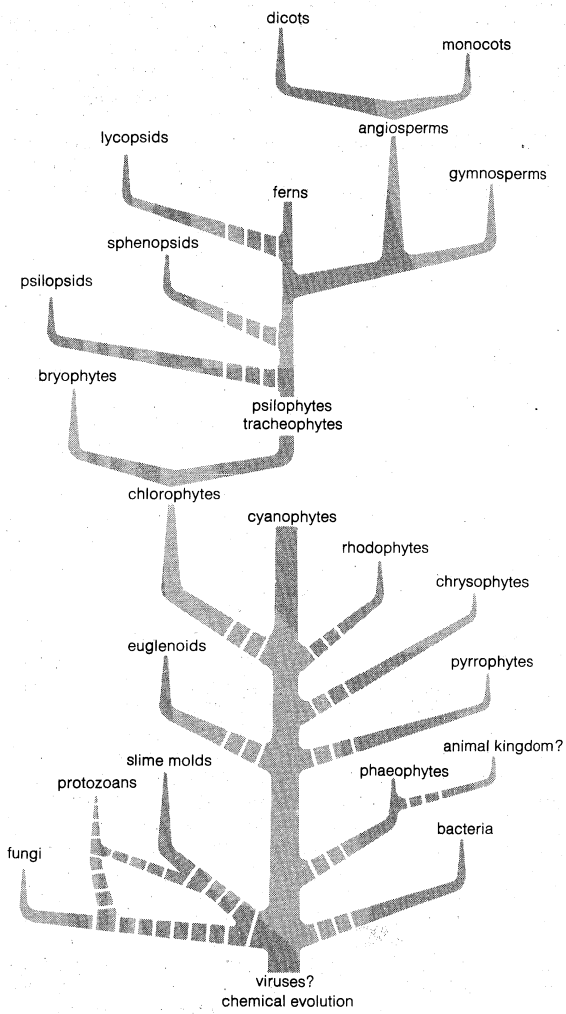

Figure 1: A summary of probable lines of plant evolution.

Although many algae are mainly single celled, most browns and reds are mainly multicellular; some, in fact, form seaweeds of very large size. Their multicellularity, however, has been achieved with a minimum of specialization of cells and of division of labour among them. The larger seaweeds form incipient organs, such as holdfasts and floats, but the body is best interpreted as a thallus, a simple aggregation of more or less similar cells, without specialized roots, stem, leaves, and conducting tissues, and lacking the specialized cell types that such structures require. Accordingly, the eucaryote algae may be grouped together as the subkingdom Thallophyta of the kingdom Plantae.

Connections between plants and animals

There are broad connections between these organisms, at the thallus level, and the animal kingdom, at the protozoan level. An amoeboid phase, for example, is prominent in the life cycles of the fungi, indicating that they probably arose from amoeboid protozoans or that both fungi and protozoans arose from the same primitive, amoeboid, ancestral eucaryote. Finally, it is difficult to draw a clear line between animal flagellates and euglenoids, on the one hand, and animal flagellates and green algae, on the other. To avoid this blurring of the lines between kingdoms, some biologists favour the interposition of the kingdom Protoctista to include the lower eucaryotes. Most algae, however, are so clearly allied to higher plants and most protozoans so clearly allied to animals that it seems better to recognize a certain amount of blurring of boundaries as a normal consequence of origin and diversification by evolution.

The range of variability of the green algae perhaps exceeds the combined ranges of the rest of the eucaryote algae. They may be unicellular (like *Chlamydomonas*), colonial (like *Pandorina*), or multicellular (like *Ulva*). Sexual reproduction is common among green algae and is always accompanied by an alternation of generations, a fundamental phenomenon in which a sexual phase, or gametophyte, containing one set of chromosomes (haploid), alternates with an asexual phase, or sporophyte, containing two sets of chromosomes (diploid).

Within this range of variability of the green algae are included most of the characters of the simpler land plants, although not all occur in any one alga. Indeed, the derivation of land plants from green algae seems to be one of the more secure conclusions of phylogeny.

Land plants. The two main groups of land plants, bryophytes and tracheophytes, are separated by many characteristics, but they also share certain features adaptive to dry-land habitats. Among these is the retention of the embryo within maternal tissue, for which these two groups are assigned to a subkingdom, Embryophyta.

The bryophytes, comprising mosses, liverworts, and hornworts, arose from green algae, have not progressed far beyond them, and have given rise to no further groups. Although they depend upon water for reproduction—for their sperm must swim to the eggs—a mere film of dew is sufficient. The fertilized egg develops within the maternal tissue, and the resulting sporophyte remains attached there even when mature, strictly dependent upon the gametophyte, for only the latter is supplied with chlorophyll. A waxy cuticle protects the exposed parts of the plant against drying.

The bryophytes were certainly derived from green algae. Many of the characteristics of the bryophytes, but not retention of the embryo within maternal tissues and possession of a cuticle, are found in green algae, although the complete ensemble is never found in any one species. Although one group of bryophytes, the hornworts, has progressive characteristics that suggest transitional stages to the vascular plants, it is certain that they did not give rise to the vascular plants, for the latter antedate the bryophytes in the fossil record by at least 100,000,000 years. The hornworts, therefore, must represent a terminal point of bryophyte evolution rather than a starting point for the higher plants.

The tracheophytes constitute a vast and richly varied assemblage that includes all of the dominant plants on earth today. They are characterized by having a dominant sporophyte phase, with the gametophyte reduced to microscopic proportions, and by having vascular elements that transport water and food within the plant. These properties have made possible the development of large plant bodies.

A further trend in the vascular plants has been the differentiation of tissues into roots, stems, and leaves, although this tendency is very tentative among the more primitive members. Finally, among the highest plants, the development of seeds and flowers is a major feature.

While it seems almost certain that the vascular plants arose from the green algae, specific details are not known,

Lignier's theory

and the fossil record has not been helpful. Around the turn of the century, a French botanist, O. Lignier, published a plausible theory that the ancestor of the vascular plants was a branching, filamentous green alga adapted to growing on tidal flats. Algae isolated in drying tide pools generally die, but one of the branches may have penetrated the soil and functioned as a root to supply the plant with water and minerals and, thus, secured its survival; meanwhile, another branch straightened to lift the reproductive parts into the air. A root system, however, could serve only a plant that had conducting tissue. Bundles of vascular tissue developed, forming transport pathways and strengthening the stems. The ends of the branches flattened and formed specialized organs of photosynthesis, the leaves. Finally, a cuticle developed to protect the exposed parts of the plant from drying.

Lignier's theory was purely speculative; nonetheless, fossils of early vascular plants have been found that accord with the theory sufficiently well that some enthusiasts have credited Lignier with describing the critical fossils before they were discovered. The oldest vascular plant known, *Cooksonia*, dates from Late Silurian time, more than 400,000,000 years ago. This simple plant approximates Lignier's hypothetical ancestral vascular plant quite closely. Later, during Early to Middle Devonian time, two other primitive plants appeared: *Psilophyton* and *Rhynia*, collectively called psilophytes. (Some authorities separate *Rhynia* as a group called rhyniophytes.) Fossils of these plants are so well preserved that even the microscopic structure is clearly apparent. The plants consisted largely of a branched, photosynthetic stem with small, spinelike "leaves" and terminal reproductive bodies (sporangia) on the aerial parts and rhizoids on the subterranean parts. The vascular tissue consisted of a simple core of large woody vessels (xylem) surrounded by smaller, thin-walled vessels (phloem).

The importance of the psilophytes derives not only from their antiquity but also from the fact that several genera displayed features that suggest other groups of vascular plants. *Psilophyton*, for example, had small, scalelike projections of the superficial layer of the stem, suggestive of the leaves of the lycopsids, or club mosses. *Hyenia* had whorled branches suggestive of the sphenopsids, or horsetails, and *Pseudosporochnus* had flattened branch tips, suggestive of the leaves of pteropsids, the ferns and flowering plants. It is probable, therefore, that all the principal groups of vascular plants may have arisen from psilophyte ancestors.

A different interpretation was widely advocated in the 1950s and later. Spores and fragments of vascular plants found in very ancient rock layers, or strata, suggest that the major groups of vascular plants must be much older than had been thought. The psilophytes appeared to be rather late offshoots of the most primitive plants rather than an ancestral group. Subsequent studies, however, have not supported this viewpoint. It appears that the fossils themselves, the strata in which they were found, or both, were misidentified; and hence the psilophytes have again taken a central position in the phylogeny of the vascular plants.

Club mosses and horsetails have not produced more progressive groups; however, the evolutionary branch leading from *Rhynia* through such genera as *Pseudosporochnus* and *Trimerophyton* to the ferns was more productive. These genera show a tendency towards flattening of whole branches to form frondlike leaves. Among the ferns, the differentiation into true roots, stem, and leaves is complete, but the stem is generally subterranean.

Seed plants. It will be recalled that one of the characteristics that permitted exploitation of the land was retention of the embryo within the maternal tissue. This trend culminated in the development of seeds. Not only is the embryo retained within the parent gametophyte but the gametophyte in turn is encased in and protected by tissue from the sporophyte that produced it. Thus, every seed includes tissues of three generations: the dominant sporophyte plant; the microscopic gametophyte phase; and the second generation sporophyte, or embryo. The seed ferns are an ancient group that originated in the Devonian Period (ending 345,000,000 years ago) and became extinct during the Mesozoic Era (ending 65,000,000 years ago). Whether they arose from true ferns or whether they developed along with true ferns from similar psilophyte ancestors is not known. In any event, they appear to have been the most primitive members of the gymnosperms.

Gymnosperms. Before they became extinct, the seed ferns gave rise to several distinct groups of gymnosperms, including the conifers (*e.g.*, pines, spruces, firs), which still form an important part of the world's vegetation.

The gymnosperms were the first plants to be independent of water for reproductive purposes. Pollen grains (male gametophytes) are released in large numbers and carried by the wind. Most released are lost, but those that alight on female cones of the same species may germinate and result in the formation of an embryo within the tissue of the female gametophyte. The embryo is encased in maternal tissue layers as the seed.

Angiosperms. The angiosperms, or flowering plants, must have arisen from gymnosperm ancestors, but little is known of their specific antecedents. The evolutionist Charles Darwin described their origin as "an abominable mystery," and it remains so today. The angiosperms appeared in great abundance among fossils of the Cretaceous Period (65,000,000–136,000,000 years ago), and it seems probable that their origin occurred much earlier. There are, indeed, fossils that possibly may be angiosperms of greater age. One of them is *Sanmiguelia*, a palmlike plant from the Triassic Period (190,000,000–225,000,000 years ago) for which no flowers have been uncovered. It is possible that it is not an angiosperm but rather a gymnosperm that approached the angiosperms in several features.

Monocotyledons and dicotyledons

Early in its history, the angiosperm group separated into two subgroups, the dicotyledons (dicots) and the monocotyledons (monocots). The dicots include the majority of flowering plants, and the monocots include lilies, palms, grasses, orchids, and a few related groups. The two subgroups contrast in many characters, of which a few easily observed ones may be mentioned. The flower parts of dicots commonly occur in fours and fives, whereas those of monocots occur in threes and sixes. The leaf veins form a network in the dicots, while those of monocots are more or less parallel. Finally, there are two cotyledons—seedling leaves in the embryo—in dicots and only one in monocots. In general, dicots appear to be more primitive than the monocots, and it is generally believed that monocots arose from some very primitive dicot by reduction of various parts.

It is generally believed—although fossil evidence is inadequate—that primitive flowers were large, with a branchlike axis on which numerous flower parts, rather leaflike in appearance, were spirally arranged. Colours of the petals served to attract insects, which pollinated the flowers. Among living plants, the magnolias approximate this plan most closely. A very general trend has been the reduction in number of floral parts. Among wind-pollinated plants especially, such as grasses, this trend is most obvious: sepals and petals may be reduced or missing altogether, and flowers may be unisexual, with pistils only (female) or stamens only (male). In some cases, flowers may be extremely reduced even though they are insect pollinated. In these, clusters, or inflorescences, of minute flowers (thus increasing the chances of many flowers being fertilized simultaneously) may be set within a whorl of white or coloured leaves that serve to attract insects. Familiar examples include the dogwood, poinsettia, and bunchberry.

Development of bilaterally symmetrical flowers is another important trend. In such flowers an insect enters only one way and is forced to brush against both stamens and stigma; thus, pollination is no longer left to chance. This trend reaches spectacular expression in the orchids among the monocots, but it is also well developed in such dicots as the snapdragon.

Fusion of parts is another common trend. The petals and sepals of trilliums are widely separate; those of Easter lilies are closely approximated to form a trumpetlike flower; and those of scilla are completely fused.

Finally, there is a trend toward aggregation of flowers into clusters. The extreme of this trend is found in the aster, or composite, family, as exemplified by asters, daisies, dandelions, and sunflowers. In this family, clusters of many flowers are gathered into compact heads, each of which resembles a single flower.

MAJOR TRENDS IN THE PHYLOGENY OF ANIMALS

Theories of the origin of animals

The problem of the origin of multicellular animals (metazoa) was long dominated by the gastrea theory of a German embryologist, Ernst Haeckel, who derived the ancestry of higher animals from the various embryological stages leading to their adult form. The higher animals, or metazoans, were believed to have come ultimately from some spherical, colonial protozoan comparable to *Volvox*. Such a hypothetical organism, called a gastread, was thought to have been structurally similar to the coelenterates (jellyfishes, corals), to which Haeckel accorded a key role in animal phylogeny. The theory, however, fell into disrepute, for it overvalued embryological evidence and undervalued other lines of evidence. In addition, the theory equated embryological stages of advanced animals with ancestral adults and assumed that embryos reflected ancestry undisturbed by adaptations to embryonic life; neither hypothesis is valid.

There are two major alternative theories. One derives the metazoans from colonial flagellates by integration of cells, leading to a flattened, ciliated animal (a planula) that gave rise to the coelenterates and, perhaps through them, to the flatworms. A minor group of parasitic worms, the mesozoans, retain planuloid structure even as adults. Whether mesozoan simplicity is primitive, or whether they have degenerated from flatworm ancestors is controversial.

The other theory derives the Metazoa from many-nucleated protozoans that subdivided into cells. This resulted first in a simple flatworm, to which is given the same importance that Haeckel gave the coelenterates. Some see close parallels between ciliates and flatworms in symmetry, excretion, reproduction, and in other respects; others feel that these similarities strain the facts. The theory suggests that flatworms gave rise to the coelenterates regressively and to all higher groups progressively.

Decisive data on these theories may never be available. Some biologists have suggested that perhaps neither is valid and that the earliest metazoans were an unknown group of planuloid worms that gave rise to coelenterates, flatworms, and mesozoans.

Several other possibilities deserve brief mention. Some biologists have suggested that the metazoans have arisen regressively from multicellular plants by loss of chlorophyll. The sudden appearance of most major groups of animals in the Cambrian Period (500,000,000–570,000,000 years ago) suggests to some that all or many of these groups may have arisen more or less simultaneously from some undefined ancestral form, probably at the procaryote level.

Changes in body plan: the lower metazoans. *Symmetry.* Symmetry, the geometrical distribution of parts about an axis, characterizes most animals. If there is a single longitudinal axis, so that any plane passing through it divides the animal into equivalent parts, radial symmetry obtains. The longitudinal axis usually includes the mouth. Radially symmetrical animals generally have a definite number of radii defined by structures (often four in jellyfishes, five in starfishes). In some protozoans and in the comb jellies, there are, in addition to the principal longitudinal axis, two secondary axes at right angles to each other and to the main axis. These axes differ structurally and are called the sagittal and transverse (*i.e.*, side-to-side) axes. A plane including the longitudinal axis and either of the other two will divide such a biradial animal into equal parts. Bilateral symmetry characterizes most animals. The same three axes are present as in radial symmetry, but the sagittal axis lies in such a way that dorsal (back) and ventral (belly) surfaces are defined. Only the plane that includes the longitudinal and sagittal axes divides the animal into equivalent parts, the right and left halves.

Some protozoans and most sponges (which are certainly derived from flagellate protozoans) are asymmetrical. Most protozoans, however are radial, without radii defined by specific structures, as in the mesozoans. Coelenterates, whether as jellyfishes or polyps, are radially symmetrical. Anemones and corals may show limited bilaterality defined only by the position of the mouthparts. This may be a minor overlay, of little significance, upon their basic radiality; but some regard it as a highly significant inheritance from flatworm ancestors, which were strongly bilateral. Their radial characteristics are considered to follow from their sedentary mode of life, for sessile animals meet the environment equally from all directions. There has been no loss of radiality in jellyfishes, however, which are highly mobile.

Asymmetrical animals

The flatworms are bilaterally symmetrical, and they are easily derivable from an ancestor with a single longitudinal axis, round in cross section, and with no defined radii. If such an animal were to become a bottom feeder, with a mouth on the under surface, the worm would tend to flatten against the surface, thus defining the secondary axes of bilateral symmetry.

Bilateral symmetry must have great selective value, for it characterizes all higher groups except the echinoderms (*e.g.*, starfishes, sea cucumbers). It is noteworthy that the larvae of echinoderms are bilateral, and it appears that their present radiality was a secondary acquisition.

The lower metazoans show a gradual progression to higher levels of organization. All metazoans are, of course, multicellular, but the sponges are at the cellular level in the sense that their cells are scarcely integrated into higher units. There are no clearly defined tissues, no organs, and scarcely more individuality than that of a protozoan colony. For these reasons and others, it is probable that the sponges are an isolated offshoot of colonial flagellates, unrelated to other metazoans. They are the sole members of the subkingdom Parazoa, the entire remaining assemblage of animals being members of the subkingdom Eumetazoa.

Development of tissues and organs. Three groups—the mesozoans, coelenterates, and ctenophores—are at the tissue level; that is, their cells are integrated into two tissues, an outer ectoderm, serving protective and sensory functions, and an inner entoderm, serving a digestive function (except in Mesozoa, in which the inner cells are reproductive). Generally, there are no organs in animals classified at the tissue level, but coelenterates and ctenophores may have fairly complex canal systems developed from the gastrovascular (digestive) cavity as well as an uncentralized nerve net and sensory organs of equilibrium. Their cell layers are separated by a greater or lesser amount of a jelly called mesoglea. There are generally some cells in the mesoglea, and in anemones they may be so abundant that they actually constitute a third cell layer, the mesoderm. There are no mesodermal organs as such, however, in these animals.

Animals organized at the organ level

The flatworms and all higher groups are at the organ level of construction. In general, the skin, sensory organs, and nervous system are formed from ectoderm; the lining of the digestive tract and the digestive glands from entoderm; and the rest of the organs from mesoderm. There is no body cavity in flatworms, but in most higher groups the principal organs are contained within a cavity (coelom) in the mesoderm. Scarcely advanced beyond the flatworms is a cluster of groups, sometimes treated as a rather loosely related group called aschelminths, in which the organs are held within highly vacuolated cells, forming what is termed a pseudocoel. In most higher groups, however, there is a true coelom, a cavity within the mesoderm and limited by a membrane called the peritoneum. Suspended within the coelom are most of the organ systems. The coelom is most striking in the annelids (segmented worms), the echinoderms, and the chordates (vetebrates and their lesser relatives).

Cephalization and segmentation. Cephalization (literally head formation) is another important trend in bilaterally symmetrical animals. The central nervous system, sense organs, and mouth are all clustered at the anterior end of the body. This tendency begins with the

flatworms, which have a simple head with an elementary brain, eye spots, and chemically sensitive lobes. In most invertebrate groups, this plan is varied in details without major improvements, but in annelid worms the central nervous system is more highly developed and the dominance of the brain more pronounced. In the arthropods (*e.g.*, insects, crustaceans), one of the most successful groups, cephalization is highly advanced, with the head including a well-developed brain, eyes, two pairs of sensory antennae, and, of course, the mouth and jaws. Some mollusks are retrograde in respect to cephalization, but one class, the Cephalopoda (octopuses, squids), have a highly developed brain and complex eyes; the head, however, is inseparably fused with the large fleshy portion called the foot. The head of chordates is the pinnacle of cephalization and includes a large brain, eyes, ears, nose, and mouth.

Segmentation of the body, with repetition of structures in every segment, is maximal in the annelids but is also prominent in the arthropods and chordates. Mollusks are generally unsegmented, but the Monoplacophora, a very ancient class of mollusks with but one known living member, are definitely segmented, suggesting that primitive segmentation was suppressed in the formation of the modern mollusks. Only the larvae of echinoderms show limited segmentation, as do some minor groups.

The origin of segmentation is conjectural. Possibly it arose as a response of the muscular system of an elongate animal to the demands of swimming, especially against the current of a stream. Serpentine swimming movements would be favoured by muscles arranged in blocks on either side of the body, capable of contracting in succession along the length of the body. This in turn would require segmental nerves from the nerve cord, and other systems might follow. In the annelids, almost every system is segmentally arranged; but in arthropods and chordates, segmentation is partially obscured by formation of complex structures from the rudiments of many segments and by suppression of some organs of many of the segments. It is probable that segmentation arose independently in the two lines of descent: annelid–arthropod and echinoderm–chordate.

Phylogenetic lines: the higher metazoans. *Monophyletic versus diphyletic theories.* With respect to lineage among higher animals, two major viewpoints are current. In the monophyletic theory, all of the metazoans are assigned to four groups, which arose in simple monophyletic, or linear, sequence from lower to higher. The theory is based on comparative anatomy, especially of the coelom and of segmentation. All of those organisms that are unsegmented and lack a true coelom, including flatworms, coelenterates, various minor groups, and even the mollusks, are assigned to the Ameria (meaning lacking segments). The strongly segmented annelids and arthropods, together with several minor groups, are presumed to have been derived from the Ameria and constitute the Polymeria. Some polymerians, such as the wormlike echiuroids and sipunculids, show a reduction of segmentation and thus lead to the Oligomeria, a group that includes insects, echinoderms, and several minor forms. The fourth group constitutes the chordates under the name of Chordonia.

The 18th-century chain of being

The originality of this theory is its greatest strength, but it goes back to the 18th-century idea of a *scala naturae*, or great chain of being, in which groups succeed one another on a linear ladder of life. These groups, however, include animals too highly diverse for most biologists to accept as being closely related. Much of the biology of mollusks and coelenterates, for example, would have to be overlooked to place them in one group under this definition.

The alternative—diphyletic—theory has been proposed by many zoologists. It envisions the higher metazoans as developing in two principal lines of descent—one culminating in the annelids, arthropods, and mollusks; the other in the echinoderms and chordates (Figure 2). The origin of these two lines has been referred to most of the lower noncoelomate groups, but it seems most probable that they took their origin from some ancient group of flatworms from which the modern flatworms also arose.

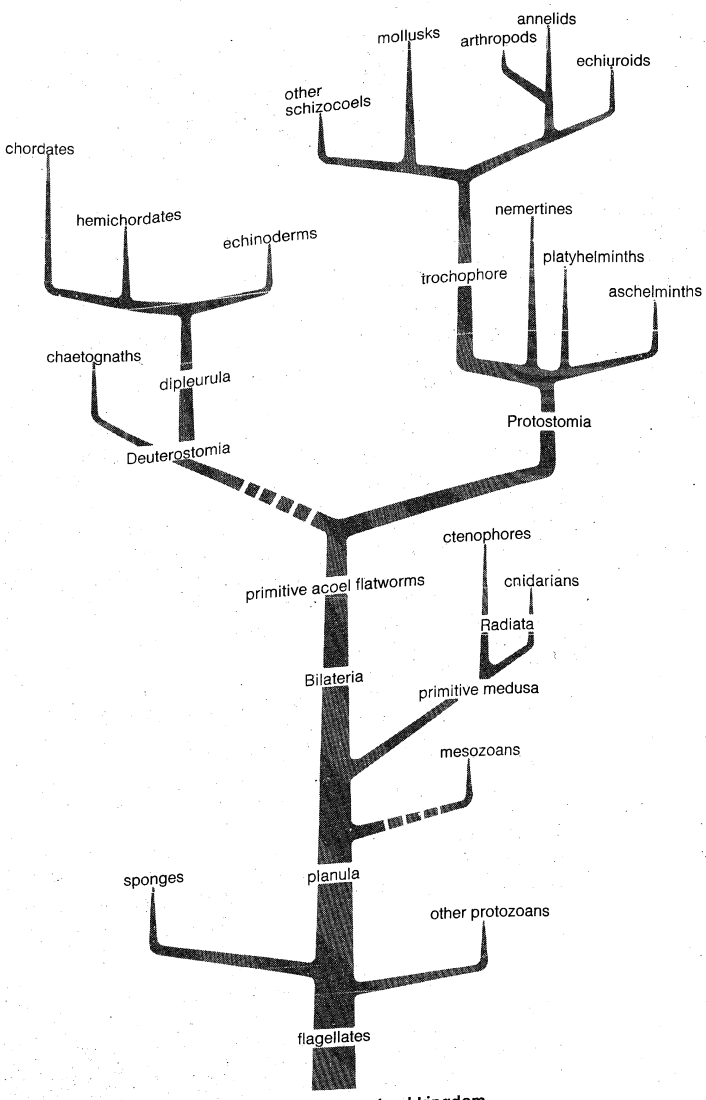

Figure 2: Hypothetical relationships in the animal kingdom.

The adult anatomies of animals in the annelid–arthropod line are strongly divergent, yet these organisms agree in many embryological traits; and a similar type of larva, called a trochophore, is common to all but the arthropods. The cleavage divisions (earliest divisions of the egg) are spiral, and they are determinate; *i.e.*, specific cells are destined to form predetermined structures. The coelom is called a schizocoel because it is formed by the splitting of the mesodermal cell mass. Finally, the embryonic mouth, or blastopore, becomes the mouth of the adult. This is the basis of the name of this line of descent, the Protostomia ("first mouth").

By contrast, the Deuterostomia show neither spiral nor determinate cleavage. Mesoderm and coelom are established at one stroke by outpocketings from the embryonic gut. The mouth is a new opening (hence the name Deuterostomia); the anus may be formed from the blastopore, or it too may form anew. Finally, there is no larval type common to all the deuterostomes (although one, the dipleurula, is common among lower deuterostomes).

Adaptive radiation. Both series show a radiation of lines of descent that exploit widely diverse structural plans and modes of life; for this reason the adults are difficult to compare, and relationships between the major groups must be proposed rather tentatively. The annelids and arthropods, however, are an exception. They share the protostome developmental characters as well as some adult traits, such as segmentation. As different as a typical worm and an arthropod such as an insect may appear, however, there is a minor group, the wormlike onychophorans, which is so nearly intermediate that the inference of close relationships is most suggestive.

The origin of chordates

The origin and phylogeny of the chordates hold especial interest, for this group climaxes the deuterostome series and includes man. Almost every invertebrate group has been considered as a source of the chordates, but the balance of evidence favours a common origin with the echinoderms, unexpected as this may seem. Chordates and echinoderms share the basic deuterostome traits. Further, the larvae of starfishes and of hemichordates (presumed lower chordates) are so similar that when the latter were first discovered, they were described as larval starfishes. The chordates are defined by three fundamental structures: a dorsal nerve tube (brain and spinal cord of vertebrates); a notochord (a supporting rod under the nerve tube); and a pharynx perforated by gill slits, at least in the embryo. The last of these is clearly developed in hemichordates, but the first two are equivocal. In balance, the hemichordates appear as a distinct group closely related to the chordates and sharing a common origin with them. Probably in Precambrian times a dipleurula-like bilateral deuterostome gave rise to two divergent lines of descent: one led to the aberrant echinoderms; the other to the more typical hemichordates and the very progressive chordates. In this line, a mutant with gill slits occurred and was favoured by selection, probably because the dipleurula was already a particle feeder; gill slits made it possible to sieve large quantities of water to extract food particles (still the principal function of gill slits in primitive chordates).

Which early chordates gave rise to the vertebrates is uncertain, but a good case has been made for the tunicates, the larvae of which show the three chordate characters with simple clarity. The earliest vertebrates were the ostracoderms, essentially "armoured lampreys" of the Ordovician Period (about 500,000,000 to 430,000,000 years ago) lacking both paired fins and jaws. They gave rise to the jawed placoderms, which had not only paired pectoral and pelvic fins but also, in some cases, a series of lesser fins between these.

Placoderms soon gave rise to sharks and to bony fishes in both salt water and fresh water. The bony fishes diversified greatly to dominate the waters of the world. They formed two groups: the ray-finned fishes, with basal bones and musculature of the fins entirely within the body wall; and the lobe-finned fishes, with the basal bones and muscles extending far into the fin itself. One group of the lobe-fins evolved into primitive amphibians during the Devonian Period. The amphibians had been preceded on land by plants and certain invertebrates. Feeding upon the latter, breathing by lungs and across the moist skin, and moving by means of lobe-fins that had become legs, the amphibians made their way upon the land. Still, because they had no protection against water loss across the skin, they were restricted to moist habitats and remained completely dependent upon water for reproduction.

Some of the early amphibians gave rise to reptiles, a group that completed the transition to dry land. A dry, hardened, outer layer of the skin restricted water loss, and the reptilian egg included membranes that enveloped the embryo and kept it bathed in fluid, thus freeing these animals of the water. Meanwhile, the reptilian limbs developed along the lines that were initiated by their amphibian ancestors.

Reptiles achieved their maximal development with the great array of dinosaurs during the Mesozoic Era, at the end of which the dinosaurs became extinct and the smaller types continued. During their greatest period of radiation, reptiles gave rise to birds and mammals. The former have many reptilian features, including hardened, scaly skin on their legs.

The mammals greatly modified reptilian structure. Three main examples may be cited. The limbs were rotated under the body, then modified adaptively in the many orders of mammals. Second, jaw structure was much simplified, and bones formerly part of the jaw suspension were relegated to the middle ear. Finally, the teeth, simple and uniform in other vertebrates, were differentiated into three types—incisors, canines, and molars—and these were further adapted to the widely different diets among the many mammalian orders.

SOME PHYLOGENETIC GENERALIZATIONS

The Precambrian fossil record consists largely of blue-green algae. Only late in the Precambrian do some invertebrates appear, and the dating of these has been disputed. Then suddenly in the Cambrian (beginning about 570,000,000 years ago) most major groups of invertebrates burst forth in profusion. Was their appearance really so sudden, or is the fossil record, which is always fragmentary, so extremely deficient at that great age that a once richly varied assemblage of life now appears almost monotypic? For more than a century, it was assumed that the Cambrian outburst was the product of a long development, the record of which had been lost. Recently, however, a highly plausible alternative theory has gained acceptance. As stated earlier, the primitive atmosphere was oxygen free, and oxygen began to accumulate only after the advent of photosynthesis. Perhaps it was only in Late Precambrian time that the oxygen level became high enough to support oxygen-breathing animals. Then, with almost all ecological positions (niches) for metazoans unoccupied, the major types evolved to fill those vacancies with startling rapidity. The Cambrian burgeoning may have been an unparalleled outburst of phylogenetic evolution.

The value of mutant types

Any group of organisms, if at all successful, produces an array of mutant types, which are tested by natural selection. The majority prove of no value in adapting the group to its shifting conditions of life, and so they tend to disappear. Occasional mutants, however, improve adaptive efficiency in some way, and these compete more successfully and contribute disproportionately more of their traits to succeeding generations. Different sets of mutant adaptations are favoured in different populations. As a result, an originally uniform group tends to fan out adaptively to occupy the widest possible range of available habitats. This positive drive toward diversification at all levels is called adaptive radiation.

After the origin of the eucaryotes, several groups of algae were quickly evolved and exploited a wide variety of aquatic habitats. One of these—the chlorophytes—was especially successful in its adaptive radiation, and its variants included protobryophytes and protopsilophytes. The latter radiated four principal adaptive types of vascular plants. One of these, the pteropsids, differentiated into three major types—ferns, gymnosperms, and angiosperms. The latter, especially, have radiated to form a large number of orders, families, and lower groups that collectively keep the world green.

More primitive groups, of course, give rise to more advanced groups, but it is noteworthy that it is not the advanced members of a group that produce new groups but, rather, the more primitive and less specialized members. For example, the early, primitive placoderms gave rise to the bony fishes and sharks. The lobe-finned fishes that blended into the amphibians were themselves primitive among the bony fishes. Similarly, the mammals arose from primitive, unspecialized reptiles.

The data and conclusions of phylogeny show clearly that the world of life is the product of a historical process, an evolution, and that degrees of resemblance within and between groups correspond to degrees of relationship by descent from common ancestors. A fully developed phylogeny is essential for the devising of a taxonomy that reflects the natural relationships within the world of living things.

Physical Sciences, History of

The physical sciences are the refined and systematic results of man's efforts to understand his inorganic environment. At any given time, the character of these sciences is determined by and helps to determine the conceptual framework in which they are enmeshed: assumptions about the ultimate constitution of the world, what we are able to find out about the world, and what sorts of terms are appropriate for scientific explanations.

Problems in history of science

Because of the constantly changing foundations of science, the writing of its history presents several knotty problems. Although it is difficult not to judge the significance of past achievements in terms of currently acceptable theories, it is, nevertheless, profoundly ahistorical to do so. Obsolete theories that appear nonscientific and mystical today are usually better regarded as the result of an entirely different conception of nature rather than as aberrations of an unscientific frame of mind. To overlook this difficulty is to overlook the fact that the history of science should indeed be history. Since only a brief survey of the field can be made in this article, the problem of the selection of materials is most pressing. To portray something of the larger patterns of historical development, it is necessary to overlook many important and interesting chapters in the history of the several sciences.

ANCIENT SCIENCE

The physical sciences ultimately derive from the rationalistic materialism that emerged in classical Greece, itself an outgrowth of magical and mythical views of the world. The Greek philosophers of the 6th and 5th centuries BC abandoned the animism of the poets and explained the world order in terms of ordinarily observable natural processes. These early philosophers posed the broad questions that still underlie science: how did the world order emerge from pre-existing chaos? What is the origin of multitude and variety in the world? How can motion and change be accounted for? What is the relation between form and matter? Culminating in the philosophy of Aristotle in the 4th century BC, Greek philosophy answered these questions in terms that provided the framework for science for nearly 2,000 years.

Astronomy. Western astronomy had its origins in Egypt and Mesopotamia. Egyptian astronomy, which was neither a very well-developed nor an influential study, was largely concerned with time reckoning. Its main lasting contribution was the civil calendar of 365 days, consisting of 12 months of 30 days each and five additional festival days at the end of each year. This calendar played an important role in the history of astronomy, allowing astronomers to calculate conveniently the precise number of days between any two sets of observations.

Babylonian astronomy, dating back to about 1800 BC, constitutes one of the earliest systematic, scientific treatments of the physical world. In contrast to the Egyptians, the Babylonians were interested in the accurate prediction of several astronomical phenomena, especially the first appearance of the new Moon. Using the zodiac as a reference system, by the 4th century BC they developed a complex system of arithmetic progressions and methods of approximation by which they were able to predict first appearances. At no point in the clay tablets comprising the Babylonian astronomical literature is there the least evidence of the use of geometric models. The mass of observations they collected and their mathematical methods were important contributions to the later flowering of astronomy among the Greeks.

The Pythagoreans (5th century BC) were responsible for one of the first Greek astronomical theories. Believing that the order of the cosmos is fundamentally mathematical, they held that man is able to discover the harmonies of the universe by contemplating the regular motions of the heavens. Postulating a central fire about which all the heavenly bodies including the Earth revolve, they constructed the first physical model of the solar system. Subsequent Greek astronomy derived its character from a comment ascribed to Plato, in the 4th century BC, who is reported to have instructed the astronomers to "save the phenomena" in terms of uniform circular motion; that is, he urged them to develop predictively accurate theories using only various combinations of uniform circular motion. As a result, Greek astronomers never regarded their geometrical models as true or as being physical descriptions of the machinery of the heavens. They regarded them simply as instruments or tools, useful for predicting planetary positions.

Eudoxus of Cnidus (4th century BC) was the first of the Greek astronomers to rise to Plato's challenge. He developed a theory of homocentric spheres, a model that represented the universe by sets of nesting concentric spheres the motions of which combined to produce the planetary and other celestial motions. Using only uniform circular motions, Eudoxus was able to "save" the rather complex planetary motions with some success. His theory required four homocentric spheres for each planet and three each for the Sun and Moon. The system was modified by Callippus, a student of Eudoxus, who added spheres to improve the theory, especially for Mercury and Venus. Aristotle, in formulating his cosmology, adopted Eudoxus' homocentric spheres as the actual machinery of the heavens. The Aristotelian cosmos was like an onion consisting of a series of some 55 spheres nested about the Earth, which was fixed at the centre. In order to unify the system, Aristotle added spheres in order to "unroll" the motions of a given planet so that they would not be transmitted to the next inner planet.

Failures of Aristotelian astronomy

The theory of homocentric spheres failed to account for two sets of observations: (1) brightness changes suggesting that planets are not always the same distance from the Earth and (2) bounded elongations (that is, Venus is never observed to be more than about 48° and Mercury never more than about 24° from the Sun). Heracleides of Pontus (4th century BC) attempted to solve these problems by having Venus and Mercury revolve about the Sun, rather than the Earth, and having the Sun and other planets revolve in turn about the Earth, which he placed at the centre. In addition, to account for the daily motions of the heavens, he held that the Earth rotates on its axis. Heracleides' theory had little impact in antiquity except perhaps on Aristarchus of Samos (3rd century

BC), who apparently put forth a heliocentric hypothesis similar to the one Copernicus was to propound in the 16th century. Aristarchus' system was rejected for both astronomical and physical reasons.

Hipparchus (flourished 130 BC) made extensive contributions to both theoretical and observational astronomy. Basing his theories on an impressive mass of observations, he was able to work out theories of the Sun and Moon that were more successful than those of any of his predecessors. His primary conceptual tool was the eccentric circle, a circle of which the Earth is at some point eccentric to the geometric centre. He used this device to account for various irregularities and inequalities observed in the motions of the Sun and Moon. He also proved that the eccentric circle is mathematically equivalent to a geometric figure called an epicycle-deferent system, a proof probably first made by Apollonius of Perga a century earlier. Among his observations, one of the most significant was that of the precession of the equinoxes; that is, a gradual apparent increase in longitude between any fixed star and the equinoctial point (either of two points on the celestial sphere where the celestial equator crosses the ecliptic).

Claudius Ptolemy (flourished AD 140) applied the theory of epicycles to compile a systematic, detailed, and quantitative account of the whole realm of Greek astronomy. He elaborated theories for each of the planets, as well as for the Sun and Moon. His theory generally fitted the data available to him with a good degree of accuracy, and his book, the *Almagest*, became the vehicle by which Greek astronomy was transmitted to astronomers of the Middle Ages and Renaissance. It essentially molded astronomy for the next millennium and a half.

Greek physics. Several kinds of physical theories emerged in ancient Greece, including both generalized hypotheses about the ultimate structure of nature and more specific theories that considered the problem of motion from both metaphysical and mathematical points of view. Attempting to reconcile the antithesis between the underlying unity and apparent multitude and diversity of nature, the Greek atomists Leucippus (mid-5th century BC), Democritus (late 5th century BC), and Epicurus (late 4th and early 3rd century BC) asserted that nature consists of immutable atoms moving in empty space. According to this theory, the various motions and configurations of atoms and clusters of atoms are the causes of all the phenomena of nature.

The first atomists

In contrast to the particulate universe of the atomists, the Stoics (principally Zeno, of Citium, bridging 4th and 3rd centuries BC, Chrysippus [3rd century BC], and Poseidonius of Apamea [flourished *c.* 100 BC]) insisted on the continuity of nature, conceiving both space and matter as continuous and as infused with an active, air-like spirit—pneuma—which serves to unify the frame of nature. The inspiration for the Stoic emphasis on pneumatic processes probably arose from earlier experiences with the "spring" (*i.e.*, compressibility and pressure) of the air. Neither the atomic theory nor Stoic physics survived the criticism of Aristotle and the dominance of his theory over later developments.

In his physics, Aristotle was primarily concerned with the philosophical question of the nature of motion as one variety of change. He assumed that a constant motion requires a constant cause; that is to say, as long as a body remains in motion, a force must be acting on that body. He considered the motion of a body through a resisting medium as proportional to the force producing the motion and inversely proportional to the resistance of the medium. He used this relationship to argue against the possibility of the existence of a void, for in a void resistance is zero, and the relationship loses meaning. He considered the cosmos to be divided into two qualitatively different realms, governed by two different kinds of laws. In the terrestrial realm, within the sphere of the Moon, rectilinear up and down motion is characteristic. Heavy bodies, by their nature, seek the centre and tend to move downward in a natural motion. It is unnatural for a heavy body to move up, and such unnatural or violent motion requires an external cause. Light bodies, in direct contrast, move naturally upward. In the celestial realm, uniform circular motion is natural, thus producing the motions of the heavenly bodies.

Archimedes (3rd century BC) fundamentally applied mathematics to the solution of physical problems and brilliantly employed physical assumptions and insights leading to mathematical demonstrations, particularly in problems of statics and hydrostatics. He was thus able to derive the law of the lever rigorously and to deal with problems of the equilibrium of floating bodies.

SCIENCE IN THE MIDDLE AGES

Greek science reached a zenith with the work of Ptolemy in the 2nd century AD. The lack of interest in theoretical questions in the Roman world reduced science in the Latin West to the level of predigested handbooks and encyclopaedias that had been distilled many times. Social pressures, political persecution, and the anti-intellectual bias of some of the early Church Fathers drove the few remaining Greek scientists and philosophers to the East. There they ultimately found a welcome when the rise of Islām in the 7th century stimulated interest in scientific and philosophic subjects. Most of the important Greek scientific texts were preserved in Arabic translations. Although the Arabs did not alter the foundations of Greek science, they made several important contributions within its general framework. When interest in Greek learning revived in western Europe during the 12th and 13th centuries, scholars turned to Islāmic Spain for the scientific texts. A spate of translations resulted in the revival of Greek science in the West and coincided with the rise of the universities. Working within a predominantly Greek framework, scientists of the late Middle Ages reached high levels of sophistication and prepared the ground for the scientific revolution of the 16th and 17th centuries.

Arab contributions

Mechanics was one of the most highly developed sciences pursued in the Middle Ages. Operating within a fundamentally Aristotelian framework, medieval physicists criticized and attempted to improve many aspects of Aristotle's physics.

The problem of projectile motion was a crucial one for Aristotelian mechanics, and the analysis of this problem represents one of the most impressive medieval contributions to physics. Because of the assumption that continuation of motion requires the continued action of a motive force, the continued motion of a projectile after losing contact with the projector required explanation. Aristotle himself had proposed explanations of the continuation of projectile motion in terms of the action of the medium. The ad hoc character of these explanations rendered them unsatisfactory to most of the medieval commentators, who nevertheless retained the fundamental assumption that continued motion requires a continuing cause.

The most fruitful alternative to Aristotle's attempts to explain projectile motion resulted from the concept of impressed force. According to this view, there is an incorporeal motive force that is imparted to the projectile, causing it to continue moving. Such views were espoused by John Philoponus of Alexandria (flourished 6th century), Avicenna, the Persian philosopher (died 1037), and the Arab Abū al Barakāt al-Baghdādi (died 1164). In the 14th century the French philosopher Jean Buridan developed a new version of the impressed-force theory, calling the quality impressed on the projectile "impetus." Impetus, a permanent quality for Buridan, is measurable by the initial velocity of the projectile and by the quantity of matter contained in it. Buridan employed this concept to suggest an explanation of the everlasting motions of the heavens.

A group of Oxford scholars in the 14th century, considering the philosophical problem of how to describe the change that occurs when qualities increase or decrease in intensity, were led to consider the kinematic aspects of motion. Dealing with these problems in a purely hypothetical manner without any attempt to describe actual motions in nature or to test their formulas experimentally, they were able to derive the result that in a uniformly accelerated motion, distance increases as the square of the time.

Criticism of Aristotle

Although medieval science was deeply influenced by Aristotle's philosophy, adherence to his point of view was by no means dogmatic. During the 13th century, theologians at the University of Paris were disturbed by certain statements in Aristotle that seemed to imply limitations of God's powers as well as other statements, such as the eternity of the world, that stood in apparent contradiction to scripture. In 1277, Pope John XXI condemned 219 propositions, many from Aristotle and St. Thomas Aquinas, which had clearly theological consequences. Many of the condemned propositions had scientific implications as well. For example, one of the condemned propositions states, "That the first cause (*i.e.*, God) could not make several worlds." Although it is unlikely that anyone in the Middle Ages actually asserted the existence of many worlds, the condemnation led to the discussion of that possibility, as well as other important problems such as the possibility of the Earth's moving. In a backhanded way, the condemnations of 1277 may have stimulated a wider discussion of scientific and cosmological questions in the late Middle Ages.

THE SCIENTIFIC REVOLUTION

During the 15th, 16th, and 17th centuries scientific thought underwent a revolution. A new view of nature emerged, replacing the Greek view that had dominated science for almost 2,000 years. Science became an autonomous discipline, distinct from both philosophy and technology, and it came to be regarded as having utilitarian goals. By the end of this period, it may not be too much to say that science had replaced Christianity as the focal point of European civilization. Out of the ferment of the Renaissance and Reformation there arose a new view of science, bringing about the following transformations: the re-education of common sense in favour of abstract reasoning; the substitution of a quantitative for a qualitative view of nature; the view of nature as a machine rather than an organism; the development of an experimental method that sought definite answers to certain limited questions couched in the framework of specific theories; the acceptance of new criteria for explanation, stressing the "how" rather than the "why" that had characterized the Aristotelian search for final causes.

Astronomy. The scientific revolution began in astronomy. Although there had been earlier discussions of the possibility of the Earth's motion, Nicolaus Copernicus was the first to propound a comprehensive heliocentric theory, equal in scope and predictive capability to Ptolemy's geocentric system. Motivated by the desire to satisfy Plato's dictum, Copernicus was led to overthrow traditional astronomy because of its alleged violation of the principal of uniform circular motion and its lack of unity and harmony as a system of the world. Relying on virtually the same data as Ptolemy had possessed, Copernicus turned the world inside out, putting the Sun at the centre and setting the Earth into motion around it. Copernicus' theory, published in 1543, possessed a qualitative simplicity that Ptolemaic astronomy appeared to lack. To achieve comparable levels of quantitative precision, however, the new system became just as complex as the old. Perhaps the most revolutionary aspect of Copernican astronomy lay in Copernicus' attitude toward the reality of his theory. In contrast to Platonic instrumentalism, Copernicus asserted that to be satisfactory astronomy must describe the real, physical system of the world.

Reception of Copernican view

The reception of Copernican astronomy amounted to victory by infiltration. By the time large-scale opposition to the theory had developed in the Church and elsewhere, most of the best professional astronomers had found some aspect or other of the new system indispensable. Copernicus' book *De revolutionibus orbium coelestium, libri VI* ("Six Books on the Revolutions of the Celestial Orbs") became a standard reference for advanced problems in astronomical research, particularly for its mathematical techniques. Thus, it was widely read by mathematical astronomers, in spite of its central cosmological hypothesis, which was widely ignored. In 1551 the German astronomer Erasmus Reinhold published the *Tabulae prutenicae* ("Prutenic Tables"), computed by Copernican methods. The tables were more accurate and more up-to-date than their 13th-century predecessor and became indispensable to both astronomers and astrologers.

In the 16th century the Danish astronomer Tycho Brahe, rejecting both the Ptolemaic and Copernican systems, was responsible for immense changes in observation, unwittingly providing the data that ultimately decided the argument in favour of the new astronomy. Using larger, more stable, more rigid, and better calibrated instruments, he observed regularly over extended periods of time, thereby obtaining a continuity of observations that were accurate for planets to within about one minute of arc—better by several factors than any previous observations. Several of Tycho's observations contradicted Aristotle's system: a nova, which appeared in 1572, exhibited no parallax and was thus contrary to the Aristotelian assertion of the immutability of the heavens; similarly, a succession of comets appeared to be moving freely through a region that was supposed to be filled with solid, crystalline spheres. Tycho devised his own world system, which was a modification of Heracleides', to avoid various undesirable implications of both the Ptolemaic and Copernican systems.

Johannes Kepler, at the end of the 16th century, placed the Copernican hypothesis on firm astronomical footing. Converted to the new astronomy as a student and deeply motivated by a neo-Pythagorean desire for finding the mathematical principles of order and harmony according to which God had constructed the world, Kepler spent his life looking for simple mathematical relationships that described planetary motions. His painstaking search for the real order of the universe forced him finally to abandon the Platonic ideal of uniform circular motion in his search for a physical basis for the motions of the heavens.

Kepler's laws

In 1609 he announced two new planetary laws derived from Tycho's data: (1) the planets travel around the Sun in elliptical orbits, one focus of the ellipse being occupied by the Sun; (2) a planet moves in its orbit in such a manner that a line drawn from the planet to the Sun always sweeps out equal areas in equal times. With these two laws, Kepler abandoned uniform circular motion of the planets on their spheres, thus raising the fundamental physical question of what holds the planets in their orbits. He attempted to provide a physical basis for the planetary motions by means of a force analogous to the magnetic force, the qualitative properties of which had been recently described in England by William Gilbert in his influential treatise, *De Magnete, magneticisque corporibus et de magno magnete tellure*. The impending marriage between astronomy and physics had been announced. In 1618, Kepler stated his third law, which was one of many laws concerned with the harmonies of the planetary motions: (3) the square of the period in which a planet orbits the Sun is proportional to the cube of its mean distance from the Sun.

Galileo's observation

A powerful blow was dealt to the traditional cosmology by Galileo Galilei, who early in the 17th century used the telescope, a recent invention of Dutch lens grinders, to look toward the heavens. In 1610 Galileo announced observations that contradicted many traditional cosmological assumptions. He observed that the Moon was not a smooth, polished surface, as Aristotle had claimed, but that it was jagged and mountainous. Earthshine on the Moon revealed that the Earth, like the other planets, shone by reflected light. Like the Earth, Jupiter was observed to have satellites; hence, the Earth had been demoted from its unique position. The phases of Venus proved that that planet orbits the Sun, not the Earth.

Physics. *Mechanics.* The battle for Copernicanism was fought in the realm of mechanics as well as astronomy. The Ptolemaic–Aristotelian system stood or fell as a monolith, and it rested on the idea of Earth's fixity at the centre of the cosmos. Removing the Earth from the centre destroyed the doctrine of natural motion and place, and circular motion of the Earth was incompatible with Aristotelian physics.

Galileo's contributions to the science of mechanics were related directly to his defense of Copernicanism. Al-

though in his youth he adhered to the traditional impetus physics, his desire to mathematize in the manner of Archimedes led him to abandon the traditional approach and develop the foundations for a new physics that was both highly mathematizable and directly related to the problems facing the new cosmology. Interested in finding the natural acceleration of falling bodies, he was able to derive the law of free fall (the distance, s, varies as the square of the time, t^2). Combining this result with his rudimentary form of the principle of inertia, he was able to derive the parabolic path of projectile motion. Furthermore, his principle of inertia enabled him to meet the traditional physical objections to the Earth's motion: since a body in motion tends to remain in motion, projectiles and other objects on the surface of the Earth will tend to share the motions of the Earth, which will thus be imperceptible to someone standing on the Earth.

The 17th-century contributions to mechanics of the French philosopher René Descartes, like his contributions to the scientific endeavour as a whole, were more concerned with problems in the foundations of science than with the solution of specific technical problems. He was principally concerned with the conceptions of matter and motion as part of his general program for science—that is, to explain all the phenomena of nature in terms of matter and motion. This program, known as the mechanical philosophy, came to be the dominant theme of 17th-century science.

Descartes's principle of inertia

Descartes's interest in foundations led him to express the principle of inertia in much the form it retains today. He addressed himself to several important problems in mechanics, in particular the problems of impact and circular motion. Taking his lead from Descartes's formulations of these problems, the Dutch physicist Christiaan Huygens later in the 17th century solved them mathematically.

The work of Sir Isaac Newton represents the culmination of the scientific revolution at the end of the 17th century. His monumental *Principia* (1687) solved the major problems posed by the scientific revolution in mechanics and in cosmology. It provided a physical basis for Kepler's laws, unified celestial and terrestrial physics under one set of laws, and established the problems and methods that dominated much of astronomy and physics for well over a century. By means of the concept of force, Newton was able to synthesize two important components of the scientific revolution, the mechanical philosophy and the mathematization of nature.

The impact of Newton

Newton was able to derive all these striking results from his three laws of motion:

1. Every body continues in its state of rest or of motion in a straight line unless it is compelled to change that state by force impressed on it;
2. The change of motion is proportional to the motive force impressed and is made in the direction of the straight line in which that force is impressed;
3. To every action there is always opposed an equal reaction: or, the mutual actions of two bodies upon each other are always equal.

From these laws, Newton was able to derive the law of universal gravitation. He demonstrated that the fact that the planets obey Kepler's laws entails and is entailed by the existence of a force of attraction that is measured by the inverse of the square of the distance between two attracting bodies. Galileo's law of free fall also is derivable from Newton's laws of motion. The same physics that accounts for the motions of bodies on the surface of the Earth answers the question of what holds the planets in their orbits.

Optics. The science of optics in the 17th century expressed the fundamental outlook of the scientific revolution by combining an experimental approach with a quantitative analysis of phenomena. Optics had its origins in Greece, especially in the works of Euclid (*c.* 300 BC), who stated many of the results in geometrical optics that the Greeks had discovered, including the law of reflection: the angle of incidence is equal to the angle of reflection. In the 13th century, such men as Roger Bacon, Robert Grosseteste, and John Pecham, relying on the work of the Arab Alhazen (died 1039), considered numerous optical problems, including the optics of the rainbow. It was Kepler, taking his lead from the writings of these 13th-century opticians, who set the tone for the science in the 17th century. Kepler introduced the point by point analysis of optical problems, tracing rays from each point on the object to a point on the image. Just as the mechanical philosophy was breaking the world into atomic parts, so Kepler approached optics by breaking organic reality into what he considered to be ultimately real units. He developed a geometrical theory of lenses, providing the first mathematical account of Galileo's telescope.

Descartes sought to incorporate the phenomena of light into the mechanical philosophy by demonstrating that they can be explained entirely in terms of matter and motion. Using mechanical analogies, he was able to derive mathematically many of the known properties of light, including the law of reflection and the newly discovered law of refraction.

Newton's theory of colours

Many of the most important contributions to optics in the 17th century were the work of Newton, especially the theory of colours. Traditional theory considered colours to be the result of the modification of white light. Descartes, for example, thought that colours were the result of the spin of the particles that constitute light. Newton upset the traditional theory of colours by demonstrating in an impressive set of experiments that white light is a mixture out of which separate beams of coloured light can be separated. He associated different degrees of refrangibility with rays of different colours, and in this manner he was able to explain the way prisms produce spectra of colours from white light.

His experimental method was characterized by a quantitative approach, since he always sought measurable variables and a clear distinction between experimental findings and mechanical explanations of those findings. His second important contribution to optics dealt with the interference phenomena that came to be called "Newton's rings." Although the colours of thin films (*e.g.*, oil on water) had been previously observed no one had attempted to quantify the phenomena in any way. Newton observed quantitative relations between the thickness of the film and the diameters of the rings of colour, a regularity he attempted to explain by his theory of fits of easy transmission and fits of easy reflection. Although he generally conceived of light as being particulate, his theory of fits involves periodicity and vibrations of the ether.

Huygens was the second great optical thinker of the 17th century. Although he was critical of many of the details of Descartes's system, he wrote in the Cartesian tradition, seeking purely mechanical explanations of phenomena. Huygens regarded light as something of a pulse phenomenon, though he explicitly denied the periodicity of light pulses. He developed the concept of wave front, by means of which he was able to derive the laws of reflection and refraction from his pulse theory and to explain the recently discovered phenomenon of double refraction.

Chemistry. Chemistry had manifold origins, coming from such diverse sources as philosophy, alchemy, metallurgy, and medicine. It emerged as a separate science only with the rise of the mechanical philosophy in the 17th century. Aristotle had regarded the four elements earth, water, air, and fire as the ultimate constituents of all things. Transmutable each into the other, all four elements were believed to exist in every substance. Alchemy, having its origins in Egypt and the Near East, had a double aspect: on the one hand it was a practical endeavour aimed to make gold from baser substances, while on the other it was a cosmological theory based on the correspondence between man and the universe at large. Alchemy contributed to chemistry a long tradition of experience with a wide variety of substances. Paracelsus, a 16th-century Swiss natural philosopher, was a seminal figure in the history of chemistry, putting together in an almost impenetrable combination the Aristotelian theory of matter, alchemical correspondences, mystical forms of

knowledge, and chemical therapy in medicine. His influence was widely felt in succeeding generations.

During the first half of the 17th century, there were few established doctrines that chemists generally accepted as a framework. As a result there was little cumulative growth of chemical knowledge. Chemists tended to build detailed systems, "chemical philosophies," attempting to explain the entire universe in chemical terms. Most chemists accepted the traditional four elements (air, earth, water, fire), or the Paracelsian principles (salt, sulfur, mercury), or both, as the bearers of real qualities in substances; they also exhibited a marked tendency toward the occult.

Effect of mechanical theory on chemistry

The interaction between chemistry and the mechanical philosophy altered this situation by providing chemists with a shared language. The mechanical philosophy had been successfully employed in other areas; it seemed consistent with an experimental empiricism, and it seemed to provide a way to render chemistry respectable by translating it into the terms of the new science. Perhaps the best example of the influence of the mechanical philosophy is the work of Robert Boyle. The thrust of his work was to understand the chemical properties of matter, to provide experimental evidence for the mechanical philosophy, and to demonstrate that all chemical properties can be explained in mechanical terms. He was an excellent laboratory chemist and developed a number of important techniques, especially colour-identification tests.

EIGHTEENTH CENTURY TO THE PRESENT

Seminal contributions to science are those that change the tenor of the questions asked by succeeding generations. The works of Sir Isaac Newton formed such a contribution. The mathematical rigour of the *Principia* and the experimental approach of the *Opticks* became models for scientists of the 18th and 19th centuries. Celestial mechanics developed in the wake of the *Principia*, extending its scope and refining its mathematical methods. The more qualitative, experimental, and hypothetical approach of the *Opticks* deeply influenced the sciences of optics, electricity and magnetism, and chemistry.

Celestial mechanics and astronomy. Eighteenth-century theoretical astronomy in large measure derived both its point of view and its problems from the *Principia*. In this work Newton had provided a physics for the Copernican world view by, among other things, demonstrating the implications of his gravitational theory for a two-body system consisting of the Sun and a planet. While Newton himself had grave reservations as to the wider scope of his theory, the 18th century witnessed various attempts to extend it to the solution of problems involving three gravitating bodies.

An English astronomer, Edmond Halley, early in the 18th century, having noted striking similarities in the comets that had been observed in 1378, 1456, and especially in those of 1531, 1607, and 1682, argued that they were the periodic appearances every 75 years or so of but a single comet that he predicted would return in 1758. Months before its expected return, the French mathematician Alexis Clairaut employed rather tedious and brute-force mathematics to calculate the effects of the gravitational attraction of Jupiter and Saturn upon the otherwise elliptical orbit of Halley's Comet. Clairaut was finally able to predict in the fall of 1758 that Halley's Comet would reach perihelion, or the point in its orbit nearest the Sun, in April of 1759, with a leeway of one month. Its actual return, in March, was an early confirmation of the wider scope and power of the Newtonian theory.

It was, however, the three-body problem of either two planets and the Sun or the Sun–Earth–Moon system that provided the most persisting and profound tests of Newton's theory. These problems, involving more regular members of the solar system (*i.e.*, those describing nearly circular orbits having the same sense of revolution and in nearly the same plane), permitted certain simplifying assumptions, thereby inviting more general and elegant mathematical approaches than the cometary problem. An illustrious group of 18th-century continental mathematicians (including Clairaut, the Swiss Bernoullis and Leonhard Euler, and the Frenchmen Jean Le Rond d'Alembert, Joseph-Louis Lagrange and Pierre-Simon Laplace) attacked these astronomical problems, as well as related ones in Newtonian mechanics, by developing and applying the calculus of variations as it had been formulated by Leibniz. It is a lovely irony that this continental exploitation of Leibniz' mathematics—which was itself closely akin to Newton's version of calculus, which he called fluxions—was fundamental for the deepening establishment of the Newtonian theory to which Leibniz had objected because it reintroduced, according to Leibniz, occult forces into physics.

In order to attack the lunar theory, which also commanded attention as the most likely astronomical approach to the navigational problem of determining longitude at sea (for the solution of which was offered a £20,000 prize set by the Board of Longitude), Clairaut, having derived general equations that neither he nor anyone else could integrate, was forced to adopt methods of approximation. Even so, Clairaut was unable to calculate from gravitational theory a value for the progression of the lunar apogee greater than 50 percent of the observed value; therefore, he supposed in 1747 (with Euler) that Newton's inverse-square law was but the first term of a series and, hence, an approximation not valid for distances as small as that between the Earth and Moon. This attempted refinement of Newtonian theory proved to be fruitless, however, and two years later Clairaut was able to obtain, by more detailed and elaborate calculations, the observed value from the simple inverse-square relation.

Certain of the three-body problems, most notably that of the secular acceleration of the Moon, defied early attempts at solution but finally yielded to the increasing power of the calculus of variations in the service of Newtonian theory. Thus it was that Laplace—in his five-volume *Traité de mécanique céleste* (1798–1827)—was able to comprehend the whole solar system as a dynamically stable, Newtonian gravitational system. The secular acceleration of the Moon reappeared as a theoretical problem in the middle of the 19th century, persisting into the 20th century, and ultimately requiring tidal action as part of its solution.

Newtonian theory was also employed in much more dramatic discoveries that captivated the imagination of a tremendously broad and varied audience. Within 40 years of the discovery of Uranus in 1781 by the English astronomer William Herschel, it was recognized that the planet's motion was somewhat anomalous. In the next 20 years the gravitational attraction of an unobserved planet was suspected to be the cause of Uranus' persisting deviations. In 1845–46 the English astronomer J.C. Adams and the Frenchman U.-J.-J. Le Verrier independently calculated the position of this unseen body. The visual discovery (at the Berlin Observatory in 1846) of Neptune in just the position predicted constituted an immediately engaging and widely understood confirmation of Newtonian theory. In 1905 the English astronomer Percival Powell predicted the position of yet another outer planet to account for further perturbations of Uranus not caused by Neptune. Pluto was finally discovered by sophisticated photographic techniques in 1930 and observed visually in 1950.

In the second half of the 19th century, the innermost region of the solar system also received attention. In 1859 Le Verrier calculated the specifications of an intramercurial planet to account for a residual advance in the perihelion of Mercury's orbit (38 seconds of arc per century), an effect that was not gravitationally explicable in terms of known bodies. While a number of sightings of this predicted planet were reported between 1859 and 1878, the first of these resulting in Le Verrier's naming the new planet Vulcan, they were not confirmed by observations made either during subsequent solar eclipses or at the times of predicted transits of Vulcan across the Sun.

The theoretical comprehension of Mercury's residual motion involved the first successful departure from Newtonian gravitational theory. This came in the form of Einstein's formulation of the principle of the general the-

ory of relativity, one consequence of which was a correction term for a body in motion; the correction involves the square of the ratio of the body's velocity to the enormous velocity of light and hence, among the planets, is appreciable only for the fastest: Mercury. Einstein's theory accounted for the residual effect, which by 1915 was calculated to be 43 seconds, and this achievement combined with the 1919 observation of the bending of a ray of light passing near a massive body (another consequence of general relativity theory) constitute the main experimental verifications of that theory. In 1967, however, the U.S. scientist Robert Dicke argued that an equatorial bulge that he had observed on the Sun sufficed to account, in good Newtonian fashion, for 4 seconds of arc which, if confirmed, leaves a residual effect of only 39 seconds to be accounted for relativistically.

Mercury's motion and the theory of relativity

The 18th-, 19th-, and early-20th-century astronomy was not quite so completely Newtonian, however. Herschel's discovery of Uranus, for example, was not directly motivated by gravitational considerations. Nine years earlier, a German astronomer, J.D. Titius, had announced a purely numerical sequence, subsequently refined by another German astronomer, Johann E. Bode, that related the mean radii of the planetary orbits—a relation entirely outside gravitational theory. The sequence is given by $0 + 4 = 4$, $3 + 4 = 7$, $3 \times 2 + 4 = 10$, $3 \times 4 + 4 = 16$, and so on, yielding additional values of 28, 52 and 100. If the measured radius of the Earth's orbit is defined as being 10, then to a very good approximation that of Mercury is 4, Venus is 7, Mars is 15 plus, Jupiter is 52, and Saturn is 95 plus. The fit where it can be made is good and continues since the next number in the sequence is 196 and the measured radius for Uranus' orbit is 191, but no planet had been observed to correspond to the Bode–Titius law value of 28. Powerful computational methods finally led to the rediscovery of the asteroid Ceres that confirmed the law. The Bode–Titius law subsequently provided first simplifying assumptions for the calculations of the predicted positions, which led to the observations of Neptune and Pluto, while the novel properties of the asteroids (nearly 500 of which had been discovered by the end of the century) stimulated star charts of the zodiacal regions, provided the means for improved measurements of solar-system distances, and forced astronomers, by their very number and variety, to face the question of the allocation of resources.

Attempts to detect the motion of the Earth provided the 18th and 19th centuries with observational problems directly motivated by the Copernican theory. In 1728 the English astronomer James Bradley attributed annual changes that he observed in stellar positions to a slight tilting of the telescope with respect to the true direction of the star's light, a tilting that compensated for the Earth's motion. This effect, which depends also upon the ratio of the Earth's velocity to the velocity of light, is the so-called aberration of light.

While attention has been focussed on the more positional aspects of astronomy, mention should be made of two other broad areas of investigation that in their 19th-century form derived largely from the work of William Herschel. These areas, dealing with more structural features of the heavens and with the physical character of the stars, developed in large measure with advancements in physics.

Optics. Since they provided the principal basis for subsequent investigations, Newton's optical views were subject to close consideration until well into the 19th century. From his researches into the phenomena of colour, Newton became convinced that dispersion necessarily accompanies refraction and that chromatic aberration (colour distortion) could therefore be eliminated by employing reflectors, rather than refractors, as telescopes. By the mid-18th century Euler and others had theoretical arguments against Newton, and Euler offered the human eye as an example of an achromatic lens system. Although he was virtually alone in this, Euler also rejected Newton's essentially corpuscular theory of the nature of light by explaining optical phenomena in terms of vibrations in a fluid ether. The dominance of Newton's theory throughout the 18th century was due partly to its successful direct application by Newton and his followers and partly to the comprehensiveness of Newton's thought. For example, Bradley's observations found an immediate and natural explanation in terms of the corpuscular theory that also was supported by the accelerating success of Newton's gravitational theory involving discrete particles of matter.

Criticism of Newton's optics

At the turn of the century, Thomas Young, an English physician studying the power of accommodation of the eye (*i.e.*, its focussing power), was led gradually to extensive investigations and discoveries in optics, including the effect of interference. By means of a wave theory of light, Young was able to explain both this effect, which in its most dramatic manifestation results in two rays of light cancelling each other to produce darkness, and also the various colour phenomena observed by Newton. The wave theory of light was developed from 1815 onward in a series of brilliant mathematical and experimental memoirs of Augustin Fresnel but was countered by adherents of the corpuscular theory, most notably by a group of French scientists, Pierre-Simon Laplace, Siméon-Denis Poisson, Étienne Malus, and Jean-Baptiste Biot, and most strikingly in connection with Malus' discovery (1808) of the polarization of light by reflection. Following Young's suggestion in 1817, Fresnel was able to render polarization effects comprehensible by means of a wave theory by considering light to be a transverse rather than a longitudinal wave, as the analogy with sound had suggested.

The propagation of a transverse wave, the velocity of which through various media and under a variety of conditions was measured terrestrially with increasing accuracy from midcentury onward, seemed to require an ether having the properties of a highly elastic solid (*e.g.*, such as steel), which, however, offered no resistance to the planetary motions. These bizarre properties stimulated a number of mechanical models of the ether, most notably those of the English physicist William Thomson, Lord Kelvin. In order to encompass the aberration of light by means of his wave theory, Fresnel had assumed that the motionless ether freely permeated the opaque Earth and thus remained unaffected by its motions. Furthermore, he derived as a theoretical consequence (verified experimentally in midcentury by Armand-Hippolyte-Louis Fizeau) that the ether was partially, and only partially, dragged along by a moving transparent substance depending upon the index of refraction of the substance. However, all subsequent investigators (most notably the U.S. physicists A.A. Michelson and Edward W. Morley, in 1887) failed in their attempts to measure the required ether drift. It was just to escape this difficulty of a necessary but undetected ether drift that George Francis FitzGerald of England and the Dutch theorist Hendrik Antoon Lorentz independently, at the close of the century, postulated the contraction of moving bodies in the direction of their motion through the ether. The Lorentz-FitzGerald contraction involves the square of the ratio of the velocity of the body to the velocity of light to insure theoretically the experimental undetectability of the ether drift. It was supported by late-19th-century considerations of the electrical nature of matter. It was partly the seeming necessity of theoretical postulations of this kind that led Einstein to his formulation of relativity theory.

Electricity and magnetism. Until the end of the 18th century, investigations in electricity and magnetism exhibited more of the hypothetical and spontaneous character of Newton's *Opticks* than the axiomatic and somewhat forbidding tone of his *Principia*. Early in the century, in England Stephen Gray and in France Charles François de Cisternay DuFay studied the direct and induced electrification of various substances by the two kinds of electricity (then called vitreous and resinous and now known as positive and negative), as well as the capability of these substances to conduct the "effluvium" of electricity. By about midcentury, the use of Leyden jars (to collect charges) and the development of

Theories of electricity

large static electricity machines brought the experimental science into the drawing room, while the theoretical aspects were being cast in various forms of the single-fluid theory (by Benjamin Franklin of the U.S. and F.M.U.T.H. Aepinus among others) and the two-fluid theory.

By the end of the 18th century, in England, Joseph Priestley had noted that no electric effect was exhibited inside an electrified hollow metal container and had brilliantly inferred from this similarity that the inverse-square law (of gravity) must hold for electricity as well. In a series of painstaking memoirs, Charles-Augustin Coulomb, using a torsion balance Henry Cavendish had used in England to measure the gravitational force, demonstrated the inverse-square relation for electrical and magnetic attractions and repulsions. Coulomb went on to apply this law to calculate the surface distribution of the electrical fluid in such a fundamental manner as to provide the basis for the 19th-century extensions by Poisson and Lord Kelvin.

The discovery of galvanic electricity and the development of voltaic electricity opened whole new areas of investigation for the 19th century by providing convenient sources of sustained electrical current. Danish physicist Hans Christian Ørsted's discovery, in 1819, of the magnetic effect accompanying an electric current led almost immediately to quantitative laws of electromagnetism and electrodynamics. By 1827, André-Marie Ampère had published a series of mathematical and experimental memoirs on his electrodynamical theory that not only rendered electromagnetism comprehensible but also ordinary magnetism, identifying both as the result of molecular electrical currents. Ampère solidly established his electrodynamics by basing it on inverse-square forces (which, however, are directed at right angles to, rather than in the line connecting the two interacting elements) and by demonstrating that the effects do not violate Newton's third law of motion, notwithstanding their transverse direction.

English scientist Michael Faraday's discovery in 1831 of electromagnetic induction (the inverse of the effect discovered by Ørsted), his experimental determination of the identity of the various forms of electricity (1833), his discovery of the rotation of the plane of polarization of light by magnetism (1845), in addition to certain findings of other investigators—*e.g.*, the discovery by James Prescott Joule in 1843 (and others) of the mechanical equivalent of heat (the conservation of energy)—all served to emphasize and re-emphasize the essential unity of the forces of nature. Within electricity and magnetism attempts at theoretical unification were conceived in terms of either gravitational-type forces acting at a distance, as with Ampère, or, with Faraday, in terms of lines of force and the ambient medium in which they were thought to travel. The German physicist Wilhelm Eduard Weber, in order to determine the coefficients in his theory of the former kind, measured the ratio of the electromagnetic and electrostatic units of electrical charge to be equal to the velocity of light. Physicist James Clerk Maxwell, drawing his conceptions from Faraday and, thus, relying fundamentally on the ether required by optical theory, while using ingenious mechanical models, developed his profound mathematical electromagnetic theory from 1855 onward. One consequence of Maxwell's mature theory was that an electromagnetic wave must be propagated through the ether with a velocity equal to the ratio of the electromagnetic to electrostatic units. Combined with the earlier results of Weber and Rudolph Kohlrausch, this result implied that light is an electromagnetic phenomenon. Maxwell's inclusion of light within his electromagnetic theory received direct experimental verification in 1886, when Heinrich Hertz detected the predicted electromagnetic waves.

The nature of light

Impressive as this synthesis was, there remained, of course, a number of outstanding problems to which fresh difficulties were immediately added. On the experimental side, for example, Hertz' discovery in 1887 of the photoelectric effect led very quickly to a number of experimental results that were fundamentally inconsistent with any conceivable wave theory of light. Theoretical problems such as those involving the nature of the electric charge, the interaction between matter and ether, the optics of moving bodies, and the dispersion of light led Lorentz toward the end of the 19th century to refine Maxwell's theory in terms of charged particles, a conception that he developed into his 20th-century theory of electrons.

Chemistry. Contemporary ideas of the nature and scope of chemistry are much less suitable for the 18th century than are modern notions of the domain of astronomy and physics. Eighteenth-century chemistry derived from and remained involved with questions of mechanics, light, and heat as well as iatrochemistry and notions of medical therapy and the interaction between substances and the formation of new substances. Like the other sciences, chemistry also took many of its problems and much of its viewpoint from the *Opticks* and especially the "Queries" with which that work ends. Newton's suggestion of a hierarchy of clusters of unalterable particles formed by virtue of the specific attractions of its component particles led directly to comparative studies of interactions and thus to the tables of affinities of the physician Herman Boerhaave and others early in the century. This work culminated at the end of the century in the Swede Torbern Bergman's table that gave quantitative values of the affinity of substances both for reactions when "dry" and when in solution and that considered double as well as simple affinities.

Seventeenth-century investigations of "airs" or gases, combustion and calcination, and the nature and role of fire were incorporated by the chemists Johann Joachim Becher and Georg Ernst Stahl of Sweden into a theory of phlogiston. According to this theory, which was most influential after the middle of the 18th century, the fiery principle, phlogiston, was released into the air in the processes of combustion, calcination, and respiration. According to the theory, air was simply the receptacle for phlogiston, and any combustible or calcinable substance contained phlogiston as a principle or element and thus could not itself be elemental. Iron, in rusting, was considered to lose its compound nature and to assume its elemental state as the calx of iron by yielding its phlogiston into the ambient air.

Investigations that isolated and identified various gases in the second half of the 18th century, most notably the English chemist Joseph Black's quantitative manipulations of "fixed air" (carbon dioxide) and Joseph Priestley's discovery of "dephlogisticated air" (oxygen), were instrumental for the French chemist Antoine Lavoisier's formulation of his own oxygen theory of combustion and rejection of the phlogiston theory. This transformation coupled with the reform in nomenclature at the end of the century (due to Lavoisier and others)—a reform that reflected the new conceptions of chemical elements, compounds, and processes—comprised the revolution in chemistry.

Very early in the 19th century, another study of gases, this time in the form of a persisting Newtonian approach to certain meteorological problems by the chemist John Dalton, led to the enunciation of a chemical atomic theory. From this theory, which was demonstrated to agree with the law of definite proportions and from which the law of multiple proportions was derived, Dalton was able to calculate definite atomic weights by assuming the most simple possible ratio for the numbers of combining atoms. For example, knowing from experiment that the ratio of the combining weights of hydrogen to oxygen in the formation of water is 1 to 8 and by assuming that one atom of hydrogen combined with one atom of oxygen, Dalton affirmed that the atomic weight of oxygen was eight, based on hydrogen as one. At the same time, however, in France, Joseph-Louis Gay-Lussac, from his volumetric investigations of combining gases, determined that two volumes of hydrogen combined with one of oxygen to produce water. While this suggested H_2O rather than Dalton's HO as the formula for water, with the result that the atomic weight of oxygen becomes 16, it did involve certain inconsistencies with Dalton's theory.

As early as 1811 the chemist Amedeo Avogadro was able to reconcile Dalton's atomic theory with Gay-Lussac's volumetric law by postulating that Dalton's atoms were indeed compound atoms, or polyatomic. For a number of reasons, one of which involved the recent successes of electrochemistry, Avogadro's hypothesis was not accepted until it was reintroduced by another chemist, Stanislao Cannizzaro, half a century later. From the turn of the century, the English scientist Humphry Davy and many others had employed the strong electric currents of voltaic piles for the analysis of compound substances and the discovery of new elements. From these results, it appeared obvious that chemical forces were essentially electrical in nature and that two hydrogen atoms, for example, having the same electrical charge, would repel each other and could not join to form the polyatomic molecule required by Avogadro's hypothesis.

Nature of chemical forces

Between the presentation of Avogadro's hypothesis in 1811 and its general acceptance soon after 1860, several experimental techniques and theoretical laws were used by various investigators to yield different but self-consistent schemes of chemical formulas and atomic weights. After its acceptance, these schemes became unified. Within a few years of the development of another powerful technique, spectrum analysis by the German physicists Gustav Kirchhoff and Robert Bunsen in 1859, the number of chemical elements whose atomic weights and other properties were known had approximately doubled since the time of Avogadro's announcement. By relying fundamentally but not slavishly upon the determined atomic weight values and by using his chemical insight and intuition, the Russian chemist Dmitry Ivanovich Mendeleyev provided a classification scheme that ordered much of this burgeoning information and was a culmination of earlier attempts to represent the periodic repetition of certain chemical and physical properties of the elements.

20th-century trends. Development after the early 20th century present special problems to the historian, placing them beyond the scope of the present article. Recent science is relatively uncharted in comparison with early periods that have been ordered and reordered by successive generations of historians. It is consequently more difficult to discern the patterns of development of recent science, as well as the connections that relate it to philosophy, religion, and other areas of intellectual and social development. Furthermore, contemporary developments are still too close to read the patterns and trends that will undoubtedly emerge in the studies of historians of a later generation. All that can now be attempted are a few observations of the breakdown of the classical picture and the emergence of what appears to be a new view of the nature of the universe. In the middle of the 1890s a few totally unexpected phenomena were observed, which, together with the more conventional accumulations of knowledge, provided the impetus for a 20th-century transformation of vast realms of the physical sciences. William Röntgen's investigations in Germany of cathode rays, a subject thoroughly studied during the preceding half century, led to his discovery of X-rays, a completely unanticipated phenomenon; and, within a few weeks, in France, Henri Becquerel, following this line, discovered radioactivity in uranium, an element that also had been known for 50 years. In England, J.J. Thomson's much more traditional investigations of the nature of cathode rays led him in 1897 to a convincing demonstration (one of several at this time) of the existence of a subatomic particle, the electron.

In 1900 physicist Max Planck employed the novel idea of discrete energy levels for the vibrations of radiating substances in order to represent mathematically the observed distribution of radiant energy, a problem of some standing in thermodynamics and statistical mechanics. Quantum theory, thus introduced into physics, was accepted and exploited by Einstein, as in his photoelectric-effect equation of 1905. Einstein's theory, coupled with the electromagnetic wave theory of light, led to the view of light in terms of fundamental wave–particle duality. Niels Bohr, in Denmark, employed the quantum theory in 1913 in his version of the Rutherford model of the atom, and its subsequent application to the realm of the atom and the nucleus has transformed man's understanding of radiation and energy processes.

The acceptance of quantum mechanics and relativity theory marked the decline of the classical Newtonian picture of the world that dominated the physical sciences since the early 18th century. Modern physics replaced the absolute space–time reference frame and determinism of classical physics with relativity and uncertainty. It is no longer theoretically possible, as Laplace asserted, to predict all future states of the universe on the basis of thorough knowledge of the present position and momentum of each particle in the universe. Physical scientists now deny the very possibility of determining both the position and momentum of any single atomic particle with arbitrary precision. The breakdown of the classical framework, following from the dramatic discoveries and reformulations of the early 20th century, leaves science re-examining in depth the breadth and implications of its foundations.

Physical Theories, Mathematical Aspects of

Practically all physical theories, from their basic concepts to their final formulations and predictive results, are essentially mathematical. Indeed, it may be said that the very language of theoretical physics is mathematics.

This article deals with some fundamental mathematical aspects of nine subdivisions of theoretical physics. An outline of the topics treated is as follows:

Mechanics of particles and systems
- Newton's laws
- Conservation of linear momentum
- Conservation of angular momentum
- Work and energy relations
- A system of particles

Fluid mechanics
- Three-dimensional flow
- Velocity and acceleration
- Equation of continuity
- Dynamic equation for an inviscid fluid
- Steady flow of an inviscid fluid
- Velocity potential and stream function

Mechanics of solids
- Elasticity; concept of stress
- Equilibrium conditions
- Tensile and compressive stress; triaxial and plane stress
- Concept of strain; Poisson's ratio
- Shear strain; general deformation; compatibility
- Relation between stress and strain
- Principal stresses and strains; invariants and strain energy

Statistical mechanics
- Basic definitions
- Probability
- Perfect gas pressure and energy density
- Maxwell-Boltzmann distribution
- Gibbs's ensembles
- The Hamiltonian
- Liouville's theorem
- Equations for ensemble probability densities
- Justification of the equations
- Quantum statistics

Electromagnetic theory
- Origin of the electromagnetic wave concept
- Maxwell's field theory
- Velocity of electromagnetic waves

Relativity theory
- Space
- Time

Riemannian geometry
- Basic properties
- Lorentz transformation and Lorentz invariance
- Lorentz contraction and time dilation

Quantum mechanics
- Transition from classical to quantum mechanics
- Wave mechanics
- Matrix form of quantum mechanics
- Transformation theory
- Statistical significance of the wave function
- Probability distribution in momentum space
- Relativistic quantum fields

Dimensional analysis
- General considerations
- The pi theorem
- Applications

MECHANICS OF PARTICLES AND SYSTEMS

Mechanics is the science concerned with the motion of bodies under the action of forces. This section is confined to basic, introductory considerations of classical, or Newtonian, mechanics and is distinct from relativistic mechanics (see RELATIVITY and the sections below *Relativity theory* and *Riemannian geometry*) and from quantum mechanics (see MECHANICS, QUANTUM and the section below *Quantum mechanics*).

A logical, mathematical development of mechanics requires that terminology must first be specified. Some terms (*e.g.*, position, time, and mass) are taken as primitive or undefined. Others may be defined by using primitive or previously defined terms: for example, velocity may be defined as time rate of change of position; acceleration as time rate of change of velocity; (linear) momentum as the product of mass times velocity. Once the terminology has been specified, a suitable set of initial assumptions or postulates is chosen from which the theorems of the theory can be deduced. Newton's three laws (see below) may be taken as such postulates; other initial assumptions are also possible.

Newton's laws. Historically, although some of the principles of mechanics were known to the ancient Greeks, the beginning of this discipline as an exact science is generally associated with the work of Galileo, who was born in 1564 and died in 1642. By brilliantly clarifying, summarizing, and extending this work, Isaac Newton, born the year that Galileo died, succeeded in formulating his three laws of motion. In modern terms, the first law states that in the absence of an external force, a particle initially at rest will remain at rest; or, if initially moving with velocity v, the particle will continue to do so with constant speed along a straight line.

The second law asserts that if an external force does act on a particle, then the time rate of change of its momentum (product of mass times velocity) is equal to (and in the same direction as) the external force. In the special but frequently occurring case of constant (unvarying) mass, the second law reduces (as shown below *Conservation of linear momentum*) to the assertion that force equals mass times acceleration. Newton, however, enunciated this second law in the first of these two forms, thus allowing for the variability of mass, well over two centuries before this property became an important physical feature in the study of rocket motion and, in a more profound manner, in Einstein's theory of relativity.

Newton's third law states that to every action, there is an equal and opposite reaction: If particle A exerts a force (action) on particle B, then particle B in turn will exert on particle A a force (reaction) such that this latter force is equal in magnitude but opposite in direction to the former. Action and reaction

From the definitions of velocity and acceleration given above, it is apparent that formulating and solving problems by means of Newton's second law require mathematical techniques for dealing with rates of change. Such techniques, along with appropriate notation, the calculus, were developed by Newton and by G.W. Leibniz (see ANALYSIS, REAL).

$$(1) \quad f = ma$$

In the usual mathematical formulation of Newton's second law for a particle of constant mass m, f is the force acting on it and a is its acceleration; f is equal to the product m times a (see Box, equation 1). Acceleration is a vector, a quantity specified by both mag-

nitude and direction; mass is a scalar, a quantity without an associated direction; and the product ma is interpreted as a vector quantity in the same direction as the vector a and of magnitude m times the magnitude of the vector a. Newton's second law then implies that the force is a vector f in the same direction and of the same magnitude as ma. This law may also be expressed in a scalar form by writing the equation in terms of components; *i.e.*, the magnitudes of the quantities along the axes OX, OY, OZ in an orthogonal (axes mutually at right angles) coordinate system. In this form, three equalities relate components of f, components of a, and m (see 2). In the case of a particle confined to a line (or plane), only one or two of these component equations are relevant.

For a particle not acted on by any force, the force is set equal to zero in Newton's second law; this implies that acceleration is zero. Recalling that acceleration is defined as the time rate of change of velocity, zero acceleration implies constant velocity, unvarying in magnitude and direction. Hence, Newton's first law is but a special case of the second law.

If the force components are known as functions of the time t, and perhaps also of the coordinates x, y, z, and of the velocity components v_x, v_y, and v_z, then Newton's second law expressed in component form becomes three second-order differential equations (so called because the acceleration components are the second derivatives of the coordinates) to be solved for $x(t)$, $y(t)$, $z(t)$. Given x, y, z and v_x, v_y, v_z at an instant t, the equations in terms of components determine the acceleration. If position, velocity, and acceleration are known at t, the change in position during a brief interval, denoted as δt, can be computed approximately by multiplying δt by the rate of change of position (*i.e.*, the velocity); similarly, the change in velocity during the interval is the product of δt times the rate of change of velocity (*i.e.*, the acceleration). It is thus plausible that the component equations (see 2) permit the motion to be traced from a position and velocity specified at some instant.

If a particle interacts with (*i.e.*, is attracted or repelled by) one or more bodies, perhaps in several ways (*e.g.*, electrically and gravitationally), it may be subject to several forces at the same time. If any one force f were acting alone, it would produce an acceleration given by Newton's second law (see 1). Because accelerations are added vectorially (in which directions as well as magnitudes are combined), the equation implies that the forces are to be combined in the same way to specify the total force f related to the total acceleration a.

For two or more interacting particles, Newton's second law is to be written separately for each particle. If any force f exerted by a particle A on a particle B appears in the equation of motion for B, then Newton's third law implies that a corresponding force $-f$ exerted by B on A must appear in A's equation of motion. Here f is a vector; $-f$ means a vector of equal magnitude, but oppositely directed.

When dealing with systems containing more than one particle, it becomes of paramount importance to be quite clear as to which particle or particles belong to any one specific system. For example, the system may be defined by means of a suitable bounding surface. It will be necessary to distinguish between internal forces, those that arise from interactions among the system's particles, and external forces that stem from interactions with particles or bodies not included in the system. The particles with masses m_1, m_2, $\cdots$ have positions located by coordinates (x_1, y_1, z_1), (x_2, y_2, z_2), $\cdots$, respectively. If f_1 and f'_1, respectively, denote the total external and internal forces on particle 1, then its equations of motion, relative to a chosen set of axes $OXYZ$, are expressed in a system of equations involving components of f, components of f', and components of a, each involving m (see 3). Similar sets of equations may be written for the other particles, 2, 3, $\cdots$, comprising the system.

Internal and external forces

Conservation of linear momentum. In the general form of Newton's second law, force is equal to the time rate of change of momentum (mv), which in differential form is written $f = \frac{d}{dt}(mv)$. For constant mass this may be rewritten as $f = mdv/dt$. Because acceleration a is the time rate of change of velocity, the x-component of the total force is expressible as a differential equation (see 4). If all such equations for the x-motion of all the particles are added, and similarly for the y- and z-motions, then a system of equations is obtained (see 5).

$$(2)\qquad f_x = ma_x, \qquad f_y = ma_y, \qquad f_z = ma_z$$

$$(3)\qquad \begin{cases} (f_x)_1 + (f'_x)_1 = m_1(a_x)_1 \\ (f_y)_1 + (f'_y)_1 = m_1(a_y)_1 \\ (f_z)_1 + (f'_z)_1 = m_1(a_z)_1 \end{cases}$$

$$(4)\qquad f_x + f'_x = ma_x = \frac{d}{dt}(mv_x)$$

$$(5)\qquad \begin{cases} \sum \frac{d}{dt} mv_x = \Sigma f_x + \Sigma f'_x \\ \sum \frac{d}{dt} mv_y = \Sigma f_y + \Sigma f'_y \\ \sum \frac{d}{dt} mv_z = \Sigma f_z + \Sigma f'_z \end{cases}$$

$$(6)\qquad \Sigma f'_x = 0; \qquad \Sigma f'_y = 0; \qquad \Sigma f'_z = 0$$

$$(7)\qquad \begin{cases} \frac{d}{dt} \Sigma mv_x = \Sigma f_x \\ \frac{d}{dt} \Sigma mv_y = \Sigma f_y \\ \frac{d}{dt} \Sigma mv_z = \Sigma f_z \end{cases}$$

Newton's third law asserts that for every action there is an equal and opposite reaction. This means that internal forces f' between particles exist in equal and opposite pairs, so that the sum of their components in any direction must vanish (see 6). This result simplifies the system of equations obtained (see 5) so that they state that the time rate of change of each component of the total linear momentum is equal to the corresponding component of the total external force (see 7).

If the total external force (or its component in any direction) is zero, then the final system obtained implies that the total linear momentum (or its component in that direction) will remain constant. This is known as the principle of conservation of linear momentum. One important consequence of this principle may be noted immediately: If two bodies collide, then the sum of their linear momenta remains constant. This is so because their interaction can only cause equal and opposite forces to act between pairs of particles. These forces, being internal to the system comprising the two bodies, can therefore produce no increment of total momentum.

Conservation of angular momentum. Two new concepts are needed at this point: torque (also called moment of force) and angular momentum (also called moment of momentum). Both are vector quantities associated with rotational motion of a mass and are related through Newton's second law as follows. For a system having a single particle, the first and second of equations (5) when multiplied by y and x, respectively, give two differential equations, in one of which y is a multiplicative factor common to all terms, in the other of which x is a factor common to all terms (see 8).

Rotational motion

Subtracting the first of these equations from the second yields an equality in which there occurs a difference between two terms, each involving derivatives (see 9).

There is an equation in which the derivative with respect to t operates upon a difference of two terms and upon factors in two other terms (see 10). The first and third terms on the right-hand side here cancel, so that there occurs an equality between terms that involve the derivative with respect to t (see 11) and hence equation (9) can be rewritten as an equation in which the derivative with respect to t operates upon a difference of two terms and a symmetry occurs in the right-hand side (see 12). The expression inside the left-hand parentheses is called the z-component of angular momentum L, and the entire expression on the right-hand side is called the z-component of the torque N. Two more equations of this type can be written, because the same procedure may be applied to obtain also the x- and y-components of L and N.

If the system is comprised of more than one particle, equation (12), after rearrangement, may by written for each particle and added to give relations in the three planes xy, xz, and yz about the respective axes z, y, and x (see 13). A sum involving differences of components as well as x and y (see 14) represents the sum of the torques about the z-axis caused by the internal forces of the particle aggregate. These forces, however, occur in pairs of which the members are equal in magnitude, collinear (lying on or passing through the same straight line), and opposite in direction. The torque caused by one member of such a pair is thus equal and opposite to that of the other, so that the total effect of the sum is zero. The above equations can therefore be reduced to the simpler form in which all internal forces are absent: three equations in components, each involving two major terms of differences (see 15). Equations (15) state that the rate of change of the total angular momentum about any fixed axis is equal to the sum of the torques due to external forces about that axis.

The principle of conservation of angular momentum can now be stated as follows. If the sum of the torques resulting from external forces about a fixed axis is zero, then the total angular momentum of the aggregate of particles about that axis is constant.

Work and energy relations. The work performed by a force f_x, acting on a particle of mass m, moving from an initial position x_A to a final position x_B, is defined by the integral from x_A to x_B of f_x (see 16). From the definition of acceleration as the time rate of change of velocity, it follows that a_x is shown through calculation to be one-half the x-derivative of the square of v_x (see 17), so that by equations (2) f_x is one-half the product of m and the derivative with respect to x of the square of v_x (see 18). Because m is constant, this may also be written so that f_x is equal to the derivative with respect to x of an expression involving m and v_x (see 19), and hence the integral becomes the integral from x_A to x_B of f_x evaluated as a difference of two terms (see 20).

For motion along the y- and z-axis, respectively, one finds by a precisely analogous procedure two integrals of the above type, one involving f_y, the other involving f_z (see 21). Because v_x, v_y, v_z are mutually perpendicular components of the velocity vector v, the magnitude of which will be denoted by s, it follows from the Pythagorean theorem of the right triangle that the square of s is equal to the sum of the squares of components of v, and the integral from A to B of products of the type $f_y dy$ is shown by calculation to equal the increment (denoted Δ) of the quantity one-half the product of m and the square of s (see 22).

Kinetic energy

The quantity $ms^2/2$ is called the kinetic energy of the particle. Equation (22) therefore asserts that the work done as the particle moves from the point A having position coordinates x_A, y_A, and z_A, or $A(x_A, y_A, z_A)$, to the point $B(x_B, y_B, z_B)$ is equal to the change in the kinetic energy of the particle, namely, $\Delta(ms^2/2)$. If that particle is one of an aggregate, the forces acting on it will in general be both external and internal. It follows from equation (22) that the change in the particle's kinetic energy is equal to the total work of the external and internal forces during the displacements in the x, y, and z directions so that appropriate limits are implied on the integrals; or, Δ of one-half the product of m and the square of s is equal to a sum of three integrals, integrated with respect to the differentials of the three coordinates (see 23).

(8) $$\begin{cases} y\dfrac{d}{dt}mv_x = yf_x + yf'_x \\ x\dfrac{d}{dt}mv_y = xf_y + xf'_y \end{cases}$$

(9) $$x\frac{d}{dt}mv_y - y\frac{d}{dt}mv_x = xf_y + xf'_y - yf_x - yf'_x$$

(10) $$\frac{d}{dt}(mxv_y - ymv_x) = mv_xv_y + x\frac{d}{dt}mv_y - mv_yv_x - y\frac{d}{dt}mv_x$$

(11) $$x\frac{d}{dt}mv_y - y\frac{d}{dt}mv_x = \frac{d}{dt}(mxv_y - ymv_x)$$

(12) $$\frac{d}{dt}(xmv_y - ymv_x) = x(f_y + f'_y) - y(f_x + f'_x)$$

(13) $$\begin{cases} \sum\dfrac{d}{dt}(xmv_y - ymv_x) = \Sigma(xf_y - yf_x) + \Sigma(xf'_y - yf'_x) \\ \sum\dfrac{d}{dt}(ymv_z - zmv_y) = \Sigma(yf_z - zf_y) + \Sigma(yf'_z - zf'_y) \\ \sum\dfrac{d}{dt}(zmv_x - xmv_z) = \Sigma(zf_x - xf_z) + \Sigma(zf'_x - xf'_z) \end{cases}$$

(14) $$\Sigma(xf'_y - yf'_x)$$

(15) $$\begin{cases} \dfrac{d}{dt}\sum m(xv_y - yv_x) = \Sigma(xf_y - yf_x) \\ \dfrac{d}{dt}\sum m(yv_z - zv_y) = \Sigma(yf_z - zf_y) \\ \dfrac{d}{dt}\sum m(zv_x - xv_z) = \Sigma(zf_x - xf_z) \end{cases}$$

(16) $$\int_{x_A}^{x_B} f_x\,dx$$

(17) $$a_x = \frac{dv_x}{dt} = \frac{dv_x}{dx}\frac{dx}{dt} = v_x\frac{dv_x}{dx} = \tfrac{1}{2}\frac{d}{dx}(v_x^2)$$

(18) $$f_x = \tfrac{1}{2}m\frac{d}{dx}(v_x^2)$$

(19) $$f_x = \frac{d}{dx}(\tfrac{1}{2}mv_x^2)$$

(20) $$\int_{x_A}^{x_B} f_x\,dx = (\tfrac{1}{2}mv_x^2)_B - (\tfrac{1}{2}mv_x^2)_A$$

(21) $$\begin{cases} \displaystyle\int_{y_A}^{y_B} f_y\,dy = (\tfrac{1}{2}mv_y^2)_B - (\tfrac{1}{2}mv_y^2)_A \\ \displaystyle\int_{z_A}^{z_B} f_z\,dz = (\tfrac{1}{2}mv_z^2)_B - (\tfrac{1}{2}mv_z^2)_A \end{cases}$$

(22) $$\begin{cases} s^2 = v_x^2 + v_y^2 + v_z^2 \\ \displaystyle\int_A^B (f_x\,dx + f_y\,dy + f_z\,dz) = (\tfrac{1}{2}ms^2)_B - (\tfrac{1}{2}ms^2)_A \\ \qquad\qquad \equiv \Delta(\tfrac{1}{2}ms^2) \end{cases}$$

Writing one such equation for each of the particles comprising the system, and then adding these equations, gives Δ of a sum extended over one-half the product of m and the square of s equal to a sum of the integrals of the above type (see 24). That is, the change in the total kinetic energy of all the particles is equal to the work done by all the forces as the system moves from one configuration to another. The concept of work done by internal and external forces is of fundamental importance in all branches of applied mechanics. An important extension of this concept follows.

A system of particles. If the total mass of a system of particles $\Sigma m = m_1 + m_2 + \cdots$ is denoted by M; then a quantity $\bar{x}$ may be defined such that M times $\bar{x}$ is equal to a sum of products of the mass of each particle times its x-coordinate (see 25). Then $\bar{x}$ can be expressed as the sum over mx divided by M; $\bar{y}$ and $\bar{z}$ can be expressed similarly (see 26). Differentiating equations (26) with respect to time gives three equalities relating M, derivatives of x, y, and z, as well as m and components of v (see 27); that is, the total momentum of the system in any of the directions OX, OY, OZ is precisely that of a hypothetical particle of mass M (the total mass) located at the position defined by the coordinates $(\bar{x}, \bar{y}, \bar{z})$. This position is called the centre of mass of the system, a concept of great utility in a number of applications of mechanics.

Centre of mass

Differentiating the preceding equations again with respect to time gives three equations of second order involving M, x, y and z, m, t and components of a (see 28), which in turn permit previous equations to be rewritten more compactly. To do this, the sums of all the external forces acting on the system are denoted by three components of F that are equal to three sums of components of f (see 29), so that, by equations (28), three equations relating components F to M and second derivatives with respect to t of x, y, and z are obtained (see 30). The idea of the total mass of the system as being located at its centre of mass can be taken further: equations (30) are precisely those of the hypothetical particle when it is imagined as being acted on by the resultant of all the external forces.

One important deduction follows immediately: if a system is acted on by external forces such that the sums of their components in the directions OX, OY, and OZ are all zero, then the centre of mass of that system must either be at rest or moving with uniform velocity in accordance with Newton's first law. A special case of this arises when a system of particles is entirely free from external forces.

Because the centre of mass is defined by the coordinates x, y, z, the coordinates of any particle within the system can be measured relative to that point. For instance, the position of particle 1 may be specified by the coordinates either x_1, y_1, z_1, or $\bar{x} + \xi_1$, $\bar{y} + \eta_1$, $\bar{z} + \zeta_1$. That is, if a set of axes, parallel to OX, OY, OZ, were erected with the centre of mass as origin, then the corresponding coordinates of 1 would be ξ_1, η_1, ζ_1. From the definitions of x, y, z, it follows that each of the quantities $\Sigma m\xi$, $\Sigma m\eta$, $\Sigma m\zeta$, together with their derivatives, must be zero.

If $\bar{x} + \xi$, $\bar{y} + \eta$ and $\bar{z} + \zeta$ are substituted for x, y, and z in the expressions for the angular momenta about the fixed axes, three equations result involving differences of terms that include derivatives as factors (see 31) for the axes OX, OY, and OZ, respectively.

Consideration of the first of these results shows that the quantity M times a difference between products of the type x times the derivative of y with respect to t (see 32) is the angular momentum about OZ of a single particle of mass equal to the total mass and located at the centre of mass. Again, by analogy with the expression on the left-hand side of equations (31), a summation of terms involving m and differences of products, each product containing a derivative with respect to t (see 33), and the corresponding expressions in the latter two equations (31) are the angular momenta calculated relative to a coordinate system, designated arbitrarily as $O\Xi HZ$, having origin O at the centre of mass (and moving with it) and axes $O\Xi$, OH, and OZ that remain parallel to the corresponding axes of the system $OXYZ$. If the system of particles comprises a single body (not necessarily rigid or even solid), then the motion of the centre of mass, given by $\bar{x}(t), \bar{y}(t), \bar{z}(t)$, may be called the orbital motion; and the motion represented by $\xi_1, \eta_1, \zeta_1; \xi_2, \cdots$ may be referred to as the internal motion. The above argument thus shows that the angular momentum can be resolved into two parts: an orbital part, and a part associated with the internal motion. The latter part is often called the spin.

Orbital motion and spin

If the new expressions $\bar{x} + \xi$, etc., are substituted for the x, y, and z coordinates in a previous equation (see 15), then, in view of the foregoing remarks, these equations reduce to three differential equations in which summation extended over differences occurs (see 34). These

(23) $$\Delta(\tfrac{1}{2}ms^2) = \int(f_x + f'_x)\,dx + \int(f_y + f'_y)\,dy + \int(f_z + f'_z)\,dz$$

(24) $$\Delta\Sigma(\tfrac{1}{2}ms^2) = \Sigma[\int(f_x + f'_x)\,dx + \int(f_y + f'_y)\,dy + \int(f_z + f'_z)\,dz]$$

(25) $$M\bar{x} = m_1x_1 + m_2x_2 + \cdots = \Sigma mx$$

(26) $$\bar{x} = \frac{\Sigma mx}{M}, \qquad \bar{y} = \frac{\Sigma my}{M}, \qquad \bar{z} = \frac{\Sigma mz}{M}$$

(27) $$\begin{cases} M\dfrac{d\bar{x}}{dt} = \sum m\dfrac{dx}{dt} = \Sigma mv_x \\ M\dfrac{d\bar{y}}{dt} = \sum m\dfrac{dy}{dt} = \Sigma mv_y \\ M\dfrac{d\bar{z}}{dt} = \sum m\dfrac{dz}{dt} = \Sigma mv_z \end{cases}$$

(28) $$\begin{cases} M\dfrac{d^2\bar{x}}{dt^2} = \sum m\dfrac{d^2x}{dt^2} = \Sigma ma_x \\ M\dfrac{d^2\bar{y}}{dt^2} = \sum m\dfrac{d^2y}{dt^2} = \Sigma ma_y \\ M\dfrac{d^2\bar{z}}{dt^2} = \sum m\dfrac{d^2z}{dt^2} = \Sigma ma_z \end{cases}$$

(29) $$F_x = \Sigma f_x, \qquad F_y = \Sigma f_y, \qquad F_z = \Sigma f_z$$

(30) $$F_x = M\frac{d^2\bar{x}}{dt^2}, \qquad F_y = M\frac{d^2\bar{y}}{dt^2}, \qquad F_z = M\frac{d^2\bar{z}}{dt^2}$$

(31) $$\begin{cases} \Sigma m(xv_y - yv_x) = M\left(\bar{x}\dfrac{d\bar{y}}{dt} - \bar{y}\dfrac{d\bar{x}}{dt}\right) + \Sigma m\left(\xi\dfrac{d\eta}{dt} - \eta\dfrac{d\xi}{dt}\right) \\ \Sigma m(yv_z - xv_y) = M\left(\bar{y}\dfrac{d\bar{z}}{dt} - \bar{z}\dfrac{d\bar{y}}{dt}\right) + \Sigma m\left(\eta\dfrac{d\zeta}{dt} - \zeta\dfrac{d\eta}{dt}\right) \\ \Sigma m(zv_x - xv_z) = M\left(\bar{z}\dfrac{d\bar{x}}{dt} - \bar{x}\dfrac{d\bar{z}}{dt}\right) + \Sigma m\left(\zeta\dfrac{d\xi}{dt} - \xi\dfrac{d\zeta}{dt}\right) \end{cases}$$

(32) $$M\left(\bar{x}\frac{d\bar{y}}{dt} - \bar{y}\frac{d\bar{x}}{dt}\right)$$

(33) $$\sum m\left(\xi\frac{d\eta}{dt} - \eta\frac{d\xi}{dt}\right)$$

(34) $$\begin{cases} \dfrac{d}{dt}\sum m\left(\xi\dfrac{d\eta}{dt} - \eta\dfrac{d\xi}{dt}\right) = \Sigma(\xi f_y - \eta f_x) \\ \dfrac{d}{dt}\sum m\left(\eta\dfrac{d\zeta}{dt} - \zeta\dfrac{d\eta}{dt}\right) = \Sigma(\eta f_x - \zeta f_y) \\ \dfrac{d}{dt}\sum m\left(\zeta\dfrac{d\xi}{dt} - \xi\dfrac{d\zeta}{dt}\right) = \Sigma(\zeta f_x - \xi f_z) \end{cases}$$

equations state that the rate of change of any component of the spin angular momentum is equal to the total torque produced by the external forces about the corresponding axis (through the centre of mass).

In a similar manner, the kinetic energy of a system of particles can be resolved into an orbital and an internal part. The kinetic energy T of the aggregate is equal to a summation, there being three squared derivatives with respect to t in the summation (see 35). If this expression is now simplified by means of the method described, then it is found that the expression for the kinetic energy reduces to a sum of two terms, each involving squares of derivatives with respect to t (see 36). The kinetic energy of a system of particles is therefore seen to be equal to that of the hypothetical particle of mass M located at the centre of mass, plus the kinetic energy of all the particles as it would be calculated by an observer moving with the centre of mass.

(Ed.)

FLUID MECHANICS

Fluid mechanics is the science concerned specifically with the motion of fluids under the action of forces. A fluid is any substance that flows, or more precisely, one that cannot sustain shear forces (see below) when in static equilibrium. Thus, two parallel but oppositely directed forces acting on a pair of plates joined by a solid pin are said to be shearing forces, because they tend to produce a sliding motion of one plate with respect to the other. If these forces are not excessive, however, the (solid) pin will be able to sustain these stresses, and no motion on the part of the plates will occur. If a fluid, on the other hand, were to replace the pin, then, regardless how small the shearing forces were, the fluid could not sustain them: static equilibrium would be impossible, and the plates would move.

Gases and liquids are two forms of the fluid state; but whereas gases are generally highly compressible, liquids are often nearly incompressible. Furthermore, although gases and liquids are composed of molecules, it is customary in this discipline to adopt a macroscopic (large-scale) point of view and thus to treat fluids as continuous media. (The microscopic point of view, taking the discrete structure of matter into account, is adopted in the section below *Statistical mechanics*.)

Three-dimensional flow. Although one- or two-dimensional descriptions are adequate for certain types of flow, a full three-dimensional formulation is often necessary. In one method, developed in the 18th century by the Swiss-born mathematician Leonhard Euler, such motion is described in terms of velocity- and pressure-distributions and other similar characteristics in the fluid. To facilitate the application of Euler's method, at any point in the fluid having coordinates x, y, z, the velocity V of the fluid may be resolved into three components denoted u, v, and w in the directions parallel to the x, y, and z axes, respectively, and each of these velocity components may be expressed in terms of the three coordinates and the time t (see 37).

The first of equations (37) asserts that the velocity component u is some function f_1 of the space coordinates x, y, z, and of the time t. Specification of any set of values for these four quantities determines the corresponding value of u; similarly, the functions f_2 and f_3 determine values of v and w. Expressions analogous to equations (37) may be written for acceleration, pressure, temperature, and other fluid characteristics. If, at each point in a given region, the values of all of these characteristics do not change with time, then the flow is said to be steady. Hence in the special but frequently occurring case of steady flow, the time t will not appear in f_1, f_2, f_3, thus rendering the velocity V time-independent, as required.

Steady flow

Velocity and acceleration. In the most general case of fluid motion, however, the velocity V may be a function of both position, such as the distance s along a streamline, and of the time t. That is, V is a function of s and t (see 38). (A streamline may be defined operationally as a curve C constructed in a manner such that the tangent at any point along C is in the direction of the fluid velocity at that point.)

The velocity V may thus change from point to point in space at any fixed instant in time and also from instant to instant in time at any fixed point in space. The total differential of V, therefore, is composed of two terms, each dependent on space or time (see 39). It is to be noted that the derivative in each term appearing on the right-hand side of equation (39) is partial; *i.e.*, is a derivative with respect to one variable only, all others held constant for that particular differentiation.

From the definition of acceleration, a, it follows that the derivative of V with respect to t is equal to a sum of terms involving partial derivatives of V with respect to s and t (see 40). The quantity $\partial V/\partial t$ is often called the local acceleration, and the term $V\partial V/\partial s$ is called the convective acceleration. The former represents the time-rate of change in the local velocity at a fixed point. For steady flow, $\partial V/\partial t = 0$.

The components of the total acceleration $a = dV/dt$ in the x-, y-, and z-directions are, respectively, du/dt, dv/dt, and dw/dt; they may be obtained by differentiating equations (37), yielding three equations identifying total derivatives for u, v, and w with expressions that involve partial derivatives (see 41).

Equation of continuity. An infinitesimal parallelepiped may be imagined embedded in a fluid; the sides have the lengths dx, dy, dz. Considering first the mass flow with velocity u in the x-direction, it is deduced that, per unit time, the mass of fluid (having a density denoted by ρ) entering the parallelepiped in the x-direction is $\rho u dydz$. In traversing the distance dx, the quantity ρu may change by an amount $(\partial/\partial x)(\rho u)$. The time-rate of mass flow leaving the opposite face is therefore a factor multiplied by a differential of y and the differential of z, the factor being composed of a sum of two terms involving u, ρ, and the differential of x (see 42). Hence,

(35) $$\sum \tfrac{1}{2}m\left\{\left[\frac{d}{dt}(\bar{x}+\xi)\right]^2+\left[\frac{d}{dt}(\bar{y}+\eta)\right]^2+\left[\frac{d}{dt}(\bar{z}+\zeta)\right]^2\right\}=T$$

(36) $$T=\tfrac{1}{2}M\left[\left(\frac{d\bar{x}}{dt}\right)^2+\left(\frac{d\bar{y}}{dt}\right)^2+\left(\frac{d\bar{z}}{dt}\right)^2\right]+ +\sum \tfrac{1}{2}m\left[\left(\frac{d\xi}{dt}\right)^2+\left(\frac{d\eta}{dt}\right)^2+\left(\frac{d\zeta}{dt}\right)^2\right]$$

(37) $$\begin{cases} u=f_1(x, y, z, t) \\ v=f_2(x, y, z, t) \\ w=f_3(x, y, z, t) \end{cases}$$

(38) $$V=f(s, t)$$

(39) $$dV=\frac{\partial V}{\partial s}ds+\frac{\partial V}{\partial t}dt$$

(40) $$\frac{dV}{dt}=\frac{\partial V}{\partial s}\frac{ds}{dt}+\frac{\partial V}{\partial t}=V\frac{\partial V}{\partial s}+\frac{\partial V}{\partial t}$$

(41) $$\begin{cases} \dfrac{du}{dt}=u\dfrac{\partial u}{\partial x}+v\dfrac{\partial u}{\partial y}+w\dfrac{\partial u}{\partial z}+\dfrac{\partial u}{\partial t} \\ \dfrac{dv}{dt}=u\dfrac{\partial v}{\partial x}+v\dfrac{\partial v}{\partial y}+w\dfrac{\partial v}{\partial z}+\dfrac{\partial v}{\partial t} \\ \dfrac{dw}{dt}=u\dfrac{\partial w}{\partial x}+v\dfrac{\partial w}{\partial y}+w\dfrac{\partial w}{\partial z}+\dfrac{\partial w}{\partial t} \end{cases}$$

(42) $$\left[\rho u+\frac{\partial}{\partial x}(\rho u)\,dx\right]dydz$$

(43) $$\frac{\partial}{\partial x}(\rho u)\,dxdydz$$

the net outflow in the x-direction, per unit time, is a product of the differentials of x, y, and z and of the partial derivative, with respect to x, of the product of ρ and u (see 43). Combining this result with those of analogous considerations of fluid transport in the y- and z-directions shows that the net outflow rate caused by variations in space alone is given by a term composed of the product of three differentials and a factor that is a sum of partial derivatives (see 44). To cover the most general case, however, allowance must also be made for a possible variation (of mass inside the parallelepiped) with time; *i.e.*, for a change by an amount that is the partial derivative of ρ with respect to t, weighted with the product of the three differentials (see 45). The principle of the conservation of mass asserts that matter can neither be created nor destroyed. Accordingly, the overall net gain—*i.e.*, the sum of the preceding two expressions—must vanish, giving an equation restricting a sum of four partial derivatives to equal zero (see 46) or, transposing the first term above to the right, a restriction that equates the sum of four partial derivatives with the negative partial derivative ρ with respect to t (see 47). The sum of three terms on the left-hand side of equation (47) is called the divergence (div) of the fluid current density, ρV, and is generally written as $\text{div}(\rho V)$. Hence, the divergence of the product of ρ and V equals the negative of the partial derivative of ρ with respect to t (see 48). This result, known as the equation of continuity, is of fundamental significance, not only in the present context but throughout many other branches of science. It states that if $\text{div}(\rho V)$ on the left of equation (48) is a positive quantity and thus signifying a net outflow (from the parallelepiped), then $\partial\rho/\partial t$ must be negative (so as to make the right-hand member also positive). That is, exact balance is maintained between the net outflow and the decrease in density, and hence mass, within the parallelepiped. The converse also holds: If the mass, and hence the density, within the parallelepiped is to increase ($\partial\rho/\partial t$ positive, right-hand side negative), then this gain must be accompanied by a net inflow, or negative $\text{div}(\rho V)$, again in exact balance, as prescribed by equation (48). If the flow is steady, the divergence of the products of ρ and V is zero (see 49) and asserts that if there is to be no change in the fluid density or mass within the parallelepiped, then the net outflow or inflow, that is, $\pm\text{div}(\rho V)$, must equal zero. Again, equation (49) also states the converse: If there is no net flow out of or into the region $\pm\text{div}(\rho V) = 0$, then there can be no change in the fluid density or mass there. Finally, in the special but frequently encountered case of an incompressible fluid, equation (49) simplifies to the divergence of V, which is zero (see 50).

Meaning of divergence

Dynamic equation for an inviscid fluid. The preceding considerations have dealt mainly with the kinematics (*i.e.*, with the geometrical aspects) of fluid motion. Now attention is focussed on fluid dynamics; that is, on the interrelation between a specified set of forces and the resultant fluid motion. For the sake of clarity, only the case of an inviscid fluid—*i.e.*, one free from viscosity (internal friction or resistance to flow)—will be treated here. An infinitesimal parallelepiped of sides dx, dy, dz can be thought to be embedded in a fluid. Examining first the pressures exerted on this mass of fluid along the x-direction only, it is reasoned that if the pressure on the left-hand face is p, then that on the right-hand face is $-(p + \frac{\partial p}{\partial x}dx)$, the minus sign indicating that this pressure is exerted along the negative x-direction. Inasmuch as pressure is defined as force f_p per unit area normal (perpendicular) to f_p ($p = f_p/A$, $A =$ area), it follows that $f_p = pA$. Using subscripts L and R to indicate quantities to be evaluated at the left- and right-hand faces, respectively, the resultant pressure force in the $+x$-direction is found to be the x component of f_p expressed in terms of the partial derivative of p with respect to x (see 51), and in an exactly analogous manner it is found that the y component of f with respect to p and the z component have similar representations (see 52). If, in addition to the pressure, the fluid is also subject to an external pressure f_b per unit volume of fluid, then the additional force exerted on the mass contained in the parallelepiped is $f_b dxdydz$. This is called a body force, and f_b is called the body-force density. (A common example of a body force is that caused by gravity, or $f_b = \rho g$, in which g is the acceleration of gravity.) If P, Q, R, respectively, denote the x, y, and z components of f_b, then Newton's second law of motion—which states that net force is equal to mass times acceleration—may be invoked to formulate an inequality between, on the one hand, the difference between P and the partial derivative of p with respect to x and, on the other hand, a product of ρ and the derivative of u with respect to t (see 53), in which the acceleration is the time-rate of change of velocity, du/dt. Upon cancellation of the infinitesimal volume $dxdydz$ appearing on both sides of this equation, and applying corresponding considerations to the y and z components, it is found that three equations relate P, Q, R with partial derivatives of p, u, v, and w, ρ being a common factor in each (see 54). These three relations, sometimes called Euler's hydrodynamic equations, can be expressed more concisely by the single vector equation that identifies the difference between f_b and the gradient of p with the product of ρ and the derivative of V with respect to t (see 55) in which the vector symbol "grad" stands for the gradient of, and has components $\partial/\partial x$, $\partial/\partial y$, $\partial/\partial z$, respectively. If desired, the components of acceleration (du/dt, etc.) appearing on the right-hand side of equation (54) may be expressed in terms of the corresponding quantities given in equations (41).

Euler's hydrodynamic equations

(44) $$\left[\frac{\partial}{\partial x}(\rho u)+\frac{\partial}{\partial y}(\rho v)+\frac{\partial}{\partial z}(\rho w)\right]dxdydz$$

(45) $$\frac{\partial}{\partial t}(\rho)\,dxdydz$$

(46) $$\frac{\partial\rho}{\partial t}+\frac{\partial}{\partial x}(\rho u)+\frac{\partial}{\partial y}(\rho v)+\frac{\partial}{\partial z}(\rho w)=0$$

(47) $$\frac{\partial}{\partial x}(\rho u)+\frac{\partial}{\partial y}(\rho v)+\frac{\partial}{\partial z}(\rho w)=-\frac{\partial\rho}{\partial t}$$

(48) $$\text{div}(\rho V)=-\partial\rho/\partial t$$

(49) $$\text{div}(\rho V)=0$$

(50) $$\text{div}\,V=\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+\frac{\partial w}{\partial z}=0$$

(51) $$(f_p)_x=p_L dydz+p_R dydz=-\frac{\partial p}{\partial x}dxdydz$$

(52) $$(f_p)_y=-\frac{\partial p}{\partial y}dxdydz,\quad\text{and}\quad(f_p)_z=-\frac{\partial p}{\partial z}dxdydz$$

(53) $$\left(P-\frac{\partial p}{\partial x}\right)dxdydz=\rho\frac{du}{dt}dxdydz$$

(54) $$\begin{cases}P-\dfrac{\partial p}{\partial x}=\rho\dfrac{du}{dt}\\ Q-\dfrac{\partial p}{\partial y}=\rho\dfrac{dv}{dt}\\ R-\dfrac{\partial p}{\partial z}=\rho\dfrac{dw}{dt}\end{cases}$$

(55) $$f_b-\text{grad}\,p=\rho dV/dt$$

Steady flow of an inviscid fluid. In the study of energy transfer and of the forces exerted between the fluid and bodies interacting with it (*e.g.*, the blades of fans, pumps, compressors, turbines, and ship propellers), a knowledge of the pressure and velocity distribution is often essential. In principle, this knowledge may be obtained by experimentation: The actual body, a prototype or, alternately, a geometrically similar body equipped with suitable sensors and placed in a wind- or water-tunnel, may serve to furnish the desired information. In practice, however, such a procedure may not be feasible for technical, economical, or other reasons. A theoretical determination, instead, is therefore desirable. That this indeed is possible, will be shown here for a system comprising an incompressible and inviscid fluid, not subject to any body forces. For the sake of clarity, it is further assumed that the flow is essentially two-dimensional; *i.e.*, describable in terms of two coordinates, x and y, only. Physically, this means that the flow pattern does not vary with z: the flow in all planes parallel to the xy-plane is identical with that in the latter. Under these conditions, equations (46) and (54), respectively, reduce to the sum of partial derivatives of u and v, one with respect to x, one with respect to y, equalling zero (see 56), and two similar equations involving, as well, p, ρ, and t (see 57). Multiplying the two equations in (57) by dx and dy, respectively, and adding the results, gives an equality involving partial derivatives of p, derivatives of u and v, and a factor ρ (see 58), which equivalently may be written as the negative of the differential of p equal to ρ times a sum of terms involving differentials of u and v (see 59); whence, by integration, the negative of p equals a sum of two terms, one involving ρ and V, one involving K (see 60), with the result that the sum of p and a term composed of one-half ρ times the square of V is a constant (see 61).

Relation (61), which is sometimes called Bernoulli's equation, after the Swiss mathematician Daniel Bernoulli, shows that if the velocity V is known at each point of interest, then it is possible to calculate the corresponding pressure distribution, and vice versa. (To evaluate the constant in Bernoulli's equation, a knowledge of pressure p and velocity V at only one single point is needed.)

Velocity potential and stream function. Physical theories, when formulated in terms of vector quantities, have the advantage of strong physical directness or immediacy. On the other hand, such formulations tend to be unwieldy. Each vector relation referring to an n-dimensional event actually consists of n independent component equations. In addition, most operations with vectors are considerably more involved than operations with scalars. For these and related reasons, much effort has been expanded to devise alternative formulations of physical theories, not in terms of vectors, but in terms of scalar point functions $h(x, y, z)$, instead. With these, only one quantity (instead of n) is needed at each point, and only the simpler rules applicable to calculating with scalars need to be used.

In the present context, two such scalar functions will be considered, the treatment again being restricted to two dimensions (for greater clarity). The first of the functions, called the velocity potential, (x, y), is defined by certain relations (see 62), in which u and v are the velocity components in the x- and y-directions. It is to be noted that the single function, symbolized by the Greek letter phi, ϕ, implicitly contains both components of the velocity V. Furthermore, if there exist two velocity fields characterized by velocity potentials ϕ_1 and ϕ_2, respectively, then the scalar representation of the resultant velocity field is obtained by simply adding these potentials algebraically; *i.e.*, $\phi = \phi_1 + \phi_2$. The resultant velocities, if desired, are again obtained merely by differentiation of ϕ. Intricate forms of flow can thus be built up by simple superposition of two or more elementary velocity potentials.

The velocity potential

Using the relations (62) in the equation of continuity (50) or (56) gives a second-order partial differential equation for the function ϕ (see 63) known as Laplace's equation (first proposed by Pierre-Simon Laplace, an 18th–19th-century French scientist), of fundamental importance in mathematical physics: It must be satisfied for all incompressible flows.

Because $\phi = \phi(x, y)$—*i.e.*, ϕ is a function of position coordinates x and y—the total differential of ϕ is a sum of differential terms involving u, v and the differentials of x and y (see 64), for which use has been made of relations (62). Accordingly, an equipotential line is defined as a path along which $d\phi = 0$. That is, by equation (64), the derivative of y with respect to x restricted by ϕ is the negative ratio of u over v (see 65), which gives the slope of the equipotential line. (The subscript here means that ϕ is to be held constant.)

The other scalar, called the stream function and denoted by $\psi(x, y)$, is defined so that u and v are partial derivatives of ψ (see 66). With the aid of these relations, the total differential of ψ is expressible in terms of differentials for x and y, with v and u being multiplicative factors (see 67). Constancy of the stream function implies $d\psi = 0$, so that the derivative of y with respect to x restricted by ψ is the ratio of v to u (see 68). Recalling that u and v, respectively, denote the x- and y-components of the fluid velocity V, it is seen that equation (68) gives the slope of a line that is everywhere tangent to the fluid velocity. By definition, this line of constant ψ is therefore a streamline.

The stream function

It is further seen that the product of the slopes (65) and (68) is equal to -1. It follows by a theorem of elementary geometry that all streamlines are perpendicular to all equipotential lines. More succinctly, the two sets of lines are said to be mutually orthogonal. This orthogonality constitutes an important mathematical property, essential for the extensive and elegant treatment of fluid mechanics by methods developed in the so-called theory of functions of a complex variable.

Another property of the stream function is that it, too, satisfies Laplace's equation: the sum of second-order partial derivatives of ψ with respect to its two arguments is zero (see 69). This follows from differentiating equations (66) and using equations (62); *i.e.*, two partial differential equations of second order relate ψ and ϕ (see 70). Because the order of differentiating in the extreme right-hand members of equations (70) is immaterial, these members are equal in magnitude, but opposite in sign. Hence, adding these two equations yields the relation (69).

The preceding paragraphs illustrate some of the mathematical elegance (*e.g.*, formal symmetry, compact expression of orthogonality) achieved through the use of scalar functions in formulating the theory of fluid mechanics. In conclusion it may be noted, however, that this advantage is attained at some sacrifice in physical immediacy. Functions such as ϕ and ψ are essentially mathematical constructs and, as such, are more abstract than the corresponding vector fields. The prevalent and continuing use of such functions, nevertheless, signifies that this loss in physical directness is strongly outweighed, in a vast number of cases, by the advantages gained. (R.C.B.)

MECHANICS OF SOLIDS

Mechanics of solids is the science concerned with the behaviour of solid materials under the influence of forces that are in equilibrium. These forces may be mechanical in origin, such as gravity, inertia, or fluid pressure; or they may be electrical or magnetic.

Although solids essentially are systems of particles, the point of view adopted here differs from that in the first section of this article in which such systems are treated. There it is assumed that solids are rigid (*i.e.*, nondeformable) and hence undergo no changes under the action of forces except with regard to equilibrium and position. In mechanics of solids, the complementary point of view is taken: Attention is focussed on the deformation and disruption of solids under the influence of forces, without regard to changes of equilibrium or position.

The mathematical description of the relation between these forces and the concomitant deformations is the subject of the theory of elasticity. Accordingly, this will now be considered.

Elasticity; concept of stress. A solid of arbitrary shape may be considered subject to three forces, P_1, P_2, P_3, that are in equilibrium and therefore leave the solid at rest. If an imaginary cut is now made, destroying the cohesion of the solid, the two parts would move away from one another because the forces acting on each of the two parts are now no longer in equilibrium. Because, before the cut, the two parts did not move apart, it must of necessity be assumed that forces are acting within the solid on the cut face that prevent this movement. The forces must, therefore, be of such a character that their resultant balances the forces applied to each of the two parts. These internal forces, called into play by external forces acting on a solid, will be distributed in some manner over the surface of the imaginary cut, and each unit of area of the internal surface will carry an appropriate proportion of the force. This proportion of internal force carried by unit area is termed the stress.

Definition of stress

If the force that has to be balanced is P, and the area over which the stress can be assumed to be distributed is A, then the average magnitude of the stress at every point of the surface will be equal to the force divided by area, or P/A. In general, the distribution of stress over the area of an imaginary cut will not be uniform, and it is one of the general problems of the theory of elasticity to determine the exact distribution of stress in the interior of a solid subject to external forces.

If a solid, instead of being divided by one cut into two parts, is divided by a large number of cuts into many small cubes of unit volume, each of these cubes by the same reasoning will transmit a stress on each of its six cube faces. These stresses will not be acting at right angles to the cube faces, but each of them can be resolved into three components of which one, the normal stress, is acting at right angles to the cube face, and two components, called shear stresses, are acting in the cube face. Because there are six cube faces, there will be 18 such components. Those designated X_x, X_y, X_z, Y_x, Y_y, Y_z, Z_x, Z_y, Z_z are related to three faces.

Shear stresses

Equilibrium conditions. Considerations of equilibrium lead to certain relations between these 18 stress components which reduce their number to 6, of which 3 are normal stresses and 3 are shear stresses. Moreover, certain first-order partial differential equations containing the derivatives of the stress components with regard to a system of rectangular coordinates (Cartesian) can be deduced from considerations of equilibrium and continuity, and these equilibrium conditions form one set of fundamental equations that must be satisfied by the solutions obtained for any stress problem.

These three equilibrium conditions, in the absence of body forces—that is, forces proportional to mass and acting on each cubical element—are obtained in the form of three partial differential equations for components of X, Y, and Z (see 71), in which X_x, Y_y, Z_z are the three normal components, and $X_y = Y_x$, $X_z = Z_x$, $Y_z = Z_y$ are the three shear stress components.

Tensile and compressive stress; triaxial and plane stress. An example may be considered in the form of a solid composed of a fine wire, at the ends of which two forces of equal magnitude but opposite direction are acting, trying to tear the wire apart. Such forces produce stresses over any cross section of the wire, directed away from the area of the cross section. Such stresses are called tensile stresses.

A short pillar or block carrying a load at the top may also be considered; an equal and opposite reaction will be produced in the base of the pillar resting on the foundation. The pillar is under the influence of two forces trying to shorten it, and in every cross section of the pillar at right angles to the forces, stresses will be produced directed toward the surface of the cross section. Such stresses are termed compressive stresses. The wire under tension and the pillar under compression illustrate two of the simplest types of stress distributions in solids. The stress at every point of the solid will be the same, and will be in the same direction. If a small cubical element is considered with its edges parallel to the applied forces, only one of the six stress components is acting; all the others will be zero. Such a state of stress is called a uniaxial state of stress. The more general case in which stresses are acting on all six cube faces is a general triaxial state of stress.

If stresses are acting on only four of the six cube faces, the number of stress components will be reduced from six to three, and the problem is one of biaxial stress or plane stress.

In the wire under tension or the pillar under compression, the state of stress is the same at every point. Such states of stress, and they need not necessarily be uniaxial, are termed homogeneous states of stress. In general, the state of stress in a solid will be nonhomo-

$$(56)\quad \frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0$$

$$(57)\quad -\frac{\partial p}{\partial x}=\rho\frac{du}{dt}, \qquad -\frac{\partial p}{\partial y}=\rho\frac{dv}{dt}$$

$$(58)\quad -\frac{\partial p}{\partial x}dx-\frac{\partial p}{\partial y}dy=\rho\left(\frac{du}{dt}dx+\frac{dv}{dt}dy\right)$$

$$(59)\quad -dp=\rho\left(\frac{dx}{dt}du+\frac{dy}{dt}dv\right)$$

$$(60)\quad -p=\rho\left(\frac{u^2}{2}+\frac{v^2}{2}\right)=\tfrac{1}{2}\rho V^2+K$$

$$(61)\quad p+\tfrac{1}{2}\rho V^2=\text{constant}$$

$$(62)\quad u=\partial\phi/\partial x, \qquad v=\partial\phi/\partial y$$

$$(63)\quad \frac{\partial^2\phi}{\partial x^2}+\frac{\partial^2\phi}{\partial y^2}=0$$

$$(64)\quad d\phi=\frac{\partial\phi}{\partial x}dx+\frac{\partial\phi}{\partial y}dy=udx+vdy$$

$$(65)\quad (dy/dx)_\phi=-u/v$$

$$(66)\quad u=\partial\psi/\partial y, \qquad v=-\partial\psi/\partial x$$

$$(67)\quad d\psi=\frac{\partial\psi}{\partial x}dx+\frac{\partial\psi}{\partial y}dy=-vdx+udy$$

$$(68)\quad (dy/dx)_\psi=v/u$$

$$(69)\quad \frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}=0$$

$$(70)\quad \begin{cases}\dfrac{\partial^2\psi}{\partial x^2}=-\dfrac{\partial v}{\partial x}=-\dfrac{\partial^2\phi}{\partial x\partial y}\\[2ex] \dfrac{\partial^2\psi}{\partial y^2}=\dfrac{\partial u}{\partial y}=\dfrac{\partial^2\phi}{\partial y\partial x}\end{cases}$$

$$(71)\quad \begin{cases}\dfrac{\partial X_x}{\partial x}+\dfrac{\partial X_y}{\partial y}+\dfrac{\partial X_z}{\partial z}=0\\[2ex] \dfrac{\partial Y_x}{\partial x}+\dfrac{\partial Y_y}{\partial y}+\dfrac{\partial Y_z}{\partial z}=0\\[2ex] \dfrac{\partial Z_x}{\partial x}+\dfrac{\partial Z_y}{\partial y}+\dfrac{\partial Z_z}{\partial z}=0\end{cases}$$

geneous; this means it will be different at every point, or mathematically speaking: the state of stress is a function of the coordinates.

Concept of strain; Poisson's ratio. Under the influence of the forces acting on the wire discussed above, the ends will be displaced from some initial point A, B to points A' and B', respectively.

If the original length of the wire AB was l, and the stretched length $A'B'$ is l', then the extension Δl of the wire by the force P is $\Delta l = l' - l$. If the material of the wire is perfectly homogeneous, each unit length of wire will make an equal contribution to the total extension and the extension per unit length will be $\Delta l/l$. This is called the longitudinal strain.

Longitudinal strain

Exact measurements of the diameter of the wire before and after application of the load would reveal that, as the wire lengthens, the diameter diminishes. The longitudinal dilatation of the wire under the influence of the tensile forces P is accompanied by a lateral contraction. This lateral contraction per unit length of diameter will be only a fraction of the longitudinal strain, so that the volume of the wire will slightly increase. The ratio of lateral contraction to longitudinal extension is a constant for a given material and is termed Poisson's ratio, μ (named after Siméon-Denis Poisson, a 19th-century French mathematician). Its value varies between 0.2 and 0.5 for different materials. If the value of Poisson's ratio approaches 0.5, as it does for cork, there will be no change in volume in consequence of stress.

$$\text{(72)}\qquad \begin{cases} \dfrac{\partial^2 e_{xx}}{\partial y^2}+\dfrac{\partial^2 e_{yy}}{\partial x^2}-\dfrac{\partial^2 e_{xy}}{\partial x\partial y}=0 \\ \dfrac{\partial^2 e_{yy}}{\partial z^2}+\dfrac{\partial^2 e_{zz}}{\partial y^2}-\dfrac{\partial^2 e_{yz}}{\partial y\partial z}=0 \\ \dfrac{\partial^2 e_{zz}}{\partial x^2}+\dfrac{\partial^2 e_{xx}}{\partial z^2}-\dfrac{\partial^2 e_{xz}}{\partial x\partial z}=0 \end{cases}$$

$$\text{(73)}\qquad \begin{cases} \dfrac{\partial}{\partial x}\left(\dfrac{\partial e_{xy}}{\partial z}+\dfrac{\partial e_{xz}}{\partial y}-\dfrac{\partial e_{yz}}{\partial x}\right)-2\dfrac{\partial^2 e_{xx}}{\partial y\partial z}=0 \\ \dfrac{\partial}{\partial y}\left(\dfrac{\partial e_{yz}}{\partial x}+\dfrac{\partial e_{xy}}{\partial z}-\dfrac{\partial e_{xz}}{\partial y}\right)-2\dfrac{\partial^2 e_{yy}}{\partial x\partial z}=0 \\ \dfrac{\partial}{\partial z}\left(\dfrac{\partial e_{xz}}{\partial y}+\dfrac{\partial e_{yz}}{\partial x}-\dfrac{\partial e_{xy}}{\partial z}\right)-2\dfrac{\partial^2 e_{zz}}{\partial x\partial y}=0 \end{cases}$$

$$\text{(74)}\qquad \begin{cases} e_{xx}=\dfrac{\partial u}{\partial x}, & e_{xy}=\dfrac{\partial u}{\partial y}+\dfrac{\partial v}{\partial x} \\ e_{yy}=\dfrac{\partial v}{\partial y}, & e_{yz}=\dfrac{\partial v}{\partial z}+\dfrac{\partial w}{\partial y} \\ e_{zz}=\dfrac{\partial w}{\partial z}, & e_{xz}=\dfrac{\partial u}{\partial z}+\dfrac{\partial w}{\partial x} \end{cases}$$

Shear strain; general deformation; compatibility. The deformation produced by a general state of strain cannot be described in terms of dilatations and contractions alone. A square $ABCD$, under the influence of shear stresses, will deform into a rhombus $ABC'D'$ much in the manner of cards sliding over each other in a pack. The deformation is described by the angle DBD', and this is called a shear strain. If, as before, a solid of arbitrary shape is divided into a large number of small cubes, each of the cubes can in the most general case undergo dilatations or contractions in the directions of the three cube edges; in addition, each of the squares bounding the cube can undergo a shear strain so that the cube is deformed into a parallelepiped. The three dilatations in the directions of the coordinate axes and the three shear strains in the coordinate planes describe the deformation of the elementary cube completely; and, if these six strain components are known as functions of the coordinates, they are known at every point of the solid and the deformation of the solid is then fully described.

There is one important condition that must be satisfied by the strain components. If they were entirely independent of each other, then each elementary cube might be deformed in such a manner that, after deformation, the cubes would no longer fit together without gaps, and the continuity of the solid would be destroyed. In order to ensure the continuity of the solid after deformation, the functions representing the strain components must satisfy a set of six second-order partial differential equations, known as the compatibility conditions.

Compatibility conditions

These six compatibility conditions are obtained in the form of second-order partial differential equations for the strain functions (see 72 and 73), in which e_{xx}, e_{yy}, e_{zz} are the three normal strains and $e_{xy} = e_{yx}$, $e_{xz} = e_{zx}$, $e_{yz} = e_{zy}$ are the three shear strains. The compatibility conditions can be derived from the fact that the components of strain are derivatives of the components of the displacement vector. The displacement vector is a measure of the displacement of each cubical element in space with regard to a fixed system of coordinate axes. If the components of the displacement vector in the three directions x, y, z of the coordinate system are designated by u, v, w, respectively, the components of strain are derived as six expressions involving partial derivatives of u, v, and w (see 74). The compatibility conditions can be derived from these six equations by eliminating the three components of the displacement vector. These six equations are therefore equivalent to the compatibility equations and are frequently used in their place.

Relation between stress and strain. It is a fact of experience that a wire subjected to equal and opposite forces P at its ends extends. The extension is considered a consequence of the stresses produced in the wire by the forces. There exists, therefore, a relation of cause and effect between stress and strain, or strain can be considered a function of stress. This functional relationship must be expressible by some mathematical law, and two distinct possibilities for postulating such a law present themselves.

The one possibility would be to determine the relationship experimentally and then find a mathematical expression representing this relationship. This meets with formidable difficulties because such measurements are possible only for relatively simple states of stress and deformation and cannot be carried out for general states of deformation resulting from triaxial states of stress. Measurements on some metal wires and metal pillars, however, show that for certain simple types of stress, when the stresses do not exceed certain limits, the strain is proportional to stress so that a linear relationship holds.

For other metals and such materials as concrete, stone or timber, the relation even for simple states of stress is not linear. Such empirical stress–strain relations could be applied with confidence only within the region for which they have been experimentally confirmed.

The second possibility, and this is the one adopted in the classical theory of elasticity, is to postulate a relationship that will result in a mathematical theory aesthetically satisfying and at the same time simple. Only the assumption of a linear law permits this.

The linear relation between stress and strain is known as Hooke's law, so named after its discoverer, Robert Hooke of England (about 1676). It is applicable in many solid materials, provided the strains are sufficiently small. This law of proportionality has to be generalized for triaxial states of stress, and six equations can be written expressing the six strain components as linear functions of stress. This would involve 36 constants of proportionality.

Hooke's law

The proportionality between stress and strain does not involve elasticity, this being the property of the solid to recover its original shape completely after the forces producing the deformation are removed. Elasticity, on

the other hand, does not necessarily require proportionality between stress and strain. Modern spring steels recover their shape completely after deformation, but stress and strain do not obey even approximately a linear law. Despite these fundamental conceptual differences between stress–strain proportionality and elasticity, the two concepts are used indiscriminately in such a way that elasticity implies proportionality and vice versa. The theory of elasticity is not primarily concerned with elasticity, that is, with the behaviour of solids after removal of the load, but is essentially employed as a linear theory with proportionality when the load is applied.

The assumption of elasticity, however, permits the application of certain thermodynamic principles that enable the reduction of the 36 independent elastic constants to 21. This number can be further reduced to 15, and if it is assumed that the material is isotropic (see below) with regard to its elastic properties, the number of elastic constants can be reduced to 2. These are the modulus of elasticity, generally denoted by the symbol E, and Poisson's ratio, μ, which has already been mentioned. The modulus of elasticity E is also called Young's modulus after Thomas Young, an 18th–19th-century English scientist, who first defined it. It is, for a given material, the ratio between stress and strain for a simple uniaxial state of stress. Isotropy with regard to elastic properties means that the properties of the material are independent of direction. This is far from being true for most engineering materials. It is obviously not so for wood, which has different properties along and across the grain. Metals produced by casting, rolling, forging, or extrusion, however, will also exhibit some directionality with regard to elastic properties.

Young's modulus

The six equations of proportionality (or Hooke's law) for a general triaxial state of stress are obtained in the following forms: (a) Strains are expressed in terms of stresses in six relations involving E and G (see 75 and 76). In these equations, G is introduced as a further elastic constant, the modulus of rigidity. This, however, is not a third independent constant, but is a function of Young's modulus E and Poisson's ratio μ (see 77). (b) Stresses are expressed in terms of strains in six equations in which the constants G, μ, and e appear (see 78). In these equations e, written as a sum of three terms (see 79), is the change in volume of the unit cube of the material under the given state of stress, the cubical dilatation.

For a state of hydrostatic stress for which the three normal stress components $X_x = Y_y = X_z$ are equal to a uniform pressure p, and the three shear stress components $X_y = X_z = Y_z = 0$, the cubical dilatation from summation of equations (75) is obtained as two expressions relating e, μ, p, k, and E (see 80) and k is called the modulus of compression or bulk modulus of the material. The value for Poisson's ratio μ cannot exceed 0.5, because for values of μ greater than 0.5 the bulk modulus becomes negative, which would require the solid to increase its volume under hydrostatic pressure.

The bulk modulus

Principal stresses and strains; invariants and strain energy. The six stress components describing the state of stress and the six strain components describing the state of strain at every point are, of course, functions of the coordinate axes and will change if a different system of coordinate axes is used. They form what are called tensors in mathematics, and from this fact two important deductions can be made with regard to the effect of transformations of the coordinate axes.

The first deduction is that there are always three orthogonal directions for which, when they are chosen as the coordinate axes, the expressions for the shear stresses and shear strains become zero and the values of the normal stresses are extrema. These directions, by definition, are those of principal stress (or strain). The largest of the three principal stresses (or strains) will be the absolute maximum value of the stress (or strain) at the given point, and the smallest of the three will be the absolute minimum value. If the state of stress or strain is written in the form of a matrix (see 81), then for the three principal directions $x \to 1$, $y \to 2$, $z \to 3$, the state of stress will be fully characterized by three principal stress components, diagonal matrix components X_1, Y_2, Z_3 (see 82), and the state of strain by three principal strain components, diagonal matrix elements expressed in terms of e_{ij} (see 83). In the case of simple tension or compression already treated, the direction of the tensile or compressive stress will be a direction of principal stress, because the shear stresses in planes at right angles and parallel to this direction must be zero.

The equations of equilibrium (71), the compatibility conditions (72 and 73), and the equations of proportionality (75, 76, and 78) can be written in terms of principal stresses without losing generality.

In tensor analysis, it is shown that certain expressions can be formed from the components of tensors of the type used for the description of states of stress or strain that are invariants with regard to transformations of the coordinate axes. This is the second important deduction, because a physical quantity in which the formal structure and/or numerical value do not depend upon the choice of a particular coordinate system is evidently—*i.e.*, by definition—of more general validity than an expression the form and value of which do change from one coordinate system to another. Invariance of a physical quantity under coordinate transformation is generally taken to reveal some profound aspect, or intrinsic property, of the system considered.

Importance of invariance

In the present context, one set of invariants involving stresses and strains, respectively, is given by two linear equations (see 84). The first of these two expres-

(75) $$e_{xx}=\frac{1}{E}[X_x-\mu(Y_y+Z_z)], \qquad e_{xy}=\frac{1}{G}X_y$$

(76) $$\begin{cases} e_{yy}=\frac{1}{E}[Y_y-\mu(X_x+Z_z)], & e_{xz}=\frac{1}{G}X_z \\ e_{zz}=\frac{1}{E}[Z_z-\mu(X_x+Y_y)], & e_{yz}=\frac{1}{G}Y_z \end{cases}$$

(77) $$G=\frac{E}{2(1+\mu)}$$

(78) $$\begin{cases} X_x=2G\left(e_{xx}+\mu\frac{e}{1-2\mu}\right), & X_y=Ge_{xy} \\ Y_y=2G\left(e_{yy}+\mu\frac{e}{1-2\mu}\right), & X_z=Ge_{xz} \\ Z_z=2G\left(e_{zz}+\mu\frac{e}{1-2\mu}\right), & Y_z=Ge_{yz} \end{cases}$$

(79) $$e=e_{xx}+e_{yy}+e_{zz}$$

(80) $$e=3p\frac{1-2\mu}{E}=kp, \qquad k=3\frac{1-2\mu}{E}$$

(81) $$\begin{pmatrix} X_x & X_y & X_z \\ Y_x & Y_y & Y_z \\ Z_x & Z_y & Z_z \end{pmatrix}, \qquad \begin{pmatrix} e_{xx} & e_{xy} & e_{xz} \\ e_{yx} & e_{yy} & e_{yz} \\ e_{zx} & e_{zy} & e_{zz} \end{pmatrix}$$

(82) $$\begin{pmatrix} X_1 & 0 & 0 \\ 0 & Y_2 & 0 \\ 0 & 0 & Z_3 \end{pmatrix}$$

(83) $$\begin{pmatrix} e_{11} & 0 & 0 \\ 0 & e_{22} & 0 \\ 0 & 0 & e_{33} \end{pmatrix}$$

(84) $$\begin{cases} I_1^x=X_1+Y_2+Z_3 \\ I_1^e=e_{xx}+e_{yy}+e_{zz} \end{cases}$$

sions indicates that the sum of the three principal stresses is a constant. The second expression is the cubical dilatation; *i.e.*, a volume change. This change is independent of the coordinate system employed.

A second set of invariants involving the components of the stress and strain tensors (81), respectively, is two quadratic equations (see 85). Combining now the two relations (85) yields another invariant, namely U, equal to an expression involving E and μ (see 86), which can be shown to represent the strain energy per unit volume of the strained solid. The source of this energy is the work done by the external forces against the resistance of the solid to being deformed. This work, stored as elastic energy within the solid, is released when the external forces producing the deformation are removed. The unwinding of a clock spring is a good example of stored strain energy.

By combining the invariants—*i.e.*, the first equations, (84) and (85)—a similar expression for the strain energy density U can be obtained as three equations that identify U, U_1, and U_2 in terms of components of X, Y, and Z (see 87). Here, the term U_1 represents that part of the total strain energy U that is absorbed in changing the volume of the solid. The other term, U_2, called the shear strain energy, or the energy of distortion, is that part of U that is absorbed in a change in form without a change in volume.

Energy of distortion

The strain energy U plays an important role in the solution of many problems in the theory of elastic solids.

(J.F.Br./R.Wk.)

STATISTICAL MECHANICS

Basic definitions. Statistical mechanics is the branch of theoretical physics that seeks to draw a connection between the macroscopic viewpoint of matter and its microscopic constitution; the method is mathematical and quantitative. The behaviour of bulk macroscopic matter is described in such terms as volume, density, pressure, temperature, etc., none of which is meaningful when applied to single atoms or molecules. Yet, bulk laboratory matter does consist entirely of atoms and molecules. The momentary states of these are described classically by giving coordinate values, and velocities or momenta. The motions are governed by the laws of mechanics. The task of statistical mechanics is to infer the behaviour of bulk matter, the macroscopic system, from a knowledge of the structure of the molecules composing it, using the laws of mechanics.

One of the simplest of thermodynamic systems, a fixed mass of some particular monatomic gas such as neon, in a given volume V, having a known energy E, will serve as an example. Instead of mass, m, use of the thermodynamic variable N denoting the number of atoms is preferred. The three specifications of V, E, N suffice to define the thermodynamic state of this simple system at equilibrium; it will have a definite temperature T, pressure P, and chemical potential per atom, given by the Greek letter mu, μ. The number of atoms N is extremely large. Even for as little as a milligram of gas, it will be of order 10^{20}.

The mechanical state, or microstate, of such a gas at a given instant of time is described classically for each of the N atoms (specified by i, in which i has all values between 1 and N) by giving $3N$ Cartesian coordinates, x_i, y_i, z_i, and $3N$ vector components of velocity v_{xi}, v_{yi}, v_{zi}. Actually, the laws of mechanics in Hamiltonian form are used in statistical mechanics; *i.e.*, the coordinates and momenta, p_{xi}, p_{yi}, and p_{zi}, p_{xi}, $= m_i v_{xi}$, etc. (*e.g.*, momentum p_{xi} equals mass m_i times velocity v_{xi}), must be used instead of coordinates and velocities. This choice greatly simplifies the mathematical treatment of more complicated systems. The combination of $3N$ coordinates and $3N$ momenta is called the phase space of the system, and following the terminology introduced by a 20th-century Austrian-Dutch physicist, Paul Ehrenfest, is known as gamma-space (γ-space), for gas phase space. In contrast, the mu-space (μ-space) for molecule space is the six-dimensional phase space for a single molecule described by six coordinates x, p_x, y, p_y, z, and p_z. For molecules consisting of two or more atoms, internal coordinates and their conjugate momenta (so-called generalized momenta related to potential and kinetic energy) are used in addition to the three Cartesian coordinates of the centre of mass. The total necessary number, γ, of coordinates is called the number of degrees of freedom and is three times the total number of atoms. The microstate of the gas is represented at any time t by a single point in γ-space, or by N points, one for each molecule, in μ-space. The number of coordinates in μ-space is equal to three times the number of atoms per molecule, and as many momenta.

Phase space

When only the macrostate V, E, N is specified, then the allowed γ-space positions include states of abnormal properties. For instance, it includes many positions in which all, or a great preponderance, of the molecules are in one half of the volume, leaving the other half almost empty; or in which all of the molecules have nonzero momentum along the x-axis only, thus exerting zero pressure on the walls parallel to this axis.

The procedure of statistical mechanics is to calculate the probability or, more precisely, the probability density (see below) that the system will be found at a given point in γ-space. In the example of fixed V, E, N this can be shown to be constant in all parts of γ-space consistent with the restraints on total volume, total energy, and number of molecules. For each point in γ-space, the mechanical properties of the system are exactly determined; for instance, the pressure on each element of wall area, caused by collisions of the molecules with the wall. From this and the probability density in γ-space, the average of any mechanical property, such as the pressure, is computable. Furthermore, the probability that the pressure will differ from the predicted average by a specified amount can also be calculated. In agreement with empirical observation, one finds that for fractional deviations greater than the errors of measurement, the probabilities are negligibly small so long as N is large. A rough rule is that, ordinarily, fractional fluctuations appreciably greater than about $10/\sqrt{N}$ have quite negligible probabilities.

Probability. The concepts of probability enter fundamentally into all of statistical mechanics. For a given population such as the independent molecules of a perfect gas at temperature T, the quantity W_ν may be defined as the probability that a randomly selected molecule will be in the internal quantum state designated by ν. The sum of probabilities W_ν over all quantum states must be one (unity), because each molecule must be in some particular state; *i.e.*, the sum of W_ν is one (see 88), in which the mathematical notation Σ is used to indicate summation over all values of ν. If f is any quantity and any particular value f_ν is known for each state ν, then the average, written as $\langle f \rangle$, for the population is a weighted sum of f_ν (see 89) and the average of the square of f is a weighted sum of the squares of f_ν (see 90).

If, instead of an integer variable (*e.g.*, the number of molecules), the variable under consideration is continuous—*i.e.*, infinitely divisible—as in the case of the energy E, then the concept of probability density $W(E)$ is used. This quantity is defined in such a way that $W(E)\Delta E$ is the probability that the energy lies between E and $E + \Delta E$, in the limit as ΔE approaches zero. The quantity $W(E)$ is thus seen to be a probability per unit energy interval, ΔE; it is for this reason that $W(E)$ is termed a probability density (in close analogy with the more familiar mass density, or simply density, meaning mass per unit volume).

Probability density

A relation analogous to equation (88) can now be obtained by introducing an auxiliary quantity $W^*(E)$, defined as the probability that the energy is less than E or, formally, an equation relating W and W^* (see 91). Because E here is a continuous variable, the summation in equation (88) must be replaced by integration, so that the integral of W as a function of E is one (see 92), in which the integration is extended over the allowed range of the variable. The average, $\langle E \rangle$,

of the variable is an integral with integrand the product of E and W (see 93); the average of its square is an integral with the integrand containing as factors the square of E and the function W (see 94).

Perfect gas pressure and energy density. If E_k is the total kinetic energy of the molecular centre of mass in a perfect gas of volume V, then the pressure, P, is expressed (see 95) in terms of the number of molecules, N, and $\langle \varepsilon_k \rangle$, their average kinetic energy, which is the average of one-half the product of m times the square of v (see 96).

This relation may be derived as follows. Given a rectangular container with rigid walls, it is provisionally assumed that all molecules move with the same speed v, one-sixth of them along the positive and one-sixth along the negative directions of each of the three Cartesian axes, x, y, z. Without loss of generality, the system of coordinate axes may be chosen so that the positive x-axis is perpendicular to the right-hand wall of the container. The number of molecules striking unit area of this wall in a time t is given by $(1/6)(N/V)vt$. This is so because all molecules moving along the positive x-direction will in time t reach the unit area under consideration provided they are inside a cylindrical volume equal to $vt \times 1$; *i.e.*, a cylinder of length vt along the x-direction and of unit cross sectional area. The total number of such molecules within the cylinder is equal to the product of two factors: the number of these molecules per unit volume, and the volume in question; *i.e.*, $(N/6V) \times vt$.

Upon elastically colliding with the wall, each molecule undergoes a change in momentum equal to $2mv$. By Newton's second law of mechanics, therefore, the force exerted by the gas per unit area of the wall, or the pressure P, is expressed in terms of m, v, N, and V (see 97), or, in terms of the molecule's kinetic energy (see 95), P equals two-thirds the product of ε_k times the ratio of N to V (see 98).

The restrictions of the same speeds for all molecules and motions only along the Cartesian axes will now be removed. The pressure is the sum of the momentum changes of all molecules impinging on unit area in unit time. Denoting by $N(v_x)dv_x$ the number of molecules in V with x-component of velocity between v_x and $v_x + dv_x$, the number $N(v_x)/V$ (in a parallelepiped of unit base and height $v_x t$, of volume $v_x t \times 1$) will, if v_x is positive, strike a unit wall area perpendicular to the x-axis in an interval of time of duration t. An equal number will leave the wall with negative v_x in that time. Their summed momentum change is $mv^2tN(v_x)/V$, which, divided by t and summed by integration over v_x from minus infinity to plus infinity, is the pressure (see 99). Because the average squares of velocity components are equal (see 100) and their sum is $\langle v^2 \rangle$, $\langle v_x^2 \rangle = \frac{1}{3} \langle v^2 \rangle$ and the proof of (97) and (98) is complete.

Definition of a perfect, or ideal, gas

A perfect, or ideal, gas is defined as one that obeys an equation in which the product of V and P is a product of N, k, and T (see 103), in which T is the ideal gas temperature and k is Boltzmann's constant, equal to $1.380\,54 \times 10^{-16}$ erg per degree. If N_0 is Avogadro's number, equal to $6.022\,52 \times 10^{23}$, then R, the gas constant per mole, is expressed as an equality that relates R, N_0, and k (see 104), with numerical value 8.314 3 joule per mole. From (96) it follows that the average of ε_k is 3/2 of the product of k and T (see 105).

Maxwell-Boltzmann distribution. The probability density, W, of molecules in three-dimensional velocity space (denoted v, with its three components v_x, v_y, and v_z, which are parallel, respectively, to the three direction coordinates x, y, and z) is known as the Maxwell-Boltzmann distribution law, which will be derived below. It is written in exponential form (106) in terms of the velocity squared (v^2), which is the square of the absolute value of v, equal to the sum of the squares of the component velocities (see 107) and in terms of the mass (m), absolute temperature (T), and Boltzmann's constant (k). (The notation exp [a] for exponential a is the same as e^a, or the Naperian number $e = 2.718 \cdots$ raised to the power a.) In momentum space, in which momentum p equals mv, $W(p)$ is expressible as a negative exponential in which the square of p appears in the argument (see 108), with p^2 equal to $|p|^2$. In

(85) $$\begin{cases} I_2^x = X_x Y_y + X_x Z_z + Y_y Z_z - X_x^2 - Y_z^2 - X_z^2 \\ I_2^e = e_{xx}e_{yy} + e_{xx}e_{zz} + e_{yy}e_{zz} - e_{xy}^2 - e_{xz}^2 - e_{yz}^2 \end{cases}$$

(86) $$U = \frac{E(1-\mu)}{2(1+\mu)(1-2\mu)}(I_1^e)^2 - \frac{E}{1+\mu} I_2^e$$

(87) $$\begin{cases} U = U_1 + U_2 \\ U_1 = \dfrac{1-2\mu}{6E}(X_x + Y_y + Z_z)^2 \\ U_2 = \dfrac{1+\mu}{6E}[(X_x - Y_y)^2 + (Y_y - Z_z)^2 + (Z_z - X_x)^2] + \\ \qquad + \dfrac{1}{2G}(X_y^2 + X_z^2 + Y_z^2) \end{cases}$$

(88) $$\sum_\nu W_\nu = 1$$

(89) $$\langle f \rangle = \sum_\nu f_\nu W_\nu$$

(90) $$\langle f^2 \rangle = \sum_\nu f_\nu^2 W_\nu$$

(91) $$W(E) = \frac{dW^*(E)}{dE}$$

(92) $$\int W(E)\, dE = 1$$

(93) $$\langle E \rangle = \int dE\, E\, W(E)$$

(94) $$\langle E^2 \rangle = \int dE\, E^2\, W(E)$$

(95) $$P = \tfrac{2}{3} E_k / V = \tfrac{2}{3} \langle \varepsilon_k \rangle (N/V)$$

(96) $$\varepsilon_k = \langle \tfrac{1}{2} mv^2 \rangle$$

(97) $$P = [\tfrac{1}{6}(N/V)\, vt](2mv/t) = \tfrac{1}{3} mv^2 (N/V)$$

(98) $$P = \tfrac{2}{3}(\tfrac{1}{2} mv^2)(N/V) = \tfrac{2}{3} \varepsilon_k (N/V)$$

(99) $$P = \int_{-\infty}^{+\infty} dv_x\, mv_x^2 [N(v_x)/V] = m(N/V)\langle v_x^2 \rangle$$

(100) $$\langle v_x^2 \rangle = \langle v_y^2 \rangle = \langle v_z^2 \rangle,\ \langle v^2 \rangle = \langle v_x^2 + v_y^2 + v_z^2 \rangle$$

(101) $$\langle v_x^2 \rangle = \tfrac{1}{3} \langle v^2 \rangle$$

(102) $$\begin{cases} P = \sum_\nu \tfrac{2}{3} \varepsilon_{k,\nu} (N_\nu / V) \\ P = \tfrac{2}{3} \langle \varepsilon_k \rangle (N/V) = \tfrac{2}{3} E_k / V \end{cases}$$

(103) $$PV = NkT$$

(104) $$R = N_0 k, \qquad k = R/N_0$$

(105) $$\langle \varepsilon_k \rangle = \tfrac{3}{2} kT$$

(106) $$W(v_x, v_y, v_z) = W(v) = \left(\frac{m}{2\pi kT}\right)^{3/2} \exp\left(-\frac{m}{2kT}\right) v^2$$

(107) $$v^2 = |v|^2 = v_x^2 + v_y^2 + v_z^2$$

(108) $$W(\mathbf{p}) = (2\pi mkT)^{-3/2} \exp\left(-\frac{1}{2mkT}\right) p^2$$

$$W(p) = 4\pi p^2 (2\pi mkT)^{-3/2} \exp\left(-\frac{1}{2mkT}\right) p^2 \tag{109}$$

$$W(\varepsilon) = 2\pi \varepsilon_k^{1/2} (\pi kT)^{-3/2} \exp(-\varepsilon_k/kT) \tag{110}$$

$$\langle \varepsilon_k^2 \rangle = (15/4)(kT)^2 \tag{111}$$

$$\begin{cases} N(\rightarrow) = Ak\, W(\boldsymbol{v}_1) W(\boldsymbol{v}_2) \\ N(\leftarrow) = Ak\, W(\boldsymbol{v}_1') W(\boldsymbol{v}_2') \end{cases} \tag{112}$$

$$|\boldsymbol{v}_1|^2 + |\boldsymbol{v}_2|^2 = |\boldsymbol{v}_1'|^2 + |\boldsymbol{v}_2'|^2 \tag{113}$$

$$W(\boldsymbol{v}_1) W(\boldsymbol{v}_2) = W(\boldsymbol{v}_1') W(\boldsymbol{v}_2') \tag{114}$$

$$W(\boldsymbol{v}) = c \exp[-\gamma |\boldsymbol{v}|^2] \tag{115}$$

$$\int_{-\infty}^{+\infty} \iiint dv_x\, dv_y\, dv_z\, W(\boldsymbol{v}) = 1 \tag{116}$$

$$W(\boldsymbol{v}_1) W(\boldsymbol{v}_2) = c^2 \exp[-\gamma(|\boldsymbol{v}_1|^2 + |\boldsymbol{v}_2|^2)] \tag{117}$$

$$H(q^{(\nu)}, p^{(\nu)}) = \sum_{i=1}^{i=N} \frac{1}{2m_i} (p_{xi}^2 + p_{yi}^2 + p_{zi}^2) + U(x_1, \cdots, z_N) \tag{118}$$

$$r = ([x_a - x_b]^2 + [y_a - y_b]^2 + [z_a - z_b]^2)^{1/2} \tag{119}$$

$$\begin{cases} \cos\theta = (z_b - z_a)/r \\ \sin\phi = (y_b - y_a)/[(x_a - x_b)^2 + (y_a - y_b)^2] \end{cases} \tag{120}$$

$$\dot{q}_\nu = (\partial H/\partial p_\nu), \qquad \dot{p}_\nu = -(\partial H/\partial q_\nu) \tag{121}$$

$$\Delta\omega = \prod_{\nu=1}^{\nu=\gamma} \Delta q_\nu \Delta p_\nu \tag{122}$$

terms of the magnitude of momentum equal to $|p|$, W as a function of p is a negative exponential in which the square of p appears in the argument and also in the factor that multiplies the exponential (see 109); and, as a function of the kinetic energy, ε_k, the probability density is an exponential times a term that includes ε_k (see 110). Using equation (93) for the average of ε_k gives equation (105) as it must; and using (99) the average of the square of ε_k is proportional to the square of k times T (see 111).

One derivation of equation (106) is obtained by invoking the principle of microscopic reversibility, which asserts that, at equilibrium, any process and its reverse proceed at equal rates. An example is the collision of two molecules of equal mass and respective velocities $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$, resulting in velocities $\boldsymbol{v}_1'$ and $\boldsymbol{v}_2'$ after collision. To an observer moving with the velocity of their centre of mass, the two molecules have equal speeds, namely, $\frac{1}{2}|\boldsymbol{v}_2 - \boldsymbol{v}_1|$, and they approach each other on a line from opposite directions, collide, and leave each other on a line at some angle with the line of approach, again with equal speeds and opposite directions. The reverse process is the collision of molecules with velocities $\boldsymbol{v}_1'$ and $\boldsymbol{v}_2'$ to produce velocities $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$. Viewed from the centre of mass this process differs from the previous one only in the sign of the angle between the line of approach and the line of departure. According to the principle cited (and using the convention of arrows to denote direction), the intrinsic rate constants $k(\rightarrow)$ and $k(\leftarrow)$ for the two processes must therefore be equal; *i.e.*, $k(\rightarrow) = k(\leftarrow) = k$, in which k is a constant. The total numbers $N(\rightarrow)$ and $N(\leftarrow)$ of the two events will be individually proportional to k and to the product of the two probability densities, $W(\boldsymbol{v})$, evaluated at the initial colliding velocity values. With A representing a constant, it is thus found that the total numbers $N(\rightarrow)$ and $N(\leftarrow)$, which must be equal at equilibrium, are proportional to the product of two probability densities (see 112). Energy conservation requires that the sum of absolute squares of the $\boldsymbol{v}_i$ equal the sum of the absolute squares of $\boldsymbol{v}'_i$ (see 113), whereas equating $N(\rightarrow)$ to $N(\leftarrow)$ in (112) requires that the product of W evaluated at $\boldsymbol{v}_i$ be equal to the product of W evaluated at the arguments $\boldsymbol{v}'_i$ (see 114) as long as (113) applies. A solution of (114) is W as a function of $\boldsymbol{v}$, an exponential in which the exponent is proportional to $\boldsymbol{v}^2$ (see 115), and in which c—a constant—and γ—a function of mass (m), absolute temperature (T), and the Boltzmann constant (k)—are to be determined. A triple integral over all space in which the integrand is the function W must have the numerical value one (see 116). It follows that the product of W evaluated at two points is an exponential in which the exponent includes a sum of absolute squares (see 117) and, by (113), equals also $W(\boldsymbol{v}_1')W(\boldsymbol{v}_2')$. It can be shown that this is the only solution of (114) subject to (113).

The condition corresponding to equation (92)—that is, the total probability in $\boldsymbol{v}$-space is equal to unity (see 116)—requires that the constant c equal $(\gamma/\pi)^{3/2}$. The average kinetic energy $\langle \varepsilon_k \rangle$ is obtained by integrating the quantity $\frac{1}{2}m|\boldsymbol{v}|^2 W(\boldsymbol{v})$, and it is found to be equal to $\frac{3}{4}(m/\gamma)$, from which, with equation (105), γ becomes $(m/2kT)$. This completes the derivation of equation (106).

Gibbs's ensembles. The European investigators of the 19th century most frequently interpreted the bulk material properties of a thermodynamic system as being given by the time-averaged value of a single isolated system. J. Willard Gibbs, a physicist of the United States, however, introduced the concept of ensemble average. A Gibbsian ensemble consists of a large number, K, of systems, with the same thermodynamic specifications, and average values of physical quantities are calculated in the limit that K approaches infinity. This average value is then interpreted as the expectation value of a physical measurement on a real equilibrium system in the given thermodynamic state.

Ensemble average

One important distinction exists between describing the states of systems composing an ensemble and the description in classical thermodynamic theory. The thermodynamic state of an equilibrium system composed of one chemical component is defined (*i.e.*, specified) if its volume (V), energy (E), and number (N) of molecules are given. The system is then assumed to have an exact pressure (P), temperature (T), and chemical potential (μ). Any of six other choices of variable sets, however, can be used to define the same thermodynamic state in classical theory. These sets are: P, E, N; V, T, N; V, E, μ; or P, T, N; P, E, μ; and V, T, μ. One of the so-called extensive variables V, E, or N must be retained to fix the size of the system. Any of the other two can be substituted by its conjugate (corresponding) intensive variable, P, T, or μ. (An intensive variable is one the value of which is not changed when only part, instead of an entire equilibrium system, is being considered. Examples are pressure or temperature. Variables the values of which do change, such as volume or energy, are extensive.)

Gibbsian ensembles, on the other hand, are not identical for such different choices of variables. The ensemble consisting of isolated systems of fixed V, E, and N values is called the microcanonical ensemble, according to Gibbs's nomenclature. That of fixed V, T, and N values is called the petite canonical or simply the canonical ensemble and consists of systems of fixed V and N, in thermal equilibrium with an infinite heat reservoir at fixed temperature (T). The energies of the systems can fluctuate. Their average energy is interpreted as the thermodynamic value. The grand canonical ensemble, for which the thermodynamic state is described by V, T, and μ, comprises systems of fixed volume (V) in equilibrium through walls, permeable to both heat and molecules, with an infinite reservoir at

temperature (T) and with molecules of the same species at chemical potential (μ). This ensemble is sometimes referred to as one of open systems. Both energy and numbers of molecules can fluctuate; their average values are identified with the thermodynamic values.

Ensembles corresponding to other choices of variables are sometimes used, but for most problems one of the three Gibbsian ensembles is generally suited best. For systems containing several chemical species, a, b, c, $\cdots$, the minimum number of variables in the thermodynamic specification is equal to the number of components plus two. The number, N_a, N_b, $\cdots$, of molecules of the different species may be used or one or all replaced by the chemical potentials, μ_a, μ_b, $\cdots$.

Other extensive variables such as the electric or magnetic moments of the systems or the extensive strain tensor may enter the thermodynamic state specifications. Their conjugate intensive state variables are electric and magnetic fields and the stress tensor, respectively. These two sets of variables correspond to generalized displacements and generalized external forces, respectively, entirely analogous to the relation between volume and pressure. If attention is to be focussed on the electric, magnetic, or elastic properties of the system, introduction of the corresponding variables poses no fundamental difficulties. In the absence of such forces, the potential existence of these variables can be ignored.

Returning to the simple one-component system without external forces other than uniform pressure, it is found that for each choice of the triad of state variables, there is a thermodynamic function that is a minimum at equilibrium. For fixed V, E, and N this function is what may be defined as negative entropy ($-S$), a function of V, E, and N, namely, $-S(V, E, N)$. For fixed V, T, and N, it is the Helmholtz free energy $A(V, T, N)$ (see THERMODYNAMICS, PRINCIPLES OF), and for fixed V, T, and μ it is the negative pressure-volume product $-VP(T, \mu)$. The symbols $q^{(\gamma)}$, $p^{(\gamma)}$ are used to denote the entire set, $q^{(\gamma)} \equiv q_1, q_2, \cdots q_\gamma$ of γ coordinates, and conjungate momenta $p^{(\gamma)} \equiv p_1, p_2, \cdots p_\gamma$, necessary to describe the microstate. For each ensemble, Gibbs writes the probability density $W(q^{(\gamma)}, p^{(\gamma)})$ over the complete phase space (γ-space) for finding a random member-system of the ensemble at $p^{(\gamma)}$, $q^{(\gamma)}$. Each of these probability densities contains a constant factor. For the microcanonical ensemble of fixed V, E, N, the factor is $\exp[-S/k]$. For the canonical ensemble of fixed V, T, N, the factor is $\exp[A/kT]$, and for the grand canonical ensemble it is $\exp[-PV/kT]$. The condition that the integral of the probability density over the allowed range of the $p^{(\gamma)}$, $q^{(\gamma)}$ must be unity fixes the value of the functions $-S(V, E, N)/k$, $A(V, T, N)/kT$, $VP(T, \mu)/kT$ in the three ensembles, respectively. The thermodynamic characteristics of any system are completely determined if any one of the functions, $S(V, E, N)$, $A(V, T, N)$ or $VP(T, \mu)$, is known over the complete range of its variables. The choice of ensemble is generally based on considerations of convenience and of mathematical tractability.

Helmholtz free energy

The Hamiltonian. For the canonical and grand canonical ensembles, the Hamiltonian $H(p^{(\gamma)}, q^{(\gamma)})$ enters the expression for the probability density. The Hamiltonian for a system composed of atoms and molecules with purely conservative forces (*i.e.*, forces that can be written as the gradient of potential energy) is simply the expression for the energy, expressed as a function of the coordinate set $q^{(\gamma)}$ and the conjugate momenta $p^{(\gamma)}$.

The atoms composing the molecules of the system are treated as point masses. If Cartesian coordinates x_i, y_i, z_i, and momenta p_{xi}, p_{yi}, p_{zi}, $p_{xi} = mv_{xi}$, $\cdots$ are used for the ith particle of mass m_i, the Hamiltonian is the sum of kinetic energies expressed in terms of momenta and the potential energy functions (U), which depend on the coordinates $x_1, \cdots x_i, y_i, z_i, \cdots, z_N$ only (see 118). Actually, for molecules consisting of more than one atom, a transformation is made to other coordinates and momenta in order to simplify the expression for the potential, U. For instance, for a diatomic molecule comprised of atoms of types a and b with masses m_a and m_b, and total mass $m = m_a + m_b$, the coordinates x, y, and z of the centre of mass are $x = (1/m)(m_a x_a + m_b x_b)$, etc.; the distance r between the atoms is the square root of a sum of squares of differences (see 119) and two Eulerian angles, θ, ϕ, necessary to define the direction of the vector pointing from atom a to atom b, are given by the cosine and sine functions (see 120). The potential energy of an isolated molecule is then a function of r alone.

If a transformation is made to generalized coordinates, generalized momenta conjugate to the new coordinates must be used. These momenta are defined as follows. Using the notation $\dot{q}_\nu$ for velocity along the coordinate q_ν, ($\dot{q} = dq_\nu/dt$), the kinetic energy, K, is evaluated as a function $K(q^{(\gamma)}\dot{q}^{(\gamma)})$ of the set $q^{(\gamma)}$ of the generalized coordinates, $q_1, q_2, \cdots, q_\nu, \cdots, q_\gamma$, and $\dot{q}^{(\gamma)}$ of the corresponding velocities. The momentum p_ν conjugate to the coordinate q_ν is $p_\nu = \partial K/\partial \dot{q}_\nu$. The Hamiltonian of (118) is then transformed into a function of the generalized coordinates and momenta.

Generalized coordinates

The product of a single coordinate q_ν with its conjugate momentum p_ν *is* $q_\nu p_\nu = q_\nu \partial K/\partial \dot{q}_\nu$. Because K is the kinetic energy, the physical dimensions of $q_\nu p_\nu$ are always those of energy times time or, equivalently, of mass times length squared divided by time, which are the dimensions (*i.e.*, physical units) of Planck's constant h. The γ-space of 2γ-dimensions made up of γ coordinates and their γ conjugate momenta therefore always has a volume element of physical dimensions h^γ, irrespective of choice of coordinates. In addition, the Jacobian that expresses the ratio of the volume element $dq_1 dp_1 \cdots dq_\gamma dp_\gamma$ in one set of coordinates and momenta, $q^{(\gamma)}$, $p^{(\gamma)}$, to that, $dq_1' dp_1' \cdots dq_\gamma' dp_\gamma'$, of another set, $q'^{(\gamma)}$, $p'^{(\gamma)}$, is always unity. This means that the integral of any function of the coordinates and momenta over a physically specified region of γ-space is invariant under a transformation from one coordinate-momenta set to another. The integral does, however, depend on the units of mass, length, and time.

One great advantage of the Hamiltonian formulation is that also the canonical equations of motion—two equations identifying the time derivatives q_ν and p_ν with partial derivatives of H with respect to p_ν and q_ν (see 121)—remain invariant in form under such transformations.

When applied to the Hamiltonian (118) expressed in terms of Cartesian coordinates and momenta, the first of equations (121) gives the familiar relation $\dot{x} = p_x/m$ between velocity $\dot{x} = v_x$ and momentum p_x along the x-axis; and the second equation expresses Newton's law of motion, because the partial differentials $-\partial H/\partial x = \partial U/\partial x = f_x$, the force along the x-axis, so that $\dot{p}_x$ is equal to f_x.

Liouville's theorem. With the aid of Hamilton's canonical equations of motion (see 121), it can be shown that the flow of any ensemble probability density in γ-space is like that of an incompressible fluid, in the following sense. At some initial time $t = 0$, a given volume in γ-space will contain a certain number of points, each representing a member-system of the ensemble. Liouville's famous theorem asserts that although the shape of the volume under consideration changes as time progresses, the volume enclosing these points and no others remains unchanged; and, hence, also the density of system points in γ-space remains constant, all in exact analogy with the density of particles constituting an incompressible fluid (see above *Fluid mechanics*).

To prove Liouville's theorem, which is of fundamental importance in statistical mechanics and in related parts of mathematical physics, the initial volume may be taken to be a 2γ-dimensional parallelepiped, so that (in analogy with the familiar three-dimensional case in which $\Delta V = \Delta x \Delta y \Delta z$) one can write $\Delta\omega = \Delta q_1 \Delta p_1 \Delta q_2 \Delta p_2, \cdots, \Delta q_\gamma \Delta p_\gamma$; or, more concisely, $\Delta\omega$ equals a product extended over γ terms of Δ of q_ν and Δ of p_ν (see 122). Here the symbol Π (pi) means "the product of all terms like this, a typical one." Defining the quantity Δa_ν as a product of

Δq_ν and Δp_ν (see 123), it is seen that the time-rate of change of Δa_ν is a sum of terms each involving a product of a time derivative with a nondifferentiated term (see 124). But by Hamilton's canonical equations (121), time derivatives of Δq_ν and Δp_ν are expressible in terms of second partial derivatives of H and undifferentiated terms (see 125). Substituting the expressions (125) into equation (124) shows that $\dot{\overline{\Delta a}}_\nu$ is equal to zero for every ν. It follows from this result and from equations (122) and (123) that time derivatives of $\Delta\omega$ and Δa_ν are zero (see 126); *i.e.*, the volume in γ-space remains constant in time, which completes the proof of the first part of the theorem. The second part, that the number of system points within $\Delta\omega$ remains constant, can now be established by showing that system points initially inside the volume cannot leave $\Delta\omega$, and similarly, those initially outside cannot enter $\Delta\omega$. In order to leave $\Delta\omega$, an initially interior point would evidently have to cross the surface S bounding $\Delta\omega$. This is impossible, however, because once such a point reached the surface, it would coincide with one of the system points defining S; *i.e.*, at that instant both points would have the same position and momentum in γ-space, so that by the laws of classical mechanics both would continue to move in identical manner: The initially interior point would always remain at the boundary and hence could never leave $\Delta\omega$. By exactly analogous reasoning it follows that also an initially exterior system point can never enter $\Delta\omega$, and thus the proof of Liouville's theorem is complete.

In general, the probability density W of an ensemble in γ-space will be a function, $W(t, q^{(\gamma)}, p^{(\gamma)})$, of time, t, and of the phase space variables. It follows from Liouville's theorem that W remains constant in time if followed along the path of motion of the systems. That is, the total derivative is zero (see 127). Using the equations of motion (121) to substitute for $\dot{q}_\nu$ and $\dot{p}_\nu$ in equation (127), it is found that a time rate of change of W, at a fixed position in γ-space, is equal to the summation over gamma terms of a difference of products of partial derivatives of the functions H and W (see 128).

If W, at each point $q^{(\gamma)}, p^{(\gamma)}$ in phase space, depends only on the Hamiltonian, $H(q^{(\gamma)}, p^{(\gamma)})$, then the partial derivatives of W are expressible in terms of partial derivatives of H (see 129), so that by equation (128) the partial derivative of W with respect to t is by calculation zero (see 130). Because the probability density of an ensemble of equilibrium systems must be independent of time, $\partial W/\partial t$ must be zero. It follows from the reasoning leading to equation (130) that an equation for W, in which its dependence on position in γ-space is through the Hamiltonian, is an acceptable solution.

In any case, W must be constant along the path actually traversed by any isolated system starting from any initial point in γ-space within the macrostate specification V, E, and N. Such a path is at constant value of the Hamiltonian.

The ergodic surmise

The notion that every path (in the mathematical sense of almost every path) covers every point in γ-space before returning to its initial starting point is known as the ergodic surmise. Despite the expenditure of much effort, it has thus far been impossible to prove in a manner useful in physics. Moreover, in some cases, the surmise is in fact incorrect. The nature of the actual physical system, however, is always adequate for the appropriate region of γ-space to be specified. Assuming the ergodic surmise, the probability density W must be constant for all γ-space corresponding to a given energy, that is, to a given value of the Hamiltonian H.

Equations for ensemble probability densities. For the three Gibbsian ensembles, the probability density for the microcanonical of fixed V, E, and N is a constant—the function W with arguments $q^{(\gamma)}$ and $p^{(\gamma)}$ is an exponential with argument the negative of S divided by k (see 131); for the petite canonical of fixed V, T, and N the function W with arguments $q^{(\gamma)}$ and $p^{(\gamma)}$ is an exponential with argument depending upon H as a function of $q^{(\gamma)}$ and $p^{(\gamma)}$ (see 132); and for the grand canonical ensemble described by V, T, and μ, W as the function of $q^{(\gamma)}$ and $p^{(\gamma)}$ is an exponential with three terms in the argument, one constituted of the function H (see 133). The thermodynamic functions $-S/k$, A/kT, and $-PV/kT$ are then determined by the condition that the sum (or integral) of each $W(q^{(\gamma)}, p^{(\gamma)})$ must be unity.

The last statement needs amplification. The functions W above do not give the probability density that molecule number one is at x_1, y_1, z_1, molecule number two

(123) $$\Delta a_\nu = \Delta q_\nu \, \Delta p_\nu$$

(124) $$\dot{\overline{\Delta a}}_\nu = \dot{\overline{\Delta q}}_\nu \Delta p_\nu + \Delta q_\nu \dot{\overline{\Delta p}}_\nu$$

(125)
$$\begin{cases} \dot{\overline{\Delta q}}_\nu = \dfrac{\partial H(\cdots q_\nu + \Delta q_\nu \cdots)}{\partial p_\nu} - \dfrac{\partial H(\cdots q_\nu \cdots)}{\partial p_\nu} \\ \qquad = \dfrac{\partial^2 H}{\partial p_\nu \partial q_\nu} \Delta q_\nu \\ \dot{\overline{\Delta p}}_\nu = -\dfrac{\partial H(\cdots p_\nu + \Delta p_\nu \cdots)}{\partial q_\nu} + \dfrac{\partial H(\cdots p_\nu \cdots)}{\partial q_\nu} \\ \qquad = -\dfrac{\partial^2 H}{\partial p_\nu \partial q_\nu} \Delta p_\nu \end{cases}$$

(126) $$\dot{\overline{\Delta\omega}} = \Delta\omega \sum_{\nu=1}^{\nu=\gamma} (\dot{\overline{\Delta a}}_\nu / \Delta a_\nu) = 0$$

(127) $$\dot{W} = \frac{dW}{dt} = \frac{\partial W}{\partial t} + \sum_{\nu=1}^{\nu=\gamma} \left[\left(\frac{\partial W}{\partial q_\nu}\right) \dot{q}_\nu + \left(\frac{\partial W}{\partial p_\nu}\right) \dot{p}_\nu \right] = 0$$

(128) $$\frac{\partial W}{\partial t} = \sum_{\nu=1}^{\nu=\gamma} \left(\frac{\partial H}{\partial q_\nu}\frac{\partial W}{\partial p_\nu} - \frac{\partial H}{\partial p_\nu}\frac{\partial W}{\partial q_\nu} \right)$$

(129)
$$\begin{cases} \partial W/\partial p_\nu = (\partial H/\partial p_\nu)\, dW/dH \\ \partial W/\partial q_\nu = (\partial H/\partial q_\nu)\, dW/dH \end{cases}$$

(130) $$\frac{\partial W}{\partial t} = \sum_{\nu=1}^{\nu=\gamma} \left[\frac{\partial H}{\partial q_\nu}\frac{\partial H}{\partial p_\nu} - \frac{\partial H}{\partial p_\nu}\frac{\partial H}{\partial q_\nu} \right] \frac{dW}{dH} = 0$$

(131) $$W(q^{(\gamma)}, p^{(\gamma)}) = \exp[-S/k]$$

(132) $$W(q^{(\gamma)}, p^{(\gamma)}) = \exp[(1/kT)\{A - H(q^{(\gamma)}, p^{(\gamma)})\}]$$

(133) $$W(q^{(\gamma)}, p^{(\gamma)}) = \exp[(1/kT)\{-PV + N\mu - H(q^{(\gamma)}, p^{(\gamma)})\}]$$

(134)
$$\begin{cases} Q(V, E, N) = \\ \qquad \lim_{\Delta E \to 0} \{\Delta E^{-1} \int\int\cdots\int (N!h^\gamma)^{-1}\, dq^{(\gamma)} dp^{(\gamma)}\} \\ E \leqslant H(q^{(\gamma)} p^{(\gamma)}) \leqslant E + \Delta E \end{cases}$$

(135) $$Q(V, T, N) = \int_0^\infty dE\, Q(V, E, N) e^{-E/kT}$$

(136) $$Q(V, T, \mu) = \sum_{N=0}^{N=\infty} Q(V, T, N) e^{N\mu/kT}$$

(137) $$S = k \ln Q(V, E, N)$$

(138) $$A = -kT \ln Q(V, T, N)$$

(139) $$PV = kT \ln Q(V, T, \mu)$$

(140) $$Q(V, T, N) = \int (N!h^\gamma)^{-1} dq^{(\gamma)} dp^{(\gamma)} \exp[-(1/kT) H(q^{(\gamma)} p^{(\gamma)})]$$

(141) $$\mathfrak{H}\Psi_K = E_K \Psi_K$$

at x_2, y_2, z_2, $\cdots$, number N at x_N, y_N, z_N, with the corresponding momentum and internal coordinate and momentum values. What they do give are the probability densities that the position sets labeled 1, 2, $\cdots$, N are occupied by molecules, and no other molecules are in volume V. For every such assignment of position in γ-space, there are $N!$ (*e.g.*, 4! equals $4 \times 3 \times 2 \times 1$) identical points differing only in the order of labelling the coordinates and momenta. Hence the integral over the phase space must be divided by $N!$ If the system comprises different species, a, b, $\cdots$ of molecules, then the integral must be divided by $N_a!\, N_b! \cdots$.

As remarked above, the volume element in γ-space depends on the units used for mass, length, and time. Thus, the computed values of S/k and of A/kT equal to the difference $(E/kT) - (S/k)$ will depend on the physical units used. (In the case of the grand canonical ensemble, it is the value of μ for a given physical system that would change rather than that of pressure P.) This is consistent with the concepts of classical thermodynamics in which only differences of entropy are defined. Classically, entropy has no absolute value.

In the early part of the 20th century, a German physical chemist, W.H. Nernst, postulated that entropy has an absolute value such that crystalline materials have zero entropy at the absolute zero of temperature. This is now well established and known as the third law of thermodynamics. It applies not only to crystals but also to liquid helium at 0° K and to hypothetical perfect gases at zero temperature. The law is a consequence of quantum mechanics. Instead of integrating over phase space, a summation should be performed over the quantum states of the system. The classical Hamiltonian, $H(q^{(\gamma)}, p^{(\gamma)})$, must be replaced by the energy, E_K, of the system in the quantum state K, and summations are to be made over all quantum states of the system. If, however, along every one of the γ degrees of freedom of the system, the energy change is small compared to kT for a change $\Delta q_\nu \Delta p_\nu$ equal to Planck's constant h in the values of the coordinate and momentum, then the classical equations are asymptotically correct (correct in the limit as the energy change divided by kT goes to zero) if the integral is divided by h^γ. This follows from the fact that in a volume $\Delta\omega$ equal to $\Delta q_1 \Delta p_1 \times \Delta q_2 \Delta p_2 \times \Delta q_3 \Delta p_3 \times \cdots$, for which $\Delta q_\nu \Delta p_\nu$ is much greater than h for every ν-value from 1 up to and including γ, there are approximately $\Delta\omega / N! h^\gamma$ allowed quantum states.

Thus, the condition for semiclassical evaluation of the thermodynamic functions from any of the three ensemble probability equations (see 131–133) is to require that the integrals over γ-space, divided by $N! h^\gamma$, be unity.

Partition functions

The results, usually called partition functions and denoted by Q, are functions of the sets of variables defining the thermodynamic state of the systems in the microcanonical (see 134), petite canonical (see 135), and grand canonical (see 136) ensembles. The dimensionless thermodynamic functions S/k, $-A/kT$, and PV/kT, which take maximum values at equilibrium for the given state variables, are the natural logarithms (denoted ln; $\ln e^x = x$) of the corresponding partition functions. The equations (137), (138), and (139) follow.

Comparing the formal structures of equations (134), (135), and (136) might suggest that the first would be the easiest to use. This, however, is rarely the case, because integration within boundaries determined by the function $H(q^{(\gamma)}, p^{(\gamma)})$ is difficult to perform. The expression (135) can be written such that Q with arguments V, T, and N is an integral in which the exponential appears with the function H as argument (see 140), which is usually easier to evaluate than (134).

Justification of the equations. A rigorous derivation of the preceding equations is beyond the scope of this article. Hence, only an outline of one method is given here. It was stated above that for an isolated system of fixed V, E, and N, the probability density at equilibrium must be independent of position in γ-space. It can also be shown that $\ln Q(V, E, N)$ is proportional to the size of the system (for the sum of two independent systems, it is the sum of their individual ln Q's). Both position-independence and size-proportionality are properties of the entropy. If a natural process is permitted to occur in a previously constrained system of constant V, E, and N, such as opening a stopcock between two flasks of gas, making thermal contact between two previously isolated parts, or introducing a catalyst for a chemical reaction, then new regions of phase space are made accessible to the system. Thus, $\ln Q(V, E, N)$ always increases or (at worst) stays constant for such removal of a constraint; and so ln Q will be a maximum at equilibrium, as will S, by equation (137). Considering the exchange of energy through thermal contact between two systems, the sum of their energies remaining constant, the condition that $\ln Q(V, E, N)$ be a maximum requires that for the two systems to be at thermal equilibrium the quantity $\partial(k \ln Q)/\partial E$ must have the same value for both systems and that, in attaining this maximum, energy flows from that system for which the quantity $\partial(k \ln Q)/\partial E$ has the lower value to the system for which it is higher. It follows that $\partial(k \ln Q)/\partial E$ may be considered as the reciprocal of a possible temperature scale. Any two systems of equal $\partial(\ln Q)\partial E$ thus have the same temperature. Similarly, by considering volume exchange of two systems of equal temperature connected by a movable piston, $\partial(k \ln Q)/\partial V$ is found to be proportional to pressure. From the first law of thermodynamics for reversible processes, $T\, dS = dE + P\, dV$, it follows that the partial derivatives of the entropy S possess precisely these two characteristics; *i.e.*, $\partial S/\partial E = T^{-1}$ and $\partial S/\partial V = P/T$. Indeed, for a perfect gas, $\partial(\ln Q)/\partial E$ actually is $1/T$ and $\partial(k \ln Q)/\partial V$ is P/T. One therefore identifies $k \ln Q(V, E, N)$ with entropy (see 137).

For the other two ensembles, in which the systems are in contact with a reservoir, the case that the systems plus reservoir have constant V, E, and N is considered. The total entropy at equilibrium is a maximum, as before; from this condition equations (132) and (133) are derived for the ensembles of the systems alone.

Experimental values of the ratio of S/k for macroscopic systems are large. For normal laboratory conditions they are of order N, which will be 10^{20} or larger. Thus the partition function $Q(V, E, N)$ has prodigious values like $10^{10^{20}}$. This is essential for the present treatment because for sufficiently small numbers of molecules (N) the equations are inconsistent with thermodynamic relations. They are strictly compatible with these relations only in the limit as N approaches infinity. The discrepancies are numerically of order $(\ln N)/N$, which for N equal to 10^{20} is about 10^{-18}, a negligible quantity.

Quantum statistics. The mathematically more elegant formulation of quantum statistics uses the so-called density matrix formulation. A simpler formalism, however, is adequate for most equilibrium problems. The microstate of a quantum mechanical system is given by a single-valued continuous state function, $\Psi(q^{(\gamma)})$, of the coordinates. This function can always be expressed as a linear combination of the time-independent solutions Ψ_K of the Schrödinger equation. Using the symbol $\mathfrak{H}$ for the Hamiltonian quantum mechanical operator obtained from the classical Hamiltonian function $H(q, p)$ by replacing each p_ν by $(h/2\pi i)(\partial/\partial q_\nu)$ (see below *Quantum mechanics*) and using E_K for the energy of the system in the quantum state designated by K, the time-independent Schrödinger equation becomes a form in which the Hamiltonian quantum mechanical operator operating upon Ψ_K is equal to a constant times Ψ_K (see 141). The number K requires the specification of as many single quantum numbers as there are coordinates, the number of degrees of freedom, γ.

The Hamiltonian quantum mechanical operator

Not all formal solutions of equation (141) are physically allowed states. Only state functions, Ψ_K, that are antisymmetric under exchange of coordinates of any pair of identical fermions (protons, neutrons, or electrons), occur in nature. That is, the exchange of each such coordinate pair must change the function Ψ_K into its negative. If, however, the sum of protons, neutrons, and electrons in an atom or molecule is even (*i.e.*, $2n$ in

which n is any integer), the function is multiplied by $(-1)^{2n}$ equal to 1 when there is a pair exchange of identical atoms or molecules. The function is then said to be symmetric. Thus helium-4 ($^4_2$He), consisting of two protons, two neutrons, and two electrons, requires symmetric state functions, and helium-4 is said to be a boson and forms a Bose-Einstein system, whereas helium-3 ($^3_2$He), having one neutron less and hence an odd number of particles, forms a Fermi-Dirac system requiring antisymmetric functions.

Because the Hamiltonian is necessarily symmetric in exchange of identical entities, every one of the $N!$ functions obtained by making all $N!$ permutations on Ψ_K will also be a solution to (141), each with the same energy E_K. Only one linear combination of these, namely the sum of all-permuted functions, is symmetric. The sum with negative sign for odd numbers of pair permutations is antisymmetric. If, however, the original function is already symmetric in some pair exchanges, then fewer than $N!$ different functions will be produced by the permutations. Indeed, the antisymmetric sum will then be zero because, under these conditions, terms differing only in pair exchange at two mutually symmetrical positions will cancel pairwise.

Thus only (approximately) the fraction $1/N!$ of the solutions of equation (141) are allowed states. There are somewhat more than $1/N!$ for bosons demanding symmetric functions, and somewhat fewer for Fermi-Dirac systems. For both cases, the quantum mechanical analogue of equation (134) is Q as a function of Z, E, and N equal to a limit as ΔE approaches zero of a product of terms depending upon ΔE (see 142). Equation (135) is valid with (142) for the partition functions for $Q(V, E, N)$, but can now be written so that Q as a function of V, T, and N is a sum of exponentials (see 143), whence (136) becomes a form in which Q as a function of V, T, and μ is a double sum of exponential type (see 144). (J.E.Ma.)

ELECTROMAGNETIC THEORY

Electromagnetic theory is the science principally concerned with the causal interrelation between time-varying electric and magnetic fields and with the propagation of these fields in space and time. The theory is one of exceptional beauty and vastness of scope. The set of four famous Maxwell equations most elegantly and concisely summarizes the fundamentals of the entire theory. From these equations, James Clerk Maxwell proved that electromagnetic fields propagate *in vacuo* with a speed equal to that of light in empty space. His theory thus brought about one of those great (and rare) syntheses in physical science: The phenomena of electromagnetism and of optics, theretofore considered totally unrelated and distinct from each other (except by a few; see below), were for the first time demonstrated to be, in fact, manifestations of the same fundamental processes (*e.g.*, visible light is an electromagnetic wave). Moreover, though unknown to Maxwell, his theory also satisfies the stringent requirements (of Lorentz invariance) that were to be demanded 50 years later by Einstein's theory of relativity (see below). The profound significance of Maxwell's theory, *per se*, is closely paralleled by the vast range of its applicability. For it is now known that the electromagnetic-wavelength spectrum spans at least some 20 orders of magnitude, ranging in wavelengths from about 10^{-10} centimetre for nuclear gamma-rays, up to about 10^{10} centimetres for radio waves, with visible light constituting but a minute fraction.

Origin of the electromagnetic wave concept. Historically, the development of science has always been an essentially collective effort. Even the greatest of advances were made possible, in part, by the work of earlier investigators. In the case of mechanics, Isaac Newton, born in 1642, had drawn upon the work of his antecedents, notably on that of Galileo (died 1642). Similarly, Maxwell's theory, too, is the culmination in part of his predecessors' efforts. Already in 1752, the Swiss-born mathematician and physicist Leonhard Euler had envisioned all electrical, light, and gravitational phenomena as being associated with states of stress in a hypothetical, tenuous, all-pervading medium, the ether, in which these states were assumed capable of being propagated with one fixed velocity. Michael Faraday, an English experimental physicist of the 19th century, held similar views, but added the notion of electric lines of force originating on positive charges and terminating on negative charges of electricity. Magnetic lines of force, on the other hand, he held to form closed curves. He further postulated, with remarkable insight, that light consists of electric and magnetic lines of force in motion, and later suggested that both light and radiant heat might well consist of transverse vibrations of the stresses portrayed by the lines of force. In 1848, Gustav Robert Kirchhoff in Germany noted, as a coincidence, that the ratio between the electromagnetic and electrostatic units of charge is equal to the velocity of light; and in 1858, a German mathematician, Bernhard Riemann, presented a paper at the Göttingen academy in which he assumed a finite velocity of propagation of electric effects and deduced that it must be equal to the same ratio of units.

Faraday's concept of lines of force

Maxwell's field theory. *Basic concepts.* The following definitions and mathematical theorems are used in the formulation of Maxwell's equations. The electric field (or electric intensity) $\boldsymbol{E}$ is defined as the force per unit electric charge held fixed at a given point (it is often printed in boldface type because it is a vector, having direction). Electric charge in motion is said to constitute an electric current (or conduction current) $\boldsymbol{I}$, the magnitude of which is determined by the amount of charge passing through a given surface area per unit time. If the surface (S) is plane and perpendicular to the velocity of the moving charge, then $\boldsymbol{I}/S$ is called the average current density over S. In the limit as S tends to zero at some point P, the ratio $\boldsymbol{I}/S$ is called the current density ($\boldsymbol{J}$) at P. Conduction currents are typically found in metals, in which there are many electrons free to move under the impressed $\boldsymbol{E}$.

In other materials, called dielectrics, the electrons remain ordinarily bound to their parent-atom or -molecule. If an electric field is applied to such materials, some of the electrons will, nevertheless, become displaced relative to the positively charged nuclei of their parent-atoms. Furthermore, if a thin metal plate is introduced into the dielectric (or into empty space), then, under the influence of the electric field, some of the electrons in the plate will be displaced from one face to the other. For some particular orientation of the plate, this displacement of electrons will be a maximum. The ratio of the charge, thus displaced, to the area of the plate (or the surface-charge density) is called the displacement vector $\boldsymbol{D}$ at that particular place in the field. In noncrystalline, isotropic media, $\boldsymbol{D}$ is proportional to the electric field $\boldsymbol{E}$, so that $\boldsymbol{D}$ equals a product of a constant ε times $\boldsymbol{E}$ (see 145), in which the proportionality constant ε is called the dielectric coefficient of the material.

Three other quantities, namely, $\boldsymbol{B}$, $\boldsymbol{H}$, and μ, are similarly related: $\boldsymbol{B}$ equals a product of a constant times $\boldsymbol{H}$ (see 146). Here, $\boldsymbol{H}$ is called the magnetic field intensity; μ is the permeability of the medium; and $\boldsymbol{B}$, called the magnetic induction, may be defined by the equation $\boldsymbol{F}_m = q\boldsymbol{v} \times \boldsymbol{B}$, in which $\boldsymbol{F}_m$ is the force experienced by the charge q moving with velocity $\boldsymbol{v}$ in the presence of $\boldsymbol{B}$. The quantity $\boldsymbol{v} \times \boldsymbol{B}$, called the vector product (or cross product) of $\boldsymbol{v}$ and $\boldsymbol{B}$, is equal to the product of their respective magnitudes, v and B, and the sine of the angle θ between them, and is a vector in the direction of $\boldsymbol{n}$—*i.e.*, vB (sin θ) $\boldsymbol{n}$—here $\boldsymbol{n}$ is a unit vector perpendicular to both $\boldsymbol{v}$ and $\boldsymbol{B}$.

Two further definitions and two theorems, all involving vectors, are needed. These are as follows. The del (for delta) operator, which, in Cartesian coordinates, is a formal sum of products of unit vectors times partial derivative operators (see 147), in which $\boldsymbol{i}$, $\boldsymbol{j}$, $\boldsymbol{k}$ are unit vectors that are directed along the positive x-, y-, and z-axis, respectively.

The scalar product (or dot product) of two vectors A, B, is the product of the magnitudes A and B and the cosine of the angle θ between the two vectors (see 148). Using relations (147) and (148), Gauss's theorem asserts the equivalence of two integrals involving a closed surface, in which A is a vector; S is the closed surface, of which dS is a typical element; and τ is the volume enclosed by S (see 149). This relation allows a volume integral to be transformed into a surface integral, and *vice versa*. A similar relation, Stokes's theorem, permits a surface integral to be transformed into a line integral, and conversely (see 150). Here the integral on the left is over the closed curve s, of which ds is a typical element. The surface S is arbitrary except that it must be bounded by the curve s.

Maxwell's equations. The four celebrated equations (in differential form) are described as follows (see 151–154). Interpreting each of these briefly, equation 151 asserts that (in the parlance of *Fluid mechanics*, above) the divergence (div or $\nabla\cdot$) of the lines of displacement D is equal to the electric charge density ρ; *i.e.*, the charge contained in unit volume. Recalling that divergence refers to the net time-rate of outflow per unit volume, it is seen that there will be a net number of lines of D leaving (or entering) a given volume τ provided that the latter contains a net positive (or negative) amount of electric charge. If ρ is zero, then div D is also zero; that is to say, the net number of lines of D issuing from (or entering into) the volume is zero, and conversely.

Equation (152) states that the divergence of the magnetic induction (B) is always zero: The net number of lines of B leaving a given volume always vanishes. Geometrically, this will happen if, as Faraday had suggested, the lines of B form closed curves. Physically, it means that the magnetic charge density ρ_m is always zero; that is, there are no single isolated magnetic poles: north poles and south poles always occur in pairs, in contradistinction to the well-known existence of positive electric charge (as on a proton), separate and apart from negative charge (as on an electron).

Absence of isolated magnetic poles

According to equation (153) (in which the dot denotes differentiation with respect to time), the existence of a time-varying magnetic induction (B) will give rise to an electric field (E). In beautiful formal symmetry, equation (154) similarly informs that the presence of a time-varying displacement D (the displacement current $\dot{D}$) and a conduction current J gives rise to a magnetic field H. (The fundamental importance of the term $\dot{D}$ is explained below.)

The basis and derivation of each of equations (151) to (154) follow. According to Gauss's law (itself crucially dependent upon Coulomb's law that the force between two point-charges q_1, q_2, a distance r apart, k being a constant the numerical value of which depends upon the units used, is $F = kq_1q_2/r^2$), thoroughly verified experimentally, the net number of lines of D leaving any closed surface S is numerically equal to the net electric charge contained within the volume bounded by S. Mathematically, the integral around S of D dotted with the differential of S is the integral over τ of ρ (see 155), all symbols having their previously defined meanings. Applying Gauss's theorem (149) to the left-hand member of equation (155) gives a final equality (see 156), whence, by considering the volume itself to be arbitrarily small, it follows that the integrands are equal (see 151).

The observational fact that the displacement lines of B are always closed means that the net number of lines issuing from or entering a closed surface S is zero (see 157), which, by another application of equation (149), can also be written as an integral over τ of $\nabla\cdot B$ integrated with respect to the differential of τ equalling zero (see 158). If τ again is chosen to be an infinitesimal volume, it follows that the divergence of the magnetic induction is zero, as asserted by equation (152).

According to Faraday's law of electromagnetic induction, the electromotive force E is equal to the negative time-rate of change of flux Φ; *i.e.*, $E = -\Phi$. Substituting for E and Φ their respective defining expressions gives an equality between integrals, one a line integral of E dotted into the differential of s, one the negative of the integral over S of the time derivative of B dotted into the differential of S (see 159). Applying Stokes's theorem (150) allows (159) to be written as an equality between two integrals over S (see 160), so that choice of infinitesimal dS assures equality of the integrands, as stated in equation (153).

The empirical basis for (154) is given in part by Ampère's circuital law, according to which the line integral involving H is equal to the surface integral involving J (see 161). Treating the left-hand integral as in (159) above gives $\nabla\times H$ equal to J (see 162), which is not quite equation (154). The reason for this is that, un-

(142) $$Q(V,E,N)=\lim_{\Delta E\to 0}\left[\Delta E^{-1}\times\left(\begin{matrix}\text{Number of allowed states } K\\ \text{for which } E\leqslant E_K=E+\Delta E\end{matrix}\right)\right]$$

(143) $$Q(V,T,N)=\sum_K e^{-E_K/kT}$$

(144) $$Q(V,T,\mu)=\sum_N\sum_K e^{+(1/kT)(\mu N-E_K)}$$

(145) $$D=\varepsilon E$$

(146) $$B=\mu H$$

(147) $$\nabla=\mathbf{i}\frac{\partial}{\partial x}+\mathbf{j}\frac{\partial}{\partial y}+\mathbf{k}\frac{\partial}{\partial z}$$

(148) $$A\cdot B=AB\cos\theta$$

(149) $$\iint_S A\cdot dS=\int_\tau \nabla\cdot A\,d\tau$$

(150) $$\oint_s A\cdot ds=\int_S \nabla\times A\cdot dS$$

(151) $$\nabla\cdot D=\rho$$

(152) $$\nabla\cdot B=0$$

(153) $$-\dot{B}=\nabla\times E$$

(154) $$\dot{D}+J=\nabla\times H$$

(155) $$\oint_S D\cdot dS=\int_\tau \rho\,d\tau$$

(156) $$\int_\tau \nabla\cdot D\,d\tau=\int_\tau \rho\,d\tau$$

(157) $$\int_S B\cdot dS=0$$

(158) $$\int_\tau \nabla\cdot B\,d\tau=0$$

(159) $$\oint_s E\cdot ds=-\int_S \dot{B}\cdot dS$$

(160) $$\int_S \nabla\times E\cdot dS=\int_S -\dot{B}\cdot dS$$

(161) $$\oint_s H\cdot ds=\int_S J\cdot dS$$

(162) $$\nabla\times H=J$$

known until Maxwell discovered and remedied it, Ampère's law (160) is not correct. (The particular conditions prevailing during Ampère's experimentation were such as to make the error too small to be noticed.) That his law is inconsistent with the equation of continuity (see 163; see also above *Mechanics of fluids*) is readily seen by forming the divergence of the conduction current ($\nabla \cdot \boldsymbol{J}$) using equation (162). This gives $\nabla \cdot \boldsymbol{J}$ equal to zero (see 164); *i.e.*, the expression $\nabla \cdot \nabla \times \boldsymbol{A}$ is identically zero for any vector $\boldsymbol{A}$ (and hence also for $\boldsymbol{H}$). Yet, the right-hand sides of equations (163) and (164) should not equal zero, because equation (151) after differentiation with respect to time, shows that ∇ dotted into the time derivative of $\boldsymbol{D}$ is equal to the time derivative of ρ (see 165), and hence $\dot{\rho}$ is different from zero if $\nabla \cdot \dot{\boldsymbol{D}}$ is. It was one of Maxwell's greatest contributions to electromagnetic theory that he correctly resolved this fundamental difficulty by introducing the displacement current $\dot{\boldsymbol{D}}$ into the right-hand side of Ampère's law (159), so that $\nabla \times \boldsymbol{H}$ is a sum of $\boldsymbol{J}$ and the time derivative of $\boldsymbol{D}$ (see 166).

Forming the divergence of the conduction current with this augmented form gives minus the divergence of the displacement current, or $\nabla \cdot \boldsymbol{J}$ is the negative of ∇ dotted into the time derivative of $\boldsymbol{D}$ (see 167); or, by equations (151) or (165), $\nabla \cdot \boldsymbol{J}$ is the negative of the time derivative of ρ (see 168), correctly, as demanded by the equation of continuity (163). It is seen that equation (166) is identical with (154).

Velocity of electromagnetic waves. It remains to show that the electric and magnetic fields, $\boldsymbol{E}$ and $\boldsymbol{B}$, do satisfy the wave equation and that the velocity of propagation of these waves, as predicted by Maxwell's theory, is indeed equal to the empirical 3×10^{10} centimetres per second (cm/sec).

To perform these calculations, Maxwell's equations (151) to (154) are used, with both ρ and $\boldsymbol{J}$ equal to zero, as appropriate for empty space. Thus differentiation of (154) with respect to time (in which the double dot denotes a second differentiation with respect to time) gives the second-order time derivative of $\boldsymbol{D}$ as a cross product between ∇ and the time derivative of $\boldsymbol{H}$ (see 169), or, using equations (146) and (153), the second-order time derivative of $\boldsymbol{D}$ is a cross product between ∇ and a constant times a cross product between ∇ and $\boldsymbol{E}$ (see 170), in which the subscript 0 refers to empty space. But by equation (145), $\boldsymbol{D} = \varepsilon_0 \boldsymbol{E}$, so the second derivative of $\boldsymbol{E}$ with respect to time is proportional to a double cross product, terms in the products being ∇, ∇, and $\boldsymbol{E}$ (see 171).

A well-known vector identity states that an equality between a double cross product and a difference of $\nabla(\nabla \cdot \boldsymbol{E})$ and the formal square of the ∇ operator exists (see 172), in which $\nabla^2 = \nabla \cdot \nabla$. But the first term on the right-hand side of equation (172) vanishes because, in equation (151), ρ is zero. Equation (171) therefore becomes a form in which ∇^2 operating upon $\boldsymbol{E}$ is proportional to the second derivative of $\boldsymbol{E}$ with respect to time (see 173), which indeed is the wave equation; *i.e.*, the differential equation known to have solutions of the form in which the x component of $\boldsymbol{E}$ is the sum of two terms each with a factor f_i and each with a factor involving x, v, and t; similar expressions hold for other components (see 174), representing transverse waves propagating with velocity v given by the coefficient of $\ddot{\boldsymbol{E}}$ raised to the power $-\frac{1}{2}$, v is the square root of the reciprocal of the product of ε_0 and μ_0 (see 175). Substitution of the appropriate numerical values for ε_0, μ_0 gives $v = 3 \times 10^{10}$ identical with the observed value of the velocity of light in empty space.

The differential equations for velocity

To show also that $\boldsymbol{B}$ obeys the wave equation, equation (153) is differentiated with respect to time, giving the second derivative with respect to time of $\boldsymbol{B}$ equal to the cross product between ∇ and the time derivative of $\boldsymbol{E}$ (see 176). But by equations (145) and (154), again with $\boldsymbol{J}$ equal to 0, ε_0, ∇, times the time derivative of $\boldsymbol{E}$ is the cross product between ∇ and $\boldsymbol{H}$ (see 177), so that, using equation (146), an equality between the negative of the second derivative of $\boldsymbol{B}$ and a triple cross product involving $\frac{1}{\varepsilon_0}$, ∇, $\boldsymbol{B}$, and μ_0 is found (see 178). Application of the vector identity (172) and of the definition (146) gives a form in which ∇^2 operating on $\boldsymbol{B}$ is a constant times the second derivative of $\boldsymbol{B}$ (see 179), showing that also the magnetic induction $\boldsymbol{B}$ does satisfy the wave equation and is propagated with the same speed v, as given in (175). This concludes the proof.

For more detailed accounts, and for the treatment of other parts of the theory, the reader is referred to the articles ELECTRICITY and ELECTROMAGNETIC RADIATION and also to the various references given in the *Bibliography*. (Ed.)

RELATIVITY THEORY

Maxwell's electromagnetic theory (see above), published in England in 1855, had brilliantly unified not only electricity and magnetism, but also electromagnetism and optics. Closely related, and in a manner remarkably parallel to this, there followed Einstein's theory of relativity, published in Germany beginning in 1905, demonstrating the fundamental unity not only of space and time, but also that of mass and energy. In this section, edited from an article originally written by Einstein for the 13th edition of *Encyclopædia Britannica*, the concepts of space and time are presented. Other mathematical aspects of the theory, namely Riemannian geometry; Lorentz-transformation, -invariance, -contraction, and time-dilation, are treated in three sections that follow below. (See also the article on RELATIVITY.) (Ed.)

All thoughts and concepts are called up by sense experiences and have a meaning only in reference to these sense experiences. On the other hand, however, they are products of the spontaneous activity of the human mind; they are thus in no wise logical consequences of the contents of these sense experiences. Therefore, to grasp the essence of a complex of abstract notions it is necessary for the one part to investigate the mutual relationships between the concepts and the assertions made about them; for the other, to investigate how they are related to the experiences.

As far as the way is concerned in which concepts are connected with one another and with the experiences, there is no difference of principle between the concept systems of science and those of daily life. The concept systems of science have grown out of those of daily life and have been modified and completed according to the objects and purposes of the science in question.

The more universal a concept is, the more frequently it enters into human thought; and the more indirect its relation to sense experience, the more difficult it is to comprehend its meaning; this is particularly the case with prescientific concepts that are customarily used from the time of childhood. Consideration of the concepts referred to in the words "where," "when," "why," "being," to the elucidation of which innumerable volumes of philosophy have been devoted, illustrate the difficulty. The philosopher fares no better in speculations than a fish which should strive to become clear as to what is water.

Space. In the present section the meaning of "where," that is, of space, is of concern. It appears that there is no quality contained in individual primitive sense experiences that may be designated as spatial. Rather, what is spatial appears to be a sort of order of the material objects of experience. The concept "material object" must therefore be available if concepts concerning space are to be possible. It is the logically primary concept. This is easily seen if an analysis is made of the spatial concepts, for example, "next to," "touch," and so forth, that is, if their equivalents in experience are sought. The concept "object" is a means of taking into account the persistence in time or the continuity, respectively, of certain groups of experience complexes. The existence of objects is thus of a conceptual nature, and the meaning of the concepts of objects depends wholly on their being connected (intuitively) with groups of elementary sense experiences. This connection is the basis of the illusion that makes primitive

experience appear to provide information directly about the relation of material bodies (which exist, after all, only insofar as they are thought).

In the sense thus indicated there is (the indirect) experience of the contact of two bodies. Attention only is called to this; nothing is gained for the present purpose by singling out the individual experiences to which this assertion alludes. Many bodies can be brought into permanent contact with one another in manifold ways. In this sense the term "position relationships" of bodies is used. The general laws of such position relationships are essentially the concern of geometry. This holds, at least, if it is not desired to regard the propositions that occur in this branch of knowledge merely as relationships between empty words that have been set up according to certain principles.

The notion of "space" in prescientific thought

Now, it is important to examine the meaning of the concept "space" which is also encountered in prescientific thought. The concept of space in prescientific thought is characterized by the sentence: "It is possible to think away things but not the space which they occupy." It is as if, without having had experience of any sort, man had a concept, even a presentation, of space; and as if he ordered his sense experiences with the help of this concept present, a priori. On the other hand, space appears as a physical reality, as a thing which exists independently of thought, like material objects. Under the influence of this view of space the fundamental concepts of geometry, the point, the straight line, the plane, were even regarded as having a self-evident character. The fundamental principles that deal with these configurations were regarded as being necessarily valid and as having at the same time an objective content. No scruples were felt about ascribing an objective meaning to such statements as "three empirically given bodies (practically infinitely small) lie on one straight line," without demanding a physical definition for such an assertion. This blind faith in evidence and in the immediately real meaning of the concepts and propositions of geometry became uncertain only after non-Euclidean geometry had been introduced.

If a beginning is made from the view that all spatial concepts are related to contact experiences of solid bodies, it is easy to understand how the concept "space" originated, namely, how a thing independent of bodies and yet embodying their position possibilities was posited. If there is a system of bodies in contact and at rest relatively to one another, some can be replaced by others. This property of allowing substitution is interpreted as "available space." Space denotes the property in virtue of which rigid bodies can occupy different positions. The view that space is something with a unity of its own is perhaps due to the circumstance that in prescientific thought all positions of bodies were referred to one body (reference body), namely the earth. In scientific thought the earth is represented by the coordinate system. The assertion that it would be possible to place an unlimited number of bodies next to one another denotes that space is infinite. In prescientific thought the concepts "space" and "time" and "body of reference" are scarcely differentiated at all. A place or point in space is always taken to mean a material point on a body of reference.

The notion of "distance" in Euclidean geometry

If Euclidean geometry is considered, it is seen that it refers to the laws regulating the positions of rigid bodies. It turns to account the ingenious thought of tracing back all relations concerning bodies and their relative positions to the very simple concept "distance." Distance denotes a rigid body on which two material points (marks) have been specified. The concept of the equality of distances (and angles) refers to experiments involving coincidences; the same remarks apply to the theorems on congruence. Now, Euclidean geometry, in the form in which it has been handed down from Euclid, uses the fundamental concepts "straight line" and "plane" which do not appear to correspond, or at any rate, not so directly, with experiences concerning the position of rigid bodies. (On this it must be remarked that the concept of the straight line may be reduced to that of distance. A hint of this is contained in the theorem: "The straight line is the shortest connection between two points." This theorem served well as a definition of the straight line, although the definition played no part in the logical texture of the deductions.) Moreover, geometricians were less concerned with bringing out the relation of their fundamental concepts to experience than with deducing logically the geometrical propositions from a few axioms enunciated at the outset.

A brief outline may be made to show how perhaps the basis of Euclidean geometry may be gained from the concepts of distance. To start from the equality of distances (the axiom of the equality of distances) makes it possible to suppose that of two unequal distances one is always greater than the other. The same axioms are to hold for the inequality of distances as hold for the inequality of numbers. Three distances $\overline{AB'}$, $\overline{BC'}$, $\overline{CA'}$ may, if CA' be suitably chosen, have their marks BB', CC', AA' superposed on one another in such a way that a triangle ABC results. The distance CA' has an upper limit for which this construction is still just possible. The points A, (BB') and C then lie in a "straight line" (definition). This leads to the concepts: producing a distance by an amount equal to itself; dividing a distance into equal parts; expressing a distance in terms of a number by means of a measuring rod (definition of the space interval between two points).

When the concept of the interval between two points or the length of a distance has been gained in this way, it is necessary to require only the following axiom in order to arrive at Euclidean geometry analytically. To every point of space (body of reference) three num-

$$\nabla \cdot J = -\dot{\rho} \tag{163}$$

$$\nabla \cdot J = \nabla \cdot \nabla \times H \equiv 0 \tag{164}$$

$$\nabla \cdot \dot{E} = \dot{\rho} \tag{165}$$

$$\nabla \times H = J + \dot{D} \tag{166}$$

$$\nabla \cdot J = -\nabla \cdot \dot{D} \tag{167}$$

$$\nabla \cdot J = -\dot{\rho} \tag{168}$$

$$\ddot{D} = \nabla \times \dot{H} \tag{169}$$

$$\ddot{D} = \nabla \times \left(-\frac{1}{\mu_0} \nabla \times E \right) \tag{170}$$

$$\varepsilon_0 \ddot{E} = -\frac{1}{\mu_0} \nabla \times (\nabla \times E) \tag{171}$$

$$\nabla \times (\nabla \times E) = \nabla(\nabla \cdot E) - \nabla^2 E \tag{172}$$

$$\nabla^2 E = (\varepsilon_0 \mu_0) \ddot{E} \tag{173}$$

$$E_x = f_1(x - vt) + f_2(x + vt), \cdots \tag{174}$$

$$v = (1/\varepsilon_0 \mu_0)^{1/2} \tag{175}$$

$$-\ddot{B} = \nabla \times \dot{E} \tag{176}$$

$$\varepsilon_0 \dot{E} = \nabla \times H \tag{177}$$

$$-\ddot{B} = \nabla \times \left(\frac{1}{\varepsilon_0} \nabla \times \frac{B}{\mu_0} \right) \tag{178}$$

$$\nabla^2 B = (\varepsilon_0 \mu_0) \ddot{B} \tag{179}$$

bers (coordinates) x, y, z may be assigned—and conversely—in such a way that for each pair of points A (x_1, y_1, z_1) and B (x_2, y_2, z_2) Pythagoras' theorem holds (see 180).

All further concepts and propositions of Euclidean geometry can then be built up purely logically on this basis, in particular also, the propositions about the straight line and the plane. These remarks are not, of course, intended to replace the strictly axiomatic construction of Euclidean geometry. It is merely wished to indicate plausibly how all conceptions of geometry may be traced back to that of distance. It would have been equally well to have epitomized the whole basis of Euclidean geometry in the last theorem above. The relation to the foundations of experience would then be furnished by means of a supplementary theorem. The coordinate may and *must* be chosen so that two pairs of points separated by equal intervals, as calculated by the help of Pythagoras' theorem, may be made to coincide with one and the same suitably chosen distance (on a solid). The concepts and propositions of Euclidean geometry may be derived from Pythagoras' proposition without the introduction of rigid bodies; but these concepts and propositions would not then have contents that could be tested. They are not "true" propositions but only logically correct propositions of purely formal content.

A serious difficulty is encountered in the above represented interpretation of geometry in that the rigid body of experience does not correspond *exactly* with the geometrical body. There are no absolutely definite marks, and, moreover, temperature, pressure, and other circumstances modify the laws relating to position. It is also to be recollected that the structural constituents of matter (such as atom and electron) assumed by physics are not in principle commensurate with rigid bodies, but that nevertheless the concepts of geometry are applied to them and to their parts. For this reason consistent thinkers have been disinclined to allow real contents of facts to correspond to geometry alone. They considered it preferable to allow the content of experience to correspond to geometry and physics conjointly.

This view is certainly less open to attack than the one represented above; as opposed to the atomic theory, it is the only one that can be consistently carried through. Nevertheless, it would not be advisable to give up the first view, from which geometry derives its origin. This connection is essentially founded on the belief that the ideal rigid body is an abstraction that is well rooted in the laws of nature.

The question arises: what is a priori certain or necessary, respectively, in geometry (doctrine of space) or its foundations? Formerly it was thought everything; nowadays it is thought nothing. Already the distance concept is logically arbitrary; there need be no things that correspond to it, even approximately. Something similar may be said of the concepts straight line, plane, of three-dimensionality and of the validity of Pythagoras' theorem. Even the continuum doctrine is in no wise given with the nature of human thought, so that from the epistemological point of view no greater authority attaches to the purely topological relations than to the others.

It is necessary yet to deal with those modifications in the space concept which have accompanied the advent of the theory of relativity. For this purpose the space concept of the earlier physics can be considered from a point of view different from that above. If the theorem of Pythagoras to infinitely near points is applied, it involves ds (see 181), in which ds denotes the measurable interval between them. For an empirically given ds the coordinate system is not yet fully determined for every combination of points by this equation. Besides being translated, a coordinate system may also be rotated. This signifies analytically: The relations of Euclidean geometry are covariant with respect to linear orthogonal transformations of the coordinates.

In applying Euclidean geometry to pre-relativistic mechanics, a further indeterminateness enters through the choice of the coordinate system: the state of motion of the coordinate system is arbitrary to a certain degree, namely, in that substitutions of the coordinates (see 182) also appear possible. On the other hand, earlier mechanics did not allow coordinate systems to be applied of which the states of motion were different from those expressed in these equations. In this sense the term "inertial systems" is used. In these favoured inertial systems there is a new property of space as far as geometrical relations are concerned. Regarded more accurately, this is not a property of space alone but of the four-dimensional continuum consisting of time and space conjointly.

Interrelationship of space and time

Time. At this point, time enters explicitly into the discussion for the first time. In their applications space (place) and time always occur together. Every event that happens in the world is determined by the space coordinates x, y, z and the time coordinate t. Thus the physical description was four-dimensional right from the beginning. But this four-dimensional continuum seemed to resolve itself into the three-dimensional continuum of space and the one-dimensional continuum of time. This apparent resolution owed its origin to the illusion that the meaning of the concept "simultaneity" is self-evident, and this illusion arises from the fact that news is received of near events almost instantaneously owing to the agency of light.

This faith in the absolute significance of simultaneity was destroyed by the law regulating the propagation of light in empty space or, respectively, by the Maxwell-Lorentz electrodynamics. Two infinitely near points can be connected by means of a light signal if a simple relation (see 183) holds for them. It further follows that ds has a value that, for arbitrarily chosen infinitely near space-time points, is independent of the particular inertial system selected. In agreement with this, it is found that, for passing from one inertial system to another, linear equations of transformation hold which do not in general leave the time values of the events unchanged. It thus became manifest that the four-dimensional continuum of space cannot be split up into a time continuum and a space continuum except in an arbitrary way. This invariant quantity ds may be measured by means of measuring rods and clocks.

The four-dimensional continuum

On the invariant ds a four-dimensional geometry may be built up which is in a large measure analogous to Euclidean geometry in three dimensions. In this way physics becomes a sort of statics in a four-dimensional continuum. Apart from the difference in the number of dimensions, the latter continuum is distinguished from that of Euclidean geometry in that ds^2 may be greater or less than zero. Corresponding to this, differentiation is made between timelike and spacelike line elements. The boundary between them is marked out by the element of the "light-cone" $ds^2 = 0$ which starts out from every point. If only elements which belong to the same time value are considered, an expression for $-ds^2$ is obtained that is formally identical with that of ds^2 given by the Pythagorean theorem (see 181). These elements ds may have real counterparts in distances at rest and, as before, Euclidean geometry holds for these elements.

This is the modification which the doctrine of space and time has undergone through the restricted theory of relativity. The doctrine of space has been still further modified by the general theory of relativity, because this theory denies that the three-dimensional spatial section of the space-time continuum is Euclidean in character. Therefore, it asserts that Euclidean geometry does not hold for the relative positions of bodies that are continuously in contact.

The empirical law of the equality of inertial and gravitational mass led to the interpretation of the state of the continuum, insofar as it manifests itself with reference to a noninertial system, as a gravitational field, and to the treatment of noninertial systems as equivalent to inertial systems. Referred to such a system, which is connected with the inertial system by a nonlinear transformation of the coordinates, the metrical in-

variant ds^2 assumes a general form (see 184) in which certain functions $g_{\mu\nu}$ are functions of the coordinates and in which the sum extended over the indices of these functions is to be taken over the indices for all combinations 11, 12, · · · , 44. The variability of the $g_{\mu\nu}$'s is equivalent to the existence of a gravitational field. If the gravitational field is sufficiently general, it is not possible at all to find an inertial system, that is, a coordinate system with reference to which ds^2 may be expressed in the simple form already given (see 185); but in this case, too, there is in the infinitesimal neighbourhood of a space-time point a local system of reference for which the last-mentioned simple form for ds holds. This state of the facts leads to a type of geometry which Riemann's genius created more than half a century before the advent of the general theory of relativity of which Riemann divined the high importance for physics.

Riemann's geometry of an n-dimensional space bears the same relation to Euclidean geometry of an n-dimensional space as the general geometry of curved surfaces bears to the geometry of the plane. For the infinitesimal neighbourhood of a point on a curved surface, there is a local coordinate system in which the distance ds between two infinitely near points is given by an equation (see 186). For any arbitrary (Gaussian) coordinate system, however, an expression of a known form (see 187) holds in a finite region of the curved surface. If the $g_{\mu\nu}$'s are given as functions of x_1 and x_2, the surface is then fully determined geometrically. For from this formula it is possible to calculate for every combination of two infinitely near points on the surface the length ds of the minute rod connecting them; and with the help of this formula all networks that can be constructed on the surface with these little rods can be calculated. In particular, the "curvature" at every point of the surface can be calculated; this is the quantity that expresses to what extent and in what way the laws regulating the positions of the minute rods in the immediate vicinity of the point under consideration deviate from those of the geometry of the plane.

This theory of surfaces by Gauss has been extended by Riemann to continua of any arbitrary number of dimensions and has thus paved the way for the general theory of relativity. For it was shown above that corresponding to two infinitely near space-time points there is a number ds which can be obtained by measurement with rigid measuring rods and clocks (in the case of timelike elements, indeed, with a clock alone). This quantity occurs in the mathematical theory in place of the length of the minute rods in three-dimensional geometry. The curves for which $\int ds$ has stationary values determine the paths of material points and rays of light in the gravitational field, and the "curvature" of space is dependent on the matter distributed over space.

Just as in Euclidean geometry the space concept refers to the position possibilities of rigid bodies, so in the general theory of relativity the space-time concept refers to the behaviour of rigid bodies and clocks. The space-time continuum, however, differs from the space continuum in that the laws regulating the behaviour of these objects (clocks and measuring rods) depend on where they happen to be. The continuum (or the quantities that describe it) enters explicity into the laws of nature, and conversely these properties of the continuum are determined by physical factors. The relations that connect space and time can no longer be kept distinct from physics proper. Nothing certain is known of what the properties of the space-time continuum may be as a whole. Through the general theory of relativity, however, the view that the continuum is infinite in its timelike extent but finite in its spacelike extent has gained in probability.

Subjective notions of time

The physical time concept derives from the time concept of the nonscientific mind. Now, the latter has its root in the time order of the experiences of the individual, and this order must be accepted as something primarily given. Man experiences the moment "now," or, expressed more accurately, the present sense experience combined with the recollection of (earlier) sense experiences. That is why the sense experiences seem to form a series, namely the time series indicated by "earlier" and "later." The experience series is thought of as a one-dimensional continuum. Experience series can repeat themselves and can then be recognized. They can also be repeated inexactly, wherein some events are replaced by others without the character of the repetition becoming lost. In this way man forms the time concept as a one-dimensional frame that can be filled in by experiences in various ways. The same series of experiences answer to the same subjective time intervals.

The transition from this "subjective" time to the time concept of prescientific thought is connected with the formation of the idea that there is a real external world independent of the subject. In this sense the (objective) event is made to correspond with the subjective experience. In the same sense, there is attributed to the "subjective" time of the experience a "time" of the corresponding "objective" event. In contrast with experiences, external events and their order in time claim validity for all subjects.

This process of objectification would encounter no difficulties were the time order of the experiences corresponding to a series of external events the same for all individuals. In the case of the immediate visual perceptions of man's daily life, this correspondence is exact. That is why the idea that there is an objective time order became established to an extraordinary extent. In working out the idea of an objective world of external events in greater detail, it was found necessary to make events and experiences depend on each other in a more complicated way. This was at first done by means of rules and modes of thought instinctively gained, in which the conception of space plays a particularly prominent part. This process of refinement leads ultimately to natural science.

The measurement of time is effected by means of clocks. A clock is a thing which automatically passes in succession through a (practically) equal series of events (period). The number of periods (clock time) elapsed serves as a measure of time. The meaning of this definition is at once clear if the event occurs in the immediate vicinity of the clock in space; for all observers then observe the same clock time simultaneously with the event (by means of the eye) independently of their position. Until the theory of relativity was propounded it was assumed that the conception of simultaneity had an absolute objective meaning also for events separated in space.

This assumption was demolished by the discovery of the law of propagation of light. For if the velocity of light in empty space is to be a quantity that is independent of the choice (or, respectively, of the state of motion) of the inertial system to which it is referred, no

(180) $$AB = \sqrt{(x_2-x_1)^2+(y_2-y_1)^2+(z_2-z_1)^2}$$

(181) $$ds^2 = dx^2 + dy^2 + dz^2$$

(182) $$\begin{cases} x' = x - vt \\ y' = y \\ z' = z \end{cases}$$

(183) $$ds^2 = c^2dt^2 - dx^2 - dy^2 - dz^2 = 0$$

(184) $$ds^2 = \sum_{\mu\nu} g_{\mu\nu}\, dx_\mu dx_\nu$$

(185) $$ds^2 = c^2dt^2 - dx^2 - dy^2 - dz^2$$

(186) $$ds^2 = dx^2 + dy^2$$

(187) $$ds^2 = g_{11}dx_1^2 + 2g_{12}dx_1dx_2 + g_{22}dx_2^2$$

absolute meaning can be assigned to the conception of the simultaneity of events that occur at points separated by a distance in space. Rather, a special time must be allocated to every inertial system. If no coordinate system (inertial system) is used as a basis of reference there is no sense in asserting that events at different points in space occur simultaneously. It is in consequence of this that space and time are welded together into a uniform four-dimensional continuum. (A.Ei.)

RIEMANNIAN GEOMETRY

As indicated in the preceding section, the geometry developed by Riemann plays a fundamental role in the mathematical formulation of relativity theory. This non-Euclidean geometry is concerned with the properties of a coordinate space $(x^1, \cdots, x^n)$ in which there is a nondegenerate quadratic differential form called the element of arc (see 188). This geometry reduces to Euclidean geometry if the element of arc takes the special form $ds^2 = (dx^1)^2 + \cdots + (dx^n)^2$. The two-dimensional case had been considered before Riemann by Carl Friedrich Gauss (born 1777) as the intrinsic geometry on a surface in ordinary Euclidean space. In pure mathematics, the differential form ds^2 is generally supposed to be positive definite, an assumption that is essential to many of the important consequences. In applications to general relativity, however, in which the Riemannian space is the physical universe, ds^2 is supposed to be hyperbolic; *i.e.*, reducible to a sum of squares minus the square of a linear differential form (see GEOMETRY, NON-EUCLIDEAN).

Basic properties. The quantity ds^2 in equation (188) allows the definition of the arc length of a curve $x^i = x^i(t)$ as an integral (see 189). Geodesics are curves that are shortest between any two of their points, sufficiently near to each other. An n-dimensional domain has a volume given by the integral $\int\sqrt{|g|}\, dx^1 \cdots dx^n$, in which g is the determinant of g_{ik}.

Geodesics

The coordinates x^i are local coordinates in the sense that they can be subjected to a general differentiable transformation $x'^i = f^i(x^1, \cdots, x^n)$, in which $i = 1, \cdots, n$, with nonvanishing Jacobian determinant (see GEOMETRY, DIFFERENTIAL). For ds^2 to be invariant under such changes of local coordinates, the quantities g_{ik} should transform according to certain equations (see 190) and are, therefore, the components of a symmetric covariant tensor field of order two. The elements g^{jl} of the inverse matrix of the matrix (g_{ik}), which are related to the elements g_{ik} by equations (see 191), are the components of a symmetric contravariant tensor field of order two. The fundamental tensors g_{ik} and g^{jl} can be used to derive new tensors from those given. Thus, if $A^{ij}{}_k$ is a given tensor field then $A^i{}_{jk}$ (see 192) is a new tensor field. The two fields are said to be associated to each other, and the process is described as that of raising or lowering indices. The length of a vector A^i is defined (see 193). The angle θ between two vectors A^i, B^j, of lengths different from zero, is defined by a formula (see 194).

From the fundamental (or metric) tensor g_{ik}, Elwin Bruno Christoffel, a German mathematician (see ANALYSIS, VECTOR AND TENSOR), constructed (in 1869) a quantity expressed in terms of partial derivatives (see 195). These are not the components of a tensor, but can be used to define the covariant derivative of a tensor field, giving a tensor field of one more covariant order. In the cases of contravariant and covariant vector fields and that of a mixed tensor field, their covariant derivatives are defined symbolically (see 196). Similar expressions are valid for the covariant derivatives of more general tensor fields. The covariant derivative of g_{ik} vanishes identically. Conversely, $\Gamma_i{}^j{}_k$ can be characterized as the set of quantities that are symmetric in i, k and for which the covariant derivative of the fundamental tensor is zero. In geometrical language, $\Gamma_i{}^j{}_k$ defines a parallel displacement of vectors along curves: the vector field A^k is parallel along a curve $x^i = x^i(t)$ if a condition holds (see 197). This is called the Levi-Civita parallelism (named after Tullio Levi-Civita, a 19th–20th-century Italian mathematician and physicist). It is an affine connection in the general terminology of connections, but is related in a special way to the Riemannian metric. Under the parallelism of Levi-Civita, the scalar product of two vectors remains unchanged. A geodesic is either a curve of zero length or one along which the unit tangent vector is parallel. The former possibility does not appear in the case of a positive definite metric.

Levi-Civita parallelism

The notion of curvature arises in studying the parallel displacement of a vector around a closed curve. When the closed curve is an infinitesimal parallelogram, the new position of the vector can be obtained from the initial position by an infinitesimal rotation. Analytically, this association is described by the Riemann-Christoffel curvature tensor (see 198). The components of the curvature tensor have symmetry properties (see 199). As a result, there are $n^2(n^2-1)/12$ independent components; *e.g.*, six for a three-space, 20 for a four-space, and one for a two-space. In the latter case the quotient $K = -R_{1212}/g$ is a scalar, called the Gaussian

(188) $$ds^2 = \sum_{1 \le i,k \le n} g_{ik}(x)\, dx^i dx^k$$

(189) $$s = \int_{t_0}^{t_1} \sqrt{\left|\sum_{i,k} g_{ik} \frac{dx^i}{dt}\frac{dx^k}{dt}\right|}\, dt$$

(190) $$g_{ik} = \sum_{j,l} g'_{jl} \frac{\partial x'^j}{\partial x^i}\frac{\partial x'^l}{\partial x^k} \quad \text{in which} \quad i,j,k,l = 1, \cdots, n$$

(191) $$\begin{cases} \sum_k g_{ik}\, g^{kl} = \delta_i^l = \begin{cases} 1, & i = l \\ 0, & i \neq l \end{cases} \\ \text{in which} \quad i,k,l = 1, \cdots, n \end{cases}$$

(192) $$A^i_{jk} = \sum_l g_{ij} A^{il}_k, \qquad A^{ijk} = \sum_l g^{kl} A^{ij}_l$$

(193) $$|A| = \sqrt{\left|\sum_{i,k} g_{ik} A^i A^k\right|}$$

(194) $$\cos\theta = \sum_{i,k} g_{ik} A^i B^k / (|A| \cdot |B|)$$

(195) $$\Gamma_{ijk} = \tfrac{1}{2}\left(\frac{\partial g_{ij}}{\partial x^k} + \frac{\partial g_{jk}}{\partial x^i} - \frac{\partial g_{ik}}{\partial x^j}\right), \qquad \Gamma^j_{ik} = \sum_l g^{jl}\Gamma_{ilk}$$

(196) $$\begin{cases} A^i_k = \dfrac{\partial A^i}{\partial x^k} + \sum_j \Gamma^i_{jk} A^j \\ A_{i,k} = \dfrac{\partial A_i}{\partial x^k} - \sum_j \Gamma^j_{ik} A_j \\ B^i_{j,k} = \dfrac{\partial B^i_j}{\partial x^k} + \sum_l (\Gamma^i_{lk} B^l_j - \Gamma^l_{jk} B^i_l) \end{cases}$$

(197) $$\begin{cases} \dfrac{dA^i}{dt} + \sum_{j,k} \Gamma^i_{jk} \dfrac{dx^j}{dt} A^k = 0 \\ \text{in which} \quad i,j,k = 1, \cdots, n \end{cases}$$

(198) $$\begin{cases} R^j_{ikl} = \dfrac{\partial \Gamma^j_{il}}{\partial x^k} - \dfrac{\partial \Gamma^j_{ik}}{\partial x^l} + \sum_m (\Gamma^m_{il}\Gamma^j_{mk} - \Gamma^m_{ik}\Gamma^j_{ml}) \\ R_{ijkl} = \sum_m g_{jm} R^m_{ikl} \end{cases}$$

(199) $$\begin{cases} R_{ijkl} = -R_{jikl} = -R_{ijlk} \\ R_{ijkl} = R_{klij} \\ R_{ijkl} + R_{iklj} + R_{iljk} = 0 \end{cases}$$

curvature. If a vector is given a parallel displacement around a closed curve on a surface, it returns with its direction changed by an amount equal to $\int K d\sigma$, the Gaussian curvature of the surface integrated over the surface area bounded by the closed curve. As a consequence, the excess (over π) of the angle sum in any geodesic triangle is $\int K d\sigma$, a theorem proposed by Gauss.

In the case of three or more dimensions, the curvature properties can no longer be expressed by a single magnitude, but require for their description the whole curvature tensor. The concept of Gaussian curvature is replaced by that of Riemannian curvature, or sectional curvature. This is, at any point p and any plane element (two-dimensional) through p, the Gaussian curvature of the geodesic surface through p and tangent to the plane element. If the latter is spanned by the vectors A^i, B^j, the Riemannian curvature is given by a formula (see 200). In general, K will depend both on the point and on the plane element through it. In other words, with regard to curvature, the space may be non-homogeneous as well as anisotropic. For $n \geq 3$, however, Schur's theorem (named after Friedrich Heinrich Schur, a 19th–20th-century Polish-German mathematician) says that if K is everywhere isotropic (*i.e.*, independent of the choice of the plane element at every point), then it is constant throughout. Riemannian spaces, for which the Riemannian curvature is constant for all points and all plane elements through them, are said to be of constant curvature. They include the Euclidean and non-Euclidean spaces. They are characterized by analytic conditions (see 201) with constant K. The curvature tensor gives, by contraction, the symmetric tensor (see 202) called the Ricci tensor (named after Curbastro Gregorio Ricci). A further contraction gives the scalar invariant (see 203).

Riemannian curvature

The space in general relativity, in particular (see RELATIVITY), is a four-dimensional Riemannian space with an indefinite metric that can be written locally as $ds^2 = \omega_1^2 + \omega_2^2 + \omega_3^2 - \omega_4^2$ ($\omega_1, \cdots, \omega_4$ are linear differential forms). The components g_{ik} of the fundamental tensor define the gravitational potential. Thus, light rays are null curves defined by the differential equation $ds^2 = 0$, whereas the trajectories of particles, without the action of external forces, are the geodesics. In this way, the geometry of the space is not a priori given, but is determined by matter. An essential restriction on the metric is given by Einstein's field equation $R_{ik} = -H(T_{ik} - \frac{1}{2}g_{ik}T)$, in which T_{ik} is the energy-momentum tensor, T is the contraction of T_{ik} relative to the fundamental tensor, and H is a constant. Many attempts have been made, some by Einstein himself in his late years, to develop a unified field theory that would include both the gravitational and the electromagnetic fields. This leads to a generalization of Riemannian geometry to more general geometric objects, such as the Weyl geometry, the Kaluza five-dimensional metric, projective relativity of Oswald Veblen. The results are not conclusive. (S.S.C.)

The unified field theory

Lorentz transformation and Lorentz invariance. It will now be shown explicitly that, though valid in Newtonian mechanics, the so-called Galilean transformation given by equations (182) and augmented by $t' = t$, is not compatible with relativity theory, but must be replaced by the Lorentz-transformation (named after the 19th–20th-century Dutch physicist Hendrik Antoon Lorentz; see 204). Here, the primed and unprimed coordinates and times (t', t) are associated with reference frames S' and S, respectively; c is the velocity of light in empty space; $\beta = v/c$, and $\gamma = (1 - \beta^2)^{-1/2}$, with v denoting the constant velocity of S' with respect to S. The two frames are supposed to be oriented so that the space axes of S' are parallel to the corresponding axes of S, and x- and x'-axes also being collinear with each other and with v.

The inverse transformation—*i.e.*, from S' to S—is readily obtained from equations (204) by interchanging primed and unprimed symbols and replacing v by $-v'$; *i.e.*, β by $-\beta$ (see 205). It will be observed that, as $\beta \to 0$ and $\gamma \to 1$—*i.e.*, as the relative velocity v becomes progressively smaller when compared to that of light, c—the Lorentz transformations (see 204 and 205) do reduce to the Galilean form (and $t' = t$; see 181).

$$K = -\frac{\sum_{i,j,k,l} R_{ijkl} A^i A^k B^j B^l}{\sum_{i,j,k,l} (g_{ik}g_{jl} - g_{il}g_{jk}) A^i A^k B^j B^l} \tag{200}$$

$$R_{ijkl} = -K(g_{ik}g_{jl} - g_{il}g_{jk}) \tag{201}$$

$$R_{ik} = \sum_j R^j_{ijk} \tag{202}$$

$$R = \sum_i R^i_i \tag{203}$$

$$\begin{cases} x' = \gamma(x - \beta ct), & y' = y, \quad z' = z \\ t' = \gamma(t - \beta x/c) \end{cases} \tag{204}$$

$$\begin{cases} x = \gamma(x' + \beta ct'), & y = y', \quad z = z' \\ t = \gamma(t' + \beta x'/c) \end{cases} \tag{205}$$

$$x^2 + y^2 + z^2 = c^2t^2 \tag{206}$$

$$(x' + vt')^2 + y'^2 + z'^2 = c^2t'^2 \tag{207}$$

$$\gamma^2(x' + \beta ct')^2 + y'^2 + z'^2 = c^2\gamma^2(t' + \beta x'/c)^2 \tag{208}$$

$$x'^2 + y'^2 + z'^2 = c^2t'^2 \tag{209}$$

$$s^2 \equiv x^2 + y^2 + z^2 - c^2t^2 = x'^2 + y'^2 + z'^2 - c^2t'^2 \tag{210}$$

As had been shown by Maxwell (see above *Electromagnetic theory*), light and all other electromagnetic waves propagate, in empty space, with velocity $c = 3 \times 10^{10}$ cm/sec relative to a given reference frame S. Hence, if a light signal is emitted from the origin O of S at time $t = 0$, then after a time t has elapsed, a spherical wave will have spread out to a distance ct (see 206). If the origin O' of system S' was in coincidence with O at time $t = 0$, then the Galilean transformation gives the equation (see 207) of a sphere centred at $x' = -vt' = -vt$. Along the $+x'$-direction of S', the wave will therefore have travelled only a distance $ct - vt = (c - v)t$, and a distance $(c + v)t$ along the negative x'-direction. Each of these deductions, however, is invalidated by an extensive series of experiments (the earliest of which was that by U.S. physicists A.A. Michelson and E.W. Morley, reported in 1887) showing that the velocity of light has the same constant value c in every reference frame.

This discrepancy and that between the analytic forms (206), (207) are what led Einstein (in 1905) to enunciate the so-called postulate of equivalence of special relativity. This states that all reference systems with constant velocities relative to one another are equivalent with regard to the mathematical form of the laws of nature; that is, the latter are to be invariant in form under transformation of coordinates from one reference frame to another. The transformations satisfying this requirement are linear in the four variables x, y, z, and t, as shown by equations (204), (205).

A corresponding postulate of general relativity (*i.e.*, relating to frames of reference in arbitrary motion relative to one another) was formulated by Einstein in 1916. In this case, invariance of the laws of nature requires that the equations of transformation be nonlinear. The following treatment will be limited to the special theory only.

Applying the transformations (205) instead of the Galilean transformation to (198) yields an equation (see 208) that, after straightforward expansion and cancellation, is found to reduce (see 209). Equation (209) represents a spherical light wave, centred at O', propagating with speed c, and has exactly the same

mathematical form in S' as the corresponding expression (205) has with respect to S. The quantity expressing the square of s in terms of the coordinates x, y, and z (see 210) is therefore Lorentz-invariant, and is thus seen to satisfy Einstein's equivalence principle and also the requirement that the velocity of light have the same value c in all uniformly moving coordinate systems. The Lorentz transformation is, therefore, the relativistically correct one. In general, quantities such as s^2 are said to be Lorentz-invariant. (Maxwell's equations of electromagnetism constitute another example.)

Denoting the variables x, y, z, and ict, respectively, by x_1, x_2, x_3, and x_4, with $i = \sqrt{-1}$, equation (210) can be rewritten: s squared equals a sum of squares of x_μ and a sum of squares of x'_μ (see 211), which, in analogy with the corresponding three-dimensional expression $(x^2 + y^2 + z^2)$, is interpreted as the invariant length squared of a so-called four-vector in four-space; *i.e.*, in the four-dimensional space-time continuum. Equations (204), (205), and (211) exhibit clearly the essentially inseparable interdependence of the coordinates of space and time.

Lorentz contraction and time dilation. These two are striking consequences of the Lorentz transformation. Thus, if $l_0 = x'_2 - x'_1$ be the length of a rod at rest in S', then by the first of equations (204), l_0 is a difference of x'_2 and x'_1 and is equal to an expression involving γ, the unprimed coordinates, and β (see 212); but the measurement of the rod's length in S must be made at the same time $t = t_1 = t_2$. It therefore follows from equation (212) that l is proportional to l_0, the proportionality constant involving β (see 213), in which $l = x_2 - x_1$. Equation (213) shows that the observer in S will judge the length of the rod to be shortened by the factor $\sqrt{1 - \beta^2}$, relative to the length l_0 determined by the observer at rest in S'. This reduction in length is known as the contraction of Lorentz and Fitzgerald (George Francis Fitzgerald, an Irish physicist).

Finally, if a given event observed in S' is found to take a time $t_0 = t'_2 - t'_1$, then it follows from the fourth of equations (204) that t_0 is a difference of primed coordinates and equals γ times an expression involving γ, β, and unprimed coordinates (see 214); but the time measurement in S is made with a clock at the fixed location $x = x_1 = x_2$, so that t is proportional to t_0, the proportionality constant being expressed in terms of β (see 215), in which $t = t_2 - t_1$ represents the time taken by the event as measured by the clock (or observer) at rest in S. Equation (215) thus shows that t, as measured in S, exceeds the corresponding determination in S' by the factor $\sqrt{1 - \beta^2}$. This phenomenon, abundantly verified by experiment, is called time-dilation. (The same factor affects also the determination of mass, if it is moving relative to the observer. For other aspects of relativity theory, see the article RELATIVITY and the *Bibliography*.)

QUANTUM MECHANICS

Quantum mechanics is the mathematical description of physical systems and phenomena based on the explicit premise that, like matter, energy too is atomistic or quantized; *i.e.*, extant in discrete amounts, or quanta, only.

Transition from classical to quantum mechanics. Although classical mechanics has proved to have an accuracy and a range of empirical validity far beyond the experimental evidence available at the time of Newton, the theory was found to be inapplicable to systems of atomic or subatomic dimensions, and also when the speeds involved are comparable to that of light. In some instances, both of these features can occur simultaneously, as in the case of electrons moving in the immediate vicinity of a heavy atomic nucleus.

Planck's quantum hypothesis. The notion that energy is quantized was introduced in 1900 by the German physicist Max Planck in a study of blackbody radiation. (A blackbody is one that absorbs all radiation incident upon it.) The next major advance came in 1905, when Albert Einstein showed that the energy of escape of an electron ejected photoelectrically from a metal could be explained by assuming that a light quantum of energy $h\nu$ is absorbed, in which ν is the frequency and h is a constant of proportionality, now called Planck's constant, equal to 6.625×10^{-27} erg-sec (see 216).

Self-consistent formulations of quantum mechanics. A great leap for theoretical physics occurred when, in 1913, the Danish physicist Niels Bohr devised a mathematical model of the atom depending crucially on Planck's quantum hypothesis. Yet, although this theory introduced certain novel concepts that have proved of lasting value to modern physics, and although the theory successfully accounted for a number of atomic phenomena not previously understood, it proved inadequate in other respects and in some instances blatantly disagreed with experiment. It thus became clear that despite its modern (*i.e.*, nonclassical) concepts, the difficulties of Bohr's quantum theory stemmed from its remaining still too closely connected to classical mechanics, with the quantum conditions grafted on, rather than forming an intrinsic part of, the basic theoretical framework. What was needed was a rational, self-consistent quantum mechanics that started afresh and evolved a mathematical framework and philosophy all its own. This was discovered in 1926, an epoch-making year in the history of physics.

The inadequacy of Bohr's atomic model

This remarkable new mechanics was the result of independent efforts by some of the leading theoretical physicists of the time. It was developed in a diversity of mathematical formulations, which, though different in superficial mathematical structure, are basically identical in physical content.

The three main mathematical forms are: (1) the wave mechanics of Erwin Schrödinger, an Austrian physicist, the outgrowth of de Broglie's concept (formulated by Louis de Broglie, a French physicist) of phase waves; (2) the matrix theory of the German physicists Max Born, Werner Heisenberg, and Pascual Jordan; and (3) the so-called transformation theory, based on kinematical indeterminism, developed by P.A.M. Dirac, a British physicist, and Jordan, and interpreted by Heisenberg.

Wave mechanics. *Hamiltonian analogy and de Broglie waves.* The version most universally used, and perhaps easiest to understand, is the so-called wave formulation. The impetus to its development came from de Broglie's interpretation of the classical Hamiltonian analogy between optics and dynamics. Readily demonstrated from Fermat's principle in optics and the principle of least action in mechanics, this analogy establishes a formal similarity between the path of the particle in a mechanical system and a hypothetical optical system in which the refractive index is correlated with the potential energy $V(x,y,z)$ in the mechanical problem. This comparison always seemed highly artificial, because the velocity in the optical system was different from that in the mechanical one. If, however, it is somehow possible to introduce the concept of wavelength into the analogy, so that it is meaningful to speak of dispersion, then there exists besides the phase velocity, also a group velocity; *i.e.*, the velocity with which signals or modulations are propagated.

De Broglie showed that, although different from the phase velocity, the velocity of the mechanical particle becomes identical with the group velocity, provided the wavelength λ is arbitrarily assumed to have the same value as the ratio of h to the product of v and m (see 217). The second form of (217) is obtained by noting that the energy constant E is the sum of the kinetic energy $mv^2/2$ and the potential energy $V(x, y, z)$. Equation (217) gives the celebrated de Broglie wavelength, characteristic of quantum-mechanical diffraction problems. When de Broglie first propounded these ideas in 1924, it was not clear whether they had actual physical significance. Two years later, however, the existence of the de Broglie wavelength was confirmed in a most striking fashion through the experiments of the U.S. physicists Clinton J. Davisson and Lester H. Germer, who showed that beams of electrons passing through a crystal are diffracted in many ways like X-rays, but with the wavelength given by de Broglie's formula $\lambda = h/mv$.

Existence of de Broglie waves confirmed

Schrödinger wave equation. Already before the Davisson-Germer experiments, however, Schrödinger recognized the great portent of the de Broglie wavelength, and by means of it was led to the fundamental equation of wave mechanics, usually called the wave equation. Schrödinger conjectured that true quantum mechanics bears the same relation to classical mechanics as physical optics does to geometrical optics: Just as the ray-tracing method of the latter fails to explain the phenomena of diffraction and interference of light waves, so, Schrödinger reasoned, ordinary mechanics could not explain atomic phenomena, the reason in both cases being that the dimensions of apertures through which light passes in diffraction experiments, or atoms, are not large compared to the wavelength. Hence, he sought to establish a procedure analogous to that used in physical optics, in which the fundamental wave equation is a second-order partial differential equation for f (see 218). Here the phase velocity u may be a function of x, y, z. In the monochromatic, or periodic, case, the solutions can be written in the form $f = \psi(x, y, z) \exp(2\pi i\nu t)$ so that the space factor ψ satisfies a second-order partial differential equation (see 219) with $\lambda = u/\nu$. For the wavelength λ, Schrödinger inserted the de Broglie value (11). Equation (219) then becomes a second-order partial differential equation for ψ in which the difference E minus V appears (see 220). This is the Schrödinger wave equation. It may be questioned how quantized phenomena can be extracted from (220), because a partial differential equation generally suggests solutions that are continuous rather than discrete. The answer is that only those solutions are physically allowed that are single-valued and continuous, together with their first derivatives; that vanish at infinity; and that are finite, except possibly at a finite number of points at which ψ may become infinite; but this in only such a way that the integrals of the absolute square of ψ and the sum of absolute squares of the partial derivatives of ψ (see 221) exist. Such physically admissible solutions are called characteristic functions, proper functions, or eigenfunctions. Now, to be sure, (220) possesses an infinity of solutions, because the latter involve arbitrary constants of integration and even arbitrary functions. Nevertheless, it often happens that not one of these solutions has the properties demanded of a characteristic function. Instead, an admissible solution is usually obtained only if the energy E is given certain particular values, called characteristic values, proper values, or eigenvalues.

The Schrödinger wave equation

A simple illustration of how the condition that the solution be physically admissible limits the parameter E is provided by the two-dimensional rotator; *i.e.*, rotating dumbbell (diatomic molecule) the motion of which is confined to a plane. Here the wave equation (220) becomes a second-order differential equation including I, E, and h (see 222), as is seen by specializing (220) to one coordinate, with $V = 0$, and noting that in a rotational problem the moment of inertia I and angle ϕ replace the mass and a linear displacement, respectively. The solution of (222) is an expression for ψ in terms of A and the cosine of a function involving I, E, h, ϕ, and ε (see 223), in which A and ε are arbitrary constants. The requirement of single-valuedness as a function of position on the circular path of rotation demands that $\psi(\phi + 2\pi) = \psi(\phi)$. This is possible only if the coefficient of ϕ, in the argument of the cosine in (223), is an integer n; that is, if E equals a certain ratio involving n, h, and I (see 224). This expression for the energy of a rotator is exactly the same as that obtainable from Bohr's old quantum theory. At first sight it would thus appear that the new quantum mechanics fails to remove the difficulty of Bohr's theory requiring half-integers for obtaining agreement with experiment on rotational energy levels. Actually, however, the end-over-end rotation of a molecule should be represented by a rotator confined not to a particular plane, but rather by one moving in three-dimensional space. When this extra degree of freedom is taken into account, it is found that the factor n^2 in (224) is replaced by $(n + \frac{1}{2})^2 - \frac{1}{4}$, so that, apart from an unimportant additive constant, the result is the same as though half quantum numbers were used in the Bohr theory.

(211) $$s^2 = \sum_{\mu=1}^{4} x_\mu^2 = \sum_{\nu=1}^{4} x_\nu'^2$$

(212) $$l_0 = x_2' - x_1' = \gamma(x_2 - \beta c t_2 - x_1 + \beta c t_1)$$

(213) $$l = l_0\sqrt{1-\beta^2}$$

(214) $$t_0 = t_2' - t_1' = \gamma\left(t_2 - t_1 - \frac{\beta x_2}{c} + \frac{\beta x_1}{c}\right)$$

(215) $$t = t_0/\sqrt{1-\beta^2}$$

(216) $$E = h\nu$$

(217) $$\lambda = \frac{h}{mv} = \frac{h}{\sqrt{2m(E-V)}}$$

(218) $$\frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2} = \frac{1}{u^2}\frac{\partial^2 f}{\partial t^2}$$

(219) $$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} = -\frac{4\pi^2}{\lambda^2}\psi$$

(220) $$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} + \frac{8\pi^2 m}{h^2}(E-V)\psi = 0$$

(221) $$\iiint |\psi|^2 \, dv \quad \text{and} \quad \iiint \left\{\left|\frac{\partial \psi}{\partial x}\right|^2 + \left|\frac{\partial \psi}{\partial y}\right|^2 + \left|\frac{\partial \psi}{\partial z}\right|^2\right\} dv$$

(222) $$\frac{\partial^2 \psi}{\partial \varphi^2} + \frac{8\pi^2 IE}{h^2}\psi = 0$$

(223) $$\psi = A\cos[(8\pi^2 IE/h^2)^{1/2}\varphi - \varepsilon]$$

(224) $$E = n^2h^2/8\pi^2 I$$

(225) $$\frac{d^2\psi}{dx^2} + \frac{8\pi^2 m}{h^2}(E - \tfrac{1}{2}ax^2)\psi = 0$$

(226) $$\begin{cases} A = \dfrac{4\pi E}{h}\left(\dfrac{m}{a}\right)^{1/2}, \qquad u = \dfrac{m^{1/4}a^{1/4}(2\pi)^{1/2}}{h^{1/2}}x \\ \psi = e^{-u^2/2}g \end{cases}$$

(227) $$\frac{d^2 g}{du^2} - 2u\frac{dg}{du} + (A-1)g = 0$$

(228) $$g = c_k u^k + c_{k+2}u^{k+2} + c_{k+4}u^{k+4} + \cdots$$

In most problems, the mathematical analysis is, of course, more complicated than in this simple illustration of the rotator. When exact closed expressions are obtained for the characteristic values of a system with one degree of freedom, they are usually derivable by the so-called polynomial method. In this, the solution is expressed as a power series and is shown to be physically admissible if the series terminates. The termination condition then usually restricts the energy parameter E to certain particular eigenvalues.

Use of the polynomial method

The polynomial method may be illustrated by the one-dimensional harmonic oscillator. Here the wave equation (220) takes the form of a second-order ordinary

differential equation for ψ in which the difference between E and one-half ax^2 appears (see 225). On the introduction of the appropriate abbreviations and changes of variables (see 226), equation (217) becomes an ordinary second-order differential equation for g in which A appears (see 227). A solution is obtainable by assuming that g is a power series in u with constant coefficients (see 228). After the indicated operations are performed, the entire left side of (227) can be expressed in the form of a series. The coefficient of each power of u in the latter must vanish if (227) is to be satisfied. The vanishing of the coefficient of the lowest power (*i.e.*, u^{k-2}) requires either $k = 0$ or $k = 1$. On equating to zero the coefficient of u^n, one obtains a recurrence formula (see 229) for determining the ratio c_{n+2}/c_n. The series (228) will terminate at the term $c_n u^n$ if $A = 2n + 1$ or, in other words, by (226), if the expressions (230) hold for E and ν_0. It can be shown that if the series does not terminate, then ψ increases without limit as x becomes arbitrarily large, and the solution is not physically admissible. Hence, the only characteristic values of the harmonic oscillator are those given by (230).

It is of interest to note that the new quantum mechanics gives the same energy levels for the harmonic oscillator as does the old Bohr theory, except for an additive constant (equivalent to the use of half-integers in the old quantum theory). Usually it is unimportant whether the extra constant is included, but by studying the shift between the electronic spectra of diatomic molecules differing only in isotopic composition, it is possible to decide experimentally between Bohr's result and (230). The results unequivocally favour the latter.

More general form of the wave equation. Equation (220) is the form of the wave equation for a conservative system consisting of a single particle and having a definite energy. A rule will now be given for forming the wave equation in other cases, involving either more than one particle or an indefinite energy, or both. (In classical theory a conservative system necessarily has a definite, constant energy, but in quantum mechanics this need not be so. As a result, it is no longer redundant to say that a conservative system has a definite energy.) The more general scheme for forming the wave equation given here also applies to the nonconservative case in which the potential energy V contains the time explicitly.

The procedure is as follows. First of all, the Hamiltonian technique is to be used; *i.e.*, the system is to have associated with it a classical Hamiltonian function (see 231), which is a function of the coordinates and momenta. One replaces p_k by an operator involving the partial derivative with respect to q_k (see 232) and in this fashion forms a linear differential equation (see 233). This is the general wave equation. One is led to it primarily by comparison with other forms of quantum mechanics, especially transformation theory, rather than through the de Broglie and Schrödinger interpretation of the Hamiltonian analogy.

If the system is conservative, so that t does not enter explicitly, (233) has a solution (234) of the form of a product of an exponential involving t times a function of ψ_m with arguments $q_1, \cdots, q_f$, in which ψ_m is independent of t, and satisfies an equation in which an operator operating upon ψ_m is zero (see 235).

An important property of (235) is that its solutions can be shown to be orthogonal, provided the operator is of the so-called self-adjoint type. This condition is one that can practically always be met. If, in addition, the arbitrary proportionality constants in the wave function are so chosen that they are normalized to unity, then the integral of the product of $\psi_l^* \psi_m$ is a δ function (see 236) provided the integration is extended over all the coordinates. Thus $d\tau$ in (236) denotes $dx_1 \cdots dz_n$ if there are n particles. The expression δ_m^l is the Kronecker delta and has the meaning that $\delta_m^m = 1$ and that $\delta_m^l = 0$ $(l \neq m)$. The asterisk is used here and elsewhere to denote the complex conjugate. It is necessary to distinguish between ψ_m and its conjugate ψ_m^* because the solutions of the Schrödinger wave equation are not necessarily real. In (236), the case $l \neq m$ expresses the orthogonality, and $l = m$ embodies the normalization.

Matrix form of quantum mechanics. *Matrices and their physical significance.* A few months before Schrödinger's discovery of wave mechanics, another, superficially much different, approach to quantum mechanics was developed by Born and Heisenberg. The impetus to this approach was Born's repeated emphasis, to his colleagues at Göttingen, that the reason the old quantum theory was then (1925) failing was that it sought to use the same kinematical concepts of space and time within the atom as in ordinary measurable large-scale events. After all, the concepts of space and time have a meaning only when a realizable procedure for their measurement is specified. Ordinary measuring rods and clocks are clearly not usable at atomic dimensions. Guided by this philosophy based on the so-called operational viewpoint, Heisenberg discovered his matrix formulation of quantum mechanics. He did not originally recognize it as such; it was Born who saw first that the equations were best interpreted in the language of matrices. The basic idea of the matrix mechanics is that the coordinates and momenta associated with the electrons in the atom are to be treated as matrices rather than as quantities having a definite numerical value. A matrix is an array (see 237). Most matrices involved in quantum mechanics are infinite; *i.e.*, have an infinite number of rows and columns.

The meaning of matrix mechanics

The Heisenberg matrix elements are intimately connected with the concept of the transition probability (probability that an atom or nucleus will change from one energy state to another) in the old quantum theory and, alternatively, with Fourier coefficients in classical mechanics. In a simple system having only one degree of freedom, the matrix index can be identified with the quantum number, and a matrix element $a(lm)$ is correlated with a transition between states of quantum numbers l and m. The expression for the transition probability is given in (238). Here $x(lm)$ is an element of the x coordinate matrix and is the quantum analogue of the Fourier coefficient x_{l-m} involved in the corresponding rough formula arrived at by means of Bohr's correspondence principle. This important part of Bohr's theory states that, in the limit of large quantum numbers, the quantum-mechanical results must reduce to those of classical mechanics. As presented here, and as Heisenberg reasoned historically, (238) is obtained by analogy with classical theory, but it can also be derived independently from the radiation theory of Dirac, which applies quantum mechanics to the degrees of freedom of the ether. By means of (238) the intensity of a spectral line can be calculated if the Heisenberg matrices are known. To compute the matrix elements needed for use in (238), it is necessary to transcribe atomic mechanics into matrix language; for this a matrix algebra and calculus are necessary.

The sum of two matrices is formed by adding corresponding elements, so that $(a + b)(lm) = a(lm) + b(lm)$. Matrices are multiplied in the same way as determinants (see 239). There is, however, the difference that, whereas a determinant has a numerical value, a numerical meaning is attached only to the individual entries of a matrix and not to its entirety. This loss of numerical value corresponds to the abandonment of ordinary kinematical relationships within the atom. The multiplication is in general noncommutative; *i.e.*, $(ab)(lm) \neq (ba)(lm)$, or more symbolically: $\boldsymbol{ab} \neq \boldsymbol{ba}$, if boldface type is used to designate the entire matrix rather than a single entry. By repeated additions and multiplications it is possible to construct functions of matrices that are in turn matrices, and thus develop a matrix algebra.

It is further necessary to have a rule for constructing the derivative of one matrix with respect to another. A consistent mathematical framework is obtained if the derivatives of a function $f(q_1, \cdots, q_f, p_1, \cdots, p_f)$ are defined as in (240). The special cases $f = p_i$ or q_i yield the so-called commutation relations (see 241).

A diagonal matrix is one that has zero entries except along the principal diagonal—*i.e.*, $a(lm) = 0$, $l \neq m$—whereas a unit matrix has the additional property $1(ll) = 1$. A diagonal matrix is the quantum analogue of a Fourier series that contains but one single constant term. Hence, in a conservative system with a definite energy, the energy matrix must be a diagonal one.

Diagonal matrices

It will be recalled that the Heisenberg matrices are infinite arrays; *i.e.*, they involve an infinite number of rows or columns. Physically, this means that each index (number of row or column) is correlated with a stationary state, and that there is an infinite number of such states. Furthermore, the permitted stationary states often form a continuous rather than a discrete manifold. In the continuous region it is necessary to introduce the (rather recondite) concept of a matrix with continuously varying indices, so that it cannot then even be tabulated in terms of rows and columns. When there is a continuum, the summation in (239) must be replaced by an integration.

Relation of matrix and wave theories. It is possible to work out the energy levels of the harmonic oscillator, rotator, hydrogen atom, etc., by means of pure matrix theory, and the results are always the same as those obtained with wave mechanics. It turns out that the two approaches are interrelated. If the Schrödinger wave functions are known, the Heisenberg matrix elements can be computed by a straightforward integration. Thus the matrix elements of a function $f(q_1, \cdots, q_f, p_1, \cdots, p_f)$ of the coordinates and momenta may be desired. Then the appropriate formula f as a function of the product lm is an integral (see 242), in which the integrand contains an operator f formed by replacing an operator composed of the partial derivative with respect to q_k (see 243). Equation (242) will not be proved, but one or two simple consequences will be noted. In the first place, the commutation relations are satisfied. For instance, if $f = p_k q_k - q_k p_k$, then f times ψ_m is by calculation proportional to ψ_m (see 244) and, except for a factor $h/2\pi i$, the integral (242) becomes identical with (236) so that the matrix elements of this function are proportional to a δ function (see 245). This result agrees with the first relation of (241) because the elements of a unit matrix are equivalent to a Kronecker delta. The remaining relations of (241) are obviously satisfied. The third relation, for instance, follows because the second partial of ψ can be taken with the two variables in either order (see 246).

Satisfaction of the wave equation (233) for a conservative system with definite energy is tantamount to making the energy a diagonal matrix. To see this it may be noted that by (233) the operator H is equivalent to multiplication by a constant E_m. Hence, if f in (244) is taken to be the Hamiltonian operator H, the integral differs from (236) merely by a constant factor and so has the value $E_m \delta_m^l$.

If one is wedded to the extreme matrix viewpoint, one regards the wave functions merely as mathematical auxiliaries used to compute the Heisenberg matrix elements by means of the matrix computing machine. Such a viewpoint is undoubtedly too one-sided and is offensive to physicists who take comfort from the parallelism of wave mechanics to classical mathematical physics, and to optics, in particular.

Transformation theory. The general interpretation of quantum mechanics as essentially a theory of probability amplitudes has been developed particularly by Jordan and by Dirac. The details of this so-called transformation theory are much too intricate and abstract to be treated here, but this formulation of quantum mechanics has elegance, generality, and a unifying influence on the interpretation of the various other viewpoints. The Schrödinger wave equation, from the standpoint of transformation theory, may be regarded as an equation for finding the probability amplitude for distribution-in-position when the energy is known. One might ask for the probability amplitude for the distribution of functions other than positional coordinates—for instance, momenta—and the known quantity might not necessarily be the energy, as certain experiments correspond to fixation of quantities other than the energy. Such more general problems can be solved by means of transformation theory.

(229) $$\frac{c_{n+2}}{c_n} = \frac{2n+1-A}{(n+1)(n+2)}$$

(230) $$E = (n+\tfrac{1}{2})h\nu_0 \quad \text{with} \quad \nu_0 = \frac{1}{2\pi}\left(\frac{a}{m}\right)^{1/2}$$

(231) $$H(q_1, \cdots, q_f, p_1, \cdots, p_f, t)$$

(232) $$\frac{h}{2\pi i}\frac{\partial}{\partial q_k}$$

(233) $$\left[H\left(q_1, \cdots, q_f, \frac{h}{2\pi i}\frac{\partial}{\partial q_1}, \cdots, \frac{h}{2\pi i}\frac{\partial}{\partial q_f}, t\right) + \frac{h}{2\pi i}\frac{\partial}{\partial t}\right]\Psi = 0$$

(234) $$\Psi = e^{-2\pi i E_m t/h}\psi_m(q_1, \cdots, q_f)$$

(235) $$\left[H\left(q_1, \cdots, q_f, \frac{h}{2\pi i}\frac{\partial}{\partial q_1}, \cdots, \frac{h}{2\pi i}\frac{\partial}{\partial q_f}\right) - E_m\right]\psi_m = 0$$

(236) $$\int \psi_l^* \psi_m d\tau = \delta_m^l$$

(237) $$a = \begin{Bmatrix} a(11) & a(12) & a(13) & \cdots \\ a(21) & a(22) & a(23) & \cdots \\ a(31) & a(32) & a(33) & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & a(nn) \end{Bmatrix}$$

(238) $$A_{l\to m} = (4e^2/3hc^3)(2\pi)^4\nu(lm)^3[|x(lm)|^2 + |y(lm)|^2 + |z(lm)|^2]$$

(239) $$(ab)(lm) = \Sigma_n a(ln)b(nm)$$

(240) $$\frac{\partial f}{\partial p_k} = \frac{2\pi i}{h}(fq_k - q_k f), \qquad \frac{\partial f}{\partial q_k} = -\frac{2\pi i}{h}(fp_k - p_k f)$$

(241) $$\begin{cases} p_k q_k - q_k p_k = (h/2\pi i)1, & p_k q_j - q_j p_k = 0, \quad (k \neq j) \\ p_k p_j - p_j p_k = 0, & q_k q_j - q_j q_k = 0 \end{cases}$$

(242) $$f(lm) = \int \psi_m^* f\left(q_1, \cdots, q_f, \frac{h}{2\pi i}\frac{\partial}{\partial q_1}, \cdots, \frac{h}{2\pi i}\frac{\partial}{\partial q_f}\right) \times \psi_l d\tau$$

(243) $$\frac{h}{2\pi i}\frac{\partial}{\partial q_k}$$

(244) $$f\psi_m = \frac{h}{2\pi i}\left[\frac{\partial}{\partial q_k}(q_k\psi_m) - q_k\frac{\partial \psi_m}{\partial q_k}\right] = \frac{h}{2\pi i}\psi_m$$

(245) $$f(lm) = (h/2\pi i)\delta_m^l$$

(246) $$\partial^2\psi/\partial q_j \partial q_k = \partial^2\psi/\partial q_k \partial q_j$$

Statistical significance of the wave function. In the following, attention will be focussed on the physical meaning of the solution of the Schrödinger wave equation, as distinct from its merely formal aspects. The wave function satisfying equation (233) has an important physical interpretation: The square of its modulus, $|\Psi|^2$, which is Ψ times its complex conjugate, is proportional to what may be called a statistical charge density. In the simple case of a system having only one

The statistical charge density

particle, the probability that the particle will be in the volume element $dxdydz$ at time t may be taken to be a differential with factor the absolute square of Ψ (see 247), provided the total probability is normalized to unity (see 248). This manner of interpretation is consistent, for it can be shown to be a consequence of the differential equation (233) that the integral in (248) is independent of the time. Otherwise, the normalization condition (248) could not be imposed. Similarly, when there are n particles, $|\Psi|^2$ determines the probability in a $3n$-dimensional space, the volume element $d\tau$ of which is $dx_1, \cdots, dz_n$.

It is to be emphasized that the density given by (247) is inherently statistical in character. The particle is not said to be in the element $dxdydz$ at time t, but merely that there is a certain probability of the particle's being there. The places where $|\Psi|$ or $|\psi_m|$ is large are those in which the particle is likely to be located, but it is never possible to say when it is there. The situation may be compared to the information obtainable from the time exposure of a firefly on a dark night. Wherever the photographic plate reveals the greatest brightness, the firefly must have spent most of the time, but one cannot infer just when the insect was at a particular spot. Similarly in quantum mechanics, the information about particles is inherently restricted because of its statistical nature.

That quantum mechanics must be interpreted statistically should be regarded as an advantage rather than as a drawback. For an analysis of atomic experiments shows that the measurements always involve statistical features.

Probability distribution in momentum space. Again confining attention to one particle only, one may wish to know the probability that the components of its momentum fall within a certain range at time t. The symmetrical roles of coordinates and momenta in the Hamiltonian technique suggest that there is a function χ such that a differential with factor absolute square of χ (see 249) determines the probability that the momenta are in the element dp_x, dp_y, dp_z at time t. There is indeed such a function, and the relation between the two functions Ψ, χ is similar to that between a function and its Fourier transform. Namely, it can be shown that Ψ is an integral of the product of χ and an exponential (see 250), and χ is an integral of the product Ψ and an exponential (see 251). Equation (250) has an intuitively very plausible form, for it is natural to regard any disturbance as being built up of a superposition of de Broglie waves, each of the structure $\exp(2\pi ipx/h)$ in one dimension, or $\exp[2\pi i(p_x x + p_y y + p_z z)/h]$ in three. In any principle of superposition in physics, the square of the amplitude governs the intensity, and so it is natural to assume that $|\chi|^2$ gives the probability. It can be shown from the mathematical theory of Fourier transforms (Plancherel's theorem) that two integrals are equal in which integrands are absolute squares of ψ and χ (see 252). If (252) were not satisfied, the physical interpretation given Ψ, χ would lack consistency, for it is necessary that the total probability for either coordinate or momentum distribution be unity; in other words, the normalization in coordinate space must also imply a corresponding normalization in momentum space. Equations (253) and (254), respectively, can be shown to give the mean value of the nth power of the x-component of momentum and of displacement when n is an integer.

It is to be noticed that in (247) or (249), expressions have been given for the probability of the particle being in an element of volume $dxdydz$ of position space, or in an element of momentum space, but that there is no probability function for a concurrent occurrence of given values of position and momentum associated with a volume element $dxdydzdp_x dp_y dp_z$. This fact is formally expressed in the Heisenberg uncertainty principle, which limits the accuracy with which it is possible to specify simultaneously the values of a coordinate and its canonically conjugate momentum. If Δp_x and Δx be the limits of precision within which p_x and x can simultaneously be determined, there exists the inequality in which the product of Δx and Δp_x is greater than or equal to the ratio of h to 4π (see 255). Thus it is meaningless to talk about the probability of a simultaneous occurrence of a given value of a coordinate and its conjugate momentum, for by (255) there is infinite uncertainty in a momentum if the position is known with complete precision, or vice versa.

The uncertainty principle should not be regarded as an additional hypothesis, artificially injected into quantum mechanics. Instead, it can be proved to be a consequence of the latter.

Application of quantum mechanics to atomic phenomena is further treated in the article MECHANICS, QUANTUM. The preceding section has covered the mathematical formalism only of nonrelativistic quantum mechanics. Dirac has shown that inclusion of relativity necessitates replacing the second-order Schrödinger equation by four simultaneous first-order equations. The solutions of these equations account for the properties of electron spin and for the existence of the positron. When spin is considered, employing the so-called Pauli exclusion principle, the structure of Mendeleyev's periodic table emerges (see PERIODIC LAW and CHEMICAL ELEMENTS). (Ed.)

Relativistic quantum fields. In this section, the structure of relativistic quantum field theories will be described. The most successful of these quantum electrodynamics is the theory describing the electromagnetic interactions of electrons, positrons, and photons, consistent with quantum theory and with relativity.

The task of quantum electrodynamics may be divided into three parts: first, to develop a formalism for describing the particles in the absence of interactions; second, to discover the nature of the interactions between the particles; and third, given this interaction, to develop a scheme for calculating any quantity of interest.

The problem of describing free—*i.e.*, non-interacting—particles has a fairly straightforward solution. In nonrelativistic quantum mechanics, a free particle is described by a known wave function $\psi(x, t)$, which is already a field. It is straightforward to generalize it to the relativistic case. Just as certain quantities (like energy) are quantized in the passage from classical to quantum mechanics, so here the field is quantized (this process is called second quantization).

Second quantization

In the course of doing this, an infinity of variables is encountered. This arises because of particle production, which is an intrinsic feature of relativistic interactions, and one that distinguishes them sharply from the non-relativistic interactions. In the relativistic case, it is possible to begin with two particles and produce many others; for example, a negative electron and a positron (positive electron) can collide to produce an arbitrarily large number of electrons, positrons, and photons. Any formalism designed to account for such reactions must possess enough variables to describe all the particles produced, and thus needs an infinite number of variables. The quantized field formalism provides this flexibility.

Having developed the free-field formalism, the next problem is to introduce the interaction. The choice is guided by analogy with classical physics. There, the interaction energy is given in terms of the charge e of an electron by $ej_\mu(x)a^\mu(x)$, in which $ej_\mu(x)$ is the electric current produced by electrons and positrons, and $a^\mu(x)$ is the electromagnetic potential. In the free-field theory, a quantized field composed of electron and positron fields, which behaves like a current of free particles, is defined by $J_\mu(x)$. The analogue of $a^\mu(x)$ turns out to be the field associated with photons, denoted by $A^\mu(x)$. One then writes the energy operator H (called the Hamiltonian) as a sum of two terms, one labelled H_{free}, one labelled $H_{interaction}$ (see 256), in which H_{free} is the energy operator of freely moving particles. It is to be noted that e determines the strength of the interaction.

The final and most difficult problem is to develop a calculational scheme for exploring the consequences of the assumed energy operator. The solution of this problem was given by physicists Shin'ichirō Tomonaga of

Japan and Julian Schwinger and Richard Feynman of the United States; its extraordinary success depends on the exceedingly small value of the so-called fine-structure constant, namely, the dimensionless parameter $\alpha = 2\pi e^2/hc$ ($\alpha \cong 1/137$); so that H_{int} (the interaction Hamiltonian) is small compared to H_{free} (the free Hamiltonian). Each physical quantity M is written as a power series (see 257), and a scheme is given for calculating the coefficients M_n. As the integer n increases, the calculation of M_n becomes increasingly difficult. But because the fine-structure constant α is a small number and the M_n are not expected to be large, the error made in neglecting terms with large n is quite small. It is thus sufficient for practical purposes to calculate only the first few terms of (257).

Feynman diagrams and rules

For this purpose, Feynman associated with each M_n a set of diagrams (Feynman diagrams) and for each diagram he gave a prescription (Feynman rules) for evaluating the contribution of that diagram to M_n. These diagrams can be considered as mnemonic devices for keeping track of the various terms contributing to M_n. They also, however, allow a physical interpretation. One can think of electrons as continually absorbing and emitting photons. Two electrons interact when one of them emits a photon, which travels to the location of the second, where it is absorbed. (It is thus seen that local interactions have replaced action at a distance.) It can happen that a photon is emitted and absorbed before it can be detected. Such a photon is termed a virtual photon, as opposed to a physical photon that can, in principle, be detected. Each Feynman diagram is a pictorial representation of the manner in which virtual particles can be emitted and absorbed.

Unfortunately, there are several serious difficulties with this formalism. The operator H_{free} does not really represent freely moving physical electrons, positrons, and photons. A physical electron, even in isolation, has a charge that sets up an electric field with which the electron itself interacts. Pictorially, each electron emits and reabsorbs its own photons. This self-interaction is ignored in H_{free}, and arises from H_{int}. Thus, H_{free} represents not a physical free electron but a hypothetical bare electron, in which all self-interactions are ignored. The mass and charge of the bare electron differ from those of the physical electron. In place of (257) H can be written as the sum of two terms (see 258), in which H_{free}^{phys} represents the free Hamiltonian of the physical electrons. H_{free}^{phys} and H_{free} differ only in that the electron mass is different. The change of mass is called mass renormalization. Similarly, the bare charge becomes renormalized to the physical charge. It should be noted that the bare mass and charge are not directly measurable, because they refer to hypothetical bare electrons.

Mass renormalization

Feynman's arguments can then be repeated, this time involving the physical mass and physical charge. In either the renormalized or unrenormalized form, however, M_n seems to become infinite for sufficiently large n, so that Feynman's prescription cannot be correct. The clue toward overcoming this severe difficulty lies in noting that the bare masses and charges are physically unobservable. It turns out that one can choose the bare mass and charge to be infinite in such a way that they exactly cancel the other infinities in the coefficients M_n. Then M_n can be expressed in terms of the physical quantities only; *i.e.*, not involving the bare mass and charge, and M_n is now finite. (It is remarkable that the infinities in any term M_n can be avoided by a unique choice of only two parameters, the bare mass and charge of the electron.) Of course, it is these finite values of M_n that must be compared with experiment, and which have been so successful. For example, the prediction of the magnetic moment of the electron has been verified to an accuracy of nine significant digits.

It is possible to extend the entire development outlined above to theories other than electrodynamics. Given an interaction Hamiltonian in terms of some fields, one can discover the Feynman diagrams and the Feynman rules appropriate to this interaction. The calculations and difficulties in these theories are analogous to those in electrodynamics. In particular, attempts have been made to study strong interactions—those responsible for nuclear forces, for example—by means of these techniques. The difficulty is that the expansion parameter, the analogue of α, is now large (approximately 15), so that subsequent terms in the expansion (257) do not fall off rapidly, and hence the first few terms cannot adequately represent the quantity M. Besides this, the appearance of infinities, even in the formalism of electrodynamics, raises the question of whether such theories are mathematically well defined.

In response to these problems, an alternate approach to quantum field theory has been developed. In this approach, several general principles that are believed valid for any field theory are postulated. These principles include (1) relativistic invariance; (2) the postulate that all physical states have positive energy; (3) existence of a unique vacuum state; (4) causality—*i.e.*, the statement that signals do not propagate faster than the speed of light; (5) a connection between the fields and the particles in the theory (the so-called asymptotic condition); (6) assumptions about the mathematical nature of the field operators.

These general principles form a framework that is flexible enough to accommodate many different quantum field theories. Consequently, these principles do not lead to detailed numerical predictions. There are, nevertheless, some properties that emerge from these principles alone and that should, therefore, be true for any field theory. For example, it follows that for every particle of a given mass and charge, there exists another one with the same mass and opposite charge (antimatter).

Axiomatic field theory

This general approach, often called axiomatic field theory, is developed with a much higher degree of

(247) $$|\Psi|^2\,dxdydz$$

(248) $$\iiint |\Psi|^2\,dxdydz = 1$$

(249) $$|\chi(p_x, p_y, p_z, t)|^2\,dp_x dp_y dp_z$$

(250) $$\begin{cases} \Psi = h^{-3/2} \iiint \chi(p_x, p_y, p_z, t) e^{2\pi i(p_x x + p_y y + p_z z)/h}\,dv \\ dv = dp_x dp_y dp_z \end{cases}$$

(251) $$\begin{cases} \chi = h^{-3/2} \iiint \Psi(x, y, z, t)\, e^{-2\pi i(p_x x + p_y y + p_z z)/h}\,dv \\ dv = dxdydz \end{cases}$$

(252) $$\iiint |\Psi|^2\,dxdydz = \iiint |\chi|^2\,dp_x dp_y dp_z$$

(253) $$\begin{cases} \iiint p_x^n |\chi|^2\,dp_x dp_y dp_z = \iiint \Psi^* \left(\frac{h}{2\pi i}\frac{\partial}{\partial x}\right)^n \Psi\,dv \\ dv = dxdydz \end{cases}$$

(254) $$\iiint x^n |\Psi|^2\,dxdydz = \iiint \chi^* \left(-\frac{h}{2\pi i}\frac{\partial}{\partial p_x}\right)^n \chi\,dp_x dp_y dp_z$$

(255) $$\Delta x \Delta p_x \geq h/4\pi$$

(256) $$\begin{cases} H = H_{\text{free}} + H_{\text{interaction}} \\ \quad = H_{\text{free}} + eJ_\mu(x)A^\mu(x) \end{cases}$$

(257) $$M = \sum_n M_n \alpha^n$$

(258) $$H = H_{\text{free}}^{\text{phys}} + H_{\text{interaction}}^{\text{phys}}$$

mathematical rigour than was the case with old-fashioned field theory. As such, it has illuminated much of the mathematical foundations of field theory. The disturbing fact remains, however, that, thus far, no example of an interacting relativistic field theory satisfying all the required principles has been constructed, nor has it been shown that such a theory indeed exists. (R.Ro.)

DIMENSIONAL ANALYSIS

General considerations. Numerical quantities, the significance of which depends upon the system of units chosen for their measurement, are said to be dimensional. Other quantities (also the result of measurements) having values independent of the system of units used are called dimensionless, abstract, or pure numbers.

Thus, the size of a given angle, for example, may be specified equivalently as a_1 radians, a_2 degrees, a_3 right angles, etc. When considered under these circumstances, the given angle is therefore a dimensional quantity. If, however, consideration is limited to only such systems of measurement wherein angles are invariably measured in radians, then the size of an angle may be considered a dimensionless quantity, or a pure number. (Radian measure of an angle, a pure number, is defined as the ratio a/r, in which a is the length of the circumferential arc of a circle, intercepted by the given angle; r, its radius; and the vertex of the angle coincides with the centre of the circle. Because a and r both have the same dimensions—*i.e.*, a length—these cancel when the ratio a/r is formed, thus resulting in a pure number.)

Systems of measurement and their associated units (cgs = centimetre, gram, second; mks = metre, kilogram, second; foot, pound, second; BTU, or British thermal unit; calorie, etc.) play a fundamental role in dimensional analysis. The use of different systems of (dimensional) units inevitably leads to different numerical coefficients in the corresponding results; *e.g.*, one foot equals 12 inches equals 30.48 centimetres, approximately, etc. Intercomparison of measured and calculated quantities is much encumbered, however, unless all such quantities are expressed in the same system of units. With this objective in mind, some efforts on the part of the scientific community have therefore been made to adopt universally one standard system of units; *e.g.*, rationalized mks units in the study of electricity and magnetism. In addition to these, considerations of another and more fundamental kind are involved in the selection of a system of units. One of these is the intrinsic nature of the physical system to be dimensioned. Thus, although a fermi (10^{-13} centimetre) is a unit suitable for describing lengths relating to the atomic nucleus, a unit 100,000 times larger, called an angstrom (10^{-8} centimetre), is appropriate for expressing lengths related to atomic events. At the opposite end of the scale of spatial extension, the astronomical unit (equal to the mean Sun-to-Earth distance, or about 93,000,000 miles) is useful for describing distances within the solar system, but it is the light-year (distance traversed by light during one year) that is most appropriate for expressing interstellar distances.

It is apparent that in the examples cited, the unit definitions were made in a frankly *ad hoc* manner; *i.e.*, primarily for the purpose of keeping the associated numerical coefficients from becoming excessively small or excessively large. In this sense, such systems of measurement are artificial and arbitrary. With regard to certain other units, however, there exists some controversy as to whether they, too, are arbitrary or whether they possess a more profound significance indicative of some underlying physical reality. The so-called atomic unit of length (0.529×10^{-8} centimetre), and the energy unit called a rydberg (approximately 13.5 electron volts) are examples. The atomic unit (according to the Bohr model) is the radius of the energetically lowest circular electron orbit in the hydrogen atom. The rydberg represents the minimum energy required to remove this electron to infinity.

In any case, in some sense the selection of a system of units is comparable to the choice of a coordinate system appropriate to the physical situation at hand: When dealing with a system bounded by a cubical enclosure, rectangular Cartesian coordinates are indicated; but if the system's geometry is spherical (*e.g.*, a stellar model comprising homogeneous concentric shells) then the choice of spherical polar coordinates is naturally suggested. More generally, just as the form of a physical law remains unchanged regardless which particular one of a suitable set of coordinate systems is used to verify the law, so also are physical regularities generally independent of the particular system of units of measurement selected from among a set of such systems. (Physical laws formulated so that they possess this kind of form-invariance are said to be complete.) That this should be so is plausible: In view of the distinctly arbitrary considerations operative in the definition of a large number of systems of measurement, it is so exceedingly improbable as to be practically impossible that any physical regularity could be discovered if it did depend on one particular system of measurement. Conversely: If a physical regularity is discovered despite the arbitrary selection and use of one out of an infinitude of possible systems of measurement, then it is so exceedingly improbable as to be practically impossible that the manifestation of the observed regularity had any essential connection with the particular system of units employed.

Basis for choosing a particular system of units

The pi theorem. This independence of a physical law from the particular system of units employed (also called completeness) is expressed by the so-called pi (π) theorem, often attributed to Edgar Buckingham, a United States physicist. If $q_1, q_2, \cdots, q_n$ denote n physical parameters and dimensional constants (such as pressure, volume, thermal conductivity, and the acceleration of gravity) contained in a physical law, then the latter can always be expressed as a functional relationship of the form in which f as a function of n arguments q equals zero (see 259). The pi theorem asserts that the above relation can also be written as g as a function of arguments π_k equal to zero (see 260), in which each argument π is an independent dimensionless product of some of the q's. The physical law is thus demonstrably independent of any particular system of measurement, a statement previously merely held plausible. The theorem is subject to the restriction, generally of little practical significance, that there exists but one independent functional relationship between the q's.

An important result obtainable from the pi theorem is the so-called principle of dimensional homogeneity, often referred to as the fundamental theorem of dimensional analysis. If equation (260) is solved for one of the arguments, say π_1, and if π_1 is further written in terms of the physical quantities q (see 261), then equation 260 can be modified (see 262). Because h is a function of the dimensionless arguments π only, the function h is itself dimensionless. But π_1 can also be written as a ratio (see 263), and because this ratio (equal to π_1) is dimensionless, it follows that the dimensions of q_1^a in the numerator [and on the left-hand side of equation (254)] are necessarily the same as those of $q_2^b q_3^c \cdots$ in the denominator [and on the right-hand side of equation (262)]. The dimensions of all the terms in equation (262) are therefore the same; *i.e.*, the physical law is dimensionally homogeneous, which was to be proved.

Principle of dimensional homogeneity

Applications. *Use in developing an equation.* Dimensional analysis yields an amount of information dependent on the skill and experience of the analyst. Positive errors are never introduced by failure to recognize special situations—it is only that less than the maximum information is obtained. In the limiting case, in which nothing whatever will be contributed to a knowledge of the nature of the physical system, dimensional analysis does not give incorrect results, but only trivial results.

A conventional introductory problem is the simple pendulum. The physical parameters defining the simple pendulum may be taken to be the mass of the bob and

the length of the suspending rod. The problem is obviously one in mechanics, and the fundamental units may be taken as mass, length, and time. A detailed solution of the equations of motion will give the time of any complete oscillation, and this oscillation may be characterized by its angular amplitude. It is sufficient to show that the time of oscillation for any particular amplitude must be uniquely determined because the bob starts from rest at the extreme point of the oscillation and the boundary conditions and the equation of motion determine a unique solution. The equations of motion will involve the force on the bob, and this will involve the acceleration of gravity; that is, in the equations of motion will appear the dimensional constant g. The detailed solution should therefore give a relationship between mass of bob, m, length of pendulum, l, angular amplitude of oscillation, θ, acceleration of gravity, g, and the period of oscillation, τ. This is a complete relationship, being deduced by mathematical manipulations from a complete equation, and therefore the pi theorem applies. The parameters are as follows:

Parameter	Dimensional formula
m	M
l	L
θ	0
g	LT^{-2}
τ	T

Requirements for use of the pi theorem

The pi theorem requires the formation of all the independent dimensionless products. There will in general be two because the number of parameters is here five and the number of primary units is here three. One of these products, θ (theta), is obvious on inspection; and one dimensionless product must be formed from the four remaining parameters. The exponents in the dimensionless product are unknowns, written as α, β, γ, δ. These four quantities must now be found so that $m^\alpha l^\beta g^\gamma \tau^\delta$ is dimensionless. The dimensional formulas are substituted for the parameters. $M^\alpha L^\beta (LT^{-2})^\gamma T^\delta$ must be dimensionless, or the total exponents of M, L, and T must vanish. This condition gives three algebraic equations (see 264). There are three equations and four unknowns, which means that one unknown may be assumed arbitrarily. The exponent δ may be taken as the arbitrary one. Then the solution is: $\alpha = 0$, $\gamma = \delta/2$, $\beta = -\delta/2$. The dimensionless product is $l^{-\delta/2} g^{\delta/2} \tau^\delta$. The pi theorem states that the solution is some functional relationship between the two independent products (see 265), in which the functional form is completely undetermined.

This equation may be rearranged by solving for the quantity in parentheses (see 266), in which f is completely undetermined. This again may be rearranged (see 267). That is, the time of swing is independent of the mass, proportional to the square root of the length, and inversely proportional to the square root of the acceleration of gravity. As far as this analysis goes it may be any function of the amplitude. The detailed solution would show that, for small amplitudes, f has approximately the constant value 2π.

Use in changing units. By writing out the dimensional formula of a quantity, a method is afforded of finding how the numerical magnitude changes when the size of the primary units of measurement changes. The method is so simple that no elaborate or formal exposition is necessary; two examples, in which the quantities are, respectively, speed and pressure, are given.

A given body is moving with a speed of 60 miles (mi) per hour (hr) and it is desired to convert this speed to feet (ft) per second (sec). One mile contains 5,280 feet and one hour contains 60 × 60 seconds: therefore, simple equalities hold (see 268). Or, a pressure of the atmosphere of 15 pounds per square inch may be expressed in kilograms per square centimetre as follows: One pound (lb) is equal to 0.4536 kilogram (kg) and one inch (in.) is equal to 2.54 centimetres (cm). Hence equalities in different dimensions follow (see 269). The method illustrated is obviously general. In fact, it may be extended to much more complicated sorts of examples in which the conversion is between systems of units different in general nature, as from a system with mass, length, and time as fundamental to one with force, velocity, and energy as fundamental. (P.W.B./L.I.S.)

(259) $$f(q_1, q_2, \cdots, q_n) = 0$$

(260) $$g(\pi_1, \pi_2, \cdots) = 0$$

(261) $$\pi_1 = q_1^a q_2^b q_3^c \cdots$$

(262) $$q_1^a = q_2^{-b} q_3^{-c} \cdots h(\pi_2, \pi_3, \cdots)$$

(263) $$q_1^a / (q_2^{-b} q_3^{-c} \cdots)$$

(264) $$\begin{cases} \alpha = 0 \\ \beta + \gamma = 0 \\ -2\gamma + \delta = 0 \end{cases}$$

(265) $$F[(l^{-1/2} g^{1/2} \tau)^\delta, \theta] = 0$$

(266) $$l^{-1/2} g^{1/2} \tau = f(\theta)$$

(267) $$\tau = f(\theta)\sqrt{l/g}$$

(268) $$60 \frac{\text{mi}}{\text{hr}} = 60 \frac{5{,}280 \text{ ft}}{3{,}600 \text{ sec}} = 88 \frac{\text{ft}}{\text{sec}}$$

(269) $$15 \frac{\text{lb}}{\text{in.}^2} = 15 \frac{0.4536 \text{ kg}}{(2.54 \text{ cm})^2} = 15 \frac{0.4536 \text{ kg}}{(2.54)^2 \text{ cm}^2} = 1.054 \text{ kg/cm}^2$$

BIBLIOGRAPHY. A nontechnical discussion of Newtonian mechanics may be found in BARRY M. CASPER and RICHARD J. NOER, *Revolutions in Physics* (1972). Elementary treatments are included in many introductory physics textbooks, such as DAVID HALLIDAY and ROBERT RESNICK, *Physics*, vol. 1 (1966). ROBERT B. LINDSAY and HENRY MARGENAU, *Foundations of Physics* (1936), discusses the logical foundations of mechanics and other areas of physics. KEITH R. SYMON, *Mechanics*, 3rd ed. (1971), is a good intermediate textbook; for an advanced treatment the reader is referred to HERBERT GOLDSTEIN, *Classical Mechanics* (1950). A classic work on fluid mechanics is HORACE LAMB, *A Treatise on the Mathematical Theory of the Motion of Fluids* (1879; 6th ed., *Hydrodynamics*, 1945). A modern treatment is found in LOUIS M. MILNE-THOMSON, *Theoretical Hydrodynamics*, 5th ed. (1968); and ARNOLD J.W. SOMMERFELD, *Mechanik der deformierbaren Medien*, 3rd ed. (1954; Eng. trans., *Mechanics of Deformable Bodies*, 1964), which is also useful for the mechanics of solids. Another reference is IVAN S. SOKOLNIKOFF, *Mathematical Theory of Elasticity*, 2nd ed. (1956), entirely devoted to the subject. A classic work on elasticity is A.E.H. LOVE, *Treatise on the Mathematical Theory of Elasticity*, 4th ed. (1944). A good introduction to statistical mechanics is found in FREDERICK REIF, *Statistical Physics* (1967). Another good textbook (intermediate level) by the same author is *Fundamentals of Statistical and Thermal Physics* (1965). Two advanced works are LEV D. LANDAU and E.M. LIFSHITZ, *Statistical Physics*, 2nd rev. ed. (1969; orig. pub. in Russian, 1951); and KERSON HUANG, *Statistical Mechanics* (1963). Elementary treatments of electromagnetic theory may be found in almost any introductory physics textbook; see HALLIDAY and RESNIK (*op. cit.*), vol. 2. Intermediate treatments include PAUL LORRAIN and DALE R. CORSON, *Electromagnetic Fields and Waves*, 2nd ed. (1970); and JERRY B. MARION, *Classical Electromagnetic Radiation* (1965). A standard advanced work is JOHN D. JACKSON, *Classical Electrodynamics* (1962). Many of the original papers on the theory of relativity are contained in ALBERT EINSTEIN *et al.*, *The Principle of Relativity* (1923). An introductory work is ANTHONY P. FRENCH, *Special Relativity* (1968). G.F.B. RIEMANN'S fundamental paper, "Über die Hypothesen welche

der Geometrie zu Grunde liegen," can be found in his *Gesammelte Werk*, 2nd ed. (1892), later published with commentaries by HERMANN WEYL, 3rd ed. (1923). For an introduction to Riemannian geometry, see LUTHER P. EISENHART, *Riemannian Geometry* (1926, reprinted 1949); TULLIO LEVI-CIVITA, *Lezioni di calcolo differenziale assoluto* (1925; Eng. trans., *The Absolute Differential Calculus*, 1927); and CHARLES WEATHERBURN, *An Introduction to Riemannian Geometry and the Tensor Calculus* (1938). For an advanced treatment of relativistic mechanics, see GOLDSTEIN (*op. cit.*), and for electrodynamics, JACKSON (*op. cit.*). For general relativity the reader might consult GEORGE C. MCVITTIE, *General Relativity and Cosmology*, 2nd ed. (1965). DAVID S. SAXON, *Elementary Quantum Mechanics* (1968), is a good introduction to its subject. More advanced works are LEONARD I. SCHIFF, *Quantum Mechanics*, 3rd ed. (1968); EUGEN MERZBACHER, *Quantum Mechanics*, 2nd ed. (1970); and ALBERT MESSIAH, *Mécanique quantique*, 2 vol. (1959; Eng. trans., *Quantum Mechanics*, 2 vol., 1961–62). Quantum field theory is the subject of many advanced works, such as JAMES D. BJORKEN and SIDNEY D. DRELL, *Relativistic Quantum Fields* (1965). There are many works available on dimensional analysis. An older work, still of value, is PERCY W. BRIDGMAN, *Dimensional Analysis*, rev. ed. (1931, reprinted 1963). See also H.E. HUNTLEY, *Dimensional Analysis* (1952); CHARLES M. FOCKEN, *Dimensional Methods and Their Applications* (1953); and L.I. SEDOV, *Similarity and Dimensional Methods in Mechanics* (1959; Eng. trans. from 4th Russian ed. of 1957).

Physics

Physics is the basic physical science. It deals with those fundamental questions on the structure of matter and the interactions of the elementary constituents of nature that are susceptible to experimental investigation and theoretical inquiry. Its goal is the formulation of comprehensive principles, or laws of physics, that summarize disparate phenomena in the most general possible way and that typically are expressed with economy and precision in the language of mathematics.

Aims of physics

Originally only a part of what was termed natural philosophy, physics now consists of what remains of basic physical science with the development of separate and autonomous scientific disciplines of astronomy, chemistry, geology, and the technological applications of fundamental science in engineering. Despite the fact that the content of physics changes continuously with the advance of scientific knowledge, its aim has remained the explication of basic observable physical phenomena without primary attention to possible applications, whereas, in such borderline fields as chemical physics, astrophysics, geophysics, and biophysics, the techniques and principles of physics are applied to the principal discipline.

Both experiment, the observation of phenomena in precise quantitative terms under strictly controlled conditions, and theory, the construction in mathematical terms of a unified conceptual framework, play essential and complementary roles in the advance of physics. Experiment discloses the facts of nature; theory attempts to make sense out of them. All physical inquiry can be reduced ultimately into the study of events involving matter in space and time, and measurable physical quantities may be expressed in terms of basic units for length, time, and mass. When a theoretical formulation has summarized the results of experiments with a reliability so great as to reflect apparently universal behaviour, it is said to be a law of physics, but always tentatively. For, if further experiment fails to confirm its predictions, it must be modified or discarded or the limited range of its applicability clearly recognized.

Perhaps the ultimate aim of physics is to comprehend the properties of the fundamental constituents of nature and their mutual interactions in a single master plan and from it to deduce the properties of aggregates of particles and all macroscopic phenomena. Certainly the search for such a grand scheme lies at the forefront of contemporary physics. Although that ultimate synthesis has not been achieved, the number of laws of physics now regarded as fundamental is remarkably small. Moreover, one segment of physics, known as classical physics, which is that segment treating the behaviour of objects that are large compared with an atom and move with speeds far less than that of light, is essentially complete within its limited applicability to the macroscopic domain. Whereas classical physics accounts for low-speed, large-scale phenomena, the quantum theory and the theory of relativity, both originating early in the 20th century and constituting the foundations of modern physics, are the basis for elucidating the submicroscopic, high-speed phenomena in atomic, nuclear, and elementary-particle physics.

THE SCOPE OF PHYSICS

The traditionally organized branches of classical and modern physics are described below.

Mechanics. Mechanics is the study of the motion of objects and their interaction as comprehended by basic physical principles. In this sense all of physics may be regarded as mechanics. Whereas classical mechanics, or Newtonian mechanics, deals with objects the size of which is large compared with that of the atom and that move at speeds far less than that of light, quantum mechanics, or wave mechanics, is the basis for understanding atomic and subatomic phenomena, and relativistic mechanics concerns high-speed phenomena.

Suborders of mechanics

Within classical mechanics, kinematics is concerned merely with the description of the motion of a particle, whereas dynamics is concerned with a particle's motion in relation to the forces acting on it. Statics, a special case of dynamics, concerns systems of objects in equilibrium. Particle dynamics treats objects as having vanishingly small dimensions and an ignorable substructure, whereas in rigid-body dynamics extended objects are imagined to be incapable of deformation. Elasticity is the mechanics of deformable solids; and hydrostatics and hydrodynamics treat, respectively, fluids at rest and in motion.

Newton's laws of motion. Isaac Newton's three laws of motion are the foundations of classical mechanics. The first law recognizes that motion in itself does not require explanation or a cause: an undisturbed object moves in a straight line at constant speed. Mechanics concentrates, then, not on motion as such but on changes in the state of motion of an object, arising from its interaction with one or more other objects, which thereby exert a force on it. Newton's second law relates the net force on an object to the rate of change of its momentum. Thus, knowing the forces acting on an object allows, at least in priniciple, its future history to be projected in detail; conversely, by studying an object's motion, one may deduce the forces to which it is subject. Newton's third law, that of action and reaction, states that when two particles interact, the forces on each are of equal magnitude but opposite direction, so that forces always appear in equal and opposite pairs.

Force of gravity. The study of the universal force of gravity is customarily placed within classical mechanics. Indeed, Newton's accounting in detail for the planetary orbits, as well as such subtle gravitational effects as the tides and the precession of the equinoxes (the slow cyclical change in direction of the Earth's axis of rotation), through this fundamental force represents the first triumph of classical mechanics. Nothing beyond it, apart from the technologies of rocketry and communications, is needed for the principal aspects of space flight.

Momentum and energy. The concepts of momentum, angular momentum, and energy and the conservation laws related to them (see below) also play a central role in classical mechanics. Indeed, they offer alternative, and often simpler, means of analyzing collections of two or more objects. Newton's laws of motion and the law of gravitation predict the motion of a planet about the Sun, giving its location at any instant; apart from any details of this motion, the total momentum, angular momentum, and energy of the planet–Sun system are each constant.

Thermodynamics and heat. The general topic of heat and the formal study of thermal systems in thermodynamics are characterized by the concept of temperature. The particular power of classical thermodynamics lies in its ability to analyze the most general types of thermal systems without regard for their detailed microstructure.

First law. The first law of thermodynamics is, in effect, the energy-conservation principle (for all changes in an isolated system, the energy remains constant) generalized to include heat, which is energy transferred by a temperature difference.

Second law. Most succinctly stated, the second law of thermodynamics is that the entropy of an isolated system increases with time, where entropy may be interpreted as a quantitative measure of the state of relative disorder of the particles comprising a system. Although one may, in principle, use Newtonian mechanics to trace out in detail the motions of the many particles in some fairly complex system (for example, the molecules of a gas) and from their detailed microscopic behaviour deduce the macroscopic properties of the gas, such a program is mathematically forbidding, practically impossible, but actually unnecessary.

Statistical mechanics. Instead, through the procedures of statistical mechanics, one concentrates not on the detailed motion of every particle but on the average behaviour of a large number, invoking the laws of probability or its physical counterpart, the assumption of molecular chaos. The basic premise is that all possible configurations of the particles are equally likely. So viewed, a gas-filled container will have essentially equal numbers of molecules in the left and right halves for the same reason that, of many tossed coins, half are heads and half tails. The disordered states, those with molecules distributed uniformly throughout the container, are much more probable than such a highly ordered state as that in which all molecules crowd together in one corner. For the enormous number of submicroscopic particles encountered in any system of reasonable size, the number of disordered states is so great compared with the ordered states that any undisturbed system will almost invariably evolve from a state of lesser disorder to one of increased disorder.

The rules of chance

Statistical mechanics interprets thermal energy as merely the energy of submicroscopic particles in disordered states, not visible macroscopically, and temperature as a quantitative measure of how energy is shared among the particles.

From a microscopic point of view, the laws of thermodynamics imply that, whereas the total quantity of energy of any system is constant, what might be called the quality of this energy is degraded as the system moves inexorably, by the laws of chance, to states of increasing disorder until it finally reaches the state of maximum disorder, that state in which all parts are at the same temperature and none of the system's energy may be employed usefully. This final condition of chaos is sometimes referred to as the "heat death."

Electricity and magnetism. First conceived of as distinctive phenomena, electricity and magnetism are subsumed under the term electromagnetism, which treats the interactions of particles having the physical property of electric charge. Charged particles at rest interact by an electric force; when in motion, an additional magnetic force comes into play. Indeed, all magnetic effects may, in fact, be traced to electrically charged particles in motion.

The field concept

The field concept plays a central role not merely in the classical formulation of electromagnetism but in all areas of classical and contemporary physics. An electrically charged particle may be thought to create an electric field in all regions of space surrounding it; and the electric force between a pair of charged particles may be described through the intermediary of the electric field as follows: particle *A* creates an electric field at the site of particle *B*, and particle *B*, finding itself in this field, responds to an electric force.

Remarkably, all of classical electromagnetism is summarized in four equations originally formulated in the 19th century by the British physicist James Clerk Maxwell; these relations embrace the interactions between charged particles and the electric and magnetic fields associated with them. Implicit in these relations is the existence of electromagnetic waves—electric and magnetic fields in space detached from the charges that create them, travelling at the speed of light, and endowed with such "mechanical" properties as energy, momentum, and angular momentum. The visible radiation, or light, to which the human eye is sensitive is but one small segment of an electromagnetic spectrum extending from long-wavelength radio waves to short-wavelength gamma rays.

Optics. Because light consists of electromagnetic waves, the subject of optics, which treats the propagation of light, may be regarded merely as applied electromagnetism. It is customary, however, to subdivide this branch of physics into geometrical optics, which is concerned merely with the tracing of light rays, and physical optics, which treats the distinctive wave phenomena of light.

While the formation of images in such optical devices as the microscope and telescope may be accounted for simply by ray optics—*i.e.*, by assuming that the passage of light may be represented by straight lines, or rays—subtle effects attributable to the wave character of visible light require the explanations of physical optics. The basic wave phenomenon is interference, whereby two waves meeting at one point in space may combine to yield an enhanced resultant wave, the crests of the component waves then adding together; or, at the other extreme, the two waves may annul, the crest of one wave being superimposed on the trough of the other. A related effect is diffraction, the interference from a large number of wave sources. Because of diffraction effects, light spreads into geometrical shadows; and the image produced by any optical device is intrinsically fuzzy to a degree controlled by the wavelength. The wave properties of light are exploited in such instruments as the interferometer and diffraction grating, which allow for the measurements to a small fraction of a wavelength of light.

Atomic physics. Classical mechanics and classical electromagnetic theory are found to be fundamentally defective when applied to problems in atomic physics. Although the relatively light electrons of an atom are attracted to its small massive nucleus, the atom is not merely a submicroscopic solar system with attraction by gravity replaced by attraction between electrically charged particles. Atomic structure is comprehensible only on the basis of quantum mechanics, and its subtler details require as well the use of relativistic mechanics (for both, see the section on them below).

Because of the minuteness of the atom, its properties must be inferred by indirect experimental techniques. Chief among these is spectroscopy, which is concerned with the measurement and interpretation of the electromagnetic radiation either emitted or absorbed by materials. The atoms of each chemical element radiate a spectrum with distinctive wavelengths, which reflect the atomic structure. Through the procedures of wave mechanics, it is found that the atomic energies and characteristic wavelengths may be computed from certain basic atomic constants, namely, the electron mass and charge, the speed of light, and the fundamental characteristic constant of the quantum theory, Planck's constant. Because the numerical predictions of atomic quantum theory are based on these fundamental constants, one motivation for increasingly high precision in their measurement is the more refined comparison between experimental observation of atomic properties and theoretical predictions.

Atomic constants

Solid-state physics. At first considered only a part of atomic physics, solid-state physics has developed into a separate branch of physics that treats the electrical, magnetic, optical, and elastic properties of solid materials and, by extension, those of materials in the condensed state. Primary attention is given to crystalline solids, because the arrangement of atoms in simple geometric array yields theoretically tractable many-particle systems for application of the quantum theory. Because the atoms in a solid are coupled together, procedures different from those used in studying the structure of single isolated atoms must be applied. Thus, whereas an electron may be associated with a single parent atom when the atom is isolated, in conducting materials the free electrons, responsible for the thermal- and electrical-conduction properties, must be regarded as belonging to the entire collection of atoms.

Nuclear physics. Nuclear physics deals with the questions of nuclear structure and the radiation from unstable nuclei. Smaller than the atom by a factor of about 10,000, the constituent particles of the nucleus attract one another so strongly (by the still incompletely understood nuclear force) that nuclear energies are approximately 1,000,000 times larger than atomic energies. The quantum theory is the principal tool for the explication of nuclear structure.

Unlike the unstable atoms, which emit an electromagnetic spectrum, unstable radioactive nuclei may also emit such particles as electrons and positrons (positively charged electron antiparticles; *i.e.*, identical to the electron in mass but opposite in magnetic and electric properties), massless neutrinos, and helium nuclei. A principal research tool for investigating nuclear properties is the scattering experiment, wherein energetic particles (having exceedingly high velocities) are used as projectiles directed against nuclear targets; and the energies, directions, and identities of the emergent particles are analyzed. In such collisions the chemical identity of the nuclear target may be altered in a so-called nuclear reaction (*i.e.*, the element of which the target consists is transmuted into a different element through changes in the nucleus). The fission and fusion nuclear reactions, in which unstable nuclei are, respectively, split into smaller or amalgamated into larger and more stable configurations are characterized by the release of energy far exceeding that in analogous chemical reactions, such as the bonding of atoms into molecules or the breaking of molecular bonds.

Particles with extremely high energies are found as well in the cosmic rays, consisting of particles of extraterrestrial origin, mostly protons, that rain continuously upon the Earth's atmosphere.

Particle physics. The frontier of contemporary physics lies in the study of the elementary particles, the fundamental constituents of all matter. This branch of physics, referred to as particle physics, or high-energy physics, searches for patterns of coherence in the relationships between the remarkably large number of entities that are thought not to be composites of still more fundamental entities. In addition to the familiar and altogether stable electron and proton, the elementary particles include highly unstable particles existing for as short a time as 10^{-23} second. High-energy particle accelerators are required to create unstable elementary particles, and their interactions are typically studied with devices such as bubble chambers (see below). Some systematic organization schemes and family relationships have been perceived among the fundamental particles, but it is still not known whether the present research in particle physics is converging toward a synthesis.

Search for coherence

Quantum mechanics. Although the several branches of physics differ in their subject matter, experimental methods, and theoretical techniques, certain general principles apply equally well to all. The forefront of contemporary advances in physics lies in the submicroscopic; and the most active research areas—atomic, nuclear, solid-state, and elementary-particle physics—are all based upon quantum theory and the theory of relativity, which form the theoretical foundations of modern physics.

Whereas classical mechanics is characterized by physical quantities that may vary continuously over a range of possible values and are causally interrelated, the distinctive characteristics of the quantum theory are discontinuity and intrinsic uncertainty.

According to the quantum theory (also known as quantum mechanics or wave mechanics) electromagnetic radiation can no longer always be considered to consist of continuous waves; instead, it must under some circumstances be viewed as a collection of particle-like photons, the energy and momentum of each photon being directly proportional to its frequency. Similarly, the quantum theory regards such a particle as an electron as endowed with wave properties, the particle's wavelength being inversely proportional to its momentum. In both instances the proportionality constant is the characteristic quantum, or Planck's constant, named after the originator of the quantum theory, the German physicist Max Planck. Because of the minute size of the quantum constant, the characteristic, and sometimes paradoxical, quantum effects are evident only at the level of microscopic or atomic phenomena. Quantum physics reduces to classical physics when applied to the macroscopic domain.

At least in principle, all of atomic structure, including the periodic table of chemical elements, can be accounted for by combining the electric force between electrically charged atomic constituents with the rules of the quantum theory and the symmetry properties of space. Roughly speaking, each atomic electron, regarded as a wave, must be fitted around the nucleus. Consequently, atomic systems are restricted to certain discrete, quantized energies. When an atom undergoes a discontinuous quantum transition, or quantum jump, its energy changes abruptly by a sharply defined amount, and a photon of corresponding energy is thereby created and emitted, or annihilated and absorbed. Although atomic energies are sharply defined, an electron's location is not. The quantum theory can yield only the probability of finding the particle at any given location.

The feature that distinguishes quantum theory from all other physics is the uncertainty principle, or principle of indeterminacy, of the German physicist Werner Heisenberg: specifying a particle's location with increasing precision necessarily increases the uncertainty in its momentum and conversely, the degree of intrinsic uncertainty being controlled by the magnitude of Planck's constant. Because both a particle's location and momentum must be known in detail to project its future history under the action of known forces, such a program is precluded by quantum theory in the micro-world. The complementary wave and particle aspects, or wave–particle duality, of electromagnetic radiation and of material particles are another manifestation of the uncertainty relation. If an electron exhibits wave characteristics, as in the phenomenon of electron diffraction, then it does not, and cannot, exhibit particle characteristics in this observation; similarly, if electromagnetic radiation interacts with matter, as in the photoelectric effect, the process is effectively a collision involving particle-like photons, and the wave nature of electromagnetic radiation is necessarily suppressed. In the principle of complementarity, the Danish physicist Niels Bohr asserts, in this spirit, that different experimental conditions require different but equally essential descriptions, whether in terms of waves or in terms of particles.

Uncertainty principle

Although it deals with probabilities and uncertainties, the quantum theory has been spectacularly successful in elucidating otherwise inexplicable atomic phenomena; and it has thus far met every experimental test.

Relativistic mechanics. In classical physics space is conceived as having an absolute character as the empty background against which events in nature unfold as time flows onward independently; events occurring simultaneously for one observer are presumed to be simultaneous for any other; mass is taken as indestructible; and particles are able to acquire an indefinitely large speed given sufficient energy. The theory of special relativity, primarily the creation of Albert Einstein in 1905 and now so adequately confirmed by experiment as to be termed the law of relativity, shows all these and still other apparently obvious assumptions to be false.

Assumptions of relativity. The specific and sometimes bizarre relativistic effects flow directly from two basic postulates: (1) All observers, whatever their state of motion relative to a light source, measure the same speed for light. (2) The laws of physics are the same in all inertial reference frames. The first postulate, the invariance of the speed of light, is an experimental fact. From it follow the distinctive relativistic phenomena of space contraction, time dilation, and the relativity of simultaneity: as measured by an observer at rest, an object in motion is contracted along the direction of motion; moving clocks run slow; and two spatially separated events that are simultaneous for a stationary observer occur in sequence for moving observers. Three-dimensional space intervals and time intervals are thus inex-

tricably related in what may be termed four-dimensional space-time.

The second postulate of relativity theory, the covariance of the laws of physics, is also basic to classical mechanics. It implies, for example, that table tennis played on a (nonaccelerating) moving train is just like table tennis played with the train at rest, the states of rest and motion being indistinguishable. Because such mechanical quantities as momentum and energy involve the speed of a particle, their relativistic forms differ from their classical counterparts. In particular, the total energy E of any object of mass m equals the product of the mass and of the square of the speed of light, c, or $E = mc^2$, so that mass and energy must be regarded as equivalent and interchangeable. Further, c represents the ultimate speed limit for a particle, its mass, energy, and momentum all approaching infinite values as the particle speed approaches that of light.

Equivalence of mass and energy

Special and general relativity. The special theory of relativity is restricted to reference frames at rest or in motion at constant velocity relative to the fixed stars (inertial frames); the general theory of relativity is an extension to accelerated frames of reference. Based on the principle of equivalence—for example, an occupant in a closed capsule finding himself pressed against one wall cannot tell whether the force on him is due to the gravitational pull of an object outside or to the acceleration of the capsule—the general theory of relativity geometrizes the phenomenon of gravitation, weaving it into the fabric of space-time. A consequence, confirmed by experiment, is that light itself interacts gravitationally with objects; thus, a beam of light is deflected as it passes close to so massive an object as the Sun, and the wavelength of light escaping from a star is increased (the gravitational red shift). Attempts to geometrize the fundamental force of electromagnetism into a unified field theory of general relativity have thus far been frustrated.

Relativity theory does not show, as some vulgarized statements of it may imply, that "everything is relative." Quite the contrary: although time and space intervals, as well as other physical quantities, are relative to an observer, the speed of light and the laws of physics are absolute.

The conservation laws. First recognized in the early stages of development of classical physics, the conservation laws have come to play an increasingly significant role in contemporary physics. Indeed, much of today's research in elementary-particle physics may be regarded as a quest for conservation laws and their relation to the fundamental forces and particles.

Every conservation law concerns a collection of two or more objects, isolated from external influence, for which some physical quantity remains unchanged in time, or is conserved, quite apart from the details of what goes on between the interacting particles within the system. The generality and simplicity of conservation laws lie in the fact that they apply and may be exploited even in situations for which one is ignorant of the details of internal mechanisms.

Generality of the laws

The conservation laws now believed to be universally valid are those for the physical quantities: (1) linear momentum; (2) mass–energy; (3) angular momentum; (4) electric charge; (5) electron number; (6) muon number; (7) baryon number. The classical counterparts of the first four laws are familiar in classical physics; the last three appear in the study of elementary particles. Roughly speaking, the linear-momentum conservation law implies that a particle cannot fly off in an explosion in one direction without a second particle flying off in the opposite direction. The mass-energy conservation law, recognizing the relativistic equivalence of mass and energy, combines the separate laws of mass and of energy conservation. The angular-momentum conservation law implies that, if one part of an object initially at rest is set spinning in one sense, another part must spin in the opposite sense. The electric-charge conservation law implies that an electrically neutral system may be comprised of equal amounts of positive and negative charge. For example, in the mutual annihilation of an electron with its antiparticle, a positron, their mass disappears; and two uncharged photons are created with the same total energy and fly off in opposite directions, thereby conserving mass–energy, linear momentum, and electric charge. The fundamental character of these four conservation laws is evident in the fact that each law may be deduced from or related to a symmetry property of space and time, together with some general requirements of relativistic electromagnetic theory.

The modern view of fundamental interactions among the elementary particles is that any conceivable process will occur, except as prohibited by a conservation law. Consequently, the failure to observe a process may imply the operation of still another conservation law and a related fundamental symmetry principle.

The conservation laws of electron number, muon number, and baryon number apply to groups of particles identified as belonging to the electron, muon, and baryon families. For example, the proton is perfectly stable; it never decays into less massive particles. This, and similar observations, identifies the proton as the lightest member of the baryon family of relatively massive elementary particles. Still other conservation laws have been identified that are not universally valid but are associated with special categories of particles.

The fundamental forces and fields. All of the forces of nature now known can be traced to four fundamental interactions: the gravitational force acting between any two particles with mass; the electromagnetic force acting between any two particles with electric charge; the strong interaction, or nuclear force, which acts between particles within the nucleus and in other interactions between massive particles; and the so-called weak interaction, which is illustrated in the decay of the neutron into a proton, electron, and antineutrino.

According to quantum field theory, each of the four fundamental interactions is mediated by the exchange of particles associated with the particular force. In classical electromagnetism a charged particle is thought to create a continuous electromagnetic field that acts on a second charged particle to transmit the force. According to quantum field theory, each charged particle continuously creates and reabsorbs field particles, consisting of virtual and unobservable photons; and the trading of such virtual photons between charged particles is the origin of the electromagnetic force. Thus, the field for each force is imagined to consist of corresponding field particles, and all processes occurring at the level of the elementary particles may be conceived to consist of the creation, annihilation, and interchange of particles. Although bizarre, this view of elementary microphysics is validated by its success in accounting for a large variety of processes and even in predicting the existence of heretofore unobserved particles.

Field particles

THE METHODOLOGY OF PHYSICS RESEARCH

Physics has evolved and continues to develop without any single strategy. Careful refinements in measurement to uncover anomalous behaviour, mathematical extrapolation of existing theory, critical re-examination of apparently obvious but untested presuppositions, argument by symmetry or analogy, aesthetic judgment, accident, and hunch all play a role. Thus, the quantum hypothesis of the German physicist Max Planck was based on the observed departures in blackbody (a body that absorbs all radiant energy, reflecting none) radiation from the predictions of classical electromagnetism; the English physicist Paul A.M. Dirac predicted the existence of the positron, and of antiparticles generally, by mathematically extending the quantum theory; the elusive neutrino, without mass or charge, was hypothesized by the Austrian-born physicist Wolfgang Pauli as an alternative to abandoning the conservation laws in the phenomena of beta-decay processes; James Clerk Maxwell conjectured that, if changing magnetic fields create electric fields, perhaps changing electric fields create magnetic fields; and Albert Einstein's formulation of special relativity theory was based upon a critical re-examination of the meaning of simultaneity, apparently without knowledge of the very

experiments on the speed of light that strongly supported his assumptions.

Whatever the detailed tactics, the physicist invariably attempts to render unsolved problems tractable by using successive approximations, first treating simplified or idealized situations to identify the principal effects and only later moving to finer details. Thus, in the kinetic-theory model of an ideal gas, the molecules are imagined to be particles like billiard balls with vanishing dimensions.

Correspondence principle

One general guiding principle, useful in extending theoretical formulations and first introduced by Niels Bohr in a more restricted context, is the correspondence principle: when a more general theory is applied to a situation in which a less general theory is known to apply, the more general theory must yield the same predictions as the less general theory; or, when theories correspond, the predictions must correspond. For example, when the wavelength of light is so small it can be ignored, the more comprehensive theory of physical optics must yield the same results as the more restricted theory of ray optics. Similarly, quantum mechanics must yield the same results as classical mechanics when the wave character of particles is small enough to be ignored or, equivalently, when the small value of the characteristic quantum constant (Planck's constant) may be taken to be zero. In like fashion, relativity physics coincides with classical physics for phenomena at such low speeds that the characteristic constant of relativistic physics (the speed of light) may be regarded as effectively infinite.

The fashion in which the experimentalist and theoretician attack and solve problems in physics may be illustrated by a few examples.

How are the elementary particles created and studied? High-energy accelerators, enormous in both size (up to miles) and cost (hundreds of millions of dollars), accelerate particles to such high energies (up to 500,000,000,000 electron volts) that, when they strike a target, unstable elementary particles are created in the conversion of energy into mass. The life history of such highly unstable, short-lived particles and the particles into which they decay may be studied in photographs taken of the tracks left by charged particles as they move through and create small bubbles in liquid hydrogen near its boiling point contained in a bubble chamber. Particles may also be detected one by one, and their energies measured, in high-resolution scintillation detectors. In such a device, a particle passing through a transparent material excites atoms to emit a weak pulse of light, which in turn dislodges an electron through the photoelectric effect. The electron current is amplified electronically, and the final output pulse is directly proportional to the energy of the initiating particle. When numerous particles are detected in rapid sequence, the output pulses from the detector may be fed to a multi-channel analyzer, which sorts and counts the pulses according to their size. What emerges finally is a record of the number of particles passing through the detector and their distribution in energy.

Use of mathematics

The theoretician uses mathematics first as a computational tool. Thus, Newton invented the calculus to solve the following problem, essential to his formulation of the universal law of gravitation: how does the Earth, imagined to consist of a large number of particles distributed throughout a sphere, attract a small object at its surface, assuming that the attractive force between any pair of particles is inversely proportional to the square of the distance separating them? The integral calculus, a procedure for summing many small contributions, yields the simple result that the Earth is equivalent to a single particle at its centre with a mass equal to that of the Earth.

The theoretical physicist also uses mathematics as a tool of logic—that is, as a means of translating one statement into another, possibly more useful, equivalent statement. Newton's work on gravity again provides an example. Astronomical observations showed that each planet, even when not maintaining a constant distance to the Sun, moves in an orbit such that an imaginary line joining the Sun to a planet sweeps out equal areas in equal time intervals. By strictly geometrical reasoning, this statement can be shown to be equivalent to the physically more significant statement that the force of the Sun on each planet always points exactly toward the Sun.

RELATIONSHIP OF PHYSICS TO OTHER DISCIPLINES AND TO SOCIETY

Impact of physics on related disciplines. Because physics elucidates the simplest fundamental questions in nature for which one may reach consensus, it is hardly surprising that it has had a profound impact on technology, other fields of science, and philosophy.

Whenever a branch of physics has reached such a degree of maturity that its basic elements are comprehended in general principles, it has moved from basic physics to applied physics, or technology. Thus, all of classical physics has become effectively applied physics, its contents forming the foundation of many branches of engineering. Discoveries in modern physics have been converted with increasing rapidity into technological innovations or analytical tools for bordering scientific fields. There are, for example, such newly created fields as nuclear engineering, solid-state electronics, quantum chemistry, and radio astronomy and such analytical tools as X-rays, radioisotopes, spectroscopy, and lasers, all originating from basic physics.

Apart from its applications, physics—especially Newtonian mechanics—has become the prototype of the method of scientific inquiry, its experimental methods and mathematical analysis sometimes being imitated in fields far removed from the physical sciences, for which physics has also served as a model.

Effect of physics on philosophy of science

The significant influence of physics on those branches of philosophy that treat the conceptual foundations of natural phenomena is indicated by its earlier designation as natural philosophy. Determinism, the philosophical doctrine that the universe is a vast machine operating on a strictly causal basis, with its future determined in detail by its present state, is rooted in the Newtonian model of mechanics, in which all future positions and velocities of a particle are determined completely by the forces on it. Moreover, the schools of Materialism, Naturalism, and Empiricism have considered physics as a model for philosophical inquiry. An extreme position is that of Logical Positivism, with its radical distrust of any elements in discourse not directly observable, whose advocates suggest that all significant statements must be formulated in the language of physics.

The uncertainty principle in the quantum theory has prompted a re-examination of the question of determinism; and the philosophical implications of this branch of physics, particularly the meaning of measurement, remain unresolved. It is fair to say that, although physicists agree that quantum mechanics works, they still differ as to what it means.

Reciprocal relationships

Impact of related disciplines on physics. The relationship of physics to its borderline disciplines is reciprocal. Just as technology feeds on fundamental science for new practical innovations, physics quickly appropriates the techniques and instrumentation of modern technology as tools for advancing basic physics. Thus, the experimental physicist utilizes increasingly refined and precise electronic devices; and he works closely with engineers in designing such machines as high-energy particle accelerators. Mathematics has always been the primary tool of the theoretical physicist, and even abstruse branches of mathematics such as group theory have become invaluable aids to the theoretician classifying elementary particles or investigating the symmetry characteristics of atoms and molecules. Much of contemporary research in physics simply could not be carried out without the high-speed computer. It allows the theoretician to undertake computations that are too tedious or complicated by conventional means; and it allows the experimentalist, by incorporating the computer "on line" into the output of his apparatus, to be provided nearly instantaneously with summarized data while an experiment is in progress.

Physics and education. Because physics is the foundation of the physical sciences and engineering, scientists

and engineers are trained in at least the elementary aspects of physics; moreover, the increasingly prominent role of quantum mechanics and nuclear physics in many branches of chemistry and engineering has resulted in further emphasis on these specialties. Professional physicists who make significant contributions in research or in applied physics typically have completed formal studies through the level of the Ph.D. degree, specializing in a subbranch of experimental or theoretical physics. They are employed chiefly in government and industrial research establishments and in academic institutions.

Professional organizations of secondary school and college teachers began in the late 1950s to give special attention to improving the quality of teaching of physics; among the efforts in secondary school curricular reform in physics in the United States are the Physical Science Study Committee and the Harvard Project Physics, programs made possible by substantial support from the federal government and foundations. The United Nations Educational, Scientific, and Cultural Organization (UNESCO), an international organization promoting the exchange of scientific and cultural information, has also been concerned with education in physics.

The physicist in society. Partly because of the esoteric character of much of contemporary physics and its remoteness from ordinary experience, physicists have sometimes appeared to be initiates in a latter-day secular priesthood who speak an arcane language and communicate the significance of their findings to laymen only with great difficulty. Yet the physicist has come to play an increasingly significant role in society, particularly since the massive efforts of physicists during World War II in developing nuclear weapons and radar. They have received substantial governmental support for research studies, even when not directly in the government employ, and the construction of such enormously costly installations as high-energy particle accelerators has been possible only through the creation of national and international laboratories, as illustrated, respectively, by the National Accelerator Laboratory at Batavia, Illinois, and the European Organization for Nuclear Research (CERN), comprised of 12 European member states and operating a large accelerator at the French–Swiss border.

The enterprise of basic physics is strongly dependent upon public support and funding; and with this development has come, albeit slowly and starting with the development of nuclear weapons, a growing recognition within the community of physicists of the social responsibilities of scientists for the consequences of their work and the more general problems of science and society.

Exchange of information in physics. The principal mode of exchange of information among physicists on scientific advances is through the publication of the results of their researches in professional journals. With the proliferation of specialized branches, the number of physics journals has reached several hundred, most published under the auspices of a comparable number of professional societies of physicists, the total international membership of which may be estimated to exceed 100,000. Among the largest groups, each comprised of member societies in specialized fields, are the European Physical Society and the American Institute of Physics. The latter organization has been active in devising improved schemes for abstracting, indexing, and making accessible information, and it maintains a Center for the History and Philosophy of Physics at New York City, the purpose of which is to document the history of recent physics and to collect archival materials.

The chief activity of the International Union of Pure and Applied Physics has been the defining of units in which physical quantities are measured and the promoting of uniformity in other matters of nomenclature.

Physiographic Effects of Man

Man accomplishes some physiographic changes directly, for instance by quarrying rock or digging canals, and also contributes to the development of the Earth's surface features by influencing the performance of other agencies, as when he promotes soil erosion by clearing vegetation or initiates channel incision by building a dam. Such indirect effects are often unforeseen and may be far more powerful and long-lived than the force by which they were set in motion or directed.

No clear distinction can be drawn between artificial and natural landforms; indeed, the direct physiographic effects of man have invited comparison with the work of glaciers, volcanoes, and termites. Though not wholly felicitous, these parallels are collectively instructive in bringing out the variety of man's handiwork. In terms of scale, the features he constructs or excavates are dwarfed by comparable landforms fashioned by other agencies; and when viewed against the geological time scale, the cumulative effect of man's activities appears insignificant. On the other hand, the indirect agency of man is outstanding in its pervasiveness, no physiographic process being wholly immune from its influence.

The role of man in fashioning the landscape has attracted interest since antiquity. Detailed investigation began in the late 18th century and advanced concurrently with the marked acceleration in the growth of man's power to intervene. In the course of these two centuries, man has come to dominate the physical environment of restricted areas, and to affect the general environment to some degree over the entire globe. The combined pressure of technological advance and population increase has tended to enhance and accelerate the influence of man through time.

This article treats the emergence of man as a physiographic agency and summarizes some of the more important direct and indirect ways in which he influences and alters the Earth's surface features. Better understanding of this subject can be gained from knowledge of the other forces and processes that influence landforms. Hence, the interested reader should see LANDFORM EVOLUTION; PHYSIOGRAPHIC EFFECTS OF TECTONISM; FLUVIAL PROCESSES; SEDIMENT YIELD OF DRAINAGE SYSTEMS; COASTAL FEATURES; GLACIATION, LANDFORMS PRODUCED BY; WIND ACTION; and CLIMATIC CHANGE. For other articles treating man's works and projects, see also MINING AND QUARRYING; AGRICULTURAL SCIENCES; CANALS AND INLAND WATERWAYS.

RISE OF HUMAN AGENCY

Importance of fire

Man became an important influence on physiographic change with the help of fire. Repeated burning of the

vegetation cover alters its composition and hence its contribution to soil development; it can also lead to erosion by wind and water. To judge from the archaeological record, man's control of fire spans an estimated 300,000 years in Europe and Asia, over 50,000 years in southern Africa, and at least 12,000 years in North America. The firing of vegetation in driving game and improving the yield of edible plants has been practiced by hunting and collecting communities in many parts of the world and presumably played a part in Paleolithic economics. Its cumulative effects can only be conjectured. Nevertheless, there is botanical evidence to suggest that the world's principal grasslands and prairies, as well as some major woodlands (among them the pinewoods of the southeastern United States and the teak forests of Burma), are the product of repeated burning over millennia. Lightning fires are too infrequent to furnish an adequate explanation. Should the agency of man be confirmed, the soils associated with the tropical and temperate grasslands would rank among the most prominent incidental effects of human agency now in evidence.

The transition from hunting and gathering to stock-raising and cultivation was slow and piecemeal; extensive territories long remained subject to temporary exploitation. The outcome was mainly to concentrate and intensify the effects of man and the animals he needed on the vegetation cover: permanent clearings spread, grazing was increasingly controlled, and preferred plant species were introduced. The trend was accentuated by the rise of farming settlements such as those to be found in many parts of Southwest Asia by 6000 BC, for they made heavy demands on timber and fuel as well as the products of plant and animal husbandry. The introduction of tillage practices enabled man to modify soil structure directly; once animal power was diverted to this purpose, areas subject to prolonged cultivation were gradually sculptured into a stepped or furrowed configuration.

Although clearing, overgrazing, and cultivation were locally accompanied by soil erosion, many of the areas thus affected had undergone much more severe erosion during Paleolithic occupation. It is not clear how far burning contributed to a primarily climatic phenomenon, but there is little justification for assuming that, until the advent of farming, man invariably respected the equilibrium between soil-forming and erosive processes.

Ancient irrigation works

Where irrigation was called for and favoured by social and physical conditions, the manipulation of soil and water left a clear imprint on the landscape. Cultivation terraces, some of them more than 3,000 years old, occupy thousands of square kilometres in Asia, Europe, Africa, and the Andes area of South America. The dikes, canals, and embankments on which the earliest urban societies depended can be traced on the great alluvial plains of the Old World. Ridged fields created in pre-Columbian times to exploit land subject to seasonal flooding have recently been identified in many parts of tropical South America. In North Africa, the control of ephemeral floods in the coastal uplands awaited Carthaginian settlement and reached its apogee in Roman times; elsewhere, it was not until the Middle Ages or later that the action of running water was significantly modified by engineering works.

Such devices had implications for landscape development that went beyond their immediate purpose. Terracing reduced the sediment yield of river basins, and the soils they held developed distinctive characteristics, especially when subject to waterlogging. In parts of Mesopotamia irrigation was not matched by adequate drainage and soon led to the accumulation of noxious salts at the surface. The embanking of streams promoted silt deposition within their channels, which, in turn, rendered them unstable and increased the incidence of flooding; the Huang Ho is a case in point. In the Nile Valley, millennia of flood irrigation have contributed to the processes tending to build up the plain; in the Tafilalt oasis of Morocco, medieval stream diversion provoked the accumulation of alluvium, reaching a maximum depth of five metres (16 feet).

Where runoff had been brought under control by damming, as in Roman Libya, or by underground drainage, as in Etruscan Italy, valley erosion was checked and the topography now contrasts sharply with that of river basins not thus protected. Conversely, irrigation made it possible to cultivate marginal areas where the role of vegetation in shielding the soil from water and wind action was especially important; the Romans, at other times hailed as supreme practitioners of conservation, have on these grounds been held responsible for the decay that ultimately overtook large parts of their empire.

Materials for the pyramids and other works

The building of cities, engineering works, harbours, monuments, and defenses had as its counterpart the extraction of large volumes of rock and clay. The Sadd-el-Kafara, a dam built south of Cairo between 2950 and 2750 BC, alone embodied 100,000 tons of material; the Great Pyramid of Khufu at Giza consists of 2,300,000 blocks with an average weight of 2.5 tons. Most of the material used in construction was obtained from quarries and floodplains.

Shafts had been employed in Neolithic flint mines throughout western Europe, notably at Spiennes, Belgium, where the resulting pitted landscape extends over two hectares (five acres). By the early fourth millennium BC, shafts were in use in the copper mines of Armenia and the Caucasus. Shafts also made possible the digging of tunnels called *qanats* or *foggara* that were as long as 20 kilometres (12 miles) in order to tap the underground water held by alluvial deposits; the aligned crater-like depressions by which they are marked are a prominent feature of the Iranian desert, where the technique has been known for 3,000 years. The scars of mining and of other forms of excavation spread with the adoption of new minerals and fuels and the dispersion of technical knowledge; *qanats* are to be found in other parts of Asia, in Europe, North Africa, and the Americas.

Aerial photography has played an important part in filling in the details of the ancient man-made landscape. It has revealed the grid laid out by Roman surveyors in Tunisia and other parts of the Mediterranean, the puzzling Nazca designs of the Peruvian desert, and many mounds and dikes that fulfilled military and religious functions. The picture that emerges is one of gradation between areas subject to long-standing, though varied, direct and indirect modification, and others where man's handiwork betrays shortlived, opportunist use of the land.

EFFECTS OF MODERN MAN

In reviewing the effects of modern man on the landscape, it is convenient to classify his activities in terms of the geological processes to which they most closely correspond. The issue of motives, and any assessment of the outcome in economic or aesthetic terms, are not central to this article.

Direct effects. The technological and demographic upsurge that characterized the 18th and 19th centuries was marked by a rapid increase in the power of direct human intervention; by 1922 it was possible to claim that, in the densely populated British Isles, man's capacity for removing and comminuting rock exceeded that of all the atmospheric forces combined.

Land cultivation and mining. The uneven spread of this power is illustrated by the distribution of cultivation methods. An estimated 11 percent of the world's land area is under cultivation, of which one-tenth is irrigated. The level of technology employed ranges from digging sticks to mechanical devices that wholly transform the existing soil structure, and from the occasional diversion of spates to the application of specified volumes of water at controlled rates. Soil chemistry may be modified by the abstraction of nutrients by plants until their exhaustion, or it may be manipulated by rotation and chemical fertilization. Other weathering agents are influenced: frost action may be encouraged to improve tilth, or checked if injurious to the crop.

The boundaries of the sown areas continue to fluctuate. In New England, large areas have reverted to forest in the course of the last century; conversely, drainage has added over 600,000 hectares (1,500,000 acres) to the cultivable

territory of Finland since 1941. The margins of arid areas are rendered especially unstable by rainfall variability.

The relief produced by plowing and the excavation of drainage and irrigation canals is limited by the stability of the soil material as well as by the available power and equipment. In this respect it conforms in vertical scale to the products of water erosion, however much it may depart from the fluvial landscape in its geometrical pattern. In contrast, the depths attained by open-pit mining are determined primarily by the economics of mining. The copper pit at Bingham, Utah, is over 800 metres (2,600 feet) deep and has not yet reached the limits of rewarding excavation. Laterally, the scope is technically unlimited, although the largest quarries, such as the Hull-Rush-Mahoning iron-ore pit in Minnesota, remain far smaller than the Aso caldera of Japan and other volcanic features.

Quarries and excavations

Open-pit mining accounts for 70 percent of the world's output of minerals and rocks. The excavations range from small borrow pits, such as the 300,000 marl pits that dot East Anglia, England, to vast stepped amphitheatres. The strip-mining of coal produces its own distinctive topography, as does the working of placer deposits by hydraulic methods or by dredging. The terrain thus affected is rapidly expanding; in the United States, for example, the production of natural aggregates increases by 5 percent each year. Because sand, gravel, and rock suitable for crushing are low in value, their extraction tends to be concentrated near urban and industrial sites. This tendency is countered, however, by the needs of highway and aqueduct construction, and it may be largely ignored where more precious minerals are involved, as in the case of the great copper open-pit mine of Chuquicamata in the Atacama Desert of Chile. Military and scientific activities, such as the explosion of atomic devices, and the craters produced by bombing, have further dispersed man's erosional activities.

Man-made pits are often bordered by waste tips and mounds. The proportion of usable to unusable solids ranges from less than 20 percent of the output in sands and gravels to as much as 14,000 percent in the case of slate. Contributing to the process are such underground workings as the gold mines of the Witwatersrand, South Africa, which yield some 60,000 tons of waste each year. The potential instability of some of these features is brought out by the collapse of tips at Espenhain, East Germany, in 1959 and Aberfan, Wales, in 1966. The unconsolidated material of which they are composed has constructional value, and, together with urban and industrial waste, it is employed to level and create building land in response to economic and social pressures.

Artificial channels and coastal works. Surface waters are more widely affected. The density of the drainage network is increased by canals, ditches, and other artificial channels. Surface drains may triple the length of channel that would otherwise characterize a particular area; in parts of Scotland the increase has been twenty-fold. Conversely, subsurface drainage can lead to the local elimination of organized runoff. Canals, including the Panama cut, exploit existing watercourses and also disregard watersheds; the channel that links Abidjan, Ivory Coast, with the sea bears little relationship to the natural drainage. The geometry of the channels and their floodplains is often modified to improve the efficiency of drainage; dikes, embankments, and auxiliary canals remain a prominent feature of the fertile alluvial valleys of the Old World and have transformed the valley of the Mississippi River. Lake Kariba, over 280 kilometres (170 miles) long, on the Rhodesia–Zambia border, is the outstanding example of further diversification produced by artificial lakes and reservoirs.

Harbours, breakwaters, and dikes

Coastal modification similarly ranges from the minor adjustment of existing features to the creation of novel landforms. Most of the major harbours of the present day, including those of Sydney, San Francisco, and New York, occupy propitious sites; a few are largely artificial, such as those of Takoradi, Ghana; Sète, France; and Algiers, Algeria. The port of Ischia, Italy, lies on a crater lake that has been opened to the sea. Offshore islands are also exploited in the building of breakwaters; artificial islands—for instance, Rincon Island in the Gulf of Mexico—may be the solution to the problems posed by offshore drilling.

Protective works range from those designed to preserve the existing situation, such as sea walls, to groins and other devices that work in conjunction with the transport by waves and currents. The creation of land at the expense of the sea has been most successfully pursued in areas already subject to coastal sedimentation. In England, the area around the Wash has gained 16,000 hectares (40,000 acres) of land since the 18th century. In the Netherlands, over 740,000 hectares (1,800,000 acres) have been won in this way since the early 13th century; the dike that blocks the Ijsselmeer lies at a maximum distance of 85 kilometres (53 miles) from the former coast and has reduced the length of the coastline by about 300 kilometres (200 miles). The material yielded by the dredging of existing facilities is sometimes used for reclamation rather than being dumped at sea: a combination of dredging and filling was employed in developing San Juan Bay, Puerto Rico.

Man's direct intervention is seen to differ from other physiographic processes chiefly in its versatility. It is not unique in effecting both chemical and physical changes and transcending the distinction between the organic and inorganic worlds. Tree roots, for example, break up rocks by mechanical means and also influence microbial activity. But human agency is not confined to a specified range of environments or sources of energy. Glaciers and rivers are creatures of topography and climate; volcanoes are restricted to well-defined zones; and even the action of wind is strongly localized. Man, however, is potentially free of such constraints.

Indirect effects. The incidental effects of man's activities on the landscape have long attracted attention. Plato, for instance, ascribed the barrenness of Attica to soil erosion consequent upon deforestation; Pausanias pointed out that silting at the mouths of the Achelous and Maeander rivers was accelerated by cultivation within their catchments. Later writers came to regard such phenomena as indicative of the tendency by modern man to disturb the equilibrium attained by nature, a viewpoint that was powerfully endorsed by the soil erosion that afflicted the U.S. Midwest in the 1930s.

The difficulties to be faced in measuring such unforeseen and often undesirable developments have long been emphasized. The need remains to rely on historical evidence and on deduction based on present-day parallels, and many of the effects are still poorly understood. Nonetheless, advances in the study of soil mechanics, meteorology, geophysics, and allied fields have thrown light on some of the mechanisms by which indirect human agency operates and have demonstrated that the consequences are sometimes out of all proportion to the energy involved in man's intervention.

Land subsidence and slope failure. In many cases the role of man is self-evident and easily evaluated. The underground extraction of solids and fluids, for example, can lead to subsidence, and its prediction presents few problems. The salt fields of Cheshire, England, are widely affected by such activity, and flooding of the depressions has formed lakes known locally as meres or flashes. The coal-mining areas of Pennsylvania provide instances both of subsidence and of collapse. Where water, oil, or gas is withdrawn from an underground stratum that is poorly consolidated, the loss of supporting pressure provided by the fluid can result in compaction. Mexico City has been subject to subsidence since pre-Columbian times because of drainage by surface channels; the process was greatly accelerated by pumping to supply urban needs, and sinking at the rate of 15 centimetres (six inches) per year was observed in places. Despite restrictions placed on pumping, parts of the city are still settling by about three centimetres each year. In the Wilmington, California, oil field, the abstraction of petroleum and gas has produced depression of the surface over an area of about 56 square kilometres (22 square miles), to a maximum depth of nine metres (30 feet). The application of large surface

Underground fluids

loads also leads to depression; at the site occupied by Lake Mead, Nevada, for example, a maximum of 175 millimetres (seven inches) of subsidence has occurred in the course of 15 years, a figure that comes close to the predicted elastic yield of the Earth's crust.

Analogous topographic changes can arise through drainage or irrigation of the soil. The drainage of organic soils promotes their shrinkage through the decomposition and oxidation of organic matter. Where the superficial deposits consist of loose, dry material of low density, such as wind-lain particles, the application of water sometimes produces the phenomenon of hydrocompaction. Over 500 square kilometres (200 square miles) have been thus affected in the San Joaquin Valley of California, and in places depression amounts to more than five metres.

Slope failure, like subsidence, occurs when gravitational stresses overcome the resistance of the rock material (see EARTH MOVEMENTS ON SLOPES). Man may bring this about by undercutting and steepening slopes, or by changing the mositure content and hence the cohesion of deposits in which they are developed. The former is illustrated by the extensive landslides that took place during construction of the Panama Canal, one of which involved 400,000 cubic metres (14,000,000 cubic feet) of material. Infiltration from gardens and cesspools allegedly triggered an extensive landslide in the Palos Verdes Hills of Los Angeles in 1956; in three years movement exceeded 20 metres (70 feet). The Vaiont Dam in Italy was destroyed when a landslide comprising over 240,000,000 cubic metres (8,500,000,000 cubic feet) slid into the reservoir; by raising the water table, the dam itself had contributed to slope instability. In areas with a permanently frozen subsoil (permafrost), thawing may be encouraged by the disturbance or removal of vegetation or superficial sediments and soils, since these act as insulators. Highway and railroad construction in Alaska has been accompanied by landslides, slumps, and rock flows, and road surfaces are distorted by frost heaving. The vibration produced by passing traffic may also trigger movement in unstable slopes.

Techniques have been developed to preserve or restore slope stability, for example by creating an insulating layer over frozen ground or by controlled drainage of terrain weakened by seepage. The Folkestone and Warren landslips of Kent, England have been controlled by drainage combined with coastal protection, because undercutting by wave action is an important contributory factor. In California, waterlogged clay slopes have been dried by circulating warm air through tunnels. The use of vegetation to bind the surface of cuttings and embankments is commonplace.

Erosion and sedimentation. Any change in the geometry, water discharge, or sediment load of a stream will disturb existing equilibrium conditions, and is followed by readjustment that may involve erosion, deposition, or both. The silt that accumulates behind a dam often forms a delta; in the case of the Furnish Dam, Oregon, the entire basin was filled in 16 years. By trapping sediment and altering the pattern of flow, dams often lower the river bed in the valley below the dam. The channel of the Red River of Oklahoma and Texas has in this way become both wider and deeper for a distance of 160 kilometres (100 miles) below the Denison Dam. River straightening and dredging sometimes lead to further incision by accelerating the velocity of flow, as in the Rhine, which has deepened its bed at Duisburg by two metres (seven feet) since 1900. On the other hand, man may promote deposition by introducing surplus sediment, as in the Sierra Nevada of California and other areas subject to hydraulic mining.

The incidental effects of stream modification extend to lakes and coasts, whether as changes in the water balance or in terms of the sediment supplied. The progressive fall that has characterized the Aral and Caspian seas in recent years is attributed largely to dam construction on their affluents (inflowing streams); it has exposed 38,000 square kilometres (15,000 square miles) of land in the former and 25,000 square kilometres (10,000 square miles) in the latter. The area of San Francisco Bay has contracted by over 700 hectares (1,700 acres) since 1850, largely because of the import of sediment by rivers affected by hydraulic mining of placer gold; in contrast, Ventura Beach, California, has been deprived of much of its sand supply by the damming of the Ventura River.

Urbanization and hydrologic change

Urbanization is a further source of hydrological change. By paving the Earth, man armours it against weathering and erosion; he also renders it impermeable and thus produces a far higher proportion of runoff (as opposed to infiltration) than would otherwise prevail. A little less than one percent of the world is occupied by buildings, roads, and kindred structures, but their uneven distribution is brought out by the corresponding figures of 10 percent for England and Wales and of over 50 percent for Brooklyn, New York. Within these units there are large areas that are entirely covered. Measurements taken in the United States have shown that, during construction, building sites release sediment at rates up to 40,000 times greater than those of corresponding rural areas under grass or woodland; for urbanized and developing zones as a whole, the factor ranges between ten and 100. Channel flow gains little from groundwater and is therefore closely related to the incidence of precipitation; runoff is rapid, and the proportion lost to sewers is quickly restored to surface drainage. Hence, discharges are relatively higher and more short-lived than in areas where infiltration plays a prominent role in the hydrologic cycle and, in turn, contribute to stream load by producing channel enlargement. In brief, the progress of urbanization enhances stream activity, always providing that some erodible material has been left exposed to the action of water.

Like river basins, stretches of shoreline operate as physiographic units that adjust to man-made modification by changes in geometry or in process. Where breakwaters, jetties, or groins are erected to trap material, further erosion may take place along the coast if the beach depends for its equilibrium on the supply of sand or shingle by longshore movement of sediment. Much agricultural land has been lost in this way near Durban and Madras, and a breakwater erected to form a harbour at Santa Barbara, California, caused silting in the harbour and erosion along more than 15 kilometres (nine miles) of coast. The extraction of shingle can be equally deleterious by robbing the beach of its protection against wave action; it has aggravated erosion along the Holderness coast of England, whose susceptibility to erosion is indicated by the loss since Roman times of a strip averaging four kilometres (two miles) in width.

At times man intervenes to restrain erosion, as when he fixes coastal dunes with the help of vegetation, or seeks to establish or restore a balance between coastal erosion and deposition. In England, trucks have been employed to carry shingle from the beaches of Rye to those from which it had been derived at Winchelsea, and a similar function is fulfilled by pumping sand across the erosive channel that leads to Palm Beach, Florida. Where the problem is to maintain or create a deep navigable channel, submarine erosive processes are turned to advantage by means of training walls or by judicious dredging. Liverpool Docks and the New York Harbor both benefit from this stratagem.

Soil erosion

Man's indirect influence is displayed most prominently in the varied physiographic changes that are grouped under the heading of soil erosion and that affect two-thirds of the Earth's land surface. In the United States, for example, 5 percent of the land suitable for cultivation or forestry has been entirely ruined, 15 percent has lost three-quarters of its topsoil, and 41 percent is subject to moderate erosion. In addition to its local implications, soil erosion affects other landscape elements and the performance of allied processes. The incidence of violence of flooding is increased by rapid runoff and low infiltration; stream channels are choked by silt; and material removed by wind erosion accumulates in drifts.

Many factors help to determine the stability of soils, and the scope for human intervention is correspondingly large. Differences in the character and density of the

vegetation cover generally account in large measure for areal variations in the severity of soil erosion; hence, the importance of fire and burning, as previously discussed. In the United States it has been found that land used for row cropping (for instance, under cotton or tobacco) may erode at rates that are 100 times greater than for woodland or pasture; in Cyprus, the sediment yields from vineyards are more than six times those on comparable terrain under forest cover. In either case, slight modification of the vegetation cover will produce disproportionate changes in the rate of soil loss.

Soil structure provides further opportunities for inadvertent triggering or acceleration of erosional activity. Vegetation and plant litter protect the soil against the impact of raindrops and the action of running water and wind. A soil structure that is resistant to these forces may be destroyed by compaction, whether by hooves or vehicle tires. Paving can give rise to new water-courses as well as favouring the activity of those already in existence. In many badly eroded areas, gullies are fed by runoff from roads that have not been provided with adequate gutters. Once linear erosion is initiated, soil moisture is locally depleted; the benefits of good soil structure are overridden by downcutting and bank collapse.

Unlike vegetative cover and soil structure, whose reinstatement is hampered and ultimately precluded by erosion, the factor of topography is amenable to correction; hence the emphasis on terracing and contour plowing in many soil conservation schemes.

Climate and air pollution. Rainfall intensity and the duration of individual storms are important factors influencing flood flow and the protective value of the vegetative mat, particularly in semiarid areas. Although large-scale weather modification (*q.v.*) by man is still in its exploratory stages, there is little doubt about man's capacity to stimulate precipitation by seeding suitable clouds with condensation nuclei. Hail suppression by this means is already practiced, and the mitigation of destructive downpours appears feasible. The climatic changes associated with urbanization are not wholly irrelevant to erosion, because they may involve increases in the total annual precipitation of up to 18 percent, a value that will be enhanced by the impermeability of the terrain on which it falls.

Air pollution, which is an important element of urban climates (*q.v.*), may be influential in rural areas if it is virulent enough to weaken the vegetation cover. The emission of sulphur dioxide by the copper smelters of Ducktown, Tennessee, has had this effect and thereby led to severe gullying; a similar chain of events has been reconstructed for the Swansea Valley of Wales in the 18th and 19th centuries. It is also suggested that overgrazing in parts of the Rājasthān desert of India has increased the local dust cover and that this, in turn, leads to greater aridity and to desert formation.

Air pollution is suspected of influencing world climate as a whole. The carbon dioxide content of the atmosphere has increased by an estimated 11 percent over its value in 1850, and the associated warming (greenhouse effect) is put at 0.6 percent between 1880 and 1940. It was formerly held that the combustion of fossil fuels was the primary source of the additional carbon dioxide; the oxidation of humus, peat, and other organic material is now regarded as a major contributor, but man retains some responsibility because the process is encouraged by forest clearing, cultivation, and the drainage of bogs. At the same time, the addition of particulate matter to the atmosphere by mankind as a whole is believed to have had a cooling effect amounting to about 0.05° C (0.09° F) each decade. In brief, the extent of human influence on long-term temperature changes remains uncertain, but the question deserves to be pursued in view of the implications such changes have for the vegetation cover and the pattern of precipitation.

Earthquakes. Forces acting within the Earth are not immune from the influence of man. It has been observed that the incidence of earthquake shocks has increased near the sites of large reservoirs, among them lakes Mead, U.S.; Kariba, Rhodesia; Koyna, India; and the Arapuni River, New Zealand. On the other hand, there is some evidence to suggest that Lake Mead has reduced earthquake activity, as the seasonal variations in its level during 1939–51 show some correlation with the number of shocks within a given radius. Underground nuclear explosions are followed by aftershocks, and some believe that they may trigger impending earthquakes in the vicinity. This has given rise to proposals for the controlled release of strains within the crust by means of explosions, in order to avert major earthquakes. The finding that the leakage of fluids into fault zones appears to affect their activity has similarly encouraged attempts to lubricate lines of crustal fracture subject to intermittent but large-scale displacement.

Interaction of human and natural forces. Other environmental changes that have been attributed wholly or in part to human agency can be explained in different ways. Many of the erosional features that are regarded as characteristic of accelerated erosion are duplicated in the geological record for periods apparently immune from human depredation. The sediment yields and erosional rhythms they represent are in some cases found greatly to exceed those now prevailing in the area. In New Mexico, for example, ancient arroyos appear to have formed at a rate that is more than nine times greater than those of the immediate prehistoric and historic period; and in some valleys in Iowa the deposition of alluvium in prehistoric times took place at over twice the modern rate. These findings are stimulating enough in challenging the view that a placid physiographic regime was disrupted by abuse of the land, although the possibility that abuse of the land is a long-standing attribute of man has already been raised. An alternative approach is to postulate changes in the climatic conditions governing physiographic processes. In the Mediterranean area, for example, erosional features often attributed to medieval deforestation and overgrazing can be interpreted in terms of a slight change in the seasonal incidence of rainfall. The onset of gullying in the southwestern United States is attributed by some to the arrival of white settlers armed with herds of cattle and metal plows, and by others to a climatic change that led to a weakening of the protective grass cover and perhaps also to a higher incidence of erosive floods.

In many such cases the answer probably lies in the combined effect of human and climatic influences. Man's potential for influencing other physiographic processes is understood; the difficulty lies in isolating his contribution to the landscape. There is great scope for work designed to reduce the area of doubt, if only because the evaluation of man's role is a prerequisite for effective control of deleterious physiographic change.

BIBLIOGRAPHY. GEORGE PERKINS MARSH, *Man and Nature* (1864), is the first general study on the subject, gloomy but not wholly pessimistic. R.L. SHERLOCK, *Man As a Geological Agent* (1922), deals with the British Isles in unusual detail. Physiographic change is one of the many topics treated in an international symposium on *Man's Role in Changing the Face of the Earth*, ed. by WILLIAM L. THOMAS, JR. (1956). ROBERT F. LEGGETT, *Geology and Engineering*, 2nd ed. (1962), considers many of the problems that confront the civil engineer. The use of air photographs in tracing prehistoric, classical, and medieval man-made features is illustrated in JOHN BRADFORD, *Ancient Landscapes* (1957).

(C.V.-F.)

Physiographic Effects of Tectonism

It has long been known that tectonism has profoundly influenced the physiography of the Earth. The Russian scientist M.V. Lomonosov stated in 1763 that the Earth's relief is formed by shaking of the Earth (earthquakes) or long-term sinking and raising of its surface. The German geographer Alexander von Humboldt suggested that mountain ridges were formed by upwelling of molten lava (volcanism) from the Earth's interior. This idea was derived from observation of volcanic activity in Central America. The French scientist Élie de Beaumont, however, thought that the Earth's relief features were principally attributable to gradual compression or shrinking of the Earth's crust because of slow cooling since its

formation. In this view, tangential pressures in the crust caused folding and general tectonic movements.

The Austrian geologist Eduard Suess noted that rock deformation was particularly intensive in mountainous areas, and he came to the conclusion that a close link existed between mountain ranges and crustal uplift and between oceanic and other basins and tectonic sinking or depression. In general, scientists today discriminate between tectonic movements that are geographically restricted and involved in mountain building (orogenic movements) and those movements that are broader, less localized, and associated with the uplift or depression of plateaus and basins (epeirogenic movements). Both types of tectonism have occurred throughout geological time and are responsible for the Earth's present relief features or physiography. Modern investigations have led to the suggestion that all tectonism is produced by the movement of great blocks of the Earth's crust relative to each other. This theory, called plate tectonics, is described in the articles SEA-FLOOR SPREADING; OCEANIC RIDGES; CONTINENTAL DRIFT; and MOUNTAIN-BUILDING PROCESSES.

This article deals with the effects of tectonism on the Earth's surface features, including the ocean floor. For further information on the several theories of formation of these features or landforms, see LANDFORM EVOLUTION.

Recent tectonic movements. *Seismic, or rapid, movements.* Direct observations and theoretical generalizations suggest a close connection between earthquakes, which periodically occur in different parts of the globe, and recent tectonic movements. Such movements are considered to be mechanical dislocations or faults within the crust. When faulting occurs, earthquakes are generated. The detection, recording, and analysis of the resulting seismic waves provides information on the intensity of an earthquake and its location—both where it occurred on the surface of the Earth and at what depth.

Tectonic movements of a seismic character are often called rapid because the physical consequences occur swiftly. The reasons for these tectonic movements cannot be directly observed because they occur at depths of hundreds of kilometres, but strong earthquakes generally manifest themselves in repeated disturbances of the Earth's crust through time and thus produce discernible physiographic effects at the surface.

Rapid tectonic movements frequently occur in the Soviet Union, where intensive earthquakes of destructive character take place several times every year; less intensive earthquakes are even more common. The earthquake epicentres are geographically localized and this provides the opportunity to carry out regional seismic investigations and to forecast the locations and the intensity of possible earthquakes. The greatest frequency of intensive, rapid tectonic movements has been established as characteristic of mountain regions—from North Africa, the Alps, Balkans, and Caucasus to the Tien Shan, Pamirs, and the Himalayas and around the margins of the Pacific Ocean (Alaska, the Aleutians, Coast Ranges, Andes, mountains of New Zealand and Indonesia, and the Japanese islands, the Kurils, and Kamchatka). There are reasons to suppose that the main sources of rapid tectonic movements are the zones of deep faults that extend from the crust into the upper mantle (zone beneath the crust) of the Earth.

Mountain regions of intensive seismic activity

Slow tectonic movements. Slow tectonic movements of the Earth's surface were detected first in Scandinavia (the Baltic or Fennoscandian Shield, an area of ancient crystalline rocks) and subsequently in the Canadian Shield. In both regions dome-shaped, elevated, ancient shorelines and deposits of former lakes and seas were discovered. These phenomena have been explained in terms of a rather broad upward arching during the last 10,000 to 12,000 years because of constant melting of thick glacial ice cover and consequent rising caused by lightening of weight. The maximum uplift of Fennoscandia for this period was about 250–275 metres (820–900 feet) in the northern part of the Gulf of Bothnia, according to some authorities; uplift in the Hudson Bay region of Canada has attained nearly 300 metres (1,000 feet). Simple calculation shows that average rate of such tectonic movements reaches two to three centimetres (0.8 to 1.2 inches) per year in the tops of arches, gradually decreasing toward their peripheral regions.

Slow tectonic uplift and subsidence with such characteristics are common almost everywhere. These slow tectonic movements were detected by precise geodetic measurements, and their average velocities ranged from tenths of millimetres to several millimetres per year for plains areas and ten millimetres (0.4 inch) or more per year in mountain regions. Unfortunately, data are available for no more than 100 years. For this reason it is not yet possible to define the general trends (or periodicity) of such movements, as is possible in regions of postglacial isostatic uplifts, where there are records or available data. Nevertheless, the main conclusion about recent tectonic mobility, supported by seismic phenomena, may at present be considered proved by numerous geodetic, oceanographic, and geomorphological investigations.

Recent horizontal movements of separate parts of the Earth's surface also have been detected with the help of precise geodetic measurements and geomorphic observations. The features of horizontal displacement along the Talass-Fergana Fault in Soviet Central Asia or more complex movements of separate points along the San Andreas Fault in California are examples. In both regions single horizontal displacements of several metres have been observed immediately after strong earthquakes.

Recent tectonic mobility must be considered proved, although not all aspects are yet understood. The evidence consists of orogenic zones that coincide with seismic phenomena, shield areas in which isostatic movements occur, and regional lines of horizontal dislocations. It is not yet possible, however, to make an evaluation of tectonic mobility through time and, in particular, to define the periodicity, if any, that is manifested. Further measurements and observations are needed for a full understanding of these phenomena.

Effects on the Earth's surface. *Uplift and denudation.* Modern concepts of the origins of the Earth's surface features are based upon acceptance of the existence of a dynamic equilibrium between vertical tectonic movements (uplift and subsidence) and denudational processes, which encompass the erosion of rocks and accumulation of the resulting sedimentary debris.

Rates of continental denudation

The German geographer Albrecht Penck considered data on the volume of transported river sediments and concluded in 1894 that a layer 0.8 millimetre (0.03 inch) thick is annually transported to the sea by rivers. More recent calculations have shown that the solid sediment transported by rivers is alone sufficient to account for reduction of the Earth's surface by 0.09 millimetre (0.004 inch) per year. Other values, given by various scientists, range from 0.01 to 0.02 millimetre (0.0004 to 0.0008 inch) in lowlands to 0.6 to 0.8 millimetre (0.02 to 0.03 inch) per year in mountains. Values as great as 0.16 millimetre per year have been given for the United States.

It should be noted that the sediments transported by rivers make up only part of the general volume of all sediments that are subject to continental denudation. Some sediment is not carried to the sea at all but is retained within the area being eroded—on terraces, hillslopes, in local closed depressions, and elsewhere. This material, which is not transported to the sea, is not included in the calculations on which the foregoing data are based. Hence, values of continental denudation are greater than stated.

The general correlation between recent tectonic movements and continental denudation may be considered an indication of dynamic stability of the Earth's surface. The stability is characterized by the following process: slow tectonic uplift of certain areas stimulates erosion and denudation, whereas other parts of the Earth's surface undergo tectonic subsidence and the eroded material tends to accumulate in place, although part of it is transported to the sea in one form or another.

Data on the rate of development of a normal soil profile (sequence of vertical layers) under a natural vegetation cover are instructive in this regard. The use of radiomet-

ric measurements for defining the absolute age of humus in the recent soils has shown that a time period ranging from several hundred to 1,000 to 3,000 years (depending on the genetic type of a soil) is required for the formation of a normally developed soil. This means that the natural "growth" of soil thickness ranges from one to ten millimetres per year. It shows that under the conditions of natural denudation, a well-regulated dynamic system exists. The three basic processes of the system—tectonic movements, soil formation, and continental denudation—tend essentially toward a state of balance. The middle component of the system, the soil-vegetation cover, serves as its main regulator.

Mudflows as an example of natural denudation

Equilibrium is lost when the natural soil-vegetation cover is disturbed, whether by man's activities or natural causes. Rather widespread phenomena of natural denudation are evident in mudflows, which form in mountains during rainstorms when there is an exceedingly high surface runoff. They are characteristic of many high mountain zones, where thick accumulations of loose sediments are present, and in arid regions, where the vegetation cover is sparse. Catastrophic displacements of ground masses on slopes (avalanches, landslides, and mudflows) are quite common in these areas. They are usually caused by earthquakes; and many interruptions of the soil-vegetation cover on mountain slopes are characteristic elements of the natural landscapes and must be considered a reflection of disturbed equilibrium.

Relief features. The state of equilibrium between tectonic movements and the processes of denudation should provide for a stable, level character of the Earth's surface; it is clear, however, that such is not the case. Aside from extraordinary disturbance of the equilibrium by catastrophic movements of sediment, more gradual tectonic movements and denudation are not balanced in the strict sense and may be progressively altered and directed over time. Consideration of this balance—or lack of balance—has led to the distinction among three main categories of elements in the structure of the Earth's surface. The largest category consists of first-order relief features, which are elements of the so-called geotecture. They include crystalline massifs, continental platforms, oceanic hollows, and large mountain systems.

Positive and negative elements of lesser magnitude make up the second-order relief features that complicate the surface of continents and ocean floors; these elements are called the morphostructure. This group includes plateaus, uplands, lowlands, ridges, and similar features. Morphostructures may be described chiefly as large forms of relief that emerge as a result of the interaction of tectonic and denudational forces. Tectonic movements play the leading role in this interaction.

Small elements of relief of the third order include such features as river valleys, lake basins, and dune or karst (cavern) forms. They are sometimes called elements of morphosculpture. The origin of these morphosculptural elements is largely dependent upon denudational processes.

Neotectonics as the basis of present-day relief

It has been suggested that all tectonic movements that are expressed in present-day relief should be called neotectonics. In papers by Soviet scientists this connotation emerges from considerations of the general amplitude and character of the most recent tectonic movements. A review map of these movements in the Soviet Union served as a model for international compilations of this type. The main basis for the work was study of the thickness of Pliocene–Quaternary deposits (younger than 7,000,000 years) that accumulated in areas of tectonic subsidence (depressions and basins) and of the amplitude of uplift of ancient surfaces in mountain ridges. In these instances, the obtained values of uplift and deposition amounted to hundreds of metres of relief over distances of several kilometres. The role of neotectonics in forming the present relief features is acknowledged by all authorities.

Tectonism of the ocean floor. It formerly was believed that the ocean floor was tectonically stable, but this idea was contradicted by the occurrence of tsunamis, large surface waves that are generated by submarine earthquakes. Because tsunamis were observed only on the coasts of the Pacific Ocean, they were thought to be related to the seismic focuses of the Pacific margin, sometimes called a ring of fire because of recurrent volcanism and tectonic movements. The most destructive tsunamis are now known to originate from earthquakes centred on the continental slope, however, where huge masses of sedimentary bottom deposits shift and slide toward lower levels.

The relief of the ocean floor is characterized by great complexity and diversity. Many landforms are similar to those on the continents, but some large and peculiar submarine geomorphic elements have no analogs on the continents. A high degree of tectonic mobility characterizes the ocean floor, particularly in the vicinity of oceanic ridges (*q.v.*). This mobility has produced complicated tectonic dislocations (transform faults), new forms of bottom relief, and the graded bedding so typical of underwater deposits resulting from density currents (*q.v.*).

The main elements of the ocean-floor relief consist of (1) underwater margins of continents, or the continental shelves; (2) transitional zones between continental shelves and the oceanic floor, namely, continental slopes; and (3) the ocean bed and midoceanic ridge systems. The latter form a single global system of mountain structures that continues through all the oceans. Each oceanic ridge is a complicated system exhibiting parallel crests with one or several groove valleys along their lengths. These structures coincide with a high degree of recent tectonic activity and volcanism and the development of a distinctive system of huge transverse breaks, which express themselves as large terraces, narrow troughs, and asymmetric ridges on the ocean floor. In a number of cases such breaks not only cross the ridges, dividing them into separate big blocks, but also extend over immense distances across the abyssal (deep sea) plains of the oceanic bed.

The unclear nature of the abyssal "plain"

The morphostructural character of the abyssal plains is less clear. The term plain, for example, is not fitting in many instances. The flattest elements of the oceanic floor occupy a very small part of the oceanic bed, not more than 10 percent. Moreover, the covering layer of bottom deposits often hides a complexly dissected underlying tectonic relief. Volcanic relief in the form of hills and seamounts occupies vast areas. A continuous generation of underwater relief probably occurs in the ancient hollows of the oceans. It is clear that if tectonic movements of the Earth's crust provide the basis of the main elements of land-surface relief, the tectonic factor must be given even greater priority when relief of the ocean floor is considered. At the great oceanic depths involved the forms of relief directly created by tectonics are probably preserved without significant change because of the absence of denudational processes and burial by bottom deposits. The relationship between recent tectonism and relief features of the Earth's surface is thus clearly evident on the ocean floor. Further study may lead to resolution of the gap in different approaches to the problem of the physiographic effects of recent and ancient tectonism.

BIBLIOGRAPHY. The following books give general but moderately technical treatment to the physiographic effects of tectonism: V.V. BELOUSOV, *Basic Problems in Geotectonics* (1962), is an English translation of a treatment of the fundamental laws and basic problems of general tectonics, with special reference to the Soviet Union and more general discussion of world tectonics. L.C. KING, *The Morphology of the Earth*, 2nd ed. (1967), provides a detailed discussion of the Earth's surface features and the fundamental forces affecting their development. The *Encyclopedia of Geomorphology*, ed. by R.W. FAIRBRIDGE (1968), includes articles on all major aspects of the physiographic effects of tectonism. For a more modern but somewhat technical account of all physical attributes of the Earth that are related to tectonism, see P.J. HART (ed.), *The Earth's Crust and Mantle* (1969).

(I.P.G.)

Physiology

The word physiology was first used by the Greeks around 600 BC to describe a philosophical inquiry into the nature of things. The use of the term with specific reference to vital activities of healthy humans, which began in the

16th century, also is applicable to many current aspects of physiology. In the 19th century, curiosity, medical necessity, and economic interest stimulated research concerning the physiology of all living organisms. Discoveries of unity of structure and functions common to all living things resulted in the development of the concept of general physiology, in which general principles and concepts applicable to all living things are sought. Since the mid-19th century, therefore, the word physiology has implied the utilization of experimental methods, as well as techniques and concepts of the physical sciences to investigate causes and mechanisms of the activities of all living things.

HISTORICAL BACKGROUND

The philosophical natural history that comprised the physiology of the Greeks has little in common with modern physiology. Many ideas important in the development of physiology, however, were formulated in the books of the Hippocratic school of medicine (before 350 BC), especially the humoral theory of disease in the treatise *De natura hominis* ("On the Nature of Man"). Other contributions were made by Aristotle (*Lykaion*, about 325 BC) and Galenos or Galen of Pergamon (*c.* AD 130-*c.* 200). Significant in the history of physiology was the teleology of Aristotle, who assumed that every part of the body is formed for a purpose and that function, therefore, can be deduced from structure. The work of Aristotle was the basis for Galen's *De usu partium* ("On the Use of Parts") and a source for many early misconceptions in physiology. The tidal concept of blood flow, the humoral theory of disease, and Aristotle's teleology, for example, led Galen into a basic misunderstanding of the movements of blood that was not corrected until William Harvey's work on blood circulation in the 17th century.

The publication in 1628 of Harvey's *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (An Anatomical Dissertation Upon the Movement of the Heart and Blood in Animals) usually is identified as the beginning of modern experimental physiology. Harvey's study was based only on anatomical experiments; despite increased knowledge in physics and chemistry during the 17th century, physiology remained closely tied to anatomy and medicine. In 1747 in Berne, Switzerland, Albrecht von Haller, eminent as anatomist, physiologist, and botanist, published the first manual for physiology. Between 1757 and 1766 he published eight volumes entitled *Elementa physiologiae corporis humani* (*Elements of Human Physiology*); all were in Latin and characterized his definition of physiology as anatomy in motion. At the end of the 18th century, Antoine Lavoisier wrote about the physiological problems of respiration and the production of heat by animals in a series of memoirs that still serve as a foundation for understanding these subjects.

Progress in the 19th century

Physiology as a distinct discipline utilizing chemical, physical, and anatomical methods began to develop in the 19th century. Claude Bernard (1813–78) in France; Johannes Müller (1801–58), Justus von Liebig (1803–73), and Carl Ludwig (1816–95) in Germany; and Sir Michael Foster (1836–1907) in England may be numbered among the founders of physiology as it now is known. At the beginning of the 19th century, German physiology was under the influence of the romantic school of *Naturphilosophie*. In France, on the other hand, romantic elements were opposed by rational and skeptical viewpoints. Bernard's teacher, François Magendie (1783–1855), the pioneer of experimental physiology, was one of the first men to perform experiments on living animals. Both Müller and Bernard, however, recognized that the results of observations and experiments must be incorporated into a body of scientific knowledge, and that the theories of natural philosophers must be tested by experimentation. Many important ideas in physiology were investigated experimentally by Bernard, who also wrote books on the subject. He recognized cells as functional units of life and developed the concept of blood and body fluids as the internal environment (*milieu intérieur*) in which cells carry out their activities. This concept of physiological regulation of the internal environment occupies an important position in physiology and medicine; Bernard's work had a profound influence on succeeding generations of physiologists in France, Russia, Italy, England, and the U.S.

Müller's interests were anatomical and zoological, whereas Bernard's were chemical and medical, but both men sought a broad biological viewpoint in physiology rather than one limited to human functions. Although Müller did not perform many experiments, his textbook *Handbuch der Physiologie des Menschen für Vorlesungen* and his personal influence determined the course of animal biology in Germany during the 19th century.

Methods

It has been said that, if Müller provided the enthusiasm and Bernard the ideas for modern physiology, Carl Ludwig provided the methods. During his medical studies at the University of Marburg in Germany, Ludwig applied new ideas and methods of the physical sciences to physiology. In 1847 he invented the kymograph, a cylindrical drum that still is used to record muscular motion, changes in blood pressure, and other physiological phenomena. He also made significant contributions to the physiology of circulation and urine secretion. His textbook of physiology, published in two volumes in 1852 and 1856, was the first to stress physical instead of anatomical orientation in physiology. In 1869 at Leipzig, Ludwig founded the Physiological Institute (*neue physiologische Anstalt*), which served as a model for research institutes in medical schools all over the world. The chemical approach to physiological problems, developed first in France by Lavoisier, was expanded in Germany by Justus von Liebig, whose books on *Organic Chemistry and its Applications to Agriculture and Physiology* (1840) and *Animal Chemistry* (1842) created new areas of study both in medical physiology and agriculture. German schools devoted to the study of physiological chemistry evolved from Liebig's laboratory at Giessen.

The British tradition of physiology is distinct from that of the continental schools. Around 1869 Sir Michael Foster became Professor of Practical Physiology at University College in London, where he taught the first laboratory course ever offered as a regular part of instruction in medicine. The pattern Foster established still is followed in medical schools in Great Britain and the U.S. In 1870 Foster transferred his activities to Trinity College at Cambridge, England, and a postgraduate medical school emerged from his physiology laboratory there. Although Foster did not distinguish himself in research, his laboratory produced many of the leading physiologists of the late 19th century in Great Britain and the U.S. In 1877 Foster wrote a major book (*Textbook of Physiology*), which passed through seven editions and was translated into German, Italian, and Russian. He also published *Lectures on the History of Physiology* (1901). In 1876, partly in response to increased opposition in England to experimentation with animals, Foster was instrumental in founding the Physiological Society, the first organization of professional physiologists. In 1878, again due largely to Foster's activities, the *Journal of Physiology*, which was the first journal devoted exclusively to the publication of research results in physiology, was initiated.

Founding of the Physiological Society

Foster's teaching methods in physiology and a new evolutionary approach to zoology were transferred to the U.S. in 1876 by Henry Newell Martin, a professor of biology at Johns Hopkins University in Baltimore, Md. The American tradition drew also on the continental schools. S. Weir Mitchell, who studied under Claude Bernard, and Henry P. Bowditch, who worked with Carl Ludwig, joined Martin to organize the American Physiological Society in 1887, and in 1898 the society sponsored publication of the *American Journal of Physiology*. In 1868 Eduard Pflüger, professor at the Institute of Physiology at Bonn, founded the *Archiv für die gesammte Physiologie*, which became the most important journal of physiology in Germany.

Physiological chemistry followed a course partly independent of physiology. Müller and Liebig provided a stronger relationship between physical and chemical approaches to physiology in Germany than prevailed else-

where. Felix Hoppe-Seyler, who founded his *Zeitschrift für physiologische Chemie* in 1877, gave identity to the chemical approach to physiology. The American tradition in physiological chemistry initially followed that in Germany; in England, however, it developed from a Cambridge laboratory founded in 1898 to complement the physical approach started earlier by Foster.

SCOPE

Intradisciplinary nature. The anatomical and medical origins of physiology still are reflected in university courses and textbooks that concentrate on functional organ systems of animals; *e.g.*, frog, dog, cat, and rat. The trend in physiology, however, is to emphasize function rather than structure; *i.e.*, comprehensive functional specializations such as nutrition, transport, metabolism, and information have replaced earlier structural studies of organ systems. This trend can be explained in part by the fact that the analysis of an organ system typically involves studies at the levels of cells and molecules, and functional emphasis accommodates such studies better than the organ-system approach.

Functional and comparative emphasis

Early in the 20th century, the emphasis on cells as units of function resulted in a view that all physiology is essentially cell physiology and that all teaching therefore should pivot around the properties of cells. In later years successful analyses of cellular mechanisms involving synthesis, control, and inheritance led to similar emphasis at a new and more fundamental level, the molecules that comprise cells. The study of physiology now encompasses molecules, cells, organs, and many types of animals, including man. The comparisons resulting from such studies not only strengthen human physiology but also generate new problems that extend into evolution and ecology. Much of the impetus for comparative physiology has resulted from the economic or medical importance to man of parasites, insects, and fishes.

Most of the physiology of micro-organisms and plants developed independently of animal physiology. The concept of comparative biochemistry provided the foundations for a physiology of micro-organisms that extended beyond parasitic forms of medical importance and resulted in recognition of the fundamental roles of micro-organisms in the biosphere. Botanists and agriculturists explore the physiology of higher plants, but fundamental differences in the modes of life of animals and plants leave little common ground above the molecular and cellular levels. In a little-known textbook, Claude Bernard stated that there is only one way to live, only one physiology of all living things. The goal of general physiology is to abstract this single physiology from the physiologies of all types of organisms. Although common or general features usually are found at the cellular and molecular levels of organization, multicellular structures also are studied. Processes that underlie cell function are emphasized in an approach based on analyses in terms of physical and chemical principles.

Topics of study. *Metabolism.* In the late 19th century the principle of conservation of energy was derived in part from observations that fermentation and muscle contraction are essentially problems in energetics. Biological energetics began with studies that established the basic equation of respiration as:

$$\text{Fuel} + \text{oxygen} \rightarrow \text{carbon dioxide} + \text{water} + \text{heat}.$$

It was realized that the heat produced in fermentation and the work performed during muscle contraction must originate in similar processes, and that fuel in the equation above is a source of potential energy. Early in the 20th century studies of animal calorimetry verified these concepts in man and other animals. Calorimetry studies showed that the energy produced by the metabolism of foodstuffs in an animal equals that produced by the combustion of these foodstuffs outside the body. After these studies, measurement of the basal metabolic rate (BMR) was used in the diagnosis of certain diseases, and data relating the composition of foodstuffs to their value as sources of metabolic energy were obtained.

Early in the 20th century it was established that measurable amounts of the carbohydrate glycogen are converted to lactic acid in frog muscles contracting in the absence of oxygen. This observation and studies of alcoholic fermentation confirmed that the energy for fermentation or muscle contraction depends on a series of reactions now known as glycolysis. In order to show that the conversion of glycogen to lactic acid could provide the necessary energy for muscular contraction, extremely delicate measurements of the heat produced by contracting muscles were required. As a result of glycolysis studies, adenosine triphosphate (ATP) was recognized as an important molecule in cellular energy transfer and utilization; *e.g.*, movement, generation of electricity, transport of materials across cell membranes, and production of light by cells. Soon it was discovered that a muscle protein called myosin acts as an enzyme (organic catalyst) by liberating the energy stored in ATP and that ATP in turn can modify the physical properties of myosin molecules. In addition, it was shown that a muscle fibre has an elaborate and ordered structure, which is based on a precise arrangement of myosin and another muscle protein called actin.

Glycolysis is an anaerobic process (*i.e.*, it does not require oxygen) and may represent one of the oldest mechanisms for cellular energy transfer, since the process could have evolved before there was free oxygen in the earth's atmosphere. Most cells, however, derive their energy from a series of reactions involving oxygen and called the Krebs tricarboxylic acid cycle. The enzymes for the cycle are part of the structure of a mitochondrion, which is an elaborate cellular component filled with membranes and often shaped like a very small bean. In the course of the oxidation, three molecules of energy-rich ATP are generated for each oxygen atom used to form a molecule of water. The mitochondrion, therefore, is the cellular site of respiratory combustion first clearly demonstrated in whole animals by Lavoisier.

The ultimate source of foodstuffs used by animals is plants. Early 19th-century studies of photosynthesis were closely related to those of respiration, and began with Joseph Priestley's demonstration that plants could restore the air used during respiration or combustion. The most important equations for living things therefore, are mutually inverse. In respiration:

$$\underset{\text{carbo-hydrate}}{(CH_2O)_n} + \underset{\text{oxygen}}{nO_2} \rightarrow \underset{\text{carbon dioxide}}{nCO_2} + \underset{\text{water}}{nH_2O} + \text{heat}.$$

In photosynthesis:

$$nCO_2 + nH_2O + \text{light} \rightarrow (CH_2O)_n + nO_2.$$

In the 1930s, it was shown that photosynthesis involves splitting hydrogen from water and that the oxygen liberated in photosynthesis comes from water. During the light reactions, light energy is captured by a green pigment called chlorophyll and used to generate reactive hydrogen and ATP that are used during dark reactions in which carbohydrates and other cell constituents are synthesized.

Integration of classical, chemical, and comparative approaches

The classical fields of organ-system physiology have a role subsidiary to that of cellular metabolism. Feeding and digestion, for example, become a means for the enzyme-catalyzed breakdown of organic compounds into relatively small molecules that can be transported readily; nutrition, therefore, is a way to supply animals with sufficient sources of energy and specific substances that they cannot synthesize. Comparative animal studies, which were of practical importance in the discovery of some vitamins, led also to the general observation that the specific nutrient requirements of animals are consequences of a slow evolutionary deterioration in which synthetic abilities are lost through changes or mutations in hereditary material.

Nutrition and digestion, however, also have been important in obtaining information at the cellular and molecular levels. It was through studies of digestion, for example, that the existence and nature of enzymes were first disclosed clearly. In addition, early recognition of similarities between digestion and fermentation foreshadowed knowledge of the important role of fermentation in cellu-

lar metabolism. Finally, the study of vitamin nutrition was closely integrated with that of cellular oxidation, in which certain vitamins play an essential catalytic role.

In intact organisms, the chemical activities of individual cells do not interfere with the functions of the organism. Much of the study of physiology now is concerned with the ways by which cells obtain their nutrients and dispose of their waste products. Knowledge of the mechanism of protein synthesis and its connections with inheritance and cellular control mechanisms have initiated new inquiries into functions at all levels; *i.e.*, cells, organs, and organisms.

Circulation of blood

Transport. Many important advances in surgery and medicine have been based on the physiology of circulation, which was first studied in 1628. The measurement of blood pressure, for example, was introduced on a practicable basis late in the 19th century and has become an important part of medical diagnosis. The physiology of circulation is concerned with the origin of blood pressure in the force of the heartbeat and the regulation of heart rate, blood pressure, and the flow of blood.

Variations in heart rate that led Aristotle to consider the heart as the seat of the emotions—a myth that persists even now—were among the phenomena whose explanation revealed the existence of the autonomic nervous system. Variations in heart rate are less important to the circulatory system, however, than is the ability of the heart to adjust the strength of its beat to meet certain demands of the body.

The peripheral control of blood pressure and blood flow depends upon a maze of interacting control mechanisms, most significant of which are direct control of the diameter of small arterial branches that enlarge or dilate in response to chemical products formed during metabolism. Increased metabolic activity of tissues such as muscles or the intestine, therefore, automatically induces increased blood flow through the dilated vessels. This action, which could result in a fall in blood pressure, is offset by central-reflex controls that constrict arterial branches not dilated as a result of local chemical effects. Certain regions of the skin and the intestines serve as reservoirs for blood that may be diverted to muscles or the brain if necessary. Peripheral control may break down if excessive demands are made upon it in hot weather (heat stroke), during vigorous exercise after meals (muscle cramp), and after extensive loss of blood or tissue damage (wound shock) or extreme emotion with consequent activation of the autonomic nervous system (emotional shock). A remarkable adaptation occurs in air-breathing vertebrates—reptiles, birds, and mammals—which dive for food or protection. During a dive, the flow of blood to all parts of the body except the brain and the heart is reduced substantially. The energy for muscle contraction is provided by the anaerobic process of glycolysis because the oxygen in the blood goes to the brain and heart, which cannot function without a constant supply of oxygen.

Comparative studies have disclosed two major patterns in circulatory systems. Among vertebrates and a few invertebrates—notably annelid worms and cephalopod mollusks—the blood flows entirely in closed channels or vessels, never coming into direct contact with cells and tissues; blood pressure and the velocity of flow are high and relatively constant, and the volume of blood is small. In many invertebrates—especially arthropods and mollusks other than cephalopods—the blood flows for part of its course in large sinuses or lacunae and comes directly into contact with the tissues. Blood pressure and the velocity of flow are low and variable in these invertebrates, and the large volume of blood is comparable to the total volume of all body fluids in vertebrates.

Consideration of the blood as a transport system has centred especially on the transport of oxygen and carbon dioxide. The colour of blood changes as it passes through the lungs; venous blood is dark purple and arterial blood is bright red because of the properties of a blood pigment called hemoglobin. The complete structure of hemoglobin now has been determined, and minute variations in this structure have enabled man to study fundamental questions of heredity at the molecular level. The development of blood-banks and the techniques involved in blood transfusions depend on knowledge of the physical, chemical, and biological properties of blood. These properties include a remarkable diversity of hemoglobin, both among individuals and species and also within an individual during development. In many instances variations in protein composition better adapt a species to its circumstances.

Transport through cell membranes

Studies of membrane transport at the cellular level are an important part of general physiology. Although quantitative theories of diffusion and osmosis that developed around 1900 were applied to cell physiology, a number of phenomena (*e.g.*, movement through membranes of certain ions and other compounds of biological importance) did not behave according to established physical principles. As a result of studies of osmotic and ionic regulation in freshwater animals, the concept of active transport was formulated. Crucial to the acceptance of this concept were studies with frog skin, which can transport sodium ions against chemical and electrical forces; the transport, specific for sodium ions, is dependent on a continuing input of metabolic energy. Efforts now are directed toward establishing a molecular mechanism that may involve an enzyme found in surface membranes of cells. This enzyme breaks down ATP and releases the energy in the molecule only if sodium and potassium ions are present.

Information transfer. The physiology of animals differs from that of plants in the rapid response of animals to stimuli. René Descartes, responsible for the concept of the reflex that dominated neurophysiology for most of its history, thought a sensory impulse was "reflected" from the brain to produce a reaction in muscles. Later studies of the effects of ions on nerves suggested that a nerve must be surrounded by a membrane and that a nerve impulse results from a change in the ability of the membrane to allow passage of potassium ions. When it was shown that nerves are made up of thousands of tiny fibres, which are processes that extend from cells located in the brain or spinal cord, the nerve impulse hypothesis was applied to individual nerve fibres rather than to whole nerves. Electronic technology provided the techniques and giant nerve fibres of squids provided the experimental material that enabled two Nobel prize winners for physiology, Alan Lloyd Hodgkin and Andrew Fielding Huxley, to extend this hypothesis into a theory of the excitation of nerve cells in which sodium ions and potassium ions play principal roles.

Reflex concept

The reflex concept, however, was not dependent on understanding the molecular basis of excitation, conduction, and transmission. Early in the 20th century the role of interaction of nervous centres in controlling muscle contractions was established. The reflex now is conceived as a unit in which nerve impulses initiated in sensory neurons or nerve cells are conducted to a centre in the brain or spinal cord. In the centre impulses initiated in motor neurons are conducted to muscles and induce a reflex response. Two processes can occur in the centre; one is associated with central excitatory states, the other with central inhibitory states. The net effect of any stimulus or group of stimuli, therefore, can be interpreted as an interaction of these opposing states in the centre.

After the demonstration that the effects of the vagus nerve in slowing the heart are mediated by a chemical substance, subsequently identified as acetylcholine, the concept of chemical transmission of nervous impulses was extended to the central nervous system. Typically, transmission of excitation from cell to cell is accomplished by the liberation of a chemical transmitter from a nerve ending.

The reflex concept gave rise to premature attempts to develop a psychology based on reflexes. These attempts (behaviourism) were advanced by the Russian I.P. Pavlov's discovery of conditioned responses. Originally known as conditioned reflexes, these responses have been found in most animals with central nervous systems. More complex than simple reflexes, their mechanism has not yet been established with certainty.

Sensory functions at cellular level

The analysis of sensory functions also extends to the cellular level. Sense organs are diverse in structure and sensitivity to specific stimuli. It may be that the common molecular basis for the differences in sensitivity is a change in permeability of a special region of the membrane surrounding a sensory cell. This change in permeability could allow a nerve fibre to become excited and initiate a nerve impulse. Neurophysiology has borrowed from, and contributed to, the information theory used in communications engineering. The function of sense organs is to gather information both from the environment and the organism. The central nervous system integrates this information and translates it into a program of response involving the entire organism. In addition, the brain can store information previously received (memory) and has the ability to initiate actions without obvious external stimulation (spontaneity). Some aspects of memory and integrative function have been modelled in electronic computers; in fact the development of computers was closely connected with the development of ideas about the functions of the central nervous system.

The analytical interpretation of central nervous function remains, however, a complex and difficult field, even though recent progress has brought closer together the study of behaviour in terms of nerve function and behavioral models. Considerable effort now is directed to the localization of brain function. Although specific centres for reception of sensory information and integration of motor programs are known, the integrative functions that tie them together, as well as the functions of memory, are not so well established.

Regulation. The concept of internal regulations is attributed to Claude Bernard, who thought of blood as an internal environment in which cells function; according to Bernard, maintenance of the internal environment at a constant level was a major responsibility of all body functions. Bernard showed in studies of the formation and breakdown of glycogen in the liver that internal organs can secrete materials into the blood. Other investigators demonstrated such a secretion and used the word hormone to describe the substance. One classical study concerned control of the secretion of digestive fluids by the pancreas; an active substance secretin was purified, as have been a number of similar materials from the digestive tract. The field of endocrinology now is a major part of physiology.

Complementary roles of hormones and nerves

The endocrine system complements the nervous system in control and coordination. Hormones, liberated into blood and other body fluids by endocrine glands and transported throughout the body, usually act either on specific target organs or on certain activities of many organs. Nervous coordination most often is concerned with rapid responses of short duration; endocrine coordination, however, usually is involved in slower responses of longer duration. Stationary-state regulation or homeostasis depends on the action of hormones at many points. The hormones insulin and glucagon, both formed in specialized endocrine tissue in the pancreas, control the level of sugar in blood. Vasopressin from the pituitary gland at the base of the brain and aldosterone from the adrenal glands near the kidneys control salt and water balance of the blood. Hormonal regulation, however, is not confined to homeostasis. The cyclic events of the female reproductive cycles in mammals, for example, are determined by a complex sequence of endocrine interactions involving hormones of the pituitary gland and the ovary.

The pervasive regulatory action of hormones is part of a large system of interactions to which the term feedback generally is applied. Hormones involved in homeostatic regulation, for example, influence their own secretion. The secretion of certain steroid hormones, which have a significant action on the conversion of amino acids to glycogen, is controlled by another hormone called the adrenocorticotropic hormone (ACTH), which is formed in the anterior pituitary gland. In turn the secretion of ACTH is controlled by a releasing factor formed in the midbrain and liberated from the stalk of the pituitary gland. ACTH liberation normally is controlled by the concentration of steroids in the blood, so that an increase in steroid concentration inhibits ACTH secretion; this negative feedback, however, may be overcome in certain conditions of intense nervous stimulation.

A similar pattern of releasing factors, by which the nervous system interacts with the endocrine system, also is known for other anterior pituitary hormones; *e.g.*, those involved in the reproductive cycle and in responses of the thyroid gland to temperature changes. In addition, neurosecretory cells—nerve cells specialized for endocrine function—liberate hormones (*e.g.*, vasopressin) that act directly on a specific target. Comparative studies show that neurosecretory cells are important in developmental and regulatory functions of most animals. Discrete endocrine glands, however, occur less frequently; in insects and crustaceans, cycles of growth, molting (shedding of the cuticle), and development are controlled by hormones. The identification of insect hormones may be useful in controlling pests through specific interference with processes of growth and development.

SOCIETIES AND PUBLICATIONS

The British and American societies of physiologists founded late in the 19th century were followed by similar organizations in other countries. These societies function primarily as organs of communication among physiologists, through the publication of scholarly journals and through meetings at which the results of research are presented and discussed. The need for international meetings was recognized in 1881, when the first International Congress of Medicine was held in England, and the Physiological Society invited foreign physiologists. In 1889 the first International Congress of Physiology was held in Basel; since then international congresses have met in various countries, usually every three years. Organization of an international congress and promotion of international cooperation among physiologists have become responsibilities of the International Union of Physiological Sciences, which was founded in 1953 and now includes societies in 40 countries.

Membership in physiological societies, long regarded as a distinction, usually is based on the publication of original scholarly research in physiology. The orientation of the societies is strongly medical, since most professional physiologists are associated with medical schools; consequently, physiologists with other interests have organized to represent fields of physiology less closely related to medicine. The Society of General Physiologists and the Biophysical Society in the U.S. are examples. French physiologists have not had quite so distinct an identity. In France and in the French cultural spheres of South America, North Africa, and Asia, the Société de Biologie has combined a variety of approaches to biology and medicine including physiology. In 1913, U.S. societies concerned with medically related fields such as physiology, pharmacology, biochemistry, and pathology joined to form the Federation of American Societies for Experimental Biology, so that meetings of related groups could be held simultaneously; societies concerned with nutrition and with immunology subsequently joined the Federation.

PROSPECTS

Physiology now is a mature science; during a century of growth, physiology has been the parent of numerous related disciplines, of which biochemistry, biophysics, general physiology, and molecular biology are the most vigorous. Physiology, however, retains an important position among the functional sciences closely related to medicine. Although many research areas, especially in mammalian physiology, have been fully exploited from a classical-organ and organ-system point of view, comparative studies in physiology may be expected to continue. Solution of the major unsolved problems of physiology will require technical and expensive research by teams of specialized investigators. Unsolved problems include the unravelling of the ultimate bases of the phenomena of life. Research in physiology also is aimed at integration of the varied activities of cells, tissues, and organs at the

level of the intact organism. Both analytical and integrative approaches uncover new problems that must be solved. In many instances, the solution is of practical value in medicine or helps to improve man's understanding of himself and other animals.

Piauí

Piauí is a state (*estado*) of northeastern Brazil, bordered by the states of Ceará, Pernambuco, and Bahia on the east and south and by Maranhão on the west and north. While it covers less than 3 percent of Brazil's total area, it is about equal in size to the Federal Republic of Germany, with 96,886 square miles (250,934 square kilometres). Its population early in the 1970s was over 1,700,000. The state capital is Teresina, located at the confluence of the Parnaíba and Poti rivers. The state has a small Atlantic coastline of about 40 miles.

Early settlers

The settlement of Piauí in the 17th century came with the expansion of cattle ranching in the backlands of the northeast, setting it apart from the sugarcane agriculture of the coastal lowlands. The settlers arrived from the east, moving up the valley of the Rio São Francisco in Pernambuco and onward in a westward direction into Piauí. One of their leaders was Francisco Dias d'Avilla, who fought bloody battles with the Indians. He and his lieutenants established ranches along the Parnaíba and Gurguéia rivers in the 1670s and 1680s.

The Rio Parnaíba runs along the western boundary of the state, linking the Atlantic port of Parnaíba with the inland cities of Teresina and Floriano. As one moves away from the river and the coastal area toward the south and east, the land rises gradually in a series of plateaus edged by cliffs. On the border of the State of Ceará, the plateau is broken by a gap through which the Rio Poti runs.

Temperatures show little variation, averaging about 79° F (26° C) in the northern part of the state and a few degrees less in some of the higher altitudes in the south. Annual rainfall is about 59 inches in the north, but, in the drier east and southeast, it averages about 20 inches a year. The dry months are in winter and spring.

The vegetation of the south and east is that of Brazil's semi-arid northeastern backlands: a thorny, deciduous scrub woodland known as *caatinga*. This gives way in the north to deciduous forests interspersed with areas of palms and cocoa trees.

Piauí is sparsely populated (about 18 persons per square mile). Most of its inhabitants are of mixed Indian and European ancestry, although a Negroid stock is found in the northeastern coastal zones, where the colonial sugar plantations once employed large numbers of African slaves. The largest city is Teresina, the capital, with an urban population of about 180,000 in 1970. Other towns include Parnaíba (70,000), near the Atlantic coast (with Luíz Correia as its port); Floriano, Campo Maior, Picos, and Oeiras. The principal economic activities are the raising of livestock and the production of palm seeds, palm oil, and palm wax from the carnauba and babassu palm trees.

Standards of living are among the lowest in Brazil. Infant mortality rates are very high, largely because of infectious or parasitic diseases. In 1969 there was one hospital bed for every 923 inhabitants. Hospital clinics reached about one-quarter of the population. The national government, however, was engaged in programs to control malaria and other endemic diseases.

Piauí had about 2,700 primary schools in 1969, with about 194,000 students. In the lower level secondary schools there were about 35,000 students. The state also had eight newspapers, nine radio stations, one theatre, and 13 cinemas.

The federal government was building a dam and hydroelectric plant on the Rio Parnaíba near Guadalupe. In 1970 the first part of the Boa Esperança project was completed, providing 108,000 kilowatts of power out of a projected 216,000 kilowatts.

Piauí's isolation

Piauí is a somewhat isolated state, lacking good communications even with neighbouring states of the Northeast. The Rio Parnaíba has not become the artery of commerce that geography suggests it should have. There is no railroad network in the backlands. Teresina, the capital, has rail connections across the State of Maranhão on the west to the port of São Luis; another railroad runs from Teresina northward through Campo Maior to the state's port of Luís Correia; but no railroad line crosses the state from east to west. One good all-weather federal highway runs from Teresina northeastward to Sobral in the State of Ceará. Of Piauí's 14,000 miles of roads at the start of the present decade, however, less than 200 miles were paved. The better roads were concentrated in the north, with Teresina as their hub, and in the central part of the state around Picos and Oeiras. Several important new highways were under construction by the federal government, including one from Teresina to Picos, another from Fortaleza in Ceará to Picos and southward toward Brasília and an east–west trans-Amazonian road that will pass through Picos.

BIBLIOGRAPHY. The few works dealing with Piauí in any depth are written in Portuguese. For its history, see R.N. MONTEIRO DE SANTANA, *Evolução Histórica da Economia Piauìense* (1964) and *Perspectiva Histórica do Piauí* (1965).

Picasso, Pablo

Unique for its volume (over 20,000 works), for its development in time (75 years of continuous creation), its diversity of style and technique—painting, drawing, engraving, and collage; sculpture and constructions; pottery and other mediums—and for its intensity, Picasso's *oeuvre* is both "autobiographical" (as an art dealer, Daniel Henry Kahnweiler, termed it) and politically committed. Of fundamental aesthetic importance, it launched, exploited, and perhaps surpassed the artistic revolution of the 20th century. Like the man himself, the work is unpredictable and complex; it lives through contrasts and disguises, though its vital essence is never hidden.

LIFE AND WORKS

Early years. Pablo Picasso, son of José Ruiz Blasco, a Castilian art teacher in Málaga (later in La Coruña and Barcelona), and of Maria Picasso, an Andalusian of Majorcan origin, was born in Málaga on October 25, 1881. At the age of 15, having brilliantly passed the entrance examination, he was admitted to La Lonja, the Barcelona school of fine arts, and in the following year he was accepted at the Real Academia de Bellas Artes de San Fernando in Madrid. But, impatient under formal training, he had scarcely shown his extraordinary precocity there before he reurned to Barcelona, where he frequent-

ed the café Els Quatre Gats (the Four Cats), a meeting place for artists fashioned after the Chat Noir (Black Cat) in Paris. Although among this young Catalan avant-garde the influence of Munich and the Jugendstil (late-19th- and early-20th-century decorative style) outweighed that of Paris, it was to Paris that the young Picasso went in October 1900. There, though constantly near starvation, he became infatuated with the street life of Montmartre, Paris' bohemian district, and made many studies of the city's poor. More importantly, he discovered the posters of the 19th-century artist Henri de Toulouse-Lautrec, which inspired some of his pastels and a "Moulin de la Galette." Returning three months later to Spain, he co-founded in Madrid the short-lived magazine *Arte Joven* (first issue March 31, 1901; "Young Art"). On a second trip to Paris, in the summer of 1901, he exhibited his works at Ambroise Vollard's fashionable gallery in the rue Lafitte and became good friends with the avant-garde poet Max Jacob. He discovered Vincent van Gogh and, influenced by him, painted "The Absinthe Drinker" (1901, William Jaffe Collection, New York City) in strident colours and "The Dwarf Dancer." Suddenly, the 20-year-old painter, who now signed himself "Picasso," the name of his mother, moved toward a symbolism of pathos and misery inspired by the French painter Maurice Denis and the Spanish painters Isidro Nonell y Monturiol and El Greco. This was his Blue Period, so called because most of these paintings were dominated by various shades of blue, heightening their mood of isolation and despair. The "Evocation" ("The Burial of Casagemas," Musée d'Art Moderne de la Ville de Paris) of 1901 (Casagemas was a bohemian friend who had committed suicide because of a broken romance); the "Maternites" (1903, Museo de Arte Moderno, Barcelona); "The Tragedy" (1903, National Gallery of Art, Washington, D.C.); "Celestine" (1903, collection of artist); "La Vie"; an etching, "Frugal Repast," of 1904; "The Old Guitarist" (1903, Art Institute of Chicago); the "Woman with a Crow" (1904, Toledo Museum of Art, Ohio); and "Woman Ironing" (1904, Justin K. Thannhauser Collection, New York) display famished figures whose forms are extended vertically in immobile and tragic poses.

Blue Period

At first dividing these financially difficult years (1902–03) between Paris and Barcelona, Picasso, in April 1904, settled for good in Paris in the so-called "Bateau-Lavoir," a dilapidated building in Montmartre, where he soon met Fernande Olivier. She has described him at the age of 23:

> small, dark, stocky, restless, disquieting, with eyes somber, deep, piercing, strange, almost staring. Clumsy gestures, womanish hands, badly dressed, rather messy. Thick hair, black and lustrous, slashing across his intelligent and stubborn forehead. Half bohemian, half worker in his appearance. . . .

Picasso's happiness with his newfound mistress may have been reflected in his work. For soon after they met in 1904, he entered his Rose Period, when his works were filled with delicate pinks and the figures, while still somewhat melancholic, were not desolate as the subjects of the Blue Period paintings had been; figures became more robust, and family groups replaced the lonely prostitutes and beggars of earlier works. Picasso, who liked to attend the Médrano Circus with his friends, painted, according to the writer Guillaume Apollinaire, in a palette with the "flatness of frescoes" his "taciturn and androgynous harlequins": the "Family of Saltimbanques," "Girl on a Ball" (1905, State Pushkin Museum of Fine Arts, Moscow), and "Woman with a Fan," an unsmiling Gioconda who raises an enigmatic hand as though bidding farewell to the works of Picasso's youth. In the course of a stay at Gósol, in Spain, in the summer of 1906, he began to paint solid, subtly distorted female nudes at their toilettes, seen in "The Coiffure" (Metropolitan Museum of Art, New York), "Nude on Red Background" (Louvre, Paris), and "La Toilette." Picasso's increased concern with formal pictorial problems is seen in two celebrated portraits, "Gertrude Stein" and "Self-Portrait," in which all psychological interpretation is excluded in favour of a purely sculptural expression.

This rough affirmation of form led suddenly, between the end of 1906 and the spring of 1907, to "Les Demoiselles d'Avignon," a revolutionary and uncompleted work, aggressive and discordant in structure. The joint influence of the Postimpressionist painter Paul Cézanne and (in the central figures) of Greco-Iberian art is combined with that of African art (in the two figures on the right). The treatment of form in this key work of the 20th century represented such a rupture with traditional Impressionism that it was not understood at the time either by Picasso's fellow iconoclast painters André Derain and Georges Braque or by the anarchist critic Félix Fénéon. Only the youthful art dealer Daniel Henry Kahnweiler recognized the work's importance. He bought all of its preliminary studies, but Picasso refused to sell the painting itself. Instead, he rolled it up and put it away out of public view for several years.

Significance of "Les Demoiselles d'Avignon"

After a brief "Negro Period" ("Woman with a Fan," 1908; Hermitage, Leningrad), Picasso painted landscapes and still lifes (at La Rue-des-Bois, where he spent the summer of 1908) marked by the influence of Cézanne. It was simultaneously the "Demoiselles," these landscapes, and those of Braque that originated the style that, in 1908, led the critic Louis Vauxcelles, following Henri Matisse, to speak of "little cubes" and shortly thereafter of "cubism."

Picasso had met Matisse at Gertrude Stein's in 1906, and he was to keep up a friendly rivalry with the older man, so different from himself. His circle at the time included the poets Apollinaire, Max Jacob, André Salmon, Maurice Raynal, and Pierre Reverdy and the painters Derain, Kees van Dongen, Juan Gris, and Henri Rousseau.

Early Cubism

Friendship with Braque. In the winter of 1908, Picasso and Braque began to work along parallel courses—and in close friendship. In their search for an impersonal and universal pictorial language, they for a long time signed their canvases only on the back. From reality they strove above all to extract volumes and space, which they expressed by a play of planes and facets. After a stay at Horta de Ebro in the summer of 1909, Picasso reduced his palette to a subtle range of ochres and greenish grays ("The Reservoir," Gertrude Stein Collection, Paris; "The Factory at Horta," Moscow; "Nude in an Armchair," Douglas Cooper Collection, New York). Each of the four years that followed his return to Paris was to see a change in his method of constructing an object, and the method mattered more than the object itself, whether the latter be café table, guitar, violin, or woman with guitar. After the remarkable portraits "Ambroise Vollard" (1909–10, State Pushkin Museum of Fine Arts, Moscow), "Wilhelm Uhde" (1910, Roland Penrose Collec-

tion, London), and "Daniel Henry Kahnweiler" (1910, Art Institute of Chicago), Picasso came close to geometric abstraction in the course of the summer he spent at Cadaqués, in Catalonia, in 1910. The following summer at Céret (Roussillon), his forms crumbled more and more, and typographical characters appeared, calling the viewer's attention to the painted surface itself. In the same year, Picasso's works were exhibited at the Photo-Secession Gallery in New York.

In 1911, when Fernande Olivier left him, he met Marcelle Humbert, the mistress of the painter Louis Marcoussis. She soon moved in with Picasso, who fondly called her "Eva," signifying that she was the first woman in his affections, and began to paint her name into several still lifes ("Ma Jolie," 1911–12, Museum of Modern Art, New York City; "J'aime Eva," 1912, Columbus Gallery of Fine Arts, Ohio).

Use of Collage

Spending the summer of 1911 with Braque at Céret and Sorgues (Vaucluse), Picasso followed his friend's example in using the tecnhique of "pasted papers": commercial paper imitating wood or marble, newspapers, matchboxes, tobacco labels, and so on. This technique marked a transition from the Analytical Cubism of 1910–11, still linked to Cézanne, to the Synthetic Cubism of the years 1912–14, which replaced traditional, recognizable images of reality by signs whose raw sculptural effect increases the expressive while decreasing the representational value. Stressing the impact of these signs was the sculpture called "scraps constructions"—guitars and still lifes of rudely painted sheet iron or wood, for example. This "conceptual" (as opposed to purely visual) art contrasts with the refined empirical realism of classical Western tradition in order to rediscover the intense style of primitive art, but it is also "materialistic" long before the artist turned to abstraction and to mixing his pigments with sand. "When I want to paint a cup," Picasso said, "I will show you that it is round, but it may be that the general rhythm and construction of the picture will oblige me to show that roundness as a square." This formal coherence confers on the work an independent existence comparable to that of a poem.

But just at the moment when Picasso's Cubism could boast most clearly of colour and imagination (the scattering of dots and pieces of wallpaper of "rococo" Cubism), circumstances created a climate unfavourable for his work. The outbreak of war in 1914 dispersed the artists, separating him from his friends. Neither Picasso nor Braque, whose works could be seen at Kahnweiler's small gallery, had participated in group exhibitions of the "minor" Cubists (Albert Gleizes and Jean Metzinger, for example), who had made cubism into a fashionable dogma and whose superficial and composite works were then better known to the public.

Set designs for the ballet

Despite the climate of chauvinism produced by World War I, the young writer Jean Cocteau tried to bridge the gap between the painters of Montparnasse and the worldly cosmopolitan European intelligentsia. In 1917 he persuaded Picasso, depressed by the sudden death of Marcelle Humbert, to leave the Cubist milieu of Paris and travel to Rome, Naples, Pompeii, and Florence in order to collaborate with Sergey Diaghilev's Ballets Russes. Picasso designed the sets for the ballet *Parade*, with book by Cocteau and choreography by Léonide Massine, in which Cubist "stage managers" were brought together with the impudent music of Erik Satie. The opening-night audience hissed the ballet but applauded Picasso's painted curtain.

Picasso, who had lived in Montmartre and then in Montparnasse (1912–16) and Montrouge (1917), now moved to an elegant quarter. In 1918 he married Olga Koklova (whom he divorced in 1935); she was a dancer with the Ballets Russes and daughter of a Russian colonel. A social climber accustomed to luxury, Olga soon changed Picasso's bohemian life-style, using his ever-increasing wealth and prestige to gain entrance to Paris' most exclusive circles. They went to fashionable resorts: Biarritz (1918), where he decorated a rich villa, Saint-Raphael (1919), Juan-les-Pins (1920). Max Jacob called this his "duchess period." His work reflected a new tendency: henceforth, instead of displaying the austere unity of his Cubist period, Picasso's art moved simultaneously in opposite directions. From 1915 on, coexisting with the audacious still lifes of the Cubist years are figures of a subtly detached classicism that has been called "Ingrism" (after the 19th-century painter Jean-Auguste-Dominique Ingres): portraits of "Ambroise Vollard" (1915); "Max Jacob" (1915); "Jean Cocteau"; Igor Stravinsky" (1917); "André Derain"; "Sergey Diaghilev" (1919); "Olga in an Armchair" (1917); "Paul as Harlequen" (1924, collection of artist); and "Paul as Pierrot" (1925). He continued his collaboration with the Ballets Russes, on Manuel de Falla's *Three-Cornered Hat* (1919), Stravinsky's *Pulcinella* (1920), de Falla's *Cuadro Flamenco* (1921), and *Le Train bleu* by Cocteau and Darius Milhaud (1924). While dancers, harlequins, and pierrots invaded his work, gigantesque Neoclassical figures also appeared, in the painting "Three Women at the Spring" (1921, Museum of Modern Art, New York) and on the curtain for the ballet *Le Train bleu*. A masterly series of large still lifes before the window (1919; Saint-Raphael) carried Cubism up to his two versions of the "Three Musicians" (1921, Museum of Modern Art, New York; Philadelphia Museum of Art). Picasso then freed Cubism of all austerity, substituting the curve for the straight line ("Still Life with Antique Head," 1925; Musée National d'Art Moderne, Paris) or literally creating a style, as on the curtain for Erik Satie's ballet *Mercure* (1924; Musée National d'Art Moderne, Paris), where the Cubist experience is combined with the sinuous and somewhat morbid elegance of the postwar period. In 1923, in the magazine *The Arts*, Picasso declared: "I do not develop, I am . . . I can hardly understand the importance given to the word research. . . . to find is the thing."

Association with the Surrealists. The year 1925 marked a sudden break. Although he had rightly stated that he was not a Surrealist, Picasso took part in the first Surrealist exhibition (at Galerie Pierre Loeb, Paris). His large canvas "The Three Dancers" (1925, Tate Gallery, London) was said to be marked by "convulsive beauty," and he was to do a collage for the cover of the first issue of *Minotaure* (1933). He was also friendly with André Breton, the author of Surrealist manifestos; the Surrealist poet Paul Éluard; and the writer Michel Leiris. One may suppose that it was under the widespread influence of Surrealism that he created his famous "metamorphoses" in which he makes cruel sport of anatomy. The anxiety of the Surrealists, which was more intellectual than Existential, seems to have engendered in him a more personal and authentic anguish. The monstrously expressive "Bathers" of the "Dinard period" (1927–30) and certain cruelly violent female heads led to the "Seated Bather," a skeleton cut from some unreal mineral substance and deposited on a beach beyond the world. Later he painted "Bathers with a Toy Boat" (1937, Peggy Guggenheim Collection, New York), portraying almost-engaging female monsters whose arbitrary obesity is enveloped by a poetic eroticism. At the same time, his new mistress, the blonde Marie-Thérèse Walter (who in 1935 gave birth to their daughter Maia), inspired in him the tender interlude of "Nude Woman in a Red Armchair" (1932, Tate Gallery, London), "The Dream" (1932, Victor Ganz Collection, New York), and "Girl Before a Mirror" (1932, Museum of Modern Art, New York), brilliant canvases, all in luminous curves whose vegetal suppleness bespeaks the artist's emergence from a period of restlessness and anxious invention.

Interest in sculpture

After buying the château of Boisgeloup, near Gisors in Normandy (1930), Picasso, who had done no sculpture since "Woman's Head" of 1909 (if one excludes his Cubist "constructions" and the famous "Glass of Absinthe" of 1914), set to work in this fundamental area, soon mastering techniques that he borrowed or invented and producing such works as "Heads" in welded sheet iron, 1931; slender "women" shaped from the uprights of canvas stretchers, 1934; a large "Head of a Woman" in gilded bronze, 1932; "Woman with Foliage," 1934; and "Woman with Apple," 1934). "Sculpture," he has said,

"is the best commentary that a painter can make on his painting." At the same time, he exercised his imagination in the illustration of literary works, which represented a kind of holiday for his genius. He produced no fewer than 35 works, including Honoré de Balzac's *Chef-d'oeuvre inconnu* ("Unknown Masterpiece"), published by Vollard, 1931; Ovid's *Metamorphoses*, 1931; the 18th-century *Histoire naturelle*, by Georges-Louis Leclerc, comte de Buffon, 1942; and *Gongora*, 1948.

After a pilgrimage in 1934 to the Spanish sources of his inspiration—San Sebastián, Madrid, Toledo, and Barcelona—Picasso's darker emotions found expression in the themes of the bull and the minotaur, notably in his 1935 etching "Minotaurochy." "Picasso's *Minotaur*, who carouses, loves and suffers," writes Kahnweiler, "is Picasso himself." Thus, the story of his life blends more and more with his work. In 1936, he began to live with a beautiful Yugoslav named Dora Maar (Markovich), and his work took on the heightened emotional intensity inspired by the new liaison. Moreover, at this time, the Spanish Civil War, which had begun in 1936, aroused in him a political passion that led to his greatest masterpiece, "Guernica." He had just set up a new studio and there engraved "The Dream and Lie of Franco," when on April 28, 1937, the small Basque town of Guernica with its civilian population was destroyed by Hitler's bombers. As early as May 1, Picasso had produced the first sketch for "Guernica," a large composition commissioned for the pavilion of the Spanish Republic at the Paris World Exhibition of 1937, and by May 11 the whole immense canvas (11 feet, 6 inches by 25 feet, 8 inches [3.50 by 7.82 metres]) was outlined. If Picasso never explained this work of anger, violence, and death, this depiction of war through the tragedy of the bullfight, it is perhaps because its full meaning cannot be articulated; for, in one critic's words, it "overflows with fullness and presence, with signs and cries."

"Guernica"

Parallel to the series "Weeping Woman" (Roland Penrose Collection, London), Picasso created for the first time, in charming portraits of Dora Maar and Nush Éluard, the wife of the French poet, faces combining a frontal and profile view in order to avoid the fixed, immobile expression characteristic of the traditional portrait. On the eve of World War II, "Night Fishing at Antibes" emerged from the memory of a walk in the port, an insignificant event thus becoming the point of departure for a work of art.

World War II and postwar period. During the war years, Picasso was forbidden to exhibit his work after the German occupation of France; under the hardships of wartime, he experienced severe hunger and want for the first time since his early days in Paris. At Royan and then in Paris, Picasso's art became harsher and more sombre, distorting the human face more than ever, as in "Seated Women" of 1937–44, which, with its cruel and discordant colours, seems to be composed of enormous braided ropes or networks of cobwebs. Picasso reached the depths of despair in a large, ghastly nude "Woman Dressing Her Hair" (1940; collection of artist); in the "Still Life with Ox Skull" (1942, Dusseldorf, West Germany), painted after the death of his friend the sculptor Julio Gonzáles; and in "Aubade" (1942, Musée National d'Art Moderne, Paris), in which immobile monsters seem carved out in airless spaces without light. "If I am Picasso," he has said, "it is because I created monsters." But the anguish that underlies these works did not exclude either a vitality or a plastic coherence that places other works, such as the famous "Bull's Head" made from the handlebars and seat of a bicycle, very far from the detached dream world of Surrealism. Turning away from the funereal "Skull" of 1941, Picasso in 1944 modelled the "Man with a Sheep," a figure of peace and hope. A bronze of this work has adorned a square in Vallauris since 1950.

Shortly after the liberation of Paris on August 25, 1944, Picasso joined the Communist Party and, also, for the first time exhibited at the Salon d'Automne. Opinion was divided, as it was to be later, in 1945, over a large Matisse–Picasso exhibition in London, which included "Guernica"; but in retrospect "Guernica" was to appear the very model of politically committed art. "One does not paint in order to decorate apartments. Painting is an instrument of offensive and defensive war against the enemy," Picasso declared in the enthusiasm of his political faith, while, as in the time of Cubism and "Guernica," retiring to spiritual solitude. Writers and artists such as Jean-Paul Sartre, Albert Camus, Éluard, Breton, Reverdy, Cocteau, Leiris, and the photographer Brassaï, Paris society, and foreign visitors invaded his studio in the rue des Grands Augustins, which was guarded, not too successfully, by his faithful friend Jaime Sabartés. But fame did not prevent this restless and tireless artist from continuing his work. A late riser, he worked far into the night under artificial light, observed a regimen of exercise, and received visitors, to whom he showed himself charming or aggressive, taciturn or ironical, but always fascinating, unpredictable, and elusive. Interested in all techniques, he resumed lithography in the workshop of Fernand Mourlot, executing 200 large lithographs between 1945 and 1949. After meeting Françoise Gilot, in 1946, he painted, during the four months spent at the Musée Grimaldi in Antibes, perhaps his happiest works—the "Femme-fleur" (1946) and a large pastoral scene, "La Joie de vivre" ("The Joy of Life," 1946; Musée Picasso, Antibes). Fauns, pipe players, nymphs dancing or sleeping, centaurs—a whole Mediterranean mythology comes to life beside the landscapes of Vallauris and the happy scenes ("Maternity with Orange," 1951, collection of artist) in which his children Claude (born in 1947) and Paloma (1949) appear.

Political commitment

Beginning in the autumn of 1947, Picasso took up pottery making in the Madoura factory belonging to the Ramié family in Vallauris, and in 1948 he exhibited 150 pieces (representing only a tenth of his production) at the Maison de la Pensée Française in Paris. Under his fingers an amphora (an ancient Greek jar) becomes a woman or a condor (1947), a gazelle or a centaur (1948); plates are transformed into the faces of fauns or swarm with battling centaurs, bullfights (1948), doves (1949), and owls. "If the monster does nothing but smile," said Picasso in connection with the exhibition, "people are disappointed." In the same year he attended the World Peace Congress in Wrocław, Poland, and in 1949 the Peace Congress in Paris used his famous dove on its poster. Picasso gained international fame, and visitors from all over the world flocked to Vallauris. Since October 1948 he had been living at the villa called La Galloise, and there he painted "Massacre in Korea" (1951, collection of artist) and the portrait of "Hélène Parmelin," wife of the painter Édouard Pignon, whom he invited to come and live "a painter's life" near himself. He also painted "War and Peace" (1952), which consists of two large panels each measuring 15 feet, 5 inches by 33 feet, 7 inches (4.70 by 10.24 metres) and now adorning the Temple of Peace attached to an old chapel in Vallauris. These are politically motivated works, more colourful and narrative in spirit than "Guernica" and deliberately optimistic.

Pottery in Vallauris

All this activity did not prevent Picasso from taking a daily swim with his family at Golfe Juan—or from renewing the language of sculpture. By using such materials or fragments as potsherds, basketwork, and bits of metal scraps, he created unexpected masterpieces: the "Goat," the "Pregnant Woman," "Woman with Perambulator" (1950), "Goat's Skull and Bottle" (1951), the "Crane" (1951–52, G. David Thompson Collection, Pittsburgh), and "Baboon and Young," which attains its powerful expression of the animal's motherhood by the superposition of two small toy automobiles to represent the head. "Angry Owl" bristles with old bent nails. No less effective in their construction are the "Women's Heads" of 1954, models for gigantic, multicoloured "signals" that 10 years later were to be executed in concrete by the Norwegian sculptor Carl Nesjar. Six "Bathers" (1956) and the "Female Bather Playing" (1958), assemblages of packing-case wood, display a geometric humanity of disconcerting humour, a kind of 20th-century "savage art."

Later life and further innovations. The year 1953 saw a break with Françoise Gilot, who left for the United States with their two children. Picasso, now 72, transposed the event into vengeful pictures on the theme of the ravisher minotaur and a series of 180 drawings (November 1953–February 1954) of incisive and dazzling virtuosity. These drawings, an indiscreet and ironic confession on the theme of the young woman and the old painter (or old clown), were a kind of spontaneous self-analysis that freed the artist from his obsessions. Elsewhere, in the "Romancero du Picador" (89 wash drawings, July 1959–June 1960), he depicts the doomed figure of the bullfighter passing from the mocking cries of the arena to an orgy with prostitutes, while a duenna hovers in the shadows.

Break with Françoise Gilot

After a charming interlude of 12 portraits of "Sylvette" (1954) in Vallauris, the painter was to produce still further surprises. Interior scenes, often enlivened by the presence of his new love Jacqueline Roque in a Turkish costume, reveal in effect "La Californie," the Belle Époque villa at Cannes that he bought in 1955. In 1958 he married Jacqueline and bought the austere château of Vauvenargues in the Sainte-Victoire chain of mountains near Aix. The location suggested to him the solemnity of Spain, but it also brought him back to subtle contrasts of vivid colours (obtained by the use of industrial lacquers, as in "Dining-Room at Vauvenargues," [1959–60, Galerie Louise Leiris, Paris]; and "Jacqueline de Vauvenargues" (collection of the artist).

Transpositions of museum masterpieces

A further innovation consisted in transforming masterpieces of the past into Picassos, "museum copies" that became original creations. He had already transposed some of El Greco's works, Nicolas Poussin's "Triumph of Pan" into "Bacchanal" (collection of artist), in 1944, and Gustave Courbet's "Les Demoiselles des bords de la Seine" into "Girls on the Banks of the Seine, a Paraphrase of Courbet" (1950, Kunstmuseum, Basel, Switzerland). In 1955 he composed 15 variations on Eugène Delacroix's "Women of Algiers," freely Cubist in a riot of oriental colours (the 15th version is in the Victor Ganz Collection, New York). "Las Meninas" ("Maids of Honour") by Diego Velázquez (of whom Picasso said, "Here is the true painter of reality!") was to serve as the theme for 44 variations executed in five months in 1957. The "Déjeuners," after Édouard Manet's "Déjeuner sur l'herbe" ("Luncheon on the Grass"), developed into a series of 27 paintings and 138 drawings (1960–61) and was completed at Mougins, where in 1961 Picasso settled in the rustic house Notre-Dame-de-Vie.

This violent and archaeological approach is meant to show, as Picasso explained, that "in art there is no past or future" and that a valid work is "capable of living always in the present." It is thus "in the present" that Picasso means to create, as when, in his 1958 mural for the UNESCO building in Paris, he treated the classical theme of the fall of Icarus in totally unexpected images. Similarly, he subjected traditional themes to an audaciously simplified technique in large canvases of 1963–65, such as "The Painter and His Model" (June 1963; Berggruen, Paris) and "Reclining Woman with Cat" (March 1964; two versions, Galerie Louise Leiris, Paris). For him this was a way of escaping all historical considerations and the tyranny of beauty in order to produce new and immediate pictorial forms.

In his pottery, on the other hand, Picasso continued to play with Mediterranean culture and antiquity: vase-women, the amphora with "Two Fauns Playing the Flute" (1950), and a fine series of owls and doves (1953). He makes profiles out of broken bricks, and, on Roman or clay tiles, he draws portraits of Jacqueline and of "musketeers" (or even "Balzac scenes" that suggest bourgeois photography). His sculpture from this time includes works in sheet iron, cut, bent, and painted to form the large woman with outspread arms, women's heads, and bearded men.

Late drawings and prints

Between the ages of 85 and 90 Picasso the prodigious draftsman produced three series of drawings of unprecedented freshness. They include mythological scenes, circus scenes, drinking and carousing scenes, and amorous scenes (82 drawings and washes, 1966–67) mingling Penelopes and Ledas, charioteers, and musketeers "*à l'espagnole.*" The same themes are treated more realistically in 347 untitled engravings (March–October 1968) showing Spanish silhouettes, nocturnal pursuits, abductions, procuresses, and audacious alcove scenes in which Pope Julius II witnesses the free and easy frolicking of Raphael and his Roman mistress. Here he had recourse with consumate artistry to all the techniques of engraving (etching and aquatint, drypoint, burin, and so on). A third series (1969–71) returns to drawing and, reintroducing a theme that had been absent since 1925, closes with the self-portraits as harlequin—these last follow the "Mousquetaires," paintings and large lithographs of 1969. In October 1971, Paris paid homage to Picasso on the occasion of his 90th birthday by displaying eight of his works in the Louvre, in the place formerly occupied by da Vinci's "Mona Lisa." He died on April 8, 1973, at Mougins, France.

Evaluation. The man was infinitely changeable, impossible to grasp. Gertrude Stein wrote in 1933 that, because he was Spanish, life for him was tragic, bitter, and painful. Others, however, have seen him as "simple and cheerful, so sure of himself," and had been struck by his extraordinary intelligence in conversation and manners, his sense of living, and the total absence of any "artistic" pose. For the critic Jean Cassou, he was above all an artist in the fullest sense of the word," a man exclusively possessed by the thing that is born and takes shape in his hands, the thing he invents or, as he says, finds." Faithful to "a fundamental and impatient temperament . . . virtuoso and actor . . . he imperturbably exercises his powers of metamorphosis." But, in his anxious desire for coherence, he could not rest until he had transformed this temperament into the strictness of form.

His work is literally invaded by man: first of all by the man himself, Picasso, through the many self-portraits—acknowledged or disguised—and mythical symbols: the melancholy harlequin, the minotaur hungry for the fruits of the Earth, the triumphant sculptor, and time and again the painter and his model; next by humanity, or rather by that image of mankind offered by the culture of the Mediterranean, which his work sometimes exalts and at other times opposes and destroys. Thus, it is not surprising that, apart from his austere Cubist phase, the human face is omnipresent and the female body constantly represented —naked, in abduction or rape, playing, sleeping, or dancing. Also evident are themes of man's struggles and leisure pastimes as well as death, culture, and art.

Anguished, complex, ironic, always intense, seldom serene, Picasso's work is the story of a life governed by art, sometimes exalting, sometimes overcoming an exceptional virtuosity. Devoid of illusions ("I have never tried to please the public"; "People don't buy my pictures, they buy my signature"), Picasso had entered into an unacknowledged competition with his contemporaries (Braque, Matisse, Fernand Léger), with the great artists of the past (Velázquez, Ingres, Delacroix, Manet), and with himself: "Modern art should be killed. . . . That means that one should kill himself." Again, "In working, one must always be against. . . . If you know in advance what you're going to do, what good is that? It's better to do something else."

A realist and therefore a resolutely figurative artist, he had nevertheless renounced, since his Cubist days, the allure of the imitative image, in order to invent new forms that live more intensely than reality itself. Nevertheless, no artist so relentlessly revolutionary has ever better expressed the nostalgia that the modern era feels for a past that it itself challenges. Picasso has been called a nihilist, an anarchist. On the contrary, one should weigh the energy, strength of affirmation, and paradoxical "humanity" of his work, in which the darkest anguish carries on a dialogue with a savage *joie de vivre* and the cruellest violence confronts an imperceptible smile.

MAJOR WORKS

PAINTING (EARLY YEARS): "Le Moulin de la Galette" (1900; Justin K. Thannhauser Collection, New York). (BLUE PERIOD): "The Mourners" (1901; Edward G. Robinson Collec-

tion, Beverly Hills, California); "The Dwarf Dancer" (1901; Museo de Arte Moderno, Barcelona); "The Blind Man's Meal" (1903; Metropolitan Museum of Art, New York); "La Vie" (1903; Cleveland Museum of Art). (SALTIMBANQUE AND ROSE PERIOD): "Woman in a Chemise" (*c.* 1905; Tate Gallery, London); "Woman with a Fan" (1905; Averell Harriman Collection, New York); "Family of Saltimbanques" (1905; National Gallery of Art, Washington, D.C.); "La Toilette" (1906; Albright-Knox Art Gallery, Buffalo, New York); "Self-Portrait with a Palette" (1906; Philadelphia Museum of Art); "Gertrude Stein" (1906; Metropolitan Museum of Art, New York). (THE NEGRO PERIOD): "Les Demoiselles d'Avignon" (1906–07; Museum of Modern Art, New York); "Fruit Dish" (1908–09; Museum of Modern Art, New York); "Bust of a Woman" (1909; Tate Gallery, London). (ANALYTICAL CUBISM): "Seated Nude" (1909–10; Tate Gallery, London); "Girl with a Mandolin" (1910; private collection, New York). (SYNTHETIC CUBISM): "Accordionist (Pierrot)" (1911; Solomon R. Guggenheim Museum, New York); "Still Life with Chair Caning" (1911–12; collection of artist); "The Aficionado" (1912; Kunstmuseum, Basel, Switzerland); "Harlequin" (1913; Municipal Museum, The Hague); "Harlequin" (1915; Museum of Modern Art, New York); (CLASSICAL PERIOD): "Harlequin" (1917; Museo de Arte Moderno, Barcelona); "Guitar" (1919; Rijksmuseum Kröller-Müller, Otterlo, The Netherlands); "Two Seated Women" (1920; Walter P. Chrysler, Jr. Collection, New York); "The Rape" (1920; Museum of Modern Art, New York); "Three Musicians" (1921; Museum of Modern Art, New York); "Pipes of Pan" (1923; collection of artist); "Seated Women" (1923; Tate Gallery, London). (LATER WORKS): "Seated Bather" (1930; Museum of Modern Art, New York); "Guernica" (1937; Museum of Modern Art, New York); "Night Fishing at Antibes" (1939; Museum of Modern Art, New York); "Les Premiers Pas" ("First Steps," 1943; Yale University Art Gallery, New Haven, Connecticut); "The Charnel House" (1945; Walter P. Chrysler, Jr. Collection, New York); "Las Meninas," 58 canvasses (1957; collection of artist).

SCULPTURE: "The Jester" (bronze, 1905; Phillips Collection, Washington, D.C.); "Woman's Head" (bronze, *c.* 1909; Museum of Modern Art, New York); "Glass of Absinthe" (painted bronze and silver spoon, 1914; Museum of Modern Art, New York); "Still Life" (painted wood with upholstery fringe, 1914; private collection, London); "Guitar" (floorcloth, string, nails, and newspaper, 1926; collection of artist); "Sculpture" (iron wire, 1928; collection of artist); "Sculpture" (bronze, 1931; collection of artist); "Head of D.M." (bronze, 1941; collection of artist); "Bull's Head" (bicycle saddle and handlebars, 1943, collection of artist); "Man with a Sheep" (bronze, 1944); "Goat" (plaster, later cast in bronze, 1950; collection of artist); "Baboon with Young" (bronze, 1951); "Steel Sculpture" (1967; Civic Center Plaza, Chicago).

PRINTS AND DRAWINGS: "Salomé" (drypoint, 1905); "Max Jacob" (pencil, 1915; Mlle Dora Maar Collection); "The Bathers" (pencil, 1918; Fogg Art Museum, Cambridge, Massachusetts); "Portrait of Stravinsky" (pencil, 1920); "The Sculptor's Studio" (a series of 46 etchings, 1933–34); "Minotauromachia" (1935); and a series of minotaur etchings (1933–35); studies for "Guernica" (1937, in various media); "Self-Portrait" (pen and ink from "Desire Caught by the Tail," 1943); "Portrait of D.M. As a Bird" (pen, ink and wash, 1943); "Françoise" (lithograph, 1946); "Model and Monkey Painter" (ink and wash, 1954).

CERAMICS: Among many examples, "Woman Vase" (1948); "Three Doves" (1953); "Plate with Bullfight" (*c.* 1957).

THEATRE DESIGN: Decor for the ballets *Parade* (1917); *The Three-Cornered Hat* (1919); *Pulcinella* (1920); *Cuadro Flamenco* (1921); *Mercure* (1924).

BIBLIOGRAPHY

Biography and Criticism: ALFRED H. BARR (ed.), *Picasso: Fifty Years of His Art* (1946), a fundamental work; WILHELM BOECK and JAIME SABARTES, *Picasso* (1955), with 596 illustrations; MAURICE RAYNAL, *Picasso* (1953), for the period to 1950; PIERRE DUFOUR, *Picasso 1950–1968* (1969, in French) —all the above contain good bibliographies. Piccard Family

A family of Swiss scholars, the Piccards have gained international renown for their original contributions to science and public affairs. Their most illustrious members were the twins Auguste and Jean, who explored both the upper stratosphere and the depths of the sea in vehicles of their own design.

Horst Tappe—EB Inc.

Jacques, 1967 (left), and Auguste Piccard, 1961.

Rodolphe (1807–88) was the first to inaugurate the family's international vocation by obtaining an appointment as painter to the court of Russia, in St. Petersburg (now Leningrad) in the 19th century. His brother, Jules-François, began the family's scientific orientation by preparing many plates for the official map of Switzerland. Two of Jules-François's sons followed in his footsteps: Jules was a professor of chemistry at the University of Basel; and Paul, an engineer from Geneva, designed and sold the first electrical turbine at Niagara Falls.

Jule's sons Auguste and Jean, identical twins, were born in Basel on January 28, 1884. They enrolled together at the Swiss Federal Institute of Technology, in Zürich, where they followed parallel careers, one in physics, the other in chemistry. When they became doctors of science, both decided to teach in universities; Jean, the chemist, going first to Munich, then to Lausanne, then to the United States; and Auguste, the physicist, staying on at the Institute. Both married foreign students: Jean married Jeannette Ridlon, an American student of his at Chicago, in 1919, and Auguste married the daughter of a French historian at the Sorbonne.

Auguste became interested in balloon ascents, not as a sport but as a means of making experiments. Oriented toward pure physics, he participated in many important research studies. When the University of Brussels in 1922 created a chair for applied physics, Auguste, who was also a mechanic and an engineer, readily accepted the post. Maintaining the youthful zest for adventure that had been inspired by his studies, Auguste, who later explored both the sky and the depths of the ocean, amply fulfilled his dreams, pursuing them with the will of an adult and the rigour of science. Having studied cosmic rays, he conceived of an experiment for observing them at 16,000 or more metres (over 50,000 feet) in the upper atmosphere. Previous ascents had shown that the stratosphere could be fatal and that to penetrate the iso-

Flights to the stratosphere

thermal layer, with its low pressure, a revolutionary balloon would be necessary. He built such a balloon in 1930, with Belgian financing. Its main innovative feature was an airtight cabin, equipped with pressurized air; today this technique has become commonplace on airplanes. Another innovation was the design of a very large balloon having sufficient ascent strength so that, on departure, it need not be completely filled. On May 27, 1931, Auguste Piccard and Paul Kipfer reached an altitude of 15,781 metres (51,762 feet), where the atmospheric pressure is about 1/10 that at sea level. A jammed valve made descent impossible in daylight, and they were obliged to wait for the cold night air to contract the balloon. They landed on an Austrian glacier. Interest in the flight was enormous: because no communication had been received from the two scientist-adventurers, they were believed to be dead. After they were found alive, they were received triumphantly, first in Zürich, then in Brussels; the tall silhouette of "Professor Piccard" became world famous.

In 1932, in a new cabin, this time equipped with a radio, Auguste Piccard was able to reach an altitude of 16,940 metres (55,563 feet). In 1933, using the same technique but with bigger balloons, other balloonists rose to 18,500 metres (60,700 feet) in the U.S.S.R. and 18,665 metres (61,221 feet) in the United States.

In 1926 Jean Piccard established residence in his wife's native land, the United States, while he was a research instructor at the Massachusetts Institute of Technology. The lives of the twins converged again in 1934, however, when, with his wife as pilot, Jean followed his brother's example by making an ascent into the stratosphere, attaining an altitude of 17,550 metres (57,564 feet). In 1936 he was appointed professor of aeronautical engineering at the University of Minnesota.

It was known that in order to go higher bigger balloons would be necessary and that they would be difficult to build. Jean Piccard attempted a launch in a cluster of large balloons in 1937; after a successful flight, the equipment was accidentally destroyed by fire. He also devised a plastic envelope that would enclose the cords supporting the nacelle, or balloon gondola. Under his direction, the University of Minnesota played a paramount role in the conquest of the stratosphere.

As a child, Auguste had been fascinated by accounts of marine fish and thought that man should also descend into the depths. As a student, he had conceived of engines capable of withstanding great pressures, yet still manoeuvrable. Now, after his aeronautical successes, he wanted to build a device capable of resisting the pressures of the ocean depths, the bathyscaphe.

Depth-resistant cabins are, of necessity, heavier than water. Up to that time around 1948 they had been suspended from a cable, but, at great depths, this procedure was not dependable. Piccard revolutionized the dive by the principle of the balloon. Just as a lighter-than-air balloon carried the nacelle, a lighter-than-water float would support the cabin. Just as the balloon required a release of ballast to rise, the bathyscaphe would release weight in order to ascend. Fundamentally lighter than water, it would be safe. Air, because it is too easily compressed, was not used in the floats; Piccard chose gasoline.

The bathyscaphe

World War II interrupted construction of the bathyscaphe, which was not completed until 1948. Dives at great depths were conducted off the coast of Senegal, where the French government had stationed a ship with a military team under the command of Jacques Cousteau. In October 1948 an unpiloted trial dive, with the bathyscaphe F.N.R.S. 2 was conducted successfully. The cabin withstood the 1,400-metre (4,600-foot) pressure perfectly, but the float was severely damaged by a heavy swell of water encountered after the dive. The float had to be abandoned, and more solid structures were built around the cabin to permit towing at sea. Although collaboration with the French navy had been secured, it was a difficult job, both administratively and practically; the sailors found it disagreeable to work with a foreigner, a civilian, and a landlubber. Tensions mounted until Jacques Piccard, Auguste's son, intervened.

Jacques, born on July 28, 1922, the only son among Auguste's five children, had become an assistant in economics at the University of Geneva and so had not followed the family tradition in science. Destiny, however, was to bring him back into the fold. As an economist, he had already conducted the negotiations with the French government. Then, while in Trieste, Italy, for the purpose of preparing a study on that port, he received an unexpected offer from local industry to build a new bathyscaphe. Thus, in August 1953, two bathyscaphes competed in the Mediterranean, at Toulon, France, and at Naples: the French craft F.N.R.S. 3 descended to 2,100 metres (6,900 feet), and the Piccards' "Trieste" went down to 3,150 metres (10,330 feet). At the age of 69, August Piccard had realized his dream. His son, abandoning economics, followed in his father's footsteps and collaborated in the construction of the bathyscaphe. It was the year of Jacques's marriage to Marie-Claude Maillard, the daughter of a minister. In 1954 Auguste Piccard retired and left Brussels for Switzerland.

The "Trieste"

France recaptured the diving record from the "Trieste" by going to a depth of 4,050 metres (13,280 feet). The "Trieste" continued to dive in 1954 and 1956; in 1957, the U.S. Navy financed 26 dives off Naples and then bought the engine. Jacques Piccard, hired as a scientific consultant, went to live in San Diego, California, and in 1959 the bathyscaphe was transported to the island of Guam, where it registered dives of 5,530 metres (18,150 feet), and then 7,000 metres (23,000 feet), and on January 23, 1960, a dive of 10,916 metres (35,800 feet).

Auguste Piccard died of a heart attack on March 24, 1962 in Lausanne; Jean, deeply affected by his brother's death, survived him only a few months (died January 28, 1963, in Minneapolis, Minnesota). Jean's wife, Jeannette, became an upper-atmosphere expert for the U.S. National Aeronautics and Space Administration. His three sons, born in 1920, 1924, and 1926, became, respectively, an engineer; a professor of political philosophy; and a manufacturer of hot-air balloons.

After completing his American contract, Jacques Piccard returned to Lausanne. He designed and built the "Auguste Piccard," a mesoscaphe, or sight-seeing submarine, the star attraction of the Swiss National Exhibition held in Lausanne in 1964 when, during the summer, it carried 33,000 tourists to a depth of 100 metres (300 feet) in the lake. Later, the vessel became the property of a United States-Canadian diving firm.

Jacques continued to develop new projects, one of which interested a large American firm: a submarine, which, by balancing in water, could be carried along by subsurface currents in the Gulf Stream; called the "Ben Franklin," it was built in Switzerland. The project involved another long stay by Jacques in the United States, this time in Palm Beach, Florida. From July 14 to August 14, 1969, the "Ben Franklin," with Jacques Piccard and five observers aboard, drifted in the Gulf Stream along the U.S. coast. As scheduled, the experiment lasted one month without the submarine's being propelled; the water was continuously monitored for several characteristics, and underwater soundings were taken.

Gulf Stream research

Jacques returned to Lausanne after completing this contract and began work on new projects, including a submarine for studying pollution in Swiss lakes. He also established a foundation for environmental protection. Though dispersed throughout the world, the family has maintained ties with the little village of Lutry, on Lake Geneva, for Swiss tradition holds that one is forever bound to the cradle of his ancestors.

BIBLIOGRAPHY. No book-length biographical study of the Piccard family exists in English; in French, see PIERRE DE LATIL and JEAN RIVOIRE, *Le Professeur Auguste Piccard* (1962). The same authors' *A la recherche du monde marin* (1954; Eng. trans., *Man and the Underwater World,* 1956), deals with their explorations. English translations of the writings of the Piccards are: *Earth, Sky and Sea* and *In Balloon and Bathyscaph* (both 1956), by AUGUSTE PICCARD; and *Seven Miles Down* (1961) and *The Sun Beneath the Sea* (1971), by JACQUES PICCARD.

(P. de L.)

Piciformes

The bird order Piciformes includes the familiar woodpeckers, their relatives the piculets and wrynecks (collectively, the family Picidae), and the exotic tropical jacamars (Galbulidae), puffbirds (Bucconidae), barbets (Capitonidae), honey guides (Indicatoridae), and toucans (Ramphastidae). This arboreal group of about 370 species is distributed on all continents except Australia and Antarctica, but only the woodpecker family is widespread outside the tropics. Although the six families comprise the order, over half of the species represent one subfamily (Picinae, true woodpeckers) of the family Picidae. The order includes such familiar birds as the European great spotted woodpecker (*Dendrocopos major*) and green woodpecker (*Picus viridis*) and the American flicker (*Colaptes auratus*) and downy woodpecker (*Dendrocopos pubescens*). Piciforms are economically important because they include many insect-eating species. A few species are harmful in eating fruit (toucans) or damaging trees (sapsuckers, genus *Sphyrapicus*), but even these species eat some insects and other animals, and they of course serve as natural balances within the ecological systems of which they are a part.

Drawing by R. Keane

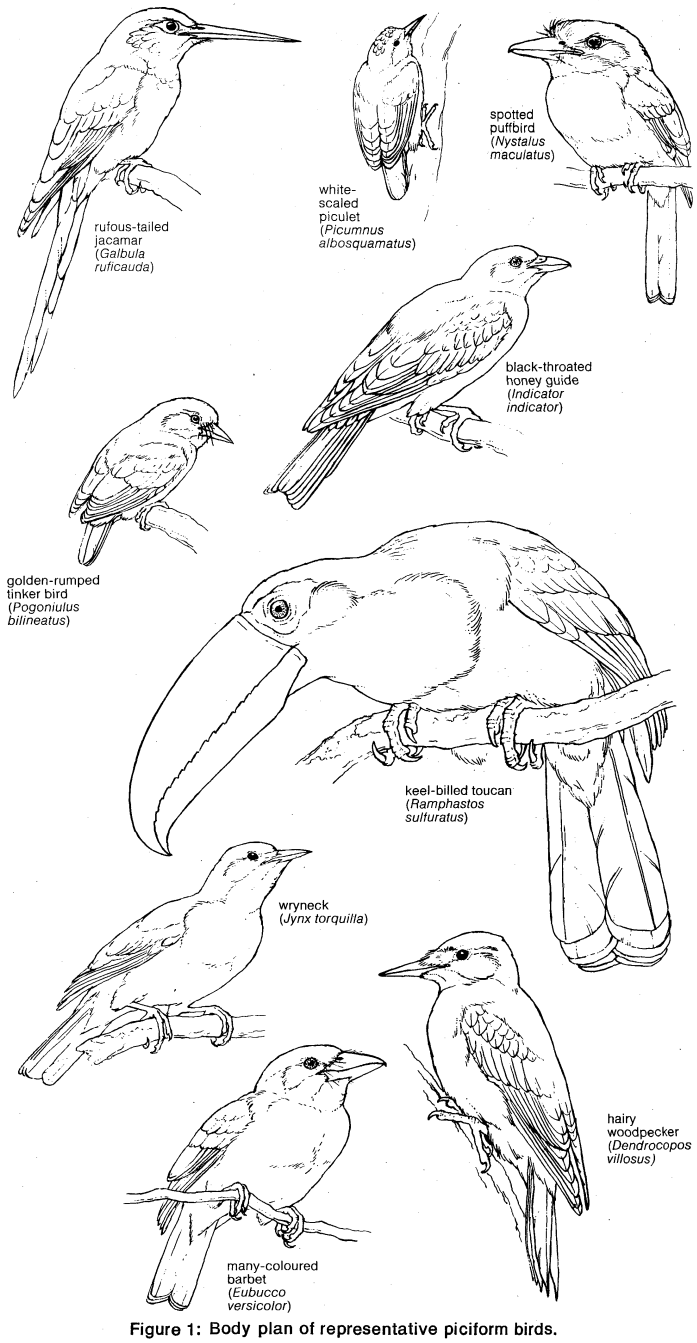

Figure 1: Body plan of representative piciform birds.

The tropical distribution of most piciform families suggests that these represent specialized remnants of a once more numerous and diverse array of arboreal birds. Perhaps many elements of the order became extinct during the geologically recent burgeoning of the diverse, ubiquitous, and highly successful order Passeriformes, which the piciforms resemble in many ways. It has even been suggested that both groups be merged into one order. Distribution of the order

Piciform species vary in size from about nine to more than 60 centimetres (3½ to 24 inches) in overall length. They vary greatly in the structure of their beaks and only slightly less in the rest of their morphology, some, such as the huge-billed toucans and the sturdy woodpeckers being very specialized. The specialized habits of the wax-eating honey guides are unique among birds. The most numerous and widely distributed groups, the barbets (70 species) and the woodpeckers (about 203 species), excavate their own nesting cavities, thereby avoiding competition with other birds and, incidentally, providing homes for many other species of vertebrates.

IMPORTANCE TO MAN

Most piciform birds consume insects, some foraging in places (within bark) reached by no other birds. Thus, they are valuable in the control of insects, even helping to prevent the spread of tree diseases, such as Dutch elm disease, by destroying insect carriers. Fruit-eating barbets and toucans spread seeds of certain tropical trees, the seeds being passed through their bodies at distances away from the parent tree. Honey guides lead men, as well as other mammals, to sources of honey. Colourful toucans, barbets, and jacamars, and even the dull-coloured puffbirds delight natives and ever-increasing visitors to the tropics. Woodpeckers are conspicuous and often colourful species of forests, and their actions have long elicited interest and admiration from man—their winter visits to suet feeders in the Northern Hemisphere are anticipated and enjoyed by millions of onlookers. The excavation of nesting and roosting holes by woodpeckers and barbets provides homes for countless birds of other species, which utilize the holes after the excavators are finished with them. Foresters in Europe frequently compensate for the lack of old woodpecker holes needed by valued insect-eating species by placing artificial nest boxes in their cultivated forests.

Fruit eating by barbets and toucans sometimes causes damage to cultivated fruit plants, especially near villages and towns. The few species of sapsuckers in North America and southern Asia occasionally destroy trees by creating openings through which disease agents may enter, although wounds in healthy trees rapidly heal. Piciform birds that excavate their nests usually choose dead or dying trees, but some excavate in live trees or cacti. The area around the excavation may be sealed off by scar tissue in some trees, especially cacti, resulting in no damage but diminishing the tree's value. Some woodpeckers damage fence posts and utility poles, particularly in open country, in well-kept woodlots, and near cultivated forests where dead trees are scarce.

NATURAL HISTORY

Distribution and ecology. Piciform birds are varied in their habits, although certain facets of behaviour relating to hole nesting, such as the snakelike hissing of young birds in the nest, are shared with some other hole-nesting birds. Jacamars and puffbirds, the fly-catching members of the order, are stolid, unsuspicious birds, allowing close approach by humans. Woodpeckers, toucans, and barbets are more wary, but the smaller species of piculets and woodpeckers sometimes can be approached closely.

Jacamars and puffbirds inhabit various portions of tropical American forests. Jacamars sit quietly on perches in openings and edges, flying infrequently, but often flicking their tails. Large insects, such as butterflies, are captured, taken to a perch, and usually beaten against it. The wings of the insects are removed if the prey are to be fed to the young.

Puffbirds are often found in farm areas, where they may be seen along the road looking something like dull-coloured forest kingfishers. They have a rapid, darting flight, and some species, such as the swallow-winged puffbird (*Chelidoptera tenebrosa*), spend much time making sorties after insects high in the trees. Others forage low in bushes, obtaining prey on the ground as well as in undergrowth. Tail-jerking movements are observed in some puffbirds (*e.g.*, the two-banded puffbird, *Hypnelus bicinctus*), as in jacamars.

The barbets are weak-flying, essentially resident birds inhabiting woodland and savannas, occasionally the fringes of deserts. They feed on insects, fruit, and even flowers and buds. The tiny African tinkerbirds (*Pogoniulus*), so named for their repetitive vocalizations, feed mainly or entirely on insects, foraging rapidly over bark and occasionally tapping with the beak, very much like piculets of the woodpecker family. Some barbets have serrated, or "toothed," edges of the bill, in the manner of toucans; these are apparently used for tearing open fruit.

Guiding by honey guides

Honey guides are nonmigratory birds, dwelling in pairs or alone in forests and savanna. They feed on insects, fruit, and beeswax. Only a few honey guides of the genus *Indicator* actually are known to "guide" certain mammals, including man, to bees' nests. Most honey guides are able to enter bees' nests without assistance, there to eat larvae and, primarily, wax, which is digested with the help of special bacteria within the birds' digestive tracts. Honey guides that "guide" use a peculiar chattering to attract the attention of an animal likely to follow. The greater honey guide (*Indicator indicator*) spreads its tail conspicuously and uses a peculiar undulating flight in attracting attention. It perches and calls again, then moves further on in another short flight, as the interested animal draws near. Upon reaching the bees' nest, the honey guide waits quietly in the vicinity until the animal has taken the honey and moved off. It then flies to the devastated nest and feeds on scattered pieces of wax and exposed larvae.

Toucans are strictly New World tropical-forest birds, although they may forage about farms. One group, the hill toucans of the genus *Andigena*, occurs in the Andes up into temperate forests. No toucans are geographically migratory, but some species make local movements up and down mountain slopes. Toucans eat much fruit, perhaps aided by their serrated beaks. Smaller pieces or small fruits are first held in the tip of the bill and then thrown back into the mouth. They also eat larger insects, birds' eggs, and even young birds. The colour patterns of the bill are distinct in each species and probably serve a behavioral function. Toucans have a peculiar habit of cocking the tail forward over the head, particularly while sleeping in a cavity; D'Arnaud's barbet (*Trachyphonus darnaudii*) also does this during displays.

The family Picidae is comprised of three distinct subfamilies. One, the Jynginae, contains two closely related species of wrynecks (*Jynx*), found in Eurasia and central Africa. Wrynecks, which have soft, unspecialized tails, forage for ants in trees and on the ground.

The piculets (Picumninae) comprise a second subfamily of soft-tailed, woodpecker-like birds. All but four of about 30 species live in forests and dry woodlands of the New World tropics. The major genus *Picumnus* is peculiarly distributed in having about 24 species in the New World and one species (*Picumnus innominatus*, the speckled piculet) in southern Asia, a pattern of distribution matched by the woodpecker genus *Celeus*. All the piculets are tiny, the largest—the peculiar Haitian piculet (*Nesoctites micromegas*)—being only sparrow sized. They feed in a woodpecker-like manner, tapping and probing usually on small branchlets and vines, and they allow close approach, continuing to forage under the eyes of an observer. Their food is composed mainly or entirely of insects.

Feeding behaviour of woodpeckers

The true woodpeckers (Picinae), with their stiffened tails, usually perch lengthwise on tree branches or trunks. Among the relatively few species that go to the ground, all hop, except for two species of flickers (campo flicker, *Colaptes campestris*, and Andean flicker, *Colaptes rupicola*) that walk. Foraging is by diverse modes. True excavating, which penetrates the substrate of the bark, is not as common as one would expect on viewing the woodpecker bill. Most woodpeckers forage mainly by gleaning items from the surface of a tree, by probing into cracks, and by occasional to frequent tapping, sufficient to break barely through the surface. Only the heavy-billed, so-called ivorybills (genus *Campephilus*) of the New World, some of their relatives, other similarly specialized Asian groups, and a few of the smaller woodpeckers (genus *Picoides*; some species of *Dendrocopos*) regularly chisel deep into trees. The food of woodpeckers is varied, mainly consisting of insects, but some species (especially of the genus *Melanerpes*) frequently eat fruits and berries. Ants are a favourite food, especially in tropical regions—fully half of the numerous tropical species feed largely or entirely on ants. Three woodpeckers (ground woodpecker, *Geocolaptes olivaceus* of Africa, the campo flicker, and the Andean flicker) are ground dwellers, feeding mostly on ants, while seven or eight other species frequently forage on the ground. The flight of woodpeckers is strong, with definite up–down undulations.

Most woodpeckers are permanent residents, the few exceptions including the North American yellow-bellied sapsucker (*Sphyrapicus varius*) and flicker, which are highly migratory.

Reproduction. The ability of most piciform birds to excavate their own nest holes is probably a major factor responsible for their success. With relatively diverse types of bills, the jacamars, puffbirds, and barbets excavate nesting cavities, as do the sturdier billed woodpeckers, although the former utilize a softer substrate such as earth or dead trees. Woodpeckers alone within the order have biologically "capitalized" on their adaptations for excavating nests, by various further specializations for nesting (even in hard, living trees) and for foraging on the surface and within the bark of trees. They have thus exploited niches unavailable to other birds, a fact that accounts for their success relative to other members of the order. Yet because of their specialized habits, only a limited number of kinds of woodpeckers can exist together, usually no more than five to eight species (more in some tropical environments), differing somewhat in size and habits.

Difficulties in the study of hole-nesting birds

Because of the concealing nature of the nest cavity, the behaviour of hole-nesting birds is more difficult to study than that of species building exposed nests. The nesting behaviour of most piciform families must be inferred from observations on a few examples, the woodpeckers being the only group that has been extensively studied.

Jacamars are usually resident wherever they occur and nest at diverse times of the year depending on the locality. Nests are excavated in banks or in steep hills. Both sexes dig with the beak, kicking out dirt with their feet. The tunnel is comparatively short, usually less than one metre (three feet) in depth. No lining is placed in the nest chamber at the end of the tunnel. Three or four white eggs are incubated by both sexes, with the female incubating at night. The incubation period of several species of jacamars is known to be from 19 to 21 days. The young are downy and hatch with their eyes closed. They remain for 20 to 26 days in their nest before leaving. Most of the food consists of large insects brought to the young by both parents. The parents do not clean debris and fecal material of the young from the nest, which becomes littered.

Puffbirds excavate their nests in the ground or in termite nests on the ground or in trees. The tunnel is usually deeper than that of a jacamar, often reaching a metre or more into the ground. Several pairs may nest close together, semicolonially. Both sexes excavate the burrow. Some species leave the chamber at the end of the tunnel unlined, while others may line it with grass or dead leaves. Several species, including the white-whiskered puffbird (*Malacoptila panamensis*), pile sticks and leaves at the mouth of the nest tunnel, effectively concealing it. Both sexes incubate the two (occasionally three) white eggs. The newly hatched young are naked and are fed by both parents until old enough to leave the nest.

Social nesting and roosting

Although the majority of barbets nest in isolated pairs, there is a marked trend toward sociality. Large numbers of one or several species may gather to feed at a fruiting tree. Some species are found in family groups, and displaying groups of several individuals may be seen during the onset of breeding. The most social of all are the plain-coloured barbets (genus *Gymnobucco*) of Africa, the brown barbet (*Calorhamphus fuliginosus*) of southeastern Asia, and some species of the genus *Megalaima* of southern Asia. These nest colonially and feed in gatherings of up to 50 or more birds (*Gymnobucco*). They are aggressive, noisy birds and may take over an entire dead tree for nesting, driving away other bird species. In some barbets of the genera *Semnornis* and *Megalaima*, communal roosting occurs, with numbers of birds spending the night together in the same hole. Nests are usually excavated in trees, but a few species burrow into the ground or into termite nests. Both sexes excavate the cavity, which typically has a nearly round entrance, small for the size of the bird. The same cavity may be used for several nesting seasons. No lining material is placed in the nest cavity. The shape of the barbet's bill, which is not at all chisel-tipped like that of a woodpecker, makes the excavation of cavities in trees a task requring great effort, and it appears that only dead, well-rotted trees are used. Two to five white eggs are laid in the cavity; both parents then incubate the eggs for 13 to 15 days or more. Both also may spend the night in the nest. The young develop slowly, spending 30 or more days in the nest. The adults clean the nest, removing excreta. Often the young and adults continue to roost together after the young have left the nest, occupying a separate "dormitory" hole excavated for that purpose. On occasions, more than one pair of birds may use the same nest (white-eared tinkerbird, *Pogoniulus leucotus*).

Most, if not all, of the honey guides are brood parasites, laying their eggs in the nests of other species, especially those that nest in holes or in deep, covered nests. The host's eggs often are punctured by the female honey guide when she lays her own egg. Only a single egg is laid in each host's nest. Because of the parasitic habit, the incubation periods of honey guides are not well known, but periods of 12 to 16 days have been found in species of *Indicator*. The young birds spend a long time in the nest, 35 to 40 days or more. When newly hatched, they have hooks on the tips of their bills, which are used to injure and kill the young of the host species. These hooks later fall off.

Toucans nest in natural cavities or in old woodpecker nests. Smaller species may usurp a nest freshly constructed by woodpeckers. Old, well-rotted cavities may be enlarged slightly. One to four eggs are laid on the floor of the nest, which may be unlined or lined with a few leaves. About 16 days are required for incubation, performed by both sexes. The birds are shy about the nest and hence difficult to observe. The young, naked when hatched, bear large pads on their heels, on which they perch in the nest. The nestling period is generally long, up to seven weeks or more, varying with the size of the birds. Toucans, except the toucanets (genus *Aulacorhynchus*), do not maintain clean nests. Family groups may remain together for a long time, for small flocks are often seen throughout the year.

Wrynecks usually nest in natural crevices, old woodpecker holes, or old swallow holes in banks. They lay two to 14 eggs, and both sexes incubate. Like the American flicker and probably other woodpeckers, the wryneck is an indeterminate layer; *i.e.*, the bird produces eggs until a certain number have accumulated.

The nests of piculets are constructed in small trees, stubs, fence posts, and the like. The entrance is tiny and rounded, resembling a barbet nest entrance. Two to four eggs are laid and incubated for about two weeks. The initially blind and naked young grow for three weeks or more before leaving the nest for the first time. Both parents incubate and feed the young, and in at least some species they both remain in the nest at night. After fledging, the young may continue to roost in the nest at night with their parents for several months. Like the wrynecks and most other birds and unlike woodpeckers, the piculets often perch crosswise on branches.

Displays of woodpeckers

The reproductive behaviour of woodpeckers is better known than that of most other Piciformes. The sexes are clearly marked by simple pattern differences, most commonly involving the presence or absence of red on the head. Observations at bird-feeding stations suggest that sexual recognition occurs throughout the year, with males dominant over females. Aggressive displays are conspicuous and numerous in woodpeckers, including various head postures centring on the bill, bill pointing, head turning, swinging of the head and body from side to side, bobbing and bowing of the head, wing flicking and spreading, tail spreading and turning, and even aerial displays. These displays exhibit the complex head markings, as well as the body, tail, and wing patterns found in most species. Many vocal and instrumental signals are used, including the widely prevalent tapping or drumming of the bill against a tree or, in cities, on tin roofing.

Most woodpeckers actively defend territories, often throughout the year. This perhaps accounts for their strongly developed aggressive behaviour. Few species are markedly social, but members of the New World genus *Melanerpes* especially tend to be, even while nesting. Up to 11 different adults of the yellow-tufted woodpecker (*Melanerpes cruentatus*) were observed feeding young in three different nests in eastern Peru. Some of the adults fed young in two and even in all three nests. Andean flickers nest in loose colonies in banks and may be seen in groups of ten or 12 birds. Otherwise, social gatherings of woodpeckers generally involve family groups during and sometimes after the breeding season. Most woodpeckers are aggressive toward others of their own species, even to some extent toward their mates and young. Aggressive encounters are most frequent between members of the same sex. When an intruding woodpecker invades the territory of a pair during the breeding season, it usually is attacked by the member of the pair that is of the same sex as the intruder. Conflicts between birds after the breeding period are more intense when the woodpeckers involved are of the same sex. Experiments with the North American flicker show that even paired birds recognize each other primarily by their sexual colour markings, for a female given an artificial black moustache stripe (characteristic of the male) was attacked and pursued unceasingly by her mate until the experimenter rescued the exhausted female and removed the "moustache." She was once again fully accepted by her mate.

Nesting of woodpeckers

Nests are excavated by the birds themselves, although a few species will accept artificial nest boxes. Two species, the ground woodpecker and the Andean flicker, always nest in the ground, digging nests in banks, and the campo flicker of South America often does so. Other woodpeckers chisel holes in trees, fence poles, cacti, or similar sites. Usually both sexes construct the nest, but either sex may do most of the work, depending on the species. The nest cavity varies with the size of the bird. A flicker (30 centimetres, or 12 inches, long) was found incubating eggs in a tree stub only 12 centimetres (five inches) thick; so less space is required for nesting than one might expect. Nevertheless, the size of the stub or tree necessary for nesting is proportional to the size of the woodpecker. Also, the size and abundance of dead or dying trees influence the abundance and types of woodpeckers that can occupy an area.

From two to nine white eggs are laid on the bare floor of the woodpecker's nest cavity. Most species probably are indeterminate layers. By removing the freshly laid eggs as they appeared daily, one experimenter induced a female flicker to lay a total of 71 eggs. The incubation period of woodpeckers varies from 11 to 20 or more days. Both adults incubate the eggs, and typically the male alone occupies the nest during the night. The young are naked and helpless when hatched and spend up to 36 days in the nest. Both parents feed the young and keep the nest clean by removing excreta frequently. In some species the young are driven off by the adults soon after they can feed themselves; in others the family remains together longer, sometimes even until the next breeding season.

Vocalizations. The voices of Piciformes are rarely melodious and are often harsh or strident. The vocalizations of jacamars are squeaky, the notes sometimes being run together into a trill. Whistles or trills may be alternated or mixed, forming a simple song. Puffbirds are relatively quiet, producing thin whistles, peeps, and twitters. The vocalizations of toucans are loud and often harsh, especially those of the larger species, such as those in the genus *Ramphastos*. The calls of barbets are monotonous and repetitive, but some are bell-like and pleasing to the ear, especially those rendered antiphonally (*i.e.*, the birds alternating) or simultaneously by members of a pair. Displays may accompany this singing. With some colour patterns like their relatives the woodpeckers, barbets have similar displays, such as head swinging, head bobbing, bill pointing, and others.

Although the vocalizations of woodpeckers are individually less complicated than the songs of passeriform birds (the order that includes the songbirds), up to eight or nine different and varying calls may be used by some species (*e.g.*, the ladder-backed woodpecker, *Dendrocopos scalaris*). These function as "advertising songs" (usually repetitive, often harsh, "rattle" or "wick" calls), as aggressive or submissive calls associated with displays, and in other ways.

FORM AND FUNCTION

Adapted for diverse modes of life, piciform birds vary strikingly in their morphology and in their habits. The interpretation of differences is difficult in many cases, especially considering that different structural means may achieve the same purpose. Thus, the fly-catching jacamars are exceptionally long-tailed, but the puffbirds, which feed similarly, are generally short-tailed.

Characteristic of all members of the order is the yoke-toed (zygodactylous) foot in which the outer toe (toe IV) as well as the hind toe (I) points to the rear. This was long considered an adaptation to climbing or perching on the vertical trunks of trees, but recent studies have shown that this type of toe arrangement may really denote a generalized perching foot. Most of the strongly wood-pecking species of the Picidae that are four-toed spread the toes laterally and anteriorly—*i.e.*, up the tree that they are climbing, with no toes pointing to the rear. Three-toed woodpeckers, such as the northern three-toed woodpecker (*Picoides tridactylus*), which have lost the hind toe (hallux, toe I), climb with all three toes facing to the front and sides and swing the inner toe (II) backward when perching on a branch. The hallux tends to be small in those Picidae that have retained it, and its loss has occurred independently in several lines of woodpeckers and piculets.

Foot specialization

Just as birds in general are structurally similar because of requirements imposed by flight, woodpeckers are structurally similar because of requirements imposed by wood-pecking habits. The special modifications responsible for their unique abilities are diverse. The tail feathers (especially the central one or two pairs) are stronger in woodpeckers, resisting the wear caused by their use in propping the bird's body as it hammers with the bill. The toe structure and associated arrangement of tendons and leg muscles form a functional complex of features enabling the woodpecker to climb tree trunks and to maintain its position while pecking the tree.

Another functional complex involves the skull, head musculature, bill, tongue, and associated structures of the woodpecker, collectively its food-gathering apparatus. The skull is unusually thick, and, in the most specialized wood-pecking species, it curves inward at the upper base of the bill, instead of meeting it directly, giving a built-in shock absorber. The head musculature is specialized to power the thrusts of the bill and to help absorb the shock caused by pecking. The long, distensible tongue is variously equipped with tiny barbs and coated with a sticky substance provided by often greatly enlarged and modified salivary glands. The horns of the hyoid apparatus responsible for the ability to extend the tongue are tremendously elongated, and when the tongue is retracted, they often extend around the back of the skull, over the top, and (rarely) even onto the bill and into a nostril (see Figure 2). The tongue can be extended into holes made

Drawing by R. Keane

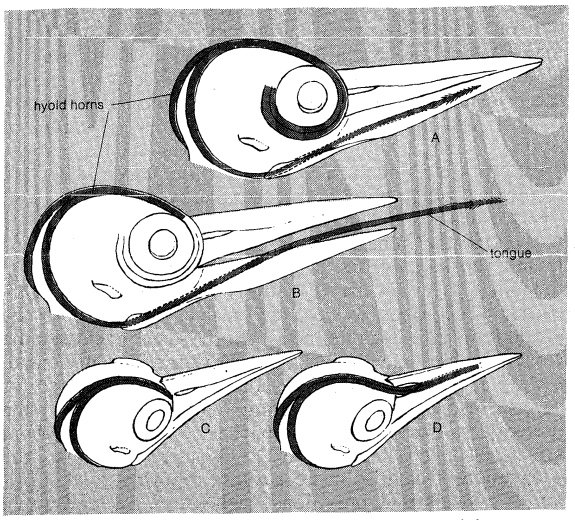

Figure 2: Position of hyoid bones (shaded) with tongue (A) retracted and (B) extended, shown in the hairy woodpecker (*Dendrocopos villosus*). (C and D) Other configurations of hyoids: C ending at the base of the beak; D entering the right nostril and lying within the upper mandible.

by the bill and can be used both as a probe and as a "spear" (by means of the barbs and sticky mucus) to locate and extract insects far beyond the bill's reach. The bill of more specialized woodpeckers is chisel tipped, broad based, and very sturdy. The nostrils are slitlike, preventing sawdust and wood chips from entering. Other parts of the body may be modified for support or to prevent damage from the shock of pecking.

An advantageous side effect of their specialization is that woodpeckers are exceptionally tough-skinned and sturdy and thus are difficult to kill. Unfortunately, this has not saved the magnificent, highly specialized ivory-billed woodpecker (*Campephilus principalis*) and its close relative the imperial ivory-billed woodpecker (*Campephilus imperialis*), by far the largest of all woodpeckers, from extinction through destruction and modification of habitat. A remnant population of the former is known to exist in Cuba, but the future for both species is bleak.

Among woodpeckers, sexual difference in bill structure and other characteristics plays a role in allowing the members of a pair to utilize somewhat different types of food, presumably facilitating more efficient foraging.

Of the other piciform families, the Indicatoridae are specialized in features, such as their thick skin, relating to their beeswax eating and brood parasitism. Other peculiarities, such as the graduated long tail of the lyre-tailed honey guide (*Melichneutes robustus*) and the presence of but nine primaries (there is usually some trace of a tenth primary feather) in the wings of most honey guides, are more difficult to interpret functionally.

The bill of the toucans, another specialized group, is something of an anomaly. Very large, with serrate edges and usually splashed with colour, it is peculiarly constructed within. Many crisscrossing, fine, bony fibres give it great strength for its size and light weight. The serrated bill may be effective in tearing open fruits, although the birds often feed on small fruits daintily picked, held at the tip of the bill, and thrown back into the mouth. Alternatively, the serrations may aid in securing insects or in plucking young birds out of nests. The colour patterns of the bill probably function as species-recognition signals or in some other way during displays. Yet the size of the bill seems greater than necessary for the serving of these functions. Studies of the feeding habits of the larger species may enable the solution of this point.

The toucan bill

EVOLUTION AND PALEONTOLOGY

Fossil species of the order Piciformes are almost unknown. Many avian fossils identified long ago are in need

of verification, including the early fossil "woodpeckers," some of which are now believed to belong in other orders. Fossil woodpeckers are now known only from the Pliocene Epoch (about 6,000,000 years ago). Except for a single specimen from the middle Miocene of Bavaria assigned to the Capitonidae, the other Recent families have no fossil records. A fossil family, Zygodactylidae, was erected in 1971 to receive three species of fossil piciform birds from the Miocene of western Europe.

The dearth of fossils leaves the evolution of existing groups open to speculation. If it is true that existing families of the order are only specialized remnants of a formerly more diverse assemblage, then the generalized groups (families or even suborders) that might have included common ancestors of some of the modern families are now extinct. Therefore, the evolution of the order must be interpreted from inferences based on the morphology of its existing families.

Little can be said about the puffbirds and jacamars. Both families are relatively uniform, and no existing species shows intermediacy or close resemblance between them. They must have evolved very early in the history of the order from a generalized, fly-catching ancestor. If the Galbulae and Pici are indeed closely related, their divergence from a common ancestor must have occurred long ago.

Ancestors of the woodpeckers and barbets

The families within the suborder Pici are definitely interrelated. The honey guides and barbets are morphologically very similar, as are the toucans and barbets. The barbets are rather diverse, foliage and branch-foraging piciform birds. An ancient species of barbet, not greatly unlike modern barbets, easily could have evolved into the ancestral toucan and another such species into the ancestral honey guide. Woodpeckers and barbets share an ancestor probably dating from an earlier period than either the barbet–toucan or the barbet–honey guide ancestor. The peculiar wrynecks, and even the piculets, may represent relicts of early evolutionary radiations along the line leading to woodpeckers. Modern woodpeckers have radiated into many groups, some specializing greatly for an arboreal wood-pecking existence, others remaining generalized, and still others becoming secondarily adapted to life on the ground.

CLASSIFICATION

Distinguishing taxonomic features. Various characteristics set the Piciformes apart from other orders and distinguish subgroups within this order. Among these features are the condition of the toes and their flexor tendons; the condition of the nostrils; the absence of basipterygoid processes at the base of the skull; the arrangement of the pelvic muscles; the size of the deltoid muscle; the condition of the syringeal muscles.

Annotated classification. The classification below is based generally upon those of a British ornithologist, P.R. Lowe, and an American, C.G. Sibley. The groupings are accepted generally among taxonomists, with disagreement centring about the taxonomic rank of the subcategories (*e.g.*, superfamily versus family) and whether or not to merge part of the order with the perching birds (Passeriformes). The family indicated by the dagger(†) is extinct.

ORDER PICIFORMES

Zygodactylous birds (toes arranged 2 in front and 2 behind); flexor tendons with a vinculum (a connecting strip), digits I, II and IV supplied by flexor hallucis, and flexor digitorum supplies digit III; nostrils impervious and holorhinal (not deeply cleft); eutaxic (5th secondary present), 9 to 11 primaries, 10 to 13 secondaries; 8 to 12 rectrices (tail feathers); aftershaft present; no down in adults; hole-nesting birds, laying all-white eggs. About 370 species.

Suborder Galbulae

Desmognathous (vomer bone of palate small or lacking; maxillopalatines connecting); nude oil gland; 2 carotid arteries; no gallbladder; 10 primaries, 10 to 12 secondaries, 10 to 12 rectrices. Catch food, usually insects, on wing; nest in ground or termite nest.

Family Galbulidae (jacamars)

Tropical and subtropical Central and South America. Bill long. Vomer lacking. Legs with long smooth scales behind and scutellate (small scales) in front. Moderately sized, long-tailed birds with iridescent plumage dominated by green. Feed by fly-catching for large insects. Nest in burrows excavated in banks.

†Family Zygodactylidae

Middle and upper Miocene of France and Bavaria; 3 species.

Family Bucconidae (puffbirds)

Tropical and subtropical Central and South America. Distinguished by a shorter, wider bill than jacamars, with a decurved tip. Vomer present. Leg scales scutellate in front and behind. Moderate or small-sized, dull-coloured birds with an unusually large head, plumage lax and noniridescent. Feed by fly-catching for insects and other arthropods and vertebrates as well. Nest in burrows in the ground, or in termite nests on the ground or in trees.

Suborder Pici

Rarely desmognathous, usually aegithognathous (vomer broad; maxillopalatines not connecting) or saurognathous (vomer a delicate rod; maxillopalatines reduced, not connecting); oil gland usually feathered; 9 to 11 primaries, 10 to 13 secondaries, 10 to 12 rectrices. Nest in tree cavity, rarely in ground. Food diverse, secured by various means, but rarely by fly-catching.

Family Capitonidae (barbets)

Tropical and subtropical New World, Africa, and Asia. Small to medium bill, not chisel-like; short, nonextensible tongue; nostrils opening onto bill surface without a fossa (depression); conspicuous bristles at base of bill. Small to medium, usually brightly coloured birds of stocky appearance. Food fruit or insects, often gleaned from tree bark or foliage. Nest hole in trees or termite nests, usually excavated by the birds.

Family Indicatoridae (honey guides)

Tropical and subtropical Africa and Asia. Small bill, not chisel-like; short, nonextensible tongue; nostrils opening onto bill in centres of large fossae, and without conspicuous bristles at base of bill. Small or medium, generally dull-coloured birds with smallish heads. Food beeswax and insects. Brood parasites, laying eggs in nests of other birds, especially piciform birds.

Family Ramphastidae (toucans)

Tropical to temperate Central and South America. Distinguished by a long and often deep and brightly coloured bill, with serrated edges. Tongue nonextensible but long and fringed. Medium to large, long-tailed and often brightly coloured birds. Food mainly fruit, also insects, even eggs and small birds. Nest in natural tree cavities or woodpecker holes, never excavated.

Family Picidae (woodpeckers, piculets, wrynecks)

Generally worldwide, except Australian region. Distinguished by a straight, usually chisel-like bill, long extensible tongue with elongated hyoid (tongue) apparatus, salivary glands secreting a sticky material that coats the tongue. Very small to large birds, often patterned in black, white, and bright colours. Forage on tree trunks and branches, rarely on the ground. Food chiefly insects, some fruit, rarely sap and seeds. Nest excavated (except wrynecks) in tree, post, cactus, or (rarely) in the ground.

Critical appraisal. Although recognizing the relationship of this order to perching birds (Passeriformes), most taxonomists prefer to keep the two groups separate as distinct orders, especially since clear evidence for relationship with a particular group of perching birds is lacking. No perching bird has the zygodactyl toe arrangement. The exact relationship between the suborders Galbulae and Pici has not been established. Lowe advocated relationship of the Galbulae with the Coraciiformes (kingfishers, bee-eaters, etc.), and the merger of the Pici in the Passeriformes. The suborder Pici is often considered to contain three superfamilies, for the toucans, the woodpeckers, and the barbets and honey guides, respectively. The above arrangement within the suborder Pici begins with the barbets, generally recognized as the least specialized group within the suborder and the most likely ancestral family. The honey guides are almost universally considered very closely related to barbets and are placed next. There is agreement that the specialized toucans, placed next, evolved from barbet-like ancestors. The exact relationship of the specialized woodpecker family with barbets is unknown, but it is likely either that woodpeckers evolved from barbets or that the two groups shared a common ancestor. No authority has suggested that woodpeckers are more closely related to toucans or

to honey guides than to barbets. Various authorities have arranged these families diversely, but nearly all place the woodpeckers last. No single arrangement is universally accepted.

BIBLIOGRAPHY. A.F. SKUTCH, "Life-History of the Black-chinned Jacamar," *Auk*, 54:135-146 (1937), is the only relatively complete study of a species of jacamar; "Life History Notes on Puff-Birds," *Wilson Bull.*, 60:81-97 (1948), although not complete on any species, contains most of the information known about the habits of puffbirds. S.D. RIPLEY, "The Barbets," *Auk*, 62:542-563 (1945), is chiefly a taxonomic, technical treatment, but summarizes the habits and characteristics of various groups; A.F. SKUTCH, "The Life-History of the Prong-Billed Barbet," *Auk*, 61:61-88 (1944), presents a fairly complete account of the habits of a barbet, one of few detailed accounts existing. H. FRIEDMANN, *The Honey-Guides* (1955), is a technical but readable account of the habits and relationships of honey guides. J. VAN TYNE, *The Life History of the Toucan* Ramphastos brevicarinatus (1929), provides a good, though technical, account of the habits of a large toucan; H.O. WAGNER, "Notes on the Life History of the Emerald Toucanet," *Wilson Bull.*, 56:65-76 (1944), is a general account of the habits of a small toucan; and A.F. SKUTCH, "Life History of the Blue-Throated Toucanet," *Wilson Bull.*, 56:133-151 (1944), a very readable study of another small toucan; "Life History of the Olivaceous Piculet and Related Forms," *Ibis*, 90:433-449 (1948), presents an interesting account of the habits of these little relatives of the woodpeckers. D. BLUME, "Uber die Lebensweise einiger Spechtarten (*Dendrocopos major, Picus viridis, Dryocopus martius*)," *J. Orn., Lpz.*, vol. 102 (supplement), in German, with English summary (1961), is the classic modern behavioral treatment of woodpeckers, covering three common European species (fairly technical). H. SIELMANN, *Das Jahr mit den Spechten* (1958; Eng. trans., *My Year with the Woodpeckers*, 1959) is a readable, accurate account of the habits of European woodpeckers. L. DE K. LAWRENCE, *A Comparative Life-History Study of Four Species of Woodpeckers* (1966), presents an accurate, not overly technical treatment of the habits of some North American species. A.C. BENT, *Life Histories of North American Woodpeckers* (1939), summarizes, at times anthropomorphically, the knowledge, through about 1938, of the habits of all North American woodpeckers. J.T. TANNER, *The Ivory-Billed Woodpecker* (1942), is an account of the habits and history of one of the largest woodpeckers, now nearly extinct on the North American continent.

(L.L.S.)

Pidgin

The term pidgin is applied to a number of varieties of speech that have grown out of English or other languages and that have been used in various parts of the world since the 17th century. Often termed "bastard jargons," "mongrel lingos," or the like, these tongues in fact are languages like any others and can be accurately delimited and described.

Definitions of lingua franca, pidgin, and creole. When a language is used as a means of communication between persons having no other language in common (*e.g.*, French in 18th-century diplomacy) it is a lingua franca. A lingua franca native to none of those using it and with a sharply reduced grammar and vocabulary is called a pidgin. (This definition of pidgin excludes both the broken English of a beginning learner and the skillful but non-native use of English in such countries as India.) When a whole speech community gives up its former language or languages and takes a pidgin as its mother tongue, the pidgin becomes a creole (is creolized).

Situations in which pidgins developed

Origins. A number of pidgins and creoles have arisen on the basis of various European languages. The first known pidgin, Lingua Franca, or "Westerners' language," of the medieval Levant and the Barbary Coast, was based chiefly on Italian. The American Indians first encountered by Englishmen in the 17th century were a tribe known as Pidians near the mouth of the Orinoco; the reduced language that emerged was termed Pidgin (= Pidian) English. Later in the same century, other varieties of Pidgin English grew up in China as a result of English commercial contacts and in Africa in connection with slave-trading activities. (Some authorities derive the word "pidgin" from a variation of English "business".) Establishment of plantation economies in the Caribbean area, with large groups of Negro slaves from different language backgrounds in West Africa, led to a number of pidgins based on English, French, Spanish, and Portuguese. Many have survived as creoles; *e.g.*, Gullah off the Sea Islands of South Carolina, the Negro English of the Antilles, and Sranantongo (formerly called Taki-Taki) in Surinam (formerly Dutch Guiana), all based on English; the French-based creoles of Louisiana, Haiti, and the Lesser Antilles; and the Papiamento of Curaçao, an outgrowth of Pidgin Spanish and Portuguese. Early contacts between settlers and natives led to the formation of pidgins in Australia and New Zealand, whereas the Pidgin English of the South Seas (called Beach-la-Mar) grew out of whaling, trading, and recruiting native labour. Pidgin English is extinct in New Zealand and the Caroline Islands and moribund in Australia but still flourishes in Melanesia (New Hebrides, Solomon Islands, New Guinea) and has become creolized in Hawaii. One variety, that of the Rabaul area (New Britain), has become the widespread and indispensable lingua franca of the Territory of Papua and New Guinea because of the official sanction given its use under German rule (1884–1914) and later Australian administrations.

Development and persistence of pidgins

Survival. Pidgin languages spring from the initial, non-intimate contacts between speakers of different languages, when quick comprehension is more highly valued than grammatical correctness or fine shades of meaning. As contacts grow closer, normally one group learns the other's language more fully, and pidgins survive the stages of initial contact only in special circumstances. Pidgins persist where a dominant group regards another as child-like or capable only of a simplified version of the "superior" language, as in the relations between Europeans and American Indians, West Africans, or South Sea natives. On plantations and in other situations where European masters were in permanent contact with native servants or labourers, pidgins served as status languages, as in New Guinea. Caste distinction, however, is not a necessary function of a pidgin; Russonorsk, for instance, was a reduced language used by Russians and Norwegians in the Arctic at the beginning of the 20th century. Chinese Pidgin English survived for three centuries and not only in master-servant relations; it also was in use between English merchants and Chinese dignitaries, primarily because each side desired to keep the other at arm's length. Slaves on Caribbean plantations, New Guinea natives in newly founded multilingual villages, and others who have come to live together with no language in common save a pidgin have used the pidgin as the customary language of the group. In such instances, the resultant creole has usually re-expanded its structure and vocabulary by borrowing from the language of a culturally dominant group; *e.g.*, Haitian Creole from French, Sranantongo and Papiamento from Dutch, and Melanesian Pidgin from English.

Spelling and sounds

Orthographies. In its original function as a lingua franca among unlettered folk, a pidgin language is a medium of purely oral communication, as also are creoles in their initial stages. Only afterward, and usually in connection with missionary or other educational programs, are spelling systems devised for pidgins or creoles. Speakers of European languages have often applied the orthographical conventions of their own languages, as when the Melanesian Pidgin sentence for "Why did you hit this policeman?" is written *Belong what name you fight 'im dis fellow police boy*? Such a spelling embodies all the inconsistencies of English orthography and is therefore difficult to learn; it distorts the structure of pidgin; and it confirms the naïve European or American in his belief that pidgin is only a ridiculous reduction of English. Those who have devised orthographies, for ease of learning, accuracy in representing linguistic structure, and emphasis on the independent status of the language, have used phonemically based systems. The most effective orthographies of this type use the letters available on typewriters or in printshops, but consistently and predictably. Thus, the Melanesian Pidgin sentence just quoted reads, in the officially recognized orthography: *Bilong wonem yu faitim dispela plisboi*? In the following discussion, forms are cited only in this type of transcription.

Phonology. The simplification which characterizes pidgin extends to all aspects of linguistic structure (sounds, forms, constructions) as well as vocabulary. In some varieties stress is automatically on the first syllable; *e.g.*, *bíkos* "because," *míshin* "machine." A minimum of five distinctive vowels is necessary, those represented in Latin or Italian pronunciations by *a* ("ah"), *e* ("eh"), *i* ("ee"), *o* ("oh"), *u* ("oo"), as in *antap* "up," *em* "he," *winim* "defeat," *kot* "coat," *tu* "also." The vowel sound *a* ("ah") combines with *i* ("ee") and *u* ("oo") in the basic diphthongs *ai* (English "i") and *au* ("ow"), as in *dai* "cease" and *nau* "now." Some, but not all, speakers make further distinctions—*e.g.*, between the *e* of *em* "he" and the *ei* ("ay") of *neim* "name." In almost all varieties of pidgin English, the two consonant sounds represented by English *th* have merged with *t* and *d* respectively: *saut* "south," *dispela* "this." Many speakers of Melanesian Pidgin merge *f* and *p* (in current official orthography, both are represented by *p*) and also merge *ch* and *sh* with *s*: *tumas* "very" (from English "too much"), *masin* "machine." Users of pidgin often carry over habits of sound production from their native languages; *e.g.*, many Melanesian languages have *mb*, *nd* as variants of *b*, *d* between vowels, and thus Melanesians often pronounce *tabak* "tobacco" as *tambak*, and *sidaun* "sit" as *sindaun*.

Morphology. Grammatical categories—such as number, gender, case, person, tense, mood, voice—are almost absent from pidgin and creole languages, as from many other languages of the world. Pidgin is not, however, "devoid of grammar," as is often asserted. Melanesian Pidgin, for example, has three inflected parts of speech: pronouns, adjectives, and verbs. The suffix *-pela* added to pronouns makes plurals, in *mi* ("I, me") versus *mipela* ("we, us") and *yu* ("you" singular) versus *yupela* ("you" plural). Another suffix, *-pela*, serves as a marker for adjectives of one syllable, demonstratives, indefinites, and numerals: *naispela* "pretty," *dispela* "this," *sampela* "some," *wanpela* "one." Verbs having a direct object (expressed or implied) take the suffix *-im*, and verbs without this suffix are intransitive or passive: *e.g.*, *rausim* "eject, remove" versus *raus* "be out, come out." Other parts of speech—nouns, prepositions, adverbs, conjunctions—are invariable but are distinguished by the types of combinations in which they occur. In other varieties of Pidgin English, the specific criteria for distinguishing classes of linguistic forms are different, but the basic structure is similar. Chinese Pidgin nouns and pronouns, for example, can take the locative suffix *-said*, in *doksaid* "at the dock (docks)," *maisaid* "at my house," and the verb suffix *-em* forms passive participles, as in *dis tri blong spoilem* "this tree is rotten."

Phrases and clauses

Syntax. The basic types of combination—phrases and clauses—found in pidgin are the same as those of English; here again, however, many details of syntax are different. Melanesian Pidgin nouns are followed not only by possessive phrases (*haus bilong mi* "house of me, my house") but also by modifying nouns (*haus pepa* "house [for] paper, office"), verbs (*haus kuk* "house [for] cooking, kitchen"), adverbs (*man nogud* "evil man," *nogud* being an adverb meaning "undesirably"), and clauses (*man mi lukim em* "the man I saw"). In Chinese Pidgin, pronouns simply precede nouns to indicate possession (*hi fes* "his face"), and relative position is shown by a noun preceding an adjective (*Ning-Po mo fa* "further than Ning Po"). With third person subjects, Melanesian Pidgin predicates are normally preceded by the predicate-marker *i-*: *ol i-singaut* "they call"; *balus i-no kamap yet* "the plane hasn't arrived yet." Melanesian Pidgin has the clause type called "equational" (also found in such languages as Russian and Hungarian) in which no verb is present: *dispela kaikai i-gudpela* "this food [is] good." Chinese Pidgin, on the other hand, has the copulative, or linking, verb *blong* "be" with nouns and adjectives in the predicate (*e.g.*, *yu fut blong plenti sor* "your foot is very sore") but uses no verb with an adverb in the predicate indicating location: *tumuchi dast tebal tapsaid* "a lot of dust [is] on the table."

Lexicon. Since vocabulary is restricted (about 700 words in Chinese Pidgin, 2,000 in Melanesian), each word necessarily has a greater range of meaning than its English counterpart. The central meaning of Melanesian Pidgin *sori* is not "sorry" but "emotionally moved," as shown by its extension to "sympathetic, grateful, glad"; similarly, *dai* means "cease" ("die" is *dai tru* "stop for good"); and *stap* is "be located; remain; continue." For many concepts, pidgin uses phrases rather than single words: with *skru* "screw; joint" are formed *skru bilong arm* "elbow," *skru bilong leg* "knee," etc. Some pidgin words belong to different parts of speech from their English counterparts; *e.g.*, the Melanesian Pidgin preposition *belong* "of" and the Chinese Pidgin copulative verb *blong* "be" from English "belong." Non-English meanings of pidgin words often reflect native social structure, as when *papa* means "uncle," since a boy's maternal uncle rather than his father (*papa tru*) is primarily responsible for his upbringing in New Guinea. Speakers of English are often naïvely amused or shocked by certain shifts of meaning, as when *ars* "buttocks" is extended to mean "bottom (of anything), foundation, reason, cause, source"; for example, *ars bilong diwai* "the base of the tree," or *God i-ars bilong olgeda samting* "God is the source of all things." In the context of native society and attitudes, however, these concepts are not taboo and no stigma attaches to the words or their use.

Vocabulary

Non-English vocabulary. The proportion of vocabulary elements in Pidgin English derived from non-English sources is small. Of the approximately 2,000 words in Melanesian Pidgin, not over 10 percent are of non-English origin. Of these, perhaps half are Melanesian (such as *kiau* "eggbomb," *diwai* "tree," *malolo* "rest," *balus* "pigeon, airplane"), and one quarter were borrowed from German, such as *mark* "shilling," *tais* "pond," *langsam* "slow," and *beten* "prayer." The remainder are from various languages—a few from Malay (such as *karabau* "water buffalo") and three from Romance sources: *save* "know," *pikinini* "child," and *pato* "duck." The percentage of non-English elements in Chinese Pidgin is even smaller.

Structural changes from English

Restructuring. In the structural reduction from English to pidgin, the main grammatical characteristics have been kept (the part-of-speech system, the dichotomy between subject and predicate, the use of phrases functioning as single parts of speech), though often with different identifying features. The various kinds of Pidgin English are definitely English and Indo-European, not (as is often said) "native languages spoken with English words." A more sophisticated version of this latter theory is that indigenous vocabulary is simply replaced with new words by "relexification," with indigenous grammatical habits continuing. However, when new functional elements (*e.g.*, pronouns, inflectional suffixes, syntactic patterns) are also taken over, the process is one of complete language-substitution, involving replacement of grammatical structure ("regrammaticalization") as well. Nevertheless there have been extensive carryovers from non-English structural patterns because speakers of native languages have translated their own constructions into pidgin, especially in the early stages of its formation. For instance, in Chinese a numeral modifying a noun must be accompanied by a special word indicating a measure of quantity, called a "numeral-classifier," as in *sān ge rén*, literally "three piece man." This type of combination was reflected in older Chinese Pidgin *tufela man* "two men," *forpisi naif* "four knives," etc., with *-fela* for animate objects, *-pisi* for inanimate objects. However, in modern Chinese Pidgin, *-fela* has not survived, and *-pisi* has lost its independent status and become simply a numeral-suffix, as in *tupisi man* "two men." Similarly, the presence of separate pronouns for "we (excluding the hearer)" and "we (including the hearer)" in Melanesian languages has led to the establishment in Melanesian Pidgin of a parallel contrast between *mipela* "we (but not you)" and *yumi* "we (including you)."

Modern function. With the coming of modern civilization and technology to New Guinea and similar areas, pidgin has proved indispensable in education and political life. Earlier opposition to pidgin—partly on puristic, partly on anticolonialistic grounds—has proved unfounded.

In New Guinea and the Solomons, and in many parts of West Africa, pidgin is no longer a status language or imposed on the people by white colonialists, but is the people's own lingua franca, indispensable for communication and easier to learn than English, which is both more complicated and more foreign to them. If skillfully used, pidgin can serve as both a medium of instruction and a bridge to English. In any case, it is clearly destined to remain as an increasingly useful lingua franca, with already manifest prospects of extensive creolization and resultant permanence as the native language of ever larger groups.

BIBLIOGRAPHY. An extensive discussion and bibliography of the problems of pidgins and creoles is given in R.A. HALL, JR., *Pidgin and Creole Languages* (1966).

(R.A.H.)

Piero della Francesca

One of the most important artists of the Italian Renaissance, Piero della Francesca made his chief contribution through an exploration of problems of perspective, both as an abstract mathematical science and as a specific method of painting. His scientific approach was tempered, however, by his sensitivity to colour, his genuine feeling for nature, and his superb sense of formal composition. Although Piero's restrained and disciplined art did not greatly influence his contemporaries, it has received widespread recognition in the 20th century.

Contributions to perspective

Formative period. The documented facts of Piero della Francesca's life, which are few, permit a reasonably accurate reconstruction of his career and interests but not an exact chronology of his surviving paintings. He was probably born in the Tuscan town of Borgo Sansepolcro (modern Sansepolcro) around 1420. His father, Benedetto de' Franceschi, was evidently a tanner and shoemaker, prosperous enough for his son to become well educated and literate in Latin. Nothing is known about Piero's early training as a painter, though it is assumed that he was instructed by local masters who had been influenced by Sienese art.

In 1439 Piero worked as an associate of Domenico Veneziano, who was then painting frescoes for the hospital of Sta. Maria Nuova in Florence, where the early Renaissance style was beginning to flourish. There he probably studied the statuary of Donatello and Luca Della Robbia, the buildings of Filippo Brunelleschi, and the paintings of Masaccio and Fra Angelico, and he might have read a theoretical treatise on painting by the Humanist and architect Leon Battista Alberti. Undoubtedly, he would have been directed to these luminaries by Domenico Veneziano, whose own works demonstrate a Renaissance emphasis on colour and light as elements of pictorial construction. It was Piero's contact with the early Renaissance art of Florence that provided the foundation of his own style.

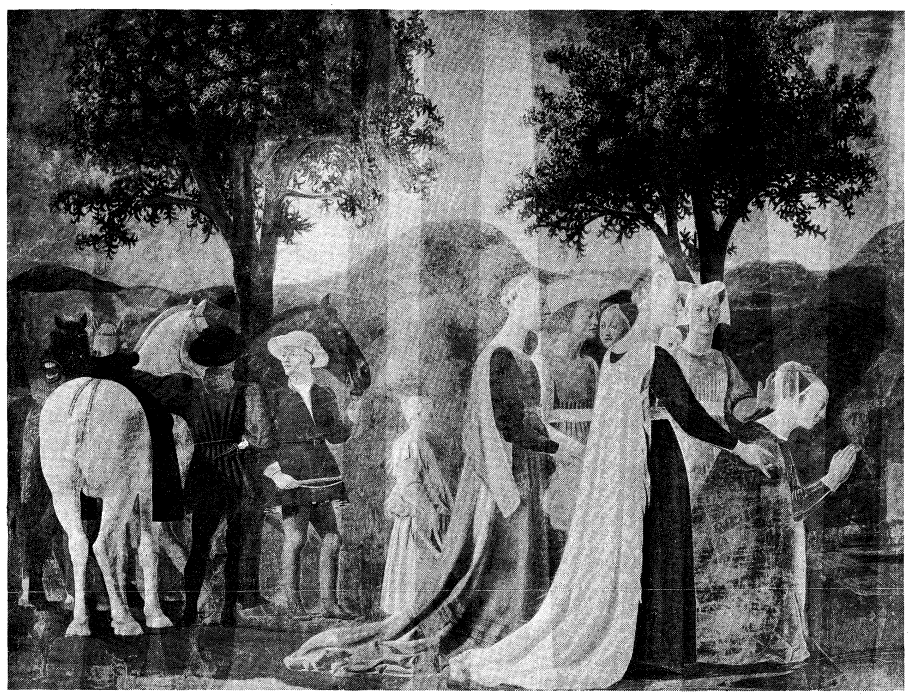
Back in Sansepolcro by 1442, Piero was elected to the town council. Three years later the Confraternità della Misericordia commissioned an altarpiece from him. This polyptych shows Piero's indebtedness to the Florentines Donatello and Masaccio, his fondness for geometric form, and the slowness and deliberation with which he habitually worked—for the altarpiece was not completed until 1462.

The Misericordia altarpiece

Periodic retreat to the provincial isolation of Sansepolcro seems to have been necessary for Piero's work. For the rest of his life he alternated between the calm of Sansepolcro and contact with the Humanistic life of the Renaissance in artistic and intellectual centres such as Ferrara and Rimini.

Around 1448 Piero probably worked in the service of Marchese Leonello d'Este in Ferrara, where he may have been influenced by northern Italian art. In 1451, at another northern Italian city, Rimini, he executed a splendidly heraldic fresco (*i.e.*, resembling a heraldic emblem in design) of "Sigismondo Malatesta Before St. Sigismund" in the Tempio Malatestiano, a memorial church that had been built according to the architectural designs of Alberti. Also to this early formative period before 1451 belongs "The Baptism of Christ."

Mature period. Piero della Francesca's mature style is revealed in frescoes painted in the choir of the church of S. Francesco at Arezzo. The decorations had been begun in 1447 by the elderly Bicci di Lorenzo, who died in 1452; Piero presumably was retained to complete the work shortly thereafter. The narrative cycle, depicting "The Legend of the True Cross," was completed by 1466. Its simplicity and clarity of structure, controlled use of perspective, and aura of serenity are all typical of Piero's art at its best. Contemporary with the Arezzo cycle are a fresco of the "Magdalen" in Arezzo Cathedral, the "Resurrection" in the Palazzo Comunale at Sansepolcro, and a "Madonna del Parto" in the chapel of the cemetery at Monterchi. In 1454 a burgher of Sansepolcro, Agnolo di Giovanni di Simone d'Angelo, commissioned an altarpiece for S. Agostino that Piero, characteristically, did not complete until 1469. The surviving panels of the altarpiece reveal Piero's interest of the creation of monumental human figures through the sculptural use of line and light.



In 1459 Piero was in Rome to paint frescoes (now destroyed) for Pope Pius II in the Vatican. "St. Luke" (Sta. Maria Maggiore), executed at the same time, was probably done by assistants in the studio he had established in Rome. More fruitful was Piero's long association with Count (later Duke) Federico da Montefeltro, whose highly cultured court was considered "the light of Italy." In the late 1450s, Piero painted the "Flagellation of Christ," originally in the sacristy of the Cathedral of Urbino; its lucid perspectival construction contrasts with treatment of the subject wherein Christ is relegated to the background while three unidentified figures dominate the foreground. The content of the picture has become the focus of modern academic controversy. A famous diptych portrait of Count Federico and his consort Battista Sforza (Uffizi, Florence), probably commemorates their marriage in 1465. The paintings show Piero's respect for visual fact in the unidealized features of the Count and in the enchanting landscape backgrounds, which also indicate that he had discovered Netherlandish painting. The reverse depicts the couple in a triumphal procession accompanied by the Virtues. The Count reappears as a kneeling donor in an altarpiece from S. Bernardino, Urbino (now in the Brera, Milan). He, the Madonna and her child, and accompanying saints are placed before the apse (semicircular choir) of a magnificent Albertian church. The painting may have been a memorial to Countess Battista, who died in childbirth, and it has been dated between 1472 and 1474. The altarpiece is one of the most accomplished Renaissance presentations of forms in space and exerted a decided influence on the development of monumental devotional paintings in northern Italian and Venetian art.

Association with Count Federico

Last years. The last two decades of Piero's life were spent in Sansepolcro, where paintings, now lost, were commissioned by local churches in 1474 and 1478. In 1480 Piero became prior of the Confraternità di San Bartolomeo. Among the few extant paintings from this period are the harmonious "Nativity," in London, the "Madonna" from the church at Sta. Maria delle Grazie near Senigallia, now in Urbino, and an awkwardly constructed altarpiece in Perugia, "Madonna with Child and Saints." The "Annunciation" from that altarpiece, however, indicates that Piero's interest in perspectival problems remained keen.

In his old age Piero seems to have abandoned painting in favour of more abstruse pursuits. Between 1474 and 1482 he wrote a treatise on painting, *De prospectiva pingendi* ("On Perspective in Painting"), dedicated to his patron, the Duke of Urbino. In its range of topics and method of organization, the book follows Alberti and the ancient Greek geometer Euclid. The principal manuscript, in Parma (Biblioteca Palatina), was handwritten by the artist himself and illuminated by him with diagrams on geometric, proportional, and perspectival problems. A second treatise, the *De quinque corporibus regularibus* ("On The Five Regular Bodies"), written some time after 1482, follows Plato and Pythagoras in dealing with the notion of perfect proportions. The manuscript,

Scientific writings

"The Queen of Sheba Worshipping the Wood of the True Cross," fresco by Piero della Francesca, 1452–66. In the church of S. Francesco, Arezzo, Italy.
Alinari

again illustrated by Piero, is in the Vatican Library. *Del abaco* ("On The Abacus," Laurentian Library, Florence) is a pamphlet on applied mathematics.

Piero's fascination with geometry and mathematics is a corollary of his own art; his manner of theoretical expression owes much to his mentor Alberti and is analogous to that of his younger contemporary, Leonardo da Vinci; the rigour and logic of the arguments, however, are unique to Piero.

A reliable local tradition of the 16th century claimed that Piero was blind in his last years. If true, this must have occurred only after 1490 because several autographs from that year survive. Moreover, his will of 1486 refers to the painter as aged but sound of mind and body. Piero della Francesca died in Sansepolcro on October 12, 1492.

Piero did not establish a lasting tradition in central Italy. Luca Signorelli and Perugino, who are presumed to be his most important pupils, followed the examples of other masters. Although Piero's reticent art had little influence on the experiments of his great Florentine contemporaries, he enjoyed great fame for his scientific contributions. In 1497 he was described as "the monarch of our times of painting and architecture," and the biographer Giorgio Vasari gave him high praise two generations later. In the 20th century, Piero's career has been reconstructed and his position re-evaluated, giving proper credit to both the science and the poetry of his art.

MAJOR WORKS

The following list includes nearly all of Piero's surviving works—panel paintings except where stated otherwise.

"The Baptism of Christ" (*c.* 1440–45; National Gallery, London); "Polyptych of the Misericordia" ("Madonna della Misericordia"; 1445–62; Palazzo Comunale, Sansepolcro); "St. Jerome Penitent" (1450; Staatliche Museen Preussischer Kulturbesitz, Berlin); "Sigismondo Malatesta Before St. Sigismund" (fresco, 1451; Tempio Malatestiano, Rimini); "The Legend of the True Cross" (fresco cycle, 1452–66; S. Francesco, Arezzo); panels from the altarpiece of S. Agostino in Sansepolcro (commissioned 1454, finished 1469): "St. Augustine" (Museu Nacional de Arte Antiga, Lisbon); "St. Michael" (National Gallery, London); "St. Simon the Apostle(?)" (Frick Collection, New York); "St. Nicholas of Tolentino" (Museo Poldi Pezzoli, Milan); and "Flagellation of Christ" (late 1450s; Galleria Nazionale delle Marche, Urbino); "Hercules" (*c.* 1460–66; Isabella Stewart Gardner Museum, Boston); "Resurrection" (fresco, *c.* 1463; Palazzo Comunale, Sansepolcro); "Portraits of Federico da Montefeltro, Duke of Urbino and of His Wife, Battista Sforza" (1465; Uffizi, Florence); "The Madonna with Child, Angels, Saints and Federico da Montefeltro, Duke of Urbino" (1470s; Brera, Milan); "Senigallia Madonna" (1470s; Galleria Nazionale delle Marche, Urbino); "Madonna with Child and Saints" (*c.* 1472–74; Galleria Nazionale dell' Umbria, Perugia); "The Nativity" (*c.* 1480; National Gallery, London).

BIBLIOGRAPHY. The earliest biography of the artist is VASARI'S "Life of Piero" (1550 and 1568), included in his *Lives of the Painters, Sculptors, and Architects,* trans. by A.B. HIND, vol. 2 (1963). ROBERTO LONGHI, *Piero della Francesca* (1927; 2nd ed., 1946; Eng. trans., 1930), is the definitive critical and scholarly monograph. A useful catalog of paintings is PIERO BIANCONI, *Tutta la pittura di Piero della Francesca,* 2nd ed. (1959; Eng. trans., *All the Paintings of Piero della Francesca,* 1962). KENNETH CLARK, *Piero della Francesca,* 2nd ed. rev. (1969), remains the standard account of the artist in English. It is a rare union of eloquence and scholarship.

(P.F.W.)

Pietism

Beginning as an influential religious reform movement in German Lutheranism in the 17th century, Pietism, with its emphasis on personal faith, spread to other countries and during the course of its history expanded its emphases to include a wide range of social and educational concerns.

NATURE AND SIGNIFICANCE

Evangelical Pietism was a religious movement historically set between two other movements, Protestant scholastic orthodoxy and rationalism (or the Enlightenment), standing in a partial cause-and-effect relationship to both. The 250 years that followed the Reformation (1575–1825) may be roughly divided into three periods in which a particular way of thinking and acting was dominant: 1575–1675, Protestant Scholasticism; 1675–1725, Evangelical Pietism; and 1725–1825, Rationalism.

Evangelical Pietism in some ways was a reaction to what James Hastings Nichols calls the "Secularization of the West." In other ways, it was a voice raised against secularism in the church. In protest to this development, Pietism sought to reassert the power of Christianity to change and shape men's lives and to revitalize the nature and role of the church. Though unsuccessful in its attempts to reverse the movement towards secularization,

it nevertheless released and directed powerful forces that in one form or another enjoyed revivals even into the 20th century.

General characteristics

It has been suggested that there are four general characteristics of Pietism. In the first place, Pietists were convinced that the essence of Christianity was an individually experienced inner change. In the second place, historic Pietism urged the idea of total commitment to the new life in Christ, a break with the old life and a disciplined practice of piety that would provide the opportunity for growth in personal holiness. Thirdly, Pietism gave renewed attention to the role of the Scriptures in Christianity. Not only was the Bible the source of Christian doctrines—this emphasis of Protestant Scholasticism was not to be denied—but it was the source of spiritual life. The Pietists at their best saw the Bible as the Holy Spirit's means for producing repentance, conversion, and the new life in Christ. The Bible mirrored one's sins, demanded the new birth, and guided the reborn in a new quality of life. At their worst, the Pietists used the Bible as a manual for a code morality and a magical book of oracles, a book to be opened at random for divine directives in decision making, a sort of biblical lottery. Fourthly, Pietism was inherently a protest movement; it was "protestant" in its opposition to the religious "establishment." This characteristic was evident in the stance of both Anglo-Saxon Puritanism and continental Pietism. Both forms of piety were in conflict with the representatives of the prevailing ecclesiastical, theological and religious status quo.

HISTORY

Thirty Years' War

Roots of Pietism. The Thirty Years' War (1618–48), though not a cause of Pietism, must be seen as one of the circumstances out of which the desire for renewal emerged. Although modern historical research has modified the exaggerated contemporary accounts of the war's effects, it is unquestioned that distress was wide-spread and profound. In some places the economy was reduced to barter, schools were closed, churches were burned, the sick and needy were forgotten. Not unexpectedly spiritual and moral deterioration accompanied the physical destruction. Drunkenness, sexual license, thievery, and greed were the despair of faithful pastors and earnest laymen.

During the war some notable signs of renewal began to appear. There was, for example, an awakened interest in the earlier devotional literature, some of which reflected the pious mysticism associated with such names as Johannes Tauler (*c.* 1300–61), Thomas à Kempis (*c.* 1380–1471), and other German, Dutch, and even Spanish authors. The mystical tradition had lived on into the Reformation century and found representatives in Kaspar Schwenckfeld (1489–1561), Valentin Weigel (1533–88), and Jakob Böhme (1575–1624). Although both Lutherans and Calvinists opposed these mystics, many of their religious and theological ideas were subsequently absorbed by orthodox theologians.

Influences from English Puritanism reached the Continent through the translation of works by Richard Baxter (1615–91), Lewis Bayly (1565–1631), and John Bunyan (1628–88). Most frequently read were Baxter's *A Call to the Unconverted*, Bayly's *The Practice of Piety*, and Bunyan's *Pilgrim's Progress*.

Dutch Pietism, influenced by the Englishman William Ames (1576–1633) whose *Medulla sacrae theologiae* (1623) and *De Conscientia* (1630) were basic textbooks for "federal theology" and Puritan casuistry in England and New England, was represented by Willem Teellinck, Johannes Cocceius, Gisbert Voetius, and Jodoeus van Lodensteyn. Impulses from these men became a part of the reform movement that had already appeared in German Lutheran circles and was to be known as "Reform Orthodoxy." Older historians of Pietism, notably Albrecht Ritschl, paid little or no attention to this reform phenomenon within Lutheranism. Ritschl saw Pietism as an alien mysticism uncongenial to the spirit of both Luther and the 17th-century theologians. More recent scholars (E. Benz, M. Schmidt, H. Leube, F.W. Kantzenbach) have exposed the Ritschlian prejudice and deepened the understanding of the role played by such representatives of "Reform Orthodoxy" as Johann Arndt (1555–1621) and Johann Dannhauer (1603–1666). The "pectoral heart theology" of these orthodox Lutherans found its highest expression and widest audience in the writings of Arndt, who, rather than Spener, can be called the "father of Pietism." His chief work, *True Christianity* (1610), was soon being read in countless homes. Although Arndt developed devotionally the *unio mystica* (mystical union), a 17th-century Lutheran doctrinal addition to the *ordo salutis* (order of salvation), the central Arndtian theme was not that of mystical union. Rather, he stressed repentance, regeneration, and the new life, and this was the very essence of Pietism.

Alongside the orthodox piety of the 17th century, one of the most significant contributions to spiritual renewal was to be found in the rich treasures of Lutheran hymnody. Examples from this classical period of church song are the works of Philipp Nicolai (1556–1608: "Wake, Awake" and "How Brightly Beams the Morning Star!"), Paul Gerhardt (1607–1676: "O Sacred Head Now Wounded," "O How Shall I Receive Thee," "Put Thou Thy Trust in God"); and Martin Rinkart (1586–1649, "Now Thank We All Our God").

Pietism in the 17th century. The various streams of concern for renewal converged in the life and work of Philipp Jakob Spener (1635–1705). In 1666, after having earned his theological doctorate at Strasbourg, he was called to be Senior of the clergy in Frankfurt am Main, where he was soon distressed by the conspicuous worldliness of the city. His sermons urged repentance and renewal, and each Sunday afternoon he held catechism classes for both children and adults. This led to efforts to revitalize the rite of confirmation, which, since the days of Martin Bucer, had been practiced in the Church of Hesse (Frankfurt).

Philipp Jakob Spener and the *collegia pietatis*

The origin of the so-called *collegia pietatis* (assembly of piety) has been traced to a sermon of 1669, in which Spener exhorted the laity to come together on Sunday afternoon not to drink, play cards, or gamble, as was the custom among Frankfurt's smart set, but to review the morning's sermon and to engage in devotional reading and conversation "about the divine mysteries." The next year, at the request of a few parishioners, such meetings were held each Sunday and Wednesday at Spener's home. Although some of the Frankfurt ministers, over whom Spener was superintendent, took a dim view of the *collegia pietatis*, the practice flourished and in time became a distinguishing feature of the movement. Those who attended the conventicles were soon called pietists.

In a relatively short time, Spener became a household name in Germany. Through his writings and extensive correspondence, especially with men in high places, Spener came to be called "the spiritual counsellor of all Germany." Most significant was the publication in 1675 of his *Pia Desideria* (*Pious Desires*). The book's first part reviewed the low estate of the church. He charged civil authorities, who since before the Peace of Augsburg (1555) were the *de jure* heads of the church, with irresponsible caesaropapism (doctrine of state control over church). He likewise flayed the clergy, many of whom were scandalous and self-seeking, often confusing assent to "true doctrine" with faith. The laymen, too, he claimed, were not blameless. Drunkenness must not be excused as a German peccadillo; prostitution, adultery, fornication, homosexuality, thievery, and assault must be rooted out lest people lose God's promised salvation. The second part of the work reminded readers of the possibility of better conditions in the church: ". . . we can have no doubt that God promised his church here on earth a better state than this." When the full number of heathen (Gentiles) had been brought in, God would even convert the Jews. But the fulfillment of these hopes was not to be achieved by sitting with folded hands. Part three, therefore, set forth a six-point reform program:

The six-point reform program

1. The Word of God—the whole Bible, not merely the pericopes (biblical texts used in a set sequence in worship services)—must be made known widely through public and private reading, group study (conventicles under the guidance of pastors), and family devotions.

2. There should be a reactivation of Luther's idea of the priesthood of believers, which included not only the "rights of the laity" but also responsibility toward one's fellowmen.
3. People should be taught that Christianity consists not only in knowing God's will but in doing it, especially by implementing love of the neighbour.
4. Religious controversies with unbelievers and heretics unfortunately may be necessary. If they cannot be avoided, they should be entered prayerfully and with love for those in error.
5. Theological education must be reformed. Professors must see that future pastors are not only theologically learned but spiritually committed.
6. Finally, preaching should have edification and the cultivation of inner piety as its goal.

Initially the *Pia Desideria* was received with enthusiasm and given wide acclaim. Some clergymen, however, felt threatened by the implications of the reform program's emphasis on the laity. Professors resented Spener's criticism of scholastic theology and advocacy of curricular reform. This was a brash intrusion on their own academic preserve. Spener's response was to emphasize more and more the *collegia pietatis*. Contrary to Spener's wishes, the conventicles in time became divisive and abrasively donatistic (referring to the Early Church heresy that held that priests must be morally righteous or the sacraments would not be valid), tending to develop into "little churches within the church" (*ecclesiolae in ecclesia*). In an attempt to stem separatism and other questionable attitudes, Spener wrote tracts that expounded the doctrines of the spiritual priesthood (1677) and ecclesiology (1684). In the latter, he argued that despite the faults of the church its teachings were not false, and separation from services and sacraments was wrong.

Spener's influence had spread widely by 1686. In many circles, not least among the nobility, he was praised and imitated. In other quarters, his emphases produced vigorous and, in many instances, unjust criticism. Weary of opposition and controversies, Spener accepted a call to be the court chaplain in Dresden, where he was soon disillusioned by the unresponsiveness and vulgarity of the court and the hostility of the pastors in this stronghold of orthodoxy. Two items of special significance from the Dresden period should be noted: (1) Here he wrote his *Impediments to Theological Study* (1690), which was hardly calculated to win friends at the famous Saxon University of Leipzig; (2) here, too, he made the acquaintance of a young instructor, August Hermann Francke (1663–1727), who was to become in a sense Spener's successor and the second great leader of Pietism.

By 1691 Spener welcomed a call from the elector of Brandenburg, who soon brought in other Pietists, opened his domain to persecuted French Huguenots, and made Berlin a strong spiritual centre, thus taking religious leadership away from rival Saxony. All of this was enhanced by the founding of a new university at Halle (1694), the theological faculty of which became, with Spener's and Francke's influence, the academic center of Pietism.

Spener's years in Berlin were not without bitterness. The conflict between Orthodoxists and Pietists had mounted to a high pitch. The theological faculty at Wittenberg, for example, charged Spener with 284 deviations and prayed that God would save "our Lutheran Zion" from the ravages of pietistic heresies.

During his last years, Spener collected and edited several volumes of his papers (*Theologische Bedencken*), continued his friendship with and support of Francke at Halle, and, significantly, served as a sponsor at the baptism of Nikolaus von Zinzendorf, who was to lead evangelical Pietism in a new direction. Spener died on February 5, 1705.

Meanwhile, Francke became the central figure of Pietism. During his student years at Leipzig, he had been engaged in group Bible study, being one of the organizers of a *collegium philobiblicum* (assembly of bible lovers), dedicated largely to the scholarly rather than devotional approach to the Scriptures. A religious experience in 1687 led Francke to make conversion—characterized by a severe penitential struggle and commitment to holy living—the norm for distinguishing the true Christians from unbelievers. Francke's Pietism, going beyond the spirit of Spener, came to stress a legalistic and ascetic way of life. Under Francke's leadership (he became professor in 1698), Halle became famous not only for its university but for the many "Halle institutions" that sprang up: an orphan asylum with affiliated schools, a publishing house and Bible institute, a Collegium Orientale Theologicum (Oriental College of Theology) for linguistic training of missionaries, and an infirmary that the medical faculty welcomed as compensation for the university's lack of a clinic. All of this gave to Halle and Franckean Pietism an energetic and activist character.

Pietism in the 18th century. *Central Europe and England.* One of Francke's institutions in Halle was the *paedagogium* (1698), which was intended for the education of boys whose well-to-do parents lived at a distance. Nikolaus Ludwig Count von Zinzendorf (1700–1760) attended the Halle boarding school from 1710 to 1716. Having been drawn earlier to Spener, his godfather, Zinzendorf was now greatly stimulated by Francke. As a 14-year-old lad he organized the "Order of the Grain of Mustard Seed," whose youthful members pledged themselves to reach out in ever-expanding love to "the whole human race."

By 1721 Zinzendorf had settled down on his estate (Berthelsdorf) near the Bohemian border, where he brought believers together in a nonseparatist *ecclesiola in ecclesia,* which denied the Halle Pietists' demand for penitential remorse as a mark of "heart religion." Zinzendorf formulated the slogan that came to play such a great role in the history of revivals: "Come as you are. It is only necessary to believe in the atonement of Christ."

A small band of Moravian exiles took refuge on his estate in 1722. Looking upon this event as an opportunity to realize his cherished project of "the Mustard Seed," he gave up his position in the Saxon civil service and welcomed other Moravian refugees. They, like Zinzendorf, had been primarily influenced by Pietism and had only a hazy idea that their ancestors were Hussites. Zinzendorf soon organized the colony, now called Herrnhut, into the community of the Bohemian Brethren. They were not to separate from the Lutheran Church of Saxony. They would attend services in the village church at Berthelsdorf and call upon the local pastor for ministerial acts; but they were to look upon themselves as "the salt" of the earth, an *ecclesiola* from which "heart religion" would be disseminated throughout Christendom. Under Zinzendorf's "superintendency" the Herrnhut Brethren became more and more a distinct church, the reborn Moravian Church, or Unitas Fratrum. Although Zinzendorf received a license as a minister in 1734 and three years later was consecrated bishop, he left Herrnhut under pressure in 1736, travelling in western Germany, England, and America. The chief centres of his missionary work in Pennsylvania were Germantown and Bethlehem. He returned to Herrnhut in 1749 and presided over the Church of the Brethren until his death (1760).

Herrnhut

The influence of the Moravians on the Evangelical Awakening in England was significant. By 1775 there were 15 Moravian congregations in England, and it was in one of these that John Wesley, founder of Methodism, had his famous "Aldersgate Street Experience" (1738) as he was listening to a Moravian preacher reading Luther's *Preface to the Romans*:

> . . . while he was describing the change which God works in the heart through faith in Christ, I felt my heart strangely warmed. I felt that I did trust in Christ . . .; and an assurance was given me that he had taken away *my* sins . . . ."

He allied himself with the Moravian society in Fetter Lane, London, and the same year journeyed to Hernnhut to learn at first hand about the people to whom he owed so much. Although Wesley later parted from the Moravians, his initial experience of saving grace in the company of the Brethren shaped the wide-reaching evangelical movement that associated the names of the two Wesleys (John and Charles) and George Whitefield.

Germany. A slightly different type of Pietism appeared in Württemberg, where Spener had established relations

with Swabian churchmen. Avoiding the extremes of Franckean Pietism, it accepted conventicles but opposed all temptation to separatism and sought an evangelical, as opposed to legalistic, sanctification of life in the congregations. Interested in academic theology and a scholarly study of the Scriptures, the leader of Württemberg Pietism, Johann Albrecht Bengel (1687–1752), was a pioneer in textual criticism and biblical, in contradistinction to systematic, theology. His *Gnomon Novi Testamenti* ("Interpretation of the New Testament," 1752) was widely distributed in the Lutheran and English world and gave a fresh approach to the Bible by its emphasis on *Heilsgeschichte* (the history of salvation).

Radical Pietism

Radical Pietism always lurked beneath the surface of Evangelical Pietism. The appeal to mystical and emotional experiences, the exaltation of psychic phenomena as evidences of the activity of the Holy Spirit, and the depiction of the church as "unholy Babylon" were common characteristics of Radical Pietism. Difficult to trace historically because of a tendency to flare up spontaneously, it can nevertheless be divided into two main forms. The first was a fanatic sectarianism in which ecstatic and visionary elements were dominant. A favourite doctrine was chiliasm (referring to the thousand-year reign of Christ at the end of history), in which the *apocatastasis* (the eventual salvation of all men) played a large role. Somewhat different but still under the first rubric were the "inspired congregations," whose inspiration was expressed in convulsive physical phenomena accompanied with *glossolalia*, "speaking in tongues." The second main form was "separatistic" or "nonchurch" and emphasized the "inner light." Because the "inner light" and human reason were often identified, the advocates of "Spiritual Pietism" tended to move toward Rationalism. Chief among these men were Gottfried Arnold (1666–1714), Johann Konrad Dippel (1673–1734), and Gerhard Tersteegen (1697–1769).

18th-century Pietism in Scandinavia, Russia, and America. *Denmark/Norway.* As in Germany, the age of orthodoxy in the Dano-Norwegian kingdom had its deeply spiritual side, which came to expression in men like Bishop Jens Dinesen Jersin (died 1632) and Holger Rosenkrantz (died 1642), both of whom taught the necessity of pious living. Also, as in Germany, the "reform orthodoxy" was evidenced in hymns, especially those of Thomas Kingo (1634–1703). Pietism, as such, arrived in Copenhagen at the turn of the century and was welcomed, strangely enough, by the unpietistic King Frederick IV. It was during his reign (1699–1730) that the royal chaplain, the German R.J. Lütkens, was able to give status to pietistic pastors and to win the King for the cause of missions in India. The King initiated a search for missionaries and, finding none in his domain (Bishop Bornemann causticalally described Danish students as being solely interested in luxury, drink, indolence, and harlotry), he turned to Germany, where Lütken's contacts brought about the connection with two young Halle-trained Pietists, Bartholomäus Ziegenbalg (1683–1719) and Heinrich Plütschau (1678–1747). Ordained at Copenhagen in 1705, these men became the founders of the famous Tamil mission at Tranquebar, India, and stimulated foreign mission interest among the Halle Pietists. To this period belongs the Christian work among the semipagan Lapps in northern Norway carried on by the Norwegian Pietist, Thomas von Westen. Another Norwegian, Hans Egede, became the pioneer missionary in Greenland. King Christian VI, known as the "Pietist on the throne," gave support to numerous pietistic causes: an orphan home and schools modelled after Halle, a missionary institute, and even conventicles (the 1741 decree permitted them only under pastoral leadership). The name of Erik Pontoppidan, court preacher at Copenhagen and later bishop of Bergen in Norway, was to have enduring significance largely because of his excellent exposition of Luther's catechism, entitled *Truth unto Godliness.* Virtually a national reader for many generations, especially in Norway, this "layman's dogmatics" combined Law and Gospel, orthodoxy and Pietism, in such a manner that its power persisted into 20th-century American Lutheranism.

Pietistic missionary activity

Comparable to Pontoppidan's range of influence was that of Hans Adolf Brorson, bishop of Ribe, a lyric poet whose hymns of the incarnation ("Thy little ones, dear Lord are we, and come thy lowly bed to see") and the ultimate glory ("Behold a host") stand out in the hymnody of Danish-Norwegian Christendom.

Sweden, Finland, and Russia. Original royal opposition to Pietism in Sweden was softened only after Francke personally visited King Charles XII on his Russian campaign. Meanwhile, Swedish students at Halle returned to their homeland imbued with Francke's ideas and practices. Following the defeat of Charles XII at Poltava in Russia (1709), thousands of Swedish prisoners of war were quartered in Siberia. Many sought comfort in religion under the leadership of a Swedish Pietist, J. Cederhielm. Correspondence with Halle and the writings of Francke and Arndt produced a strong pietistic movement in the prison camps from which only 5,000 of the original 30,000 captives were able to return to Sweden by 1724. The zealous returnees carried their pietistic convictions back to Swedish parishes. In a short time, both church and government looked upon Pietism as a threat to national unity. The result was the Conventicle Act of 1726, which retarded Pietism and held Swedish church life to conventional forms for the next century. Finns as well as Swedes had followed Charles XII to defeat. Those who returned from Russia were the apostles of a religious awakening. For a time the literature of Pietism was influential, but due to the Conventicle Act of 1726 (Finland was partially a Swedish domain), its role was somewhat limited.

Meanwhile, Pietism came to the Russian-occupied Baltic states where it experienced greater freedom than under the Swedes. In the foreign quarter of Moscow, inhabited mainly by German Lutherans, the work of Francke reached out to influence Peter the Great and some of his governmental ministers. Impulses from the 18th-century activity may have prepared the ground for 19th-century "Stundism," (devotion or Bible reading "hour") which was brought by Württembergian settlers to southern Russia.

America. In 1703 three pastors from New Sweden on the Delaware River ordained Justus Falckner, a Halle-educated Pietist, for service among the Dutch Lutherans in New York. Most of the Dutch Lutherans were of Pietist orientation, as were the many Germans from the Rhineland and Southern German valleys. These "Palatines," who settled in New York and Pennsylvania, and the famous refugee Salzburgers, who settled in Georgia, came via London where the Pietist court chaplain M. Ziegenhagen assisted them on their way to America. Accompanying the Salzburgers were two Francke-selected pastors, J.M. Boltzius and I.C. Gronau, who naturally shaped the spiritual life of the Georgia settlement. Zinzendorf's visit to America (1741–42) led to a clash between his type of Pietism and that of Halle, represented by Henry Melchior Mühlenberg (1711–87). The victory belonged to Mühlenberg, who became the organizing genius and spiritual leader, later called "The Patriarch of American Lutheranism." Meanwhile, the Great Awakening, especially in its "Middle Colony" manifestation among the Dutch Reformed, appeared among the Scottish-Irish Presbyterians. Here the revivals inspired by William Tennent (*c.* 1673–1745) prepared the soil for George Whitefield (1714–70), whose name, together with that of Jonathan Edwards (1703–58), was associated with the final phase of the Great Awakening.

Pietism in the 19th century. *Germany.* Before and for some time after 1815 an awakening occurred in Germany as a reaction against the Enlightenment. In philosophy, literature, and music the reaction found expression in German Idealism and Romanticism. In the congregations the reaction took the form of Pietism. Pietistic orthodoxism and biblicism continued to live on among "the quiet in the land." Some solitary thinkers with pronounced religious interests sought to preserve and awaken genuine Christianity and to point out the banality of the Enlightenment. Among these were Johann Georg Hamann (1730–88), a theologian who understood Luther's *theologia crucis* (theology of the cross) better than any 18th-

century person and a thinker given to brilliant paradoxical thought. Matthias Claudius (1740–1815) was another representative of the antirationalist mood of the dawn of the 19th century. Johann Friedrich Oberlin (1740–1826) mixed his biblicistic piety with a concern for social missions. J.A. Urlsperger (1728–1806) sought to promote piety by organizing the Christentumsgesellschaft ("A Society for Christianity"), the German counterpart of the British "Society for Promoting Christian Knowledge." Out of it grew the Basel Mission Society. G.C. Storr (1746–1804) and J.F. Flatt (1759–1821) represented the "Old Tübingen school" of biblical Supernaturalism.

Revival of Pietism

It was in such a climate that the revival of Pietism occurred. Many of the people involved in the awakening were not interested, at least in the beginning, in reviving former confessional differences. They were satisfied with being known as "Christians" or "evangelicals." But in time some of these new Pietists, influenced by Romanticism's admiration for the past, began to assert the need of linking their pietistic interests with the traditional confessional heritage of the church. True religion (Pietism), they argued, is really Lutheranism properly understood. Thus beginning with a renewal of heart religion (Pietism), they came to a neoconfessionalism. There were three discernible "schools" in this revival of Lutheranism. "The Repristination Theology" (*i.e.*, restoration of earlier norms) made the 17th-century orthodoxy normative for the interpretation of Luther and the confessions, and it fought the rising historical-critical approach to the Bible by affirming the verbal inspiration and inerrancy of the original manuscripts (autographs) of the scriptures. Ernst Wilhelm Hengstenberg (1802–69) was the champion of this school of "Old Lutherans." A second group, the Neo-Lutherans, felt that the Repristinationists, though not basically wrong, needed correction and improvement especially in their view of the church, the ministry, and the sacraments. These Neo-Lutherans ("high churchmen"), influenced by Romanticism, were the German counterpart of the Oxford movement in England. Chief exponents were August Vilmar (1800–68) and Wilhelm Löhe (1808–72), the latter having strong influence in American Lutheranism. The third group, the so-called Erlangen school, rejected Rationalism, Repristination, and Romantic catholicizing of the church. They asserted that theology must see the relationship of faith to history, thus providing a new setting for understanding both the Bible and the Lutheran confessions. Chief representatives were Gottfried Thomasius (1802–75) and J.C.K. von Hofmann (1810–77).

Denmark. The Spener-Francke tradition of Pietism survived the age of Rationalism in Denmark by being nurtured here and there by pietistic pastors and congregations, especially in rural Jutland. The rebirth of Danish spiritual life and the conquest of rationalism in the first half of the 19th century, however, came not from Pietism but from the religious and cultural impact of N.F.S. Grundtvig (1783–1872) and Søren Kierkegaard (1813–55). Both of these men were profoundly religious and at times may have sounded like Pietists, but neither had any essential sympathy for Pietism. Grundtvig was in fact definitely opposed to Pietism, while Kierkegaard, though stressing "the individual" and his existential involvement in the truth, found little time for Pietism as such. The actual renaissance of Pietism in Denmark was associated with the Inner Mission Society (established in the 1850s) and its leader Vilhelm Beck (1829–1901), who, deeply influenced by Kierkegaard's *Øieblikket* ("The Present Moment"), brought some of his emphases into the church that Kierkegaard so bitterly criticized.

Norway. Nineteenth-century Pietism in Norway may be seen in three episodes: (1) the life and work of Hans Nielsen Hauge (1771–1824), (2) the pietistic confessionalism of Gisle Johnson (1822–94), and (3) the conflict over liberal theology (*c.* 1875–1908). Hauge was a layman theologically untrained but at home in the Bible, Luther's catechism, and the works of Arndt, Pontoppidan, and Kingo. Converted in 1796, his sense of mission eventually produced a national revival. Hauge and Haugeanism, though sharply critical of the established church, became an example of conventicle Christianity within the framework of the state church. Arrested no less than ten times for violation of the long-neglected Conventicle Act of 1741, Hauge's final imprisonment lasted from 1804 to 1811. Although he thought of himself solely as a religious awakener, Hauge and his movement contributed to the socio-political revival in Norway through the influence of laymen who had been trained in an activistic type of Pietism. A characteristic feature of Haugeanism was its concept of a person's daily work as a divine calling. Imitating Hauge's example, many Haugeans became successful business men, shippers, and farmers. The second figure in Norwegian Pietism gave his name to a revival that occurred in the 1850s, the Johnsonian Awakening. Influenced by the German "Erlangen school," Johnson was joined on the theological faculty in Christiania (Oslo) by a staunch Hengstenbergian Repristinationist, C.P. Caspari, a converted German Jew. The Johnsonian Awakening, unlike the lay-oriented Haugean movement, was consciously directed toward pastors and church leaders. Like the Beckian revival in Denmark, it produced powerful lay organizations that promoted inner and foreign missions. The third phase of Norwegian Pietism was manifested in the conflict over theological liberalism during the last quarter of the 19th century. Increasingly, the university-oriented Norwegian intellectuals—clergy and lay—were drawn toward liberal positivism, historical relativism, and progressive optimism, the whole structure of which was based on natural science and Biblical criticism. The orthodox Pietists of the Johnsonian school led the attack on the liberal professors now dominating the theological faculty. By the turn of the century the idea of establishing a faculty independent of state control and supported by the faithful in the congregations was born. This was realized in 1908 when the Menighetsfakultetet (The Congregational Faculty) was created.

Sweden. Like Norway, Sweden was visited with a variety of pietistic movements in the 19th century. The first was militant revivalism in northern Sweden, where Moravian Herrnhuters interested in Lapland missions merged their enthusiasms with those of pietistic Lutherans and together were called the "Old Pietists." Lay conventicles, encouraged by some clergymen, emphasized devotional reading of the liturgy, the Bible, and Luther's and Arndt's sermons. The movement, called the Läsare ("The Readers"), soon came under attack, resulting in the emigration of a group under Erik Jansson to Bishop Hill, Illinois. A second revival in the first half of the century was associated with the name of Henrik Schartau (1757–1825), who was pastor and dean at Lund, Sweden. What distinguished Schartauism as a revival movement was its strong churchly character. It was catechetical, liturgical, orthodox, and anticonventicle. Yet its profound piety produced an awakening in southwest Sweden, the results of which remained into the 20th century. The third revival occurred toward the middle of the century under the leadership of Carl Olof Rosenius (1816–68), a lay preacher strongly influenced by George Scott, an English Methodist evangelist. Rosenian Pietism, or the "New Evangelism," as it was called, made much of "objective justification," appealing to sinners to "Come as you are." Again, as in Denmark and Norway, a healthy inner mission society was one of the fruits of revival, the National Missionary Society. Following the death of Rosenius, leadership came into the hands of Paul Peter Waldenström (1838–1917), whose subjective views of the atonement led to the formation of the Swedish Mission Covenant Church (1878).

Schartauism

Generally speaking, the two Swedish universities, Lund and Uppsala, represented high and low churchism respectively. The latter viewpoint influenced Parliament to allow the Church of Sweden its own Convocation (1865) with lay representation.

America. The great 19th-century German and Scandinavian immigration began in 1839–40. The first Germans to arrive were "Old Lutherans" from Prussia whose original pietistic impulses had given way to a high-church confessionalism of the Hengstenbergian and "New Lutheranism" line. Colonies of about 1,000 "Old Lutherans"

under J.A.A. Grabau settled in the vicinity of Buffalo and others in and around Milwaukee. They were the forerunners of the Buffalo Synod (1845). Saxon immigrants, under Martin Stephan and C.F.W. Walther likewise arrived in 1839 and settled near St. Louis to become by 1847 the Missouri Synod. Stephan had practiced conventicle Pietism in Germany and had influenced Walther and others in this direction. Walther and other Missouri Synod leaders later moved to a staunch confessionalism that left little room for conventional Pietism. The Norwegians, who also arrived in 1839, were almost entirely of the Haugean persuasion, one of their first leaders, Elling Eielsen (1804–83), being an extremely legalistic lay follower of Hauge. Most of the subsequent waves of immigrants were sympathetic to Pietism, the laity inclining towards Haugeanism, the clergy towards Johnsonianism. The Danish immigrants, fewer in number, eventually split over the question of Pietism. The anti-Pietists, or Grundvigians, were known as "the Happy Danes," while the pietistic, inner-mission disciples of Beck were denominated "the Sad Danes." The Swedish-Americans reflected "*Läsare*" and Rosenian Pietism initially, but after the Evangelical Lutheran Augustana Synod was formed in 1860 it soon began to evidence a churchly type of Pietism that perhaps could be traced to Schartauism.

Pietism in the 20th century. In central Europe Pietism in the 20th century was most prominent in Württemberg, where the churchly Pietism of Bengel persisted; in Norway, where the Haugean and Johnsonian lay-mission organizations continued to challenge and even to denigrate the national church; and in Finland, where the extreme Lastaedian Pietism (emphasizing lay confession and absolution) and the *glossalalia*-inclined followers of Ruotsalainen were tempered by the Swedish Pietism of Rosenius.

In America, Lutheran Pietism survived primarily among the descendants of 19th-century Scandinavian immigrants, especially in the Evangelical Lutheran Church (Norwegian), Augustana Synod (Swedish), United Evangelical Lutheran Church (Danish), and the Suomi Synod (Finnish).

THEOLOGY, PRACTICES, AND INSTITUTIONS

Although evangelical Pietism looked upon itself primarily as a practical reform rather than as a theological movement, certain theological positions differing from traditional orthodoxy were implicit in its teachings. In the first place, Pietism emphasized regeneration rather than justification by grace through faith. Pietists obviously did not deny the doctrine of justification but felt that overemphasis on its objective (forensic) character led to a weakening of the New Testament teaching concerning new birth and new life. Unconsciously, perhaps, this involved the Pietists in an alteration of basic theological categories. The Reformers, if not the later orthodox dogmaticians whom the Pietists were reacting against, looked upon justification in dynamic, existential, and relational terms. Justification was concerned with man's status, his existence, his relation to God. The Pietists, though assuming this, now shifted the focus from "existence" to "essence." Regeneration meant a change in being; man was a new creation. Theologically, this meant a move from the existential and relational category of justification to the ontological category of regeneration, the "new being" in Christ. This, in turn, modified the concept of the church. The church was no longer the congregation of those called (*ecclesia*) by Word and sacraments, but the association of the regenerate, the new beings. Thus the church, in the true sense, consisted of the *ecclesiola in ecclesia*, the kernels within the husks of corruption and decay. Within the *ecclesiola* of the reborn, each individual under the eye of his fellow Pietists was to occupy himself with growth in holiness, denial of worldiness, and conformity to the indwelling Christ. This "edification of the inner man" (Spener's phrase) led to a preoccupation with individualism, whereas the New Testament concept of edification was invariably related to the upbuilding of the congregation.

Emphases

The chief instrument for edification was the reading of the Bible. Pietists believed that in it one saw mirrored the destructive power of sin and death and the possibility of victory over the forces of evil by daily repentance and faith, prayer, and a life of love and obedience to the will of God. Despite the appearance of joyless and legalistic asceticism in some pietistic quarters, the concern for personal and social ethics was cultivated by this devotional use of the Bible. The Pietistic social concern, seen in the vast network of institutions of mercy, schools, Bible societies, and mission societies, was an unprecedented breakthrough. Some of the inner-mission institutions (for example, Bethel bei Bielefeld in Westphalia, Germany), even in the 20th century, are unique in both Protestant and Catholic institutional ministries to men's needs. Apart from some questionable attitudes that attended an unhistorical biblicism, Pietism made the Bible a more popular book than it had ever been before. Closely related to this was the development of a new theological discipline, biblical theology.

INFLUENCE OF PIETISM TODAY

In the religious world of the 20th century, one of the outstanding features of the post-World War I era was the emergence of biblical theology. In part, this new interest can be traced back to the pietistic preference for the study of Scripture rather than dogmatics and ecclesiastical tradition. It led to an intense scholarly attention to the biblical texts in the original Greek and Hebrew, an activity closely akin to the biblical interests of the Reformation age. This, in turn (to the dismay of the Pietists), led to the historical ("higher") criticism, which seemed destructive of biblical authority. But by the 20th century this same biblical concern had found a new approach, the theological understanding of the Scripture, which introduced the church again to what Karl Barth (1886–1968), the Swiss theologian who was the founder of what is called Neo-Orthodoxy, called "the strange new world of the Bible."

In the area of interconfessional cooperation, the Pietists were in large measure the pioneers of modern ecumenism. Men like Spener, and more especially von Zinzendorf, were far less interested in doctrinal differences that separated Christians than in the confession of Christ that united them. Thus a great simplification in dogmatics took place. Orthodox theology had no salvatory power: Christ alone was Saviour. It might be possible for one to err theologically and yet possess genuine trust (faith) in Christ, and where such faith existed, unitive rather than divisive forces were present. This was echoed with great clarity by Anders Nygren at the Lund Faith and Order Conference (1952): the age of "comparative ecclesiology" has come to an end; the starting point of ecumenism is Christological, that is, the commonality of faith in Jesus Christ.

Ecumenism

In the third place, Pietism reached into the 20th century by its destruction of the notion that one can be a Christian by being religious. "Religionless Christianity" had definite pietistic roots. Adherence to "religion" or the practice of religiosity was as abhorrent to Pietists as to Kierkegaard or Dietrich Bonhoeffer (1906–45), the German Lutheran theologian martyred by the Nazis. The imperative of personal decision and the involvement of the whole man was a tenet that did not originate in the last third of the 20th century.

Although the forms in which Pietism expressed itself in the 18th and 19th centuries will hardly be repristinated in the contemporary world, certain emphases of evangelical Pietism can be expected to reappear perennially because they grow out of what is believed to be the biblical witness to God's redemptive action in history. Among these are (1) the emphasis on religion as personal and experiential; (2) the call for total commitment; (3) the continuing reverence for the Bible as God's address to men; and (4) the noble discontent with, and willingness to protest against, forms without content, bodies without life, men and institutions without soul.

Piezoelectric Devices

Piezoelectric devices, widely used for such purposes as converting sound into electrical impulses in sound reproduction, are based on the fact that certain crystals, when deformed by pressure, generate an electrical charge. The phenomenon is due to the electrically polar nature of the crystals; that is, to the fact that they contain positively and negatively charged ions, which separate when the crystals are subjected to stress. About two-thirds of the major classes of crystals can be made to yield an electric charge by the application of stress (Greek *piezo*, "press"). Asymmetrical crystals in particular have this property; the more symmetrical the crystal, the greater amount of stress is required to produce a charge.

Conversely, if an electric charge is impressed on such a crystal, it yields mechanical motion. One of the simplest crystals, zinc sulfide, illustrates how separation comes about. The unit cell shown in Figure 1 consists of two types of atoms: zinc atoms (dark circles), with a positive

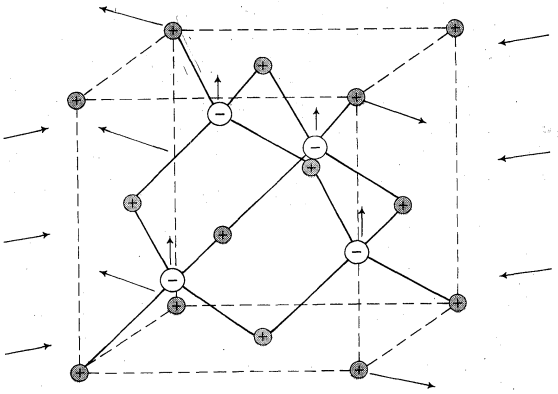

Figure 1: Unit cell of cubic zinc-sulfide crystal with positive zinc and negative sulfur atoms. Long arrows indicate applied shearing strain, short arrows the associated displacement.

charge, and sulfur atoms (light circles), with a negative charge. Compressional stresses do not produce the separation of the charge centres, but a shearing stress, indicated by the long arrows in the illustration, produces a motion of the sulfur atoms, indicated by the short arrows. This motion results in separation of the charge centres (polarization).

History. The piezoelectric effect was discovered experimentally by two brothers, Pierre and Paul-Jacques Curie, in 1880, while still young researchers at the University of Paris. By placing a weight on a crystal, they could observe a voltage on the surface of the crystal. They found this effect in a considerable number of crystals, including quartz, Rochelle salt, and tourmaline. The converse piezoelectric effect, elongation of the crystal with the application of voltage, was predicted theoretically by another investigator in 1881 and verified by the Curies in the same year.

Though Pierre Curie and his wife, Marie, later used the effect in quartz to study radioactivity, piezoelectricity in general remained a scientific curiosity until World War I, when the effect was used to produce acoustic waves in seawater to detect the presence of submarines (see SONAR).

Early applications

Further experimentation, during World War I, led to recognition of the reaction of the mechanical resonance of a vibrating crystal on its electrical behaviour and, hence, to frequency control of oscillators (see below *Frequency control*). Crystals soon found wide application as frequency-control elements in broadcasting and radiocommunication systems. During World War II, the U.S. alone used about 50,000,000 quartz-crystal elements.

Another major application for piezoelectric crystals was in the development of very selective electrical filter circuits; these are employed, for example, to keep undesired signals out of a radio receiver and have been widely used in coaxial-cable, radio, and submarine-cable communications systems (see below *Wave filters*). More than 2,000,000 crystal units a year are now employed for this purpose alone. Studies in the late 1960s made it possible to arrange the contacts on a crystal in such a manner that the desired degree of filtering could be obtained with a single crystal plate. These are called monolithic filters.

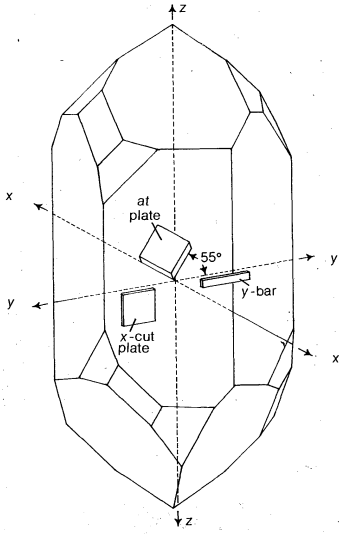

Figure 2: *Quartz crystal with three most important piezoelectric elements.* The *x*-cut is used for expansion or contraction in thickness direction upon the application of an electric field in the *x* direction; the *y*-bar expands and contracts in length direction when the field is applied in the *x* direction. The plate *at* shows shear in side faces when the field is applied in the thickness direction; it excels in low-temperature variation on resonance frequency.

The crystal Rochelle salt was an early discovery. Its properties were originally called Seignette electricity (in honour of its French discoverer) by Soviet researchers, who led in its study in the early 1930s. Since 1945, the term ferroelectricity has been more generally accepted. About 1940 the ferroelectric nature of the ceramic material barium titanate was recognized, and it was soon learned that treatment in a high electric field at temperatures near the Curie point (the temperature below which the material becomes ferroelectric) caused the material

Piezoelectric ceramics

to become strongly piezoelectric when cooled. This process is now known as polarization. Other ceramics, such as lead titanate–zirconate and sodium potassium niobate, with the same properties and a higher Curie point, have largely displaced other materials in uses in which relatively large amounts of power are transformed from electrical to mechanical energy or vice versa.

Piezoelectric crystals. Though Rochelle salt was one of the first and most widely used natural piezoelectric crystals, its sensitivity to temperature eventually caused its replacement, except in phonograph pickups and a few other applications, discussed later.

Because it can be cut in different ways for different applications and because it can produce stable oscillations, which are virtually independent of temperature changes, quartz is the most widely used piezoelectric crystal. The temperature stability of quartz crystals is invaluable in two-way radios. A two-way-radio-equipped policeman, for example, who moves from a warm building to a winter street, exposes his radio to extremes of temperature. Yet the quartz crystals in its transmitter and receiver continue operating exactly on frequency.

Piezoelectric transducers. Transducers are devices that convert one physical effect into another; for example, sound waves into alternating electrical current and vice versa. Piezoelectric devices are used in two types of transducers, nonresonant and resonant, depending on whether the device operates at its normal frequency of vibration (resonant) or is made to operate at a different frequency (nonresonant). Each has special applications.

Nonresonant devices. Nonresonant piezoelectric devices have been used to determine the piezoelectric properties of a crystal; that is, to measure the amount of charge generated by an applied stress or to measure the mechanical movement for a given applied electric field. Such devices are not useful for static measurements, since the charge generated leaks off quite rapidly, but they have been successfully applied in measuring rapidly changing states of motion, as with gauges for measuring the forces generated in an explosion or blast, in which case their natural resonant frequency is far above the frequencies being measured.

Phonograph pickups and microphones

Other nonresonant dynamic applications include phonograph pickups and acoustic microphones. The largest use in terms of manufactured units is the phonograph pickup, in which the piezoelectric device transforms the motion of the needle into an electrical voltage that can drive an amplifier. A typical phonograph-crystal mounting is shown in Figure 3. A lateral motion of the stylus causes a torque (twisting stress) on the two-element (bimorph) unit. The voltage generated is typically one volt for a 5-to-10-gram stylus pressure. For hill-and-dale recording (in which the motion of the needle is vertical), the piezoelectric unit is made up of a bimorph unit obtained by cutting a crystal of Rochelle salt into a pair of expander bars, in which the piezoelectric effect occurs lengthwise in the bars. Expander bars can also be obtained from piezoelectric ceramics; these materials have the advantages of being free from temperature and atmospheric-humidity problems and are easily adapted to lightweight construction. Some lead titanate, lead zirconate compositions are used for this application.

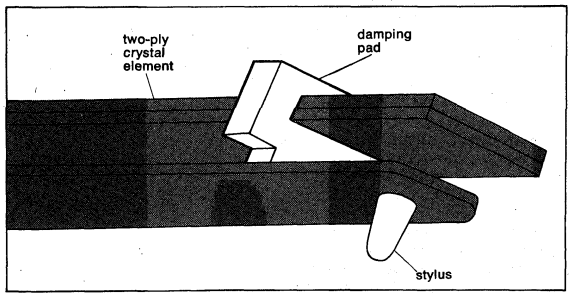

Figure 3: Rochelle salt phonograph pickup.

Another use for piezoelectric pickups is in microphones. In such devices, a diaphragm, actuated by sound waves, is mechanically coupled to the crystal in such a way as to twist or bend it, thus producing an electrical output. Another construction consists of two concentric ceramic pieces with a metallic hemisphere in the middle acting as an air-wave-pickup device. The outside edge of the ceramic is mounted between paper shims, slips of paper that limit the motion but not the bending. Such devices were not extensively employed in the early 1970s, but, with the advent of integrated circuits, which provide amplification very inexpensively, they promised to be of greater importance.

Resonant devices: measurements. Dynamic resonance in piezoelectric crystals is probably their most widely applied characteristic. Freely vibrating crystals are used for frequency and time standards and for very selective electrical wave filters. Resonant crystals and ceramics are also used as transducers to generate mechanical waves in solids and liquids.

To obtain the desired action, piezoelectric elements are cut to closer tolerances with respect to dimensions and to the natural crystal axes. For precision quartz-crystal oscillators, dimensions must be accurate to within one part in 1,000,000,000.

An important characteristic of the crystal is a factor that represents the amount of sharing of electrical and elastic energy through the piezoelectric effect, called the electromechanical coupling factor. This can be determined directly from the resonance measurements. It is an important factor in wave-filter and transducer applications, since it determines the maximum bandwidth, or frequency range, for which the device transmits efficiently. This bandwidth is usually expressed as the ratio of the frequency range to the mean frequency of the device. For quartz, the coupling is about 10 percent, but for many piezoelectric ceramics it may be as high as 70 percent. Ceramic, therefore, is used when wide frequency bands are required, while quartz is particularly applicable when narrower bands but very selective devices or very stable frequencies are required.

Resonant devices: applications. Some of the resonant frequency devices that have received wide application are sonar transducers; delay line transducers; high-amplitude devices for use in testing properties of materials, in drilling, and in welding; and freely vibrating crystals used as oscillators or filters.

Underwater sound

One of the largest applications of resonant transducers is in the production of underwater sound equipment (see SOUND). They are particularly adapted to this application because the mechanical impedances of the devices are well matched to the mechanical impedance of seawater; that is, maximum energy transfer takes place from the device to the water. Most such transducers are of the ceramic type, with lead titanate–zirconate being the most used. Bars of ceramic in the form of a mosaic are mounted on steel backing plates. Power outputs as high as one megawatt have been achieved with some installations.

Similar devices are finding increasing use as ultrasonic cleaning devices, operating in the frequency range of 10 to 100 kilohertz. For the high-frequency range, ceramics vibrating in their thickness mode (the plate becomes alternately thicker and thinner as it vibrates) are usually employed. Curved shapes can also be employed for focussing or concentrating the energy in small areas to produce intensities high enough to remove scale (corrosion) and even to cause plastic flow in metals (see also ULTRASONICS AND INFRASONICS).

Another useful application of piezoelectric transducers is in delay lines; *i.e.*, devices for slowing down or introducing a delay in a signal path. An acoustic wave travels through most materials much more slowly than do electromagnetic or radio waves. A piezoelectric transducer converts the electrical signal to an acoustic wave; this wave travels through some such material as quartz and is delayed in the process; the signal is then reconverted to an electrical signal by another transducer. Delay lines of this type are used in certain kinds of radar systems in which only moving objects are displayed and in computers.

Another use for a resonant transducer is to generate high strains and produce large motions that can be used for processing applications. Figure 4 shows such a transducer, usually made of a piezoelectric ceramic, coupled to a mechanical transformer to produce large motions and strains. Such a device has been used in studying the mechanisms producing metal fatigue.

From *Journal of Applied Physics* (November 1968)

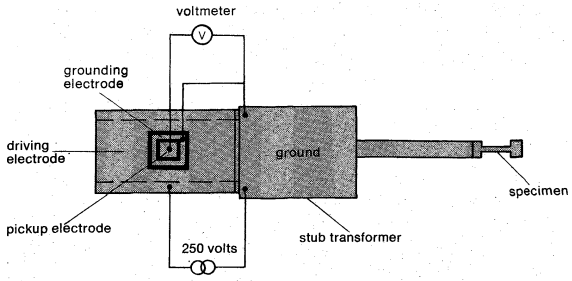

Figure 4: Ceramic resonant transducer for converting a 250-volt ac input to mechanical vibrations, and a mechanical (stub) transformer for coupling these vibrations to the load (specimen; see text).

By mounting a suitable tool on the end of the transformer and by using abrasives, a hole of any shape can be cut in brittle metals and ceramics. Wear studies carried out by the use of tools on the end of the transformer, have shown that most of the wear is caused by tangential motions and is least in polymers and rubbery materials. Large tangential motions coupled with a normal force have also been used for welding thin layers of metals and thin layers of plastics.

Application of freely vibrating crystals. In addition to driving vibrating devices, crystals vibrating freely have been used widely in frequency control of radio transmitters, wave filters in telephone-communications applications, and experimental work on light modulators for optical communications. The first two applications usually employ quartz crystals, although some newer crystals, such as lithium tantalate and lithium niobate, are receiving consideration.

Frequency control. Frequency-control devices such as are required for radio and TV broadcast stations and most radio communications transmitters mainly require low-temperature coefficients and high values of quality factor, or Q (that is, they maintain their oscillations with very little energy input), which are admirably met by the quartz crystals. Specially cut plates, if prepared very accurately, are independent of temperature variations over a wide range. The Q of the crystal is also high, and

Crystal-controlled clocks

such crystals are widely used to control frequency and time standards. Crystal-controlled clocks give extremely accurate time measurement by applying an electric field along the thickness direction, generating transverse oscillations. For 8 megahertz (8,000,000 cycles per second) resonant frequency, a thickness of 0.008 inches (0.02 centimetres) is required. The driving circuit is forced to oscillate at an exact frequency, controlled by the quartz crystal. Without temperature control, a stability within 0.001 percent (one second a day) can be maintained. By holding the temperature constant to within 0.001° C with temperature-controlled ovens and using carefully prepared quartz crystals, stabilities of one part in 1,000,000,000 have been held for many months. Such clocks are more constant than the rotation of the earth itself. Other uses for crystal-controlled oscillators are in broadcasting transmitters, military communication equipment, and on a distance-measuring device called loran (see NAVIGATION). Frequencies from one kilohertz to 100 megahertz can be used by employing various crystal cuts, shapes, and thicknesses.

Wave filters. Freely vibrating crystals are used to make selective wave filters that pass a given frequency band (for example, a voice frequency band of 4,000 hertz for telephone circuits) and eliminate all other frequencies. This permits superimposing a number of telephone conversations on a carrier signal for long-distance transmission. The width of the frequency pass band for a typical quartz crystal is 0.4 percent of the resonant frequency. There are techniques by which bandwidths up to 10 percent are obtainable. Because of the high stability of quartz, it is possible to space the voice bands with very little protective frequency range between them.

Light modulators. Piezoelectric crystals are also employed as light modulators by utilizing the electro-optic effect; that is, a change in the optical properties of the crystal when voltage is applied to it. While this effect depends on the change of the dielectric constant with applied field rather than on the motion of the crystal due to the piezoelectric effect, the constants for the electro-optic effect satisfy the same mathematical expressions as the piezoelectric effect, and, hence, light modulation occurs in all piezoelectric crystals.

This system has achieved great importance since the invention of the laser, which can produce a high-intensity light beam. By using an electro-optic modulator, a large number of communication channels can be transmitted over a laser light beam. The crystal most often used for electro-optic effects is potassium dihydrogen phosphate, or the heavy-water modification (water formed from the heavy isotope of hydrogen deuterium), which has a larger electro-optic effect. In this crystal, the light has to be transmitted in the same direction as the applied field to obtain the greatest effect. Certain cubic crystals, such as copper chloride, zinc sulfide, lithium niobate, and lithium tantalate have the advantage that the light direction and the applied field direction are at right angles to each other. Because this is a rapidly developing field, new crystals are constantly being investigated.

Specialized applications. Piezoelectric materials, particularly the ceramics, have a number of specialized applications, stemming from the high voltage that can be produced by a medium strain. For example, a force of 1,000 pounds (455 kilograms) applied to a block of quartz one centimetre (0.4 inch) on each side can produce an open-circuit voltage of 25,000 volts. A lower voltage but more total energy can be obtained from a ceramic material. This simple technique for generating voltage leads to many uses for ceramic transducers: *e.g.*, in hand grenades, to produce an electrical impulse to trigger an explosive on contact with a solid object; to produce the voltage for the spark plugs on small gasoline engines; as high-voltage generators; as prods for herding cattle and sheep; and for many other high-voltage applications. The reverse effect—that is, the production of a large motion in a ceramic material with an easily obtainable alternating voltage—has been utilized in pumps for oil burners and as generators of ultrasonic sound for burglar alarms, door openers, and ultrasonic cleaning and drilling. High-frequency ceramic units have been used for intermediate-frequency filtering on radio receivers—usually at 455,000 hertz (cycles per second).

Many more applications are receiving attention, and the search for new and improved piezoelectric and electro-optic crystals is part of the expanding field of solid-state physics. The search has already produced a number of new materials that may be expected to take the place of a number of the crystals mentioned here. All of these crystals require specialized methods for growing large-sized specimens.

Piłsudski, Józef Klemens

Revolutionary and man of action, Józef Piłsudski was one of the greatest and probably the first of the Polish public figures of the period that saw the rebirth of the Polish state in the 20th century. Poland had been partitioned in the 18th century among Russia, Prussia, and Austria; its revival after World War I stemmed partly from the efforts of two leaders—Roman Dmowski, the cautious statesman, and Józef Piłsudski.

Culver Pictures

Piłsudski.

Early political activities

Piłsudski was born at Żułów on December 5, 1867, the second son of an impoverished Polish nobleman. His mother, *née* Maria Billewicz, inspired him with hatred for the Russian imperial regime, which was treating the Poles with great harshness after their insurrection of 1863. On leaving the secondary school in Wilno (modern Vilnius), Piłsudski studied medicine at Kharkov in 1885 but was suspended as politically suspect in 1886. Returning to Wilno, he consorted with young Socialists and tried to read Karl Marx's *Kapital*, but its abstract argument proved uncongenial. Arrested in March 1887 on a false charge of plotting the assassination of the tsar Alexander III, he was banished to eastern Siberia for five years.

Piłsudski returned in 1892, determined to prepare an insurrection and to work for the re-establishment of Poland's independence. He joined the newly founded Polish Socialist Party (PPS), of which he soon became a leader. He started a clandestine newspaper, *Robotnik* ("The Worker"), in Wilno. In July 1899 he married, in a Protestant church, the beautiful Maria Juszkiewicz, the divorced wife of a Polish civil engineer, and moved to Łódź, where he continued to edit and print his paper.

In February 1900 he was incarcerated by the Russians in the Warsaw citadel. He feigned insanity so successfully that he was transferred to a military hospital in St. Petersburg, from which he escaped in May 1901. He took refuge in Cracow in Austrian Poland, but in April 1902 he was back in Russian Poland looking after the party organization.

When the Russo-Japanese War broke out in February 1904, Piłsudski went to Tokyo to solicit Japanese assistance for an insurrection in Poland. He had been preceded by Dmowski, his rival in the patriotic movement, who had told the Japanese that Piłsudski's plan was impracticable. The two Polish leaders agreed to disagree. Piłsudski returned clandestinely to Russian Poland to help direct the revolutionary movement that was spreading throughout the empire. After the Russian revolution was put down late in 1905, a split occurred within the PPS: the left wing, which proposed to delete from the party's program the stipulation that its main aim was an independent Poland, broke with Piłsudski's group, which insisted on that stipulation.

Aware of the Russian Empire's structural weakness and foreseeing a European war, Piłsudski concluded that it was imperative to organize the nucleus of a future Polish army. In 1908 he formed a secret Union of Military Action—financed with a sum of money stolen from a Russian mail train by an armed band led by Piłsudski himself. In 1910, with the help of the Austrian military authorities, he was able to convert his secret union into a legal Union of Riflemen, actually a school for Polish officers. At a meeting of Polish sympathizers in Paris in 1914, he declared that war was imminent and that

Attempts to organize a Polish army

> . . . the problem of the independence of Poland will be definitely solved only if Russia is beaten by Austria-Hungary and Germany, and Germany vanquished by France, Great Britain and the United States; it is our duty to bring that about.

World War I justified Piłsudski's prediction. Until 1916 the three brigades of the Polish Legion, technically under Austro-Hungarian command, distinguished themselves against the Russians. On November 5, 1916, Germany and Austria-Hungary, short of manpower, proclaimed the independence of Poland, hoping that Polish divisions could be deployed on the eastern front so that German divisions could be moved to the west. Piłsudski, appointed head of the military department of the newly created Polish council of state, accepted the idea of a Polish army on condition that it be part of a sovereign Polish state. His position was unexpectedly reinforced by the Russian Revolution of March 1917. The German government, however, refused to bind itself as to Poland's future, demanding instead that the existing Polish units should swear "fidelity in arms with the German and Austrian forces." Piłsudski, refusing to comply, was arrested in July 1917 and imprisoned in Magdeburg.

Released after the German collapse in the west, Piłsudski arrived in Warsaw on November 10, 1918, as a national hero. Four days later he was unanimously accepted as head of state and commander in chief of the Polish army. From that moment he ceased to be the man of a party, though his main support came from the left and from the centre; the right saw its leader in Dmowski, who had been heading the Polish National Committee in Paris and was now appointed by Piłsudski to be Poland's first delegate at the peace conference.

Piłsudski devoted himself to protecting Poland against the Russian Red Army, which was trying to fight its way into Germany in order to consolidate the revolution there. He led the Polish forces far to the east, occupying large areas that had belonged to Poland before the 18th-century partitions. He envisioned a federal state comprising Poles, Lithuanians, and Ukrainians, whereas Dmowski argued that these areas should simply be incorporated within a unitary Poland. In 1920 a counteroffensive by the Red Army forced the Poles to retreat westward almost to the suburbs of Warsaw, but Piłsudski, made marshal of Poland on March 19, conceived and directed a manoeuvre that in August brought victory to Poland.

After the adoption of a democratic constitution and a new general election, Piłsudski transmitted his powers on December 14, 1922, to his friend Gabriel Narutowicz, the newly elected president of the republic, who two days later was assassinated. Stanisław Wojciechowski, another of Piłsudski's old colleagues, was next elected president, the marshal agreeing to serve as chief of the general staff. When a right-wing government assumed power, Piłsudski resigned his post on May 29, 1923, and went into retirement at Sulejówek, near Warsaw, with his second wife, *née* Aleksandra Szczerbińska, and his two daughters.

Piłsudski became disillusioned with the working of the parliamentary system, and on May 12, 1926, during a time of economic depression, he marched on Warsaw at the head of a few regiments. Wojciechowski and his government resigned two days later. The parliament elected Piłsudski president of the republic on May 31, but he refused the honour, and another of his old friends, Ignacy Mościcki, was elected instead. In the new government Piłsudski assumed the ministry of defense, which he held

till his death. During the ensuing years he was the major influence behind the scenes, especially in the field of foreign policy.

With few exceptions, Piłsudski's former Socialist friends abandoned him and joined a centre–left coalition, which in the summer of 1930 started a mass campaign to overthrow his "dictatorship." Piłsudski's reaction was ruthless; to "cleanse" political life, he had 18 party leaders arrested and imprisoned in the fortress of Brześc. Though all of them were subsequently released, and their political parties were not dissolved, the country was ruled by Piłsudski's men. The most prominent among them was Col. Józef Beck, Piłsudski's former *chef de cabinet,* who became deputy foreign minister in December 1930 and foreign minister in November 1932.

When Hitler came to power in Germany on January 30, 1933, Piłsudski sent to Paris a secret emissary, Count Jerzy Potocki, his former aide-de-camp, to find out whether France, Poland's ally from 1921, would cooperate in joint military action against Germany. The latter had been openly rearming in flagrant violation of the Treaty of Versailles. The French leadership answered in the negative, and consequently Piłsudski accepted Hitler's suggestion of a ten-year German–Polish nonaggression agreement (January 24, 1934). To show that Poland's intentions were above suspicion, Beck was sent to Moscow in February, and the existing Soviet–Polish nonaggression treaty was prolonged to December 31, 1945. Later, Hitler repeatedly suggested a German–Polish alliance against the U.S.S.R., but Piłsudski took no notice of the proposal; he also declined to meet with Hitler. Piłsudski sought to gain time, believing that Poland should be ready to fight when the necessity arose. Such were the last instructions he gave to Beck. Shortly afterward, he died in Warsaw on May 12, 1935, of cancer of the liver. He was buried in a crypt of the Wawel Cathedral in Kraków, among Polish kings.

A romantic revolutionary, a great soldier without formal military training, a man of rare audacity and will power, as well as of great insight into European politics, Piłsudski was nevertheless poorly equipped to rule a modern state. He left Poland undeveloped economically and with an army that was ready to fight heroically but was doomed because of its composition and inadequate armament.

BIBLIOGRAPHY. The best biography of Piłsudski in English is W.F. REDDAWAY, *Marshal Pilsudski* (1939). Two authoritative works in French are J. DE CARENCY (K.M. SMOGORZEWSKI), *Joseph Pilsudski, soldat de la Pologne restaurée* (1929), and *Joseph Pilsudski et les activistes polonais pendant la guerre,* 2 vol. (1930–31). There is also a biography of him by his second wife, A. PILSUDSKA, *Pilsudski: A Biography by His Wife Alexandra* (1941). Of political interest is R. MACHRAY, *The Poland of Pilsudski* (1936). For some of Pilsudski's writings, see D.R. GILLIE, (trans. and ed.), *Joseph Pilsudski: The Memories of a Polish Revolutionary and Soldier* (1931).

(K.M.S.)

Pindar

The tradition of Greek choral lyric culminated during the 5th century BC with the odes of Pindar. These are not easy to evaluate and appreciate, but it is still more difficult to comprehend and assess the poet who composed them. Even to his contemporaries, Pindar must have seemed an aloof and somewhat enigmatic figure. His origins were aristocratic, so that he would more naturally have been a patron of poetry than himself a poet; he came from a part of central Greece that had made a relatively small contribution to literature and the arts. Because ancient biographies, dating from the 4th and 3rd centuries BC, are highly unreliable and of little help, any approach to the poet must be made through his poetry, and this involves a consideration of the historical setting, the religious usages, and the literary conventions that helped to shape his art. A modern reader needs a sympathetic insight into the nature and traditions of Greek aristocratic society before he can begin to understand how Pindar's subject matter—victory in an athletic contest or in a chariot race—could inspire poetry characterized by high seriousness and deep feeling. Pindar cannot, indeed, speak across the centuries with the directness of Homeric epic poetry or Sophoclean tragedy, but he does create, with disciplined mastery of a sophisticated and complex art form, a choral lyric of unsurpassed splendour and sustained nobility.

Early training. Pindar was born in 518 BC, or possibly 522 BC, at Cynoscephalae, a hamlet in Boeotia (central Greece), in Theban territory. He was of noble birth, possibly belonging to a Spartan family, the Aegeids, though the evidence for this is inconclusive. His parents, Daiphantus and Cleodice, survive only as names; his uncle Scopelinus, a skilled flute player, doubtless helped with Pindar's early musical training. The family possessed a townhouse in Thebes (to be spared by express command of Alexander the Great in the general destruction of that city by the Macedonians in 335 BC). Such a background would give Pindar a ready entrée into aristocratic circles in other Greek cities, where his manifest gifts as a poet might be valued more highly than in his native Boeotia, which had little enough to offer in the way of precept and encouragement. (Two contemporary Boeotian poetesses, Myrtis and Corinna, were of a very different tradition, more primitive and essentially feminine, though Corinna is reported to have criticized the lushness of Pindar's early style, advising him to "sow with the hand, not with the full sack.") It was natural, then, that Pindar should be sent to neighbouring Athens to complete his training and education. Athens and Thebes were seldom on neighbourly terms, but relationships between noble families transcended such difficulties. Pindar's horizons would have widened in the exciting atmosphere of a city beginning to realize its destiny, poised as it was on the verge of political and cultural greatness. He must have studied the choral lyric poets of the past, Alcman and Stesichorus in particular, and the work of his elder contemporaries, Simonides of Ceos and Lasus of Hermione. He would have steeped himself in the poetry of Homer and Hesiod, and he must have received detailed and systematic training in the techniques of choral composition in the city where dithyramb (a choral lyric) was cultivated and where tragedy was beginning to evolve from the dramatic ritual dance performed at religious festivals associated with the god Dionysus. Tradition has it that one of his instructors in music was Agathocles, the teacher also of Damon, who was to become a leading figure in the intellectual and musical life of 5th-century Athens.

Training in techniques of choral composition

Professional career. Seventeen volumes of Pindar's poetry, comprising almost every genre of choral lyric, were known in antiquity. Only four books of *epinicia,* odes celebrating victory in athletic contests, have survived complete, doubtless because they were chosen by a teacher as a school book in the 2nd century AD. They are supplemented by numerous fragments, and in recent years finds of papyri have helped toward a deeper understanding of Pindar's achievement, especially in paeans and dithyrambs (both choral religious lyrics). All the evidence, however, suggests that the *epinicia* were Pindar's masterpieces. These are divided as Olympian, Pythian, Isthmian, or Nemean—the games in which the victories he celebrated were held; the *epinicia* number 44 odes in all. The earliest surviving *epinicion* (*Pythian Ode* 10) dates from 498, and Pindar already had an assured mastery of his medium when he wrote it. It would have been quite possible for him to evolve into a cosmopolitan artist like Simonides, welcome all over the Greek world and moving easily from city to city. No doubt Pindar visited the Panhellenic festivals, at Delphi (where the Pythian games were held) and Olympia in particular, to absorb the atmosphere of the games and the victories he celebrated. He would also have seen in person the homes of the aristocrats and the courts of the tyrants whose triumphs he sang. But in general he preferred to remain loyal to his native land and to reside in Thebes: it is Pindar's characteristic that his standards and values, like his poetry, changed little if at all over the years. Such patriotism meant sacrifices. Thebes, like Delphi, collaborated with the enemy in the Persian War—though admittedly Thebes had little alternative. But whereas Delphi's

Earliest surviving *epinicion*

prestige was quickly restored after the retreat of the Persians, Thebes's defection was not lightly forgiven or forgotten. Athens was to dominate the history of the 5th century, and for the first two-thirds of it Athens had very much the better of its long, drawn-out quarrel with Thebes: from 457 to 447 BC Boeotia was virtually an Athenian dependency. And almost everywhere, the aristocratic way of life, integral alike to Pindar's personality and to his art, was threatened. Politically and economically the monopolies of power by the noble families were broken. The aristocratic code, with its ultimately selfish individualism (summed up in a famous line of Homer, "ever to excel and to surpass other men") was undermined by the radical rationalism of a new age. Choral lyric itself had little future as a separate art form: tragedy absorbed into itself what was most vital in the tradition, and Pindar had no worthy successors. It is a tribute to the quality of Pindar's poetry that although he must have regarded these contemporary cultural and political developments with disdain, or at best with indifference (apart perhaps from his reinterpretation of some of the traditional stories concerning the gods), he was universally respected and accepted as a major creative artist.

Pindar's early poems have almost all been lost; it is probable, however, that what gave him a growing reputation beyond the borders of Boeotia were hymns in honour of the gods. Pindar was born at the time of the Pythian festival, and from his youth he had a close connection with the Pythian priesthood, which served the oracular shrine of Apollo at Delphi. Pindar and his descendants, indeed, enjoyed special privileges at Delphi, where his memory was cherished in later times and where an iron chair, in which it was said he had sat to sing, was exhibited. The first commissions for *epinicia* came mostly from aristocratic connections: the Aleuads in Thessaly (*Pythian Ode* 10; 498 BC); the Alcmaeonids in Athens (*Pythian Ode* 7; 486 BC); Agesidamus of Epizephyrian Locri (*Olympian Ode* 11; 484 BC); and above all the Aeacids of the island of Aegina (the series begins with *Paean* 6, dating from 490, and continues with *Nemean Ode* 7). Progress in winning recognition seems to have been steady, if slow. A significant breakthrough came when Pindar established a link with the court of Theron of Acragas through the tyrant's brother Xenocrates, whose chariot won the Pythian contest (*Pythian Odes* 6 and 12; both 490 BC). But the Persian invasion of Greece came before the promise of this new connection could be fulfilled. Pindar faced a crisis of divided loyalties, torn between a sense of solidarity with the aristocracy of Boeotia, who followed a pro-Persian policy, and a growing appreciation of Spartan and Athenian heroic resistance. Pindar was first and foremost a Theban and stood by his friends, many of whom paid for their policy with their lives. But it was Simonides, not Pindar, who wrote the poems of rejoicing at Greece's victories and of mourning for its glorious dead.

First commissions for *epinicia*

It took Pindar some years to re-establish himself: fortunately, his friends in Aegina were staunch (*Isthmian Ode* 8; 478 BC). It is virtually certain that he visited Sicily in 476–474 BC and was made welcome at the courts of Theron of Acragas and Hieron I of Syracuse. They were to elicit much of his greatest poetry, and it was through these connections that Pindar's reputation spread all over the Greek world so that commissions flowed in from the mainland, the islands, and also from the remoter outposts of Hellenism. Promising new contacts were made with the royal houses of Macedon and Cyrene (Alexander of Macedon, Fragment 120; Arcesilas of Cyrene, *Pythian Odes* 4 and 5; 462/461 BC). Theron and Hieron respected and admired Pindar, but his aristocratic temper made him dangerously outspoken. Diplomatic tact and finesse were not among his qualities, and his adroit rivals, Simonides and Bacchylides, were more pliant and adaptable (Bacchylides, not Pindar, celebrated Hieron's Olympic victory in the chariot race in 468 BC). Echoes of Pindar's bitter resentment sound in his poetry. So, too, Pindar's intervention on behalf of Damophilus, a noble exile from Cyrene (*Pythian Ode* 4, 279 ff.), seems to have been taken amiss, and he was not invited to commemorate Arcesilas' triumph at Olympia in 460 BC. Nevertheless, these were the years of supreme achievement, and Pindar found a growing demand for his poetry and a growing appreciation of his skill. His debt to Athens was amply paid in a famous tribute (Fragment 76) that the Athenians never tired of citing, one that earned the poet special honours in that city (and, according to ancient tradition, a fine at Thebes). It was probably in this period that Pindar married.

The subsequent decade of Athenian domination in central Greece coincided with a period when Delphi was controlled by Phocis in northern Greece. These were dark years for Pindar, and his poetic output dwindled. But he continued to celebrate Theban victories (*Isthmian Odes* 1 and 7); and he found inspiration in the achievements of his Aeacid friends of Aegina, though their days of nominal independence were clearly numbered (*Isthmian Odes* 5, 6; *Nemean Odes* 3–8; all celebrate Aeginetan successes). Pindar's last extant poem (*Pythian Ode* 8) appropriately commemorates an Aeacid victory.

The tradition that Pindar lived to the age of 80 may be true, but there is no surviving poem from later than 446 BC. It is known that he died at Argos.

Poetry. The *epinicion* form, which in Simonides' hands seems to have evolved into a relatively simple poem of rejoicing enhanced by touches of realism and humour, is assimilated by Pindar to the religious hymn. The praise and worship of the god whose festival is being celebrated set the tone, and thanksgiving is an integral part of the structure. A second constituent element is the myth, impressionistically treated in a series of short, sharply visualized scenes and meant to link the glorious present to the yet more glorious past, to give a new dimension to the transient moment of victory. A third ingredient is the aphoristic moralizing, often in Pindar of extreme beauty, even sublimity, in which the dangers of excessive pride in achievement are repeatedly stressed. The emotional impulse throughout stems from the aristocratic ideal of self-assertion, competition, and leadership —an ideal expressing itself most finely in battle but also finding fulfillment in athletic contests, in which the palm goes to superior physique and morale deriving from superior birth. His metrical range is exceptionally wide, with no two poems being identical in metre, and he controls difficult and involuted techniques with consummate professional mastery. His dialect is literary and eclectic, with few Boeotian elements; the vocabulary is enriched, poetic, and highly personal. Each poem is fused into a unity by the fire of Pindar's poetic inspiration, by a sweep and soar of imagination that give his poetry power and magnificence, by the shaping and controlling discipline of a fastidious art expressed in an intensely personal style. Delphic religious teaching found in Pindar a ready pupil, and he constantly spiritualized his material, turning away from the cruder traditional stories of the gods, avoiding the mundane details of the contest, striving to catch the fleeting radiance that plays about the moment of supreme endeavour when a man transcends his own limitations of physique and character and so proves worthy of his birth and ancestry. Delphi also profoundly influenced his style, which is frequently cryptic and oracular. He regarded himself as the Muse's prophet: she is the pythoness and he is the priest who puts her inspired message into intelligible shape.

Constituent elements of the *epinicion*

The only other major poet produced by Boeotia was Hesiod, who had flourished in the 8th century BC. The two are poles apart in background and temperament, but they share a deep religiosity, a groping toward something more profound and satisfying than contemporary cults could offer, a fondness for abrupt and violent transitions in thought and mood, and a forthright pungency of speech. A somewhat muted epitaph preserved in the "Greek Anthology" (7, 35) describes Pindar as the servant of the Muses, welcomed by strangers, beloved by his fellow citizens. Perhaps the poet would have regarded it as adequate.

Pindar's odes make great demands on the modern reader, and it is only in recent times that his art has begun to be appreciated for what it is. (The so-called Pindaric

ode has had a long and distinguished history in English literature, but it derives from an almost total misunderstanding and misapprehension of Pindar's own style and technique.) Even so, much essential evidence is missing. The musical settings that he composed to accompany his words are lost forever, though in view of the quality of the poetry it is probable that the words dominated the setting (as must have been the case in most Greek lyric). It is therefore impossible to re-create even in imagination the approximate sound of a Pindaric ode, or indeed to reconstruct visually the appearance and constitution of the choir: how many participated; what range of voices was employed; whether the singers were static, moved in procession, or danced—these are questions that cannot now be answered. Nor is it possible to picture at all clearly the festive occasion that was the background for the poetry. Yet efforts to understand the odes are rewarded by at least a glimpse of the poet behind them. The aristocratic society and standards, which meant everything to Pindar, were dead or dying. But in his art he re-created them, giving them new and permanent existence and value.

MAJOR WORKS

The *Epinikia* (498-446 BC; *The Odes of Pindar*), consisting of: *Olympionikai* (*The Olympian Odes*), *Pythionikai* (*The Pythian Odes*), *Nemeonikai* (*The Nemean Odes*), and *Isthmionikai* (*The Isthmian Odes*).

Although it is difficult to make a choice, special mention may perhaps be made of "Olympionikai i, Hieroni Syrakousio" (476 BC; "For Hieron of Syracuse"); "Olympionikai ii and iii, Theroni Akragantino" (476 BC; "For Theron of Acragas"); "Pythionikai i, Hieroni Aitnaio" (470 BC; "For Hieron of Aetna"); "Pythionikai iv, Arkesila Kyrenaio" (462 BC; "For Arcesilas of Cyrene"); "Pythionikai vi, Xenokratei Akragantino" (490 BC; "For Xenocrates of Acragas"); and "Pythionikai ix, Telesikratei Kyrenaio" (474 BC; "For Telesicrates of Cyrene"). A translation of all Pindar's odes is available in the "Loeb Series" (1915).

BIBLIOGRAPHY. A full account of editions, commentaries, translations, and criticism to 1966 may be found in DOUGLAS E. GERBER, *A Bibliography of Pindar, 1513–1966* (1969). The most up-to-date text is that of BRUNO SNELL, *Pindari Carmina cum fragmentis*, 2 vol. (1953 and 1964). O. SCHROEDER, *Pindari Carmina*, 5th ed. (1923), is the authoritative edition of a distinguished scholar who devoted his life to the study and elucidation of the poet. The best verse translations in English are by R.A. LATTIMORE, *The Odes of Pindar* (1947); and by C.M. BOWRA, *The Odes of Pindar* (1969). A magisterial treatment of Pindar's life and work is provided by ULRICH VON WILAMOWITZ-MOELLENDORFF, *Pindaros* (1922). R.W.B. BURTON, *Pindar's Pythian Odes* (1962), analyzes and explains these *epinicia* poem by poem. C.M. BOWRA, *Pindar* (1964), gives a sensitive appreciation of the poet's personality and art.

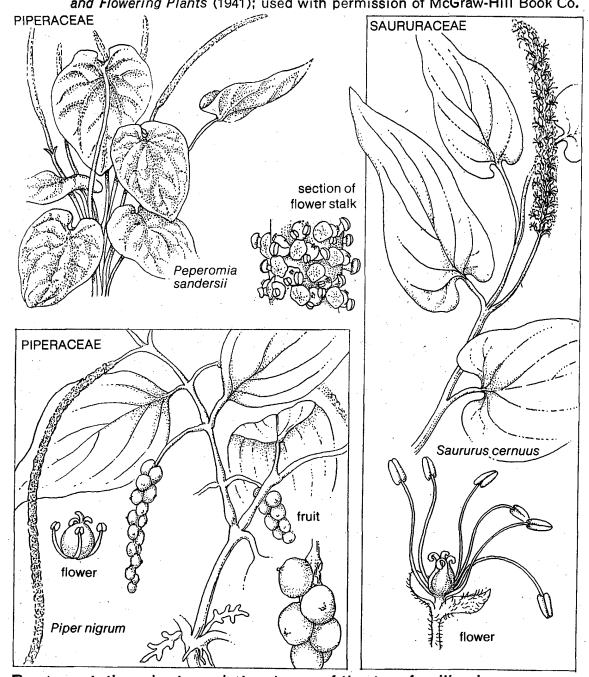
(D.E.W.W.)

Piperales

The Piperales, an order of the flowering plants (division Angiospermae, class Dicotyledoneae), comprises two families, the Piperaceae, or pepper family, and Saururaceae, or lizard's-tail family. In some systems of classification the family Chloranthaceae is also included within this order.

General features. Members of this order are mostly herbs or shrubs. The leaves are usually rather broad and alternately arranged on the stems. The densely aggregated flowers are quite small and lack petals and sepals. Reduced leaves, or bracts, are present below the flowers and in a few species are petallike in appearance. The flowers are most often bisexual, with one to ten stamens and usually a single superior ovary (*i.e.*, the ovary is above the other flower parts, the sepals, petals, and anthers, all of which attach at the base of the ovary). The ovary develops into a single-seeded or a few-seeded fruit.

The family Piperaceae is composed of ten genera, mostly shrubs, many vinelike, and largely confined to the tropics of both the Old World and the New World. The genus *Piper*, with centres of distribution in South America and Malaysia, contains around 1,000 species and is one of the larger ones in the plant kingdom. *Peperomia*, a genus of over 500 species, is also widely distributed in the tropics and subtropics of both hemispheres, a few species extending into Florida. A number of geophilous (ground-dwelling) species of *Peperomia* are found at high altitudes in the American tropics. Some taxonomists classify the genus *Peperomia*, along with a few other genera, as a third family, the Peperomiaceae, which differs from the Piperaceae proper by the absence of stipules (appendages at the base of leafstalks) and in characters of the stem anatomy and pollen. The family Piperaceae includes a number of species used by man, the most important of which is *Piper nigrum*, the source of the black and white pepper of commerce.



The family Saururaceae, which comprises three to five genera, depending on the authority followed, is made up of perennial herbs found in eastern Asia and North America. The genus *Saururus* (lizard's-tail) has one species in eastern North America and another in Asia. *Anemopsis* (yerba mansa) of the western United States and Mexico is the other member of the family found in the United States. Some species of Saururaceae often have a general resemblance to some of those of the family Polygonaceae (order Polygonales).

The two Piperales families are most readily distinguished from each other by the number of ovules, one in the Piperaceae and two to ten in the Saururaceae. The Piperaceae family also lacks the showy bracts, or upper leaves, found in Saururaceae. The ovary and the stem anatomy of the two families also differ fundamentally.

Little detailed information on the floral biology and natural history of the plants of this order is available. Many species have no obvious specialized means for dispersal of the seeds, but it has been suggested that seeds of many species are eaten by birds and thus disseminated. The small fruits of *Peperomia* are covered with a mucilaginous substance that allows them to adhere to objects. Thus, both birds and other small animals could serve as agents of seed dispersal.

Agents of seed dispersal

Representative plants and structures of the two families in the pepper order.

Economic importance. Pepper, prepared from the fruits, called peppercorns, of *Piper nigrum*, is one of the world's most important spices. It sometimes is referred to as black and white pepper to distinguish it from red, chili, and cayenne peppers, which belong to the genus *Capsicum* of the family Solanaceae (order Scrophulariales). Pepper, one of the first spices known to man, was mentioned in Indian writings more than 3,000 years ago and

was observed by Marco Polo to be in extensive use in China as a condiment in the 13th century; it later became one of the first articles of trade between the Far East and Europe. Although much appreciated by the early Greeks and Romans, pepper did not assume great importance in Europe until the Middle Ages. In addition to its use for seasoning food and in the preserving of meats, it also had considerable application in medicine at that time. Peppercorns were also once used as a medium of exchange to pay rent and taxes.

Pepper production. *Piper nigrum* is adapted to hot, wet tropical climates. It is said still to occur wild in Assam and northern Burma and apparently first became a cultivated plant in that part of the world. The plant, a woody climber, reaches 30 feet or more in height. The aerial portion produces roots that allow the plant to attach itself to the trees or poles on which it is usually cultivated. The shiny, ovate, prominently veined leaves are from five to ten inches (13 to 25 centimetres) long. The inconspicuous, self-pollinated flowers hang in spikes, four to five inches (ten to 13 centimetres) long. Each spike produces from 50 to 60 single-seeded, berrylike fruits, which change from green to red or yellowish red when ripe and dry to a blackish colour.

In commercial planting the pepper is propagated vegetatively from stem cuttings. Harvest begins in the third to fifth year, and the berries mature nine months after flowering. Plants continue bearing well for 12 to 15 years. Harvesting is done by hand when the berries are green but mature. For the manufacture of black pepper, the berries are allowed to dry in the sun after picking until they darken and are ready for shipment. The whole peppercorns are then ground to produce black pepper. For the preparation of white pepper, the fruits, often picked when fully ripe, are placed in water for several days to rot the fruit coat. Then the outer hull of the fruit is removed by trampling underfoot or by other means. After drying, the peppercorns eventually turn white and are ready to be ground into white pepper. Peppers contain the alkaloids piperine and piperidine, the latter in small amounts. A resin known as chavicine, however, is considered responsible for most of their pungency. An essential oil prepared from steam distillation of pepper flavours meat products and various sauces.

Preparation of black and white pepper

Until World War II, Indonesia produced 80 percent of the pepper for the world trade; since then India has become the chief exporter. Other countries exporting pepper include Malaysia, Brazil, Cambodia, and the Malagasy Republic. Annual world exports amount to between 50,000 and 75,000 tons. The United States is the world's chief importer.

Various other Asiatic species of *Piper*, generally called long pepper, also have uses similar to those of *Piper nigrum*. The two most important are *Piper retrofractum*, or Javanese long pepper, which occurs wild in Malaysia, and *Piper longum*, Indian long pepper, native to India. Both species are cultivated to a limited extent but do not enter world trade. In addition to their use as a spice, both are still employed in local medicine for a great variety of complaints. In early times among the Greeks and Romans, long pepper was more highly esteemed than black pepper.

Other products. Several other species of *Piper* are of economic importance. The leaves of the betel pepper, *Piper betle*, are chewed with the nuts of betel palm as a masticatory in much of the Old World tropics from Zanzibar to Oceania. Betel chewing is important at ceremonial occasions and acts as a mild stimulant as well as serving to sweeten the breath. This species also finds medicinal uses among native peoples of the areas where it occurs. Its cultivation is most advanced in India, where it is called *sireh*. Cubeb, *Piper cubeba*, native to Indonesia, is used as a medicine and formerly had some importance as a spice.

Kava, the Polynesian "national beverage"

Kava, or kawa, (*yagona*), made from *Piper methysticum*, has been referred to as the "national beverage" of Polynesians. It is widely cultivated in Oceania for its use as a ceremonial and social drink as well as for medicine. Peeled roots were once chewed, but for making the beverage scrapings from the root are fermented in water. Kava is a narcotic and is used primarily for its relaxing effects; excessive use can lead to intoxication.

The leaves of a few of the species of *Piper* occasionally are used as condiments. In both South America and Malaysia some species have been used as an ingredient of arrow poisons, apparently for their irritating effect, and as a poison to stupefy fish.

Other useful plants in the order include several species grown as ornamentals, especially *Peperomia*, of the Piperaceae family. The peperomias are mostly low herbs, occasionally epiphytic (*i.e.*, growing among the branches of trees), with fleshy leaves. Several species are cultivated as houseplants for their attractive foliage. *Saururus cernuus*, lizard's-tail, so named because of the shape of its inflorescence (flower cluster), is a plant of bogs and marshes of eastern North America and is occasionally cultivated in pool or bog gardens.

Classification.

Annotated classification.

ORDER PIPERALES

Mostly herbs and shrubs; usually with broad, alternate, entire, petiolate (stalked) leaves with stipules attached to the petiole or lacking; flowers bisexual or, rarely, unisexual, perianth lacking, subtended by bracts, borne in dense spikes or, rarely, racemes, hypogynous to epigynous, stamens 1–10; carpels 1–4 or, rarely, 5, free or united, usually with a single ovule; fruit a drupe, follicle, or capsule; seeds with copious endosperm, a mealy perisperm, and minute embryo with 1 or 2 cotyledons. Members mostly tropical.

Family Piperaceae

Erect, trailing, or climbing herbs, shrubs, or (rarely) small trees; vascular bundles of the stem often scattered, as in the class Monocotyledoneae; leaves usually alternate, rarely opposite or whorled, sometimes fleshy, stipules present or absent; flowers minute, without perianth, usually bisexual (plants rarely dioecious), borne in dense, sometimes rather fleshy spikes; stamens 1–10, anthers 2-locular, distinct or confluent, dehiscent by longitudinal slits; ovary superior, stigmas 1–5, carpels 2–5, united, 1-loculed with 1 erect ovule; fruit (frequently called a berry) a dry or fleshy drupe. About 10 genera with perhaps 3,000 species (although conservative estimates would place it at half that number) in the tropics of both hemispheres.

Family Saururaceae

Perennial herbs, usually of moist habitats; vascular bundles of stem united into a single ring; leaves ovate, alternate, stipules present, upper leaves, or bracts, often coloured or showy; flowers bisexual, in dense spikes or racemes; stamens 6–8 or sometimes fewer, anthers 2-locular, dehiscent by vertical or longitudinal slits; ovary superior to half-inferior, styles and stigmas the same number as the carpels, carpels 3–4, free, each with 1-locule, or compound; ovules 2–10 in each carpel on parietal placentas; fruit a fleshy follicle or capsule, apically dehiscent. Three to 5 genera with a total of 4 to 7 species in southeastern Asia, the United States, and Mexico.

Critical appraisal. The family Chloranthaceae is placed in the Piperales order in many systems of classification, whereas others assign it to the order Laurales. Chloranthaceae is readily separated from the Piperaceae and Saururaceae families by its opposite leaves, petioles that are somewhat connate (fused around the stem) at the base, small, free stipules, and more or less inferior ovary.

Modern authorities are generally in agreement that the Piperales is a rather primitive order, representing a slight advance over the Magnoliales order, from which it is thought to have been derived.

Pirandello, Luigi

Author of short stories and novels, as well as the plays, for which he is best known, and the winner of the 1934 Nobel Prize for Literature, the Italian writer Luigi Pirandello was one of the revolutionary innovators of 20th-century literature. By his invention of the "theatre within the theatre" (with *Sei personaggi in cerca d'autore*; *Six Characters in Search of an Author*), he provides a metaphor for the contradictions of existence in the equivocal relationship between actors and the characters they represent.

Pirandello.

Early years and marriage

Pirandello was born near Girgenti (modern Agrigento), Sicily, on June 28, 1867, the son of a sulfur merchant who wanted him to enter commerce. Pirandello, however, was not interested in business; he wanted to study. He first went to Palermo, the island's capital, and, in 1887, to the University of Rome. After a quarrel with the professor of classics, he went in the following year to the University of Bonn, Germany, where in 1891 he gained his doctorate in philology for a thesis on the dialect of Girgenti.

In 1894 his father arranged his marriage to Antonietta Portulano, the daughter of a business associate, a wealthy sulfur merchant. This marriage gave him financial independence, allowing him to live in Rome and to write. He had already published an early volume of verse, *Mal giocondo* (1889), which paid tribute to the poetic fashions set by Giosuè Carducci; and this was followed by other volumes of verse, including *Pasqua di Gea* (dedicated to Jenny Schulz-Lander, the love he had left behind in Bonn) and the translation of Goethe's *Römische Elegien* (*Elegie romane*). But his first significant works were short stories, at first contributed to periodicals without payment.

In 1903 a landslide shut down the sulfur mine in which his wife's and his father's capital was invested. Suddenly poor, Pirandello was forced to earn his living not only by writing but also by teaching Italian at a teacher's college in Rome. As a further result of the financial disaster, his wife developed a persecution mania, which manifested itself in a frenzied jealousy of her husband. His torment ended only with her removal to a sanatorium in 1919 (she died in 1959). It was this bitter experience that finally determined the theme of his most characteristic work, already perceptible in his early short stories—the exploration of the tightly closed world of the forever changeable human personality.

Pirandello's early narrative style stems from the *verismo* ("realism") of two distinguished Italian novelists of the late 19th century—Luigi Capuana and Giovanni Verga. The titles of Pirandello's early collections of short stories —*Amori senza amore* (1894; "Loves without Love"), *Beffe della morte e della vita* (1902–03; "The Jests of Life and Death")—suggest the wry nature of his realism that is seen also in his first novels: *L'esclusa* (1901) and *Il turno* (1902). Success came with his third novel, often acclaimed as his best, *Il fu Mattia Pascal* (1904). Although the theme is not typically "Pirandellian," since the obstacles confronting its hero result from external circumstances, it already shows the acute psychological observation that was later to be directed toward the exploration of his characters' subconscious.

First novels and stories

Pirandello's understanding of psychology was sharpened by reading such works as *Les altérations de la personnalité* (1892), by the French experimental psychologist Alfred Binet; and traces of its influence can be seen in the long essay *L'umorismo* (1908), in which he examines the principles of his art. Common to both books is the theory of the subconscious personality, which postulates that what a person knows, or thinks he knows, is the least part of what he is. Thus, before the work of Sigmund Freud, the founder of psychoanalysis, was known to Pirandello, and before the French novelist Marcel Proust had published any of his works, the themes of psychology had become material for literature. They found their most complete expression in the volumes of short stories, *La trappola* (1915) and *E domani, lunedì . . .* (1917), and in such individual stories as *Una voce, Pena di vivere così*, and *Con altri occhi.*

Later novels

Meanwhile, he had been writing other novels, notably *I vecchi e i giovani* (1913) and *Uno, nessuno e centomila* (1925–26). Both are more typical than *Il fu Mattia Pascal.* The first, a historical novel, reflecting the Sicily of the end of the 19th century and the general bitterness at the loss of the ideals of the Risorgimento (the movement that led to the unification of Italy), suffers from Pirandello's tendency to "discompose" rather than to "compose" (to use his own terms, in *L'umorismo*), so that individual episodes stand out at the expense of the work as a whole. *Uno, nessuno e centomila,* however, is at once the most original and the most typical of his novels. It is a surrealistic description of the consequences of the hero's discovery that his wife (and others) see him with quite different eyes than he does himself. Its exploration of the reality of personality is of a type better known from his plays.

He had first turned to the theatre in 1898 with *L'epilogo,* but the accidents that prevented its production until 1910 (when it was retitled *La morsa*) kept him from other than sporadic attempts at drama until the success of *Così è (se vi pare)* in 1917. This delay may have been fortunate for the development of his dramatic powers. *L'epilogo* does not greatly differ from other drama of its period, but *Così è (se vi pare)* began the series of plays that were to make him world famous in the 1920s. A demonstration, in dramatic terms, of the relativity of truth, and a rejection of the idea of any objective reality not at the mercy of individual vision, it anticipates Pirandello's two great plays, *Sei personaggi in cerca d'autore* (1921) and *Enrico IV* (1922). *Sei personaggi . . .* is the most arresting presentation of the typical Pirandellian contrast between art, which is unchanging, and life, which is an inconstant flux. Characters that have been rejected by their author materialize on stage, throbbing with a more intense vitality than the real actors, who, inevitably, distort their drama as they attempt its presentation. And in *Enrico IV* the theme is madness, which lies just under the skin of ordinary life, and is, perhaps, superior to ordinary life in its construction of a satisfying reality. The play finds dramatic strength in its hero's choice of retirement into unreality in preference to life in the uncertain world.

Fame and influence

The production of the first of these two plays in Paris in 1923 made Pirandello widely known, and his work became one of the central influences on the French theatre; French drama from the existentialistic pessimism of Jean Anouilh and Jean-Paul Sartre to the absurdist comedy of

Eugène Ionesco and Samuel Beckett is tinged with "Pirandellianism." His influence can also be detected in the drama of other countries, even in the religious verse dramas of T.S. Eliot.

In 1920 Pirandello said of his own art:

> I think that life is a very sad piece of buffoonery; because we have in ourselves, without being able to know why, wherefore or whence, the need to deceive ourselves constantly by creating a reality (one for each and never the same for all), which from time to time is discovered to be vain and illusory . . . My art is full of bitter compassion for all those who deceive themselves; but this compassion cannot fail to be followed by the ferocious derision of destiny which condemns man to deception.

This despairing outlook attained its most vigorous expression in Pirandello's plays, which were criticized at first for being too "cerebral" but later recognized for their underlying sensitivity and compassion. The plays reflect the *verismo* of Capuana and Verga in dealing mostly with people in modest circumstances, such as clerks, teachers, and lodginghouse keepers, but from whose vicissitudes he draws conclusions of general human significance.

World tour with his own company

The universal acclaim that followed *Sei personaggi . . .* and *Enrico IV* sent Pirandello touring the world (1925–27) with his own company, the Teatro d'Arte in Rome. It also emboldened him to disfigure some of his later plays (*e.g.*, *Ciascuno a suo modo* [1924]) by calling attention to himself, just as in some of the later short stories it is the surrealistic and fantastic elements that are accentuated.

After the dissolution, because of financial losses, of the Teatro d'Arte in 1928, Pirandello spent his remaining years in frequent and extensive travel. He died in Rome on December 10, 1936. In his will he requested that there should be no public ceremony—only "a hearse of the poor, the horse and the coachman."

MAJOR WORKS

VERSE: *Mal giocondo* (1889); *Pasqua di Gea* (1891); *Pier Gudrò* (1894); *Elegie renane* (1895); *Elegie romane* (1896), translations from Goethe's *Römische Elegien*; *Zampogna* (1901); *Scamandro* (1909), verse play; *Fuori di chiave* (1912).

CRITICISM: *Arte e scienza* (1908); *L'umorismo* (1908).

SHORT STORIES: (a chronological list of the first book editions of collections of *novelle*): *Amori senza amore* (1894); *Beffe della morte e della vita* (1902–03); *Quand'ero matto . . .* (1902); *Bianche e nere* (1904); *Erma Bifronte* (1906); *La vita nuda* (1910); *Terzetti* (1912); *Le due maschere* (1914); *La trappola* (1915); *Erba del nostro orto* (1915); *E domani, lunedì . . .* (1917); *Un cavallo nella luna* (1918); *Berecche e la guerra* (1919); *Il carnevale dei morti* (1919). English translations have appeared in the following selections: *Horse in the Moon* (1932), contains *Un cavallo nella luna* and 11 other stories; *Better Think Twice About It!* [*Pensaci, Giacomino!*] *and Twelve Other Stories* (1933); *The Naked Truth* [*La vita nuda*], *and Eleven Other Stories* (1934, new ed. 1947); *A Character in Distress* (1938, U.S. title, *His Medals*, 1939), "La tragedia d'un personaggio" and 18 other stories; *Short Stories* (1959), translations of 22 stories, including "Pena di vivere così," "Such Is Life"; *Short Stories*, selected, translated, and introduced by Frederick May (1965), includes "Capannetta," "The Little Hut," Pirandello's earliest known prose work, and "La giara," "The Jar," probably his best known story.

NOVELS: *L'esclusa* (written 1893, published 1901; *The Outcast*, 1925); *Il turno* (written 1895, published 1902); *Il fu Mattia Pascal* (1904; *The Late Mattia Pascal*, 1923); *Suo marito*, later title *Giustino Roncella nato Boggiòlo* (1911); *I vecchi e i giovani* (1913; trans. by C.K. Scott-Moncrieff, *The Old and Young*, 1928); *Si gira . . .*, later title, *Quaderni di Serafino Gubbio operatore* (1916; trans. by Scott-Moncrieff, *Shoot! Si gira . . . the Notebooks of Serafino Gubbio, Cinematograph Operator*, 1927); *Uno, nessuno e centomila* (1925–26; *One, None and a Hundred Thousand*, 1933).

PLAYS: Pirandello wrote more than 50 plays. The following is a selection from the basic 31-volume Bemporad-Mondadori edition of the plays collected under the title *Maschere nude*, "Naked Masks" (1920–35): *Tutto per bene* (1920: *All for the Best*, 1960); *Sei personaggi in cerca d'autore* (1921; trans. by F. May, *Six Characters in Search of an Author*, 1954); *Enrico IV* (1922; *Henry IV*, trans. by F. May, 1960); *Vestire gli ignudi* (1923; *To Clothe the Naked*, 1962); *La vita che ti diedi* (1924; *The Life I Gave You*, 1959); *Ciascuno a suo modo* (1924; *Each in His Own Way*, 1924); *Così è (si vi pare)* (1925, first pub. 1918; *Right You Are* [*If You Think So*], trans. by F. May, 1960; by Eric Bentley as *Right You Are*, 1954); *Sagra del Signore della Nave*; *L'altro figlio*; and *La giara* (1925: *Our Lord of the Ship*; *The House with the Column*; and *The Jar*, in *The One-Act Plays of Luigi Pirandello*, 1928); *Il piacere dell'onestà* (1925, first pub. 1918; *The Pleasure of Honesty*, in *To Clothe the Naked, and Two Other Plays*, 1962); *Il giuoco delle parti* (1925, first pub. 1919; *The Rules of the Game*, in *To Clothe the Naked, and Two Other Plays*, 1962); *All'uscita* (first pub. 1916); *Il dovere del medico* (first pub. 1912); *La morsa* (first pub. 1898 with the title *L'epilogo*); *and L'uomo dal fiore in bocca* (1926: *At the Gate; The Doctor's Duty*; *The Vise*; and *The Man with the Flower in His Mouth*, in *The One-Act Plays of Luigi Pirandello*, 1928); *Diana e la Tuda* (1927; *Diana and Tuda*, 1950); *La nuova colonia* (1928; *The New Colony*, in *The Mountain Giants and Other Plays*, 1958); *Lazzaro* (1929; *Lazarus*, 1952); *Questa sera si recita a soggetto* (1930; *Tonight We Improvise*, 1932); *Come tu mi vuoi* (1930; *As You Desire Me*, 1931); *Quando si è qualcuno* (1933; *When Someone Is Somebody*, in *The Mountain Giants and Other Plays*, 1958).

BIBLIOGRAPHY

Editions: The most complete edition of Pirandello's works is the so-called *edizione definitiva* in the series *I classici contemporanei italiani* (1956–60). It consists of the following volumes: *Novelle per un anno*, 2 vol. (1956–57); *Tutti i Romanzi* (1957); *Maschere nude*, 2 vol. (1958); *Saggi, poesie, scritti varii* (1960).

Pirandello had planned to write 365 short stories, one for each day of the year, and himself began to edit the stories in a series entitled *Novelle per un anno;* the first volume appeared in 1922 and the 15th and last in 1937.

Bibliography: MANLIO LO VECCHIO MUSTI, *Bibliografia di Pirandello*, 2nd ed. (1952).

Biography: F.V. NARDELLI, *L'uomo segreto: Vita e croci di Luigi Pirandello*, 3rd rev. ed. (1962), first written in 1932, with the collaboration of Pirandello himself, revealed the tortured background of Pirandello's life with Antonietta Portulano. It is fundamental for an understanding of the author, although from the circumstances of its writing, it appears now somewhat hero-worshipping in tone. GASPARE GIUDICE, *Luigi Pirandello* (1963), presents the life and work of Pirandello in the setting of his time; it is probably the best general account of the author (in Italian).

Criticism: W. STARKIE, *Luigi Pirandello, 1867–1936*, 4th ed. (1967), a very personal, critical account, with extracts and synopses, of Pirandello's work in the context of European literature; THOMAS BISHOP, *Pirandello and the French Theater* (1960), a useful discussion of Pirandello's ideas, and an account of his lasting influence on the French theatre; J.H. WHITFIELD, "Pirandello and T.S. Eliot: An Essay in Counterpoint," in *English Miscellany* (1958), a study, not of influences, but of affinities and contrasts, not always expected; and "Pirandello and the Question-Mark of the Twentieth Century," in *A Short History of Italian Literature*, 2nd ed. (1969), a thumbnail account of Pirandello's work and importance; GLAUCO CAMBON (ed.), *Pirandello: A Collection of Critical Essays* (1967), a helpful set of discussions of various aspects of Pirandello criticism; OSCAR BUDEL, *Pirandello*, 2nd ed. (1969), a little book that will be more useful to those who already have some idea of the European background of Pirandello.

(J.H.W.)

Pisa

A university town in central Italy, Pisa is the capital of the province of Pisa in the region of Tuscany. It lies in the alluvial plain of the Arno River, about six miles from the Ligurian Sea. Its population was about 100,000 in 1970.

History. Pre-Roman Pisa (Pisae), the origins of which have been a matter of controversy since ancient times, was possibly inhabited by the Ligurians, before coming under Roman control as a naval base and a frontier post against the Ligurians to the north.

Situated on the northern bank of the Arno, Pisae became a Roman colony soon after 180 BC and flourished as a station on the coastal road leading northward from Rome. Fortifications, theatres, baths, and other public buildings were constructed, and by AD 313 Pisa had a Christian bishop.

As the Roman Empire disintegrated in the 4th and 5th centuries, the land route northward lost importance, and

Pisa, the baptistery, cathedral, and campanile (the leaning tower).
Fotocielo

Pisa was isolated from the chief areas of conflict and maintained its urban character, securing from its Lombard conquerors a degree of autonomy and freedom to trade that made it the only Lombard port of any importance. Pisa's navy defended the adjacent coasts, while some shipping continued to arrive from Corsica and Sardinia. Despite Saracen (Muslim) incursions in the 9th century, which led to a sharp decline in trade, Pisa was the greatest city in Tuscany in the 10th century. Agriculture and local trade, both by road and water, probably brought more wealth than did overseas commerce. During the 11th century Pisa not only exploited the products and markets of its large Tuscan hinterland but it also took the initiative against Muslim raiders; in 1016 the Pisans and Genoese drove the Saracens from Sardinia, and in 1063 the Pisan fleet sacked Muslim Palermo. Participation in the Crusades secured valuable commercial positions for Pisan traders in Syria.

Pisa grew in wealth and strength to rival Venice, as the establishment of overseas settlements and protectorates —especially in the western Mediterranean—brought trading opportunities and raw materials. These developments were accompanied by territorial expansion in Corsica and Sardinia as well as in Tuscany, by a growth of population and of industrial production in wood and leather, by the emergence of a commune, and by a republican form of government that provided a measure of participation and power for the middle and merchant groups in society. Pisa usually enjoyed the support of the German emperors in its long conflicts with Genoa at sea and with its Tuscan rivals, Lucca and Florence, on land. These struggles culminated in Pisa's defeat by the Genoese fleet at the decisive Battle of Meloria in 1284.

Battle of Meloria

Despite the loss, after Meloria, of its power at sea and of much of its trade overseas, Pisa experienced an astonishing industrial revolution late in the 13th century. The accelerated transfer of woollen manufacturing from the countryside to the town permitted industry to increase in efficiency and to employ cheap labour, thus reducing its costs; this, in turn, encouraged a shift of population to the city and the profitable enclosure of cultivated land for sheep grazing. As agricultural activity dwindled, the population of the town and its suburbs rose from perhaps 15,000 in the mid-12th century to some 50,000 in about 1315. The Levant trade was largely abandoned, but Pisan ships still brought grain to Tuscany, exported local products, and carried timber, wines, and other goods all over the western Mediterranean. Large quantities of merchandise continued to pass through the city until the 15th century, when serious silting, accompanied by changes in land levels and in the course of the river, made the movement of laden galleys up the Arno almost impossible. Porto Pisano and subsequently Leghorn, both on the coast, were then used for the actual loading and unloading of large ships.

Pisan prosperity was reflected in the characteristic *casa-torre*, a tall inhabited tower usually built of brick and stone, and in the city's churches, particularly the grandiose and spectacular group of cathedral, baptistery, and campanile—the leaning tower, which formed a harmonious ensemble constructed of white marble in a distinctively Pisan blend of Romanesque and Gothic. The cathedral and the baptistery were decorated by a succession of distinguished sculptors, including Guglielmo Pisano, who made the cathedral's first pulpit (1162); Bonanno Pisano, sculptor of its bronze doors (1180); Nicola Pisano, who carved the baptistery pulpit (1260); and Nicola's son Giovanni Pisano, sculptor of the existing cathedral pulpit (1310).

Economic change was accompanied by social tensions. During the 13th century the *popolo*, a group that included vigorous petty merchants of rural origins, provided a new political element; yet popular constitutions and anti-magnate legislation never really deprived the nobility of power and influence. Social divisions, in fact, remained vague and shifting, as aristocrats and businessmen rose, fell, and intermingled. Industry flourished, but foreign trade and agriculture were in decay, and the town, overcrowded, unhygienic, and surrounded by the stagnant swamps of the Arno's floodplain, suffered from endemic malaria. The catastrophic visitations of plague, the Black Death, which first came in 1348, brought further disaster. Military and economic failures, accentuated by internal faction, led to political apathy; to increasingly tyrannical rule by captains and local despots; and finally, in 1406, to Pisa's subjugation by Florence, which had long outdistanced its rival in population and industrial power. Pisa's independence was over.

Florentine rule

Florentine rule, though oppressive and galling, brought a revival of trade and other material advantages. Pisans were deported, heavily taxed, and excluded from office and from the full profits of commerce but they benefitted from the organization of a Florentine fleet and the consequent restoration of Pisa as a trading and shipbuilding centre. There was a new citadel and an unwelcome garrison but the Florentines, who had strong public and private interests in Pisa, improved the countryside, encouraged immigration into the town, and often resided there themselves.

When French armies invaded Italy in 1494, Pisa temporarily reasserted its independence; the city sustained a series of wars and sieges until Florence reconquered it in 1509. Thereafter it continued to decay as a provincial Tuscan town; by 1550 the population had fallen below 9,000. The Florentine rulers of Pisa were not always unenlightened; they encouraged Pisa's university, to which the great scientist Galileo Galilei—born at Pisa in 1564—was connected; they founded an office for the reclamation of marshlands; and in 1562 they instituted the Order of the Knights of Saint Stephen to combat the Barbary pirates.

The modern city. Pisa survived as a tranquil and elegant city, the seat of an archbishopric and of a great university. It is an important railway junction, and its light industries have brought prosperity. Widespread destruction in World War II diminished Pisa's charm, but tourists continued to flock there to see the world-famous leaning tower, now in some danger of collapse.

BIBLIOGRAPHY. The only full treatment in English, now outdated, is J. ROSS and N. ERICHSEN, *The Story of Pisa* (1909). In addition to the detailed scientific studies and bibliographical references in the bulletin, *Bollettino Storico Pisano* (1932–), see A. NEPPI-MODONA, *Forma Italiae Regio VII: Etruria*, vol. 1, *Pisae* (1953); and E. TOLAINI, *Forma Pisarum: problemi e ricerche per una storia urbanistica della città di Pisa* (1967), for ancient and medieval history and topography; W. Pisano, Nicola and Giovanni

Nicola Pisano, a sculptor who worked in Tuscany between 1260 and 1278, was reponsible for introducing a classical style inspired by the art of antiquity into the mainstream of Italian medieval art. His son, Giovanni (active 1265–1314), began his career in his father's workshop and so thoroughly assimilated the ideas he found there that his early work is difficult to distinguish from that of his father. After Nicola's death Giovanni carried on the traditions of this studio and lent to them his own distinctive artistic personality. These two sculptors and their workshops created a new sculptural style for the late 13th and 14th century in Italy; the echoes of this tradition remain noticeable throughout the Italian Renaissance. Nicola's origins are unclear. He is first recorded in 1260 in Pisa (or perhaps 1259, if corrections are made for the medieval Pisan calandar), where he had just completed a hexagonal freestanding pulpit in the baptistery of the cathedral. Although his signature on the pulpit clearly reads "Nicola Pisanus" (thus Nicola Pisano), or "Nicola, the Pisan," documents of 1266 relating to a later work twice call him "Master Nicola from Apulia," Apulia being the province located in the southeastern section of the Italian peninsula. While most scholars now accept an Apulian birth for Nicola, there is still much dispute about his artistic training. Since the sculpture of the Pisa pulpit indicates that Nicola was a mature artist by 1260, his birth date has been postulated to have been some time in the decade 1220–30, thus making him an artist in his 30s at the time of the carving of the Pisa pulpit. Later sources indicate that his son, Giovanni Pisano, was born in Pisa somewhere around 1250, a date that does not contradict the supposed date for Nicola's own birth and that also proves he had already settled in Pisa by mid-century.

Nicola's Apulian origins

Alinari

"Adoration of the Magi," detail from the marble pulpit of the Pisa Baptistery by Nicola Pisano.

Nicola's sculptural training, in line with medieval practices, was probably obtained through an apprenticeship in an already established workshop. If Nicola began his training in Apulia he would most likely have been taught by one of the army of craftsmen whom the Hohenstaufen emperor Frederick II had employed to decorate his vast new building projects. Frederick's artists consciously imitated an ancient Roman style of sculpture in order to give visual support to his role as the Holy Roman emperor. If, on the other hand, Nicola had actually left Apulia before receiving his sculptural training, he might have apprenticed himself either to local Tuscan or Lombard workshops; strong echoes of both regional styles appear in his work.

Although no work can definitely be attributed to Nicola before the Pisa pulpit, the strong classical spirit which motivates its forms suggests more than simple first-hand experience and fascination with then visible ancient Roman sculpture. Quite specific formal motifs in the figures of the Pisa pulpit compare closely with sculptural fragments representing Jupiter and imperial advisers from Frederick's triumphal gateway over the Via Appia at Capua (now in the Museo Provinciale Campano in Capua) and argue persuasively for Nicola's training in the artistic workshops of the Emperor. Pisa's close alliance with the empire of Frederick II, even after Frederick's death in 1250, would have provided good reasons both for Nicola's emigration to that city and for the rather sudden emergence of the overtly classicizing style of the pulpit which he carved.

Artistic importance of the Pisa pulpit

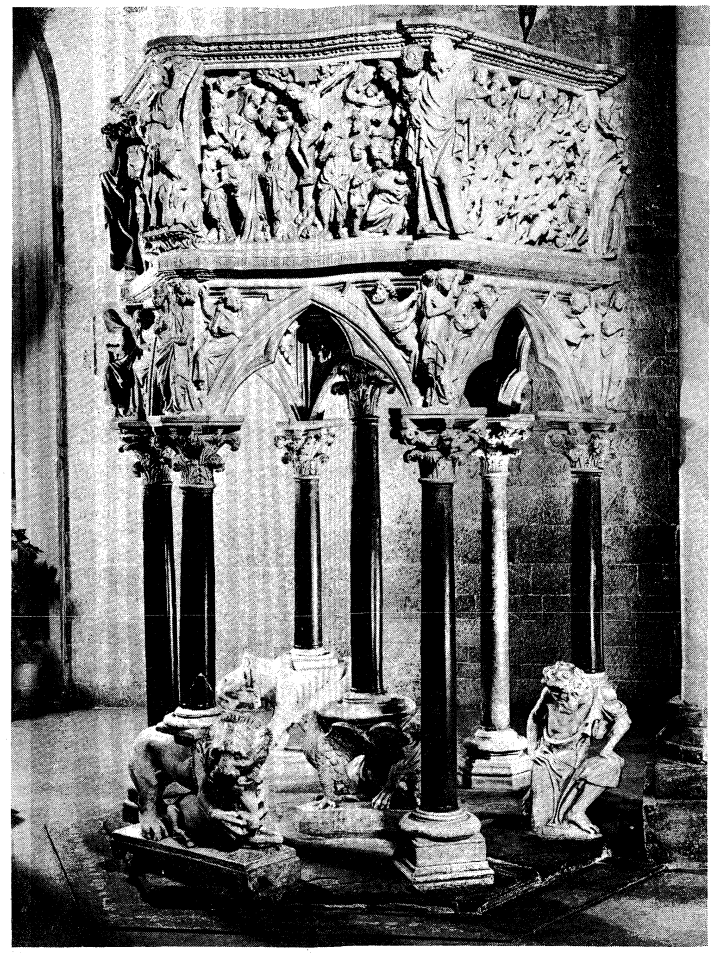
The Pisa pulpit marks one of the extraordinary moments in the history of Western art when a new style, distinct from all its predecessors, though indebted to them, clearly asserted itself and opened new avenues for artistic expression. Whatever Nicola's actual formal artistic training may have been, the Pisa pulpit indicates the widest possible range of artistic experiences. Nicola's familiarity with antique style could have resulted from study of extant Roman reliefs at such places as Benevento (on the via Appia from Apulia to Rome) and at Rome itself; actual borrowings from Roman reliefs preserved in the Campo Santo in Pisa have long been recognized in Nicola's Pisan reliefs. Roman minor arts, such as gems and cameos, which formed part of Frederick II's avidly amassed collections, could also have played a role in forming Nicola's style, as could early Christian fresco and mosaic decorations in the city of Rome. Nicola's work also shows references to localized Tuscan and Lombard forms, as well as isolated motifs deriving from French Gothic sculpture and architecture about which he may have learned either by visiting French-influenced centres in Apulia or by an actual trip to France. Nicola assimilated this encyclopaedic array of artistic expressions and transformed them into a brilliantly unified whole that gave new grandeur and new energy to his narratives and a new sense of direction to art in Tuscany from 1260 onward.

Nicola's style changed dramatically during the carving of the Pisa pulpit from the amplitude of form and rhythmic fluency of movement evident in the relief panel of "The Presentation of Christ in the Temple," to a greatly more agitated treatment of the space and forms in which figures become smaller in relationship to the entire surface area of the relief and pile up on one another in a surface rather than a spatial organization. The figures themselves become more animated and are twisted to emphasize their dramatic potential more fully. Rather than being a rejection of Nicola's earliest known style, however, this later style in fact grew directly out of his concern for presenting the human emotional content of his subject matter. Some of this stylistic change, especially the last two reliefs from the Pisa pulpit, may also be attributable to apprentices or members of his workshop, including Giovanni Pisano, Nicola's son.

Commissions in Siena and Perugia

Nicola's workshop, including Giovanni Pisano, Fra Guglielmo, and Arnolfo di Cambio, also shared in his next commissions, the pulpit for the Cathedral of Siena, 1265–68, and the Fontana Maggiore in the main square of Perugia of 1278. In the Siena pulpit, the form of which is much like that of the Pisa pulpit, Nicola continued the investigations of expressive human figures which permeate the Pisan reliefs. Yet although Nicola's authorship of the design is evident throughout the pulpit, the individual dispositions of the various assisting sculptors toward ancient Roman or Gothic forms is equally obvious; the separate strains of the two traditions which Nicola had so successfully united in the Pisa pulpit again reassert their independence at Siena. This uneasy relationship between the Antique and the Gothic becomes

increasingly clear at Perugia where the 25-sided fountain mixes tales from Romulus and Remus with fables from Aesop, classical personifications of nearby places with representations of the liberal arts and the labours of the months, and contemporary historical figures with Old Testament characters and heraldic animals. The shifts in the style of the sculpture at Perugia were also influenced by the fact that single figures were employed rather than complex narratives as in Nicola's earlier work.



It was in the contract (1265) for the Siena pulpit that Giovanni Pisano is first specifically mentioned as an assistant to his father. Since he was at that time not referred to as "magister," or independent master craftsman, Giovanni must still have been in his teens. Although there is much scholarly dispute over assigning particular sculptural work from the Siena pulpit or the Perugia fountain to Giovanni, there is factual evidence that by September 1285 Giovanni had rejected his Pisan citizenship and had become a resident of Siena. Around this time he began his work on the design and sculptural ornamentation of the facade for the Cathedral of Siena which became, in its lavishness and ordering, the model for virtually all future Gothic facade decoration in central Italy. Unlike French examples, in which figural ornament pulsates over the entire facade, Giovanni's designs for the Siena facade offer a much more architectural approach to the problem. The lower story is simply decorated with colonnettes (small columns) and a restrained foliate pattern, which follows the vertical movement of the colonnettes. Aside from the carved lintels over the doors, figural sculpture begins at the level of the arches over the entrances with slightly larger than life-size figures of prophets and sibyls and continues throughout the rest of the facade. Although each figure inhabits a discrete niche, agitated, forward-bending poses cause them to converse across the vast space of the facade and soften the otherwise clearly stated architectonic lines that order the structure. Recent research has emphasized particularly close relationships in design between the sculpture of the Siena facade and French foliate patterns and figural reliefs, especially from the cathedral at Auxerre. Since there are no known documentary references to Giovanni Pisano between 1268 and 1278, the possibility of a trip through France during these years seems extremely likely.

Giovanni's works in Siena and Pistoia

Next to the Siena Cathedral facade, Giovanni's pulpit in Pistoia, completed in 1301, is his greatest achievement. The five narrative reliefs of this pulpit roughly parallel the subject matter of Nicola's Pisa pulpit 40 years earlier, as does the overall architectural format; but the style pushes the expressive qualities innate in Nicola's Pisa pulpit to a new level of intensity. In the "Annunciation," the "Nativity," and the "Annunciation to the Shepherds," the extreme agitation that characterizes all the reliefs for the Pistoia pulpit pulsates throughout the panel. Figures, animals, drapery, and landscape features are wrenched into physically impossible configurations; light shatters over the broken surfaces and deeply cut relief; and each figure responds convulsively to the individual situations in which he acts as a participant.

In Pistoia, as well as in the Siena pulpit and the Fontana Maggiore at Perugia, there is a strong interest in Gothic forms such as twisted and bent figures, angular contortions of bodies, and a heightened narrative emotional intensity; yet a simple labelling of such forms as Gothic ignores the roots of the relief style and denies the consistent use that both Nicola and Giovanni made of antique sculpture. The later reliefs of the Pisani are explicitly Roman in inspiration and derive from battle or hunt type sarcophagi of the 3rd century. The careful layering, or distinct tiering, of French and German reliefs is not used by the Pisani until after 1302. What is critical to the change in style from the first Pisa pulpit reliefs to the Pistoia reliefs is a preference for an overall agitated and deeply cut surface as opposed to the earlier more massive and monumental organization of forms.

Giovanni never repeated the frenzy of forms which covers the Pistoia pulpit. Instead he returned to the more stately, classical spirit which had been at the heart of

Pulpit, marble, of the church of S. Andrea, Pistoia, Italy, by Giovanni Pisano, 1297–1301.
SCALA, New York

Nicola's earliest work. The reasons for this cannot be documented, but they most likely stem in part from Giovanni's experience with Giotto's monumental and heroic style which was already in the ascendancy by the time that the Pistoia pulpit was completed. Giovanni, in fact, carved a marble Madonna and Child for the Arena Chapel in Padua at approximately the same time that Giotto painted his profoundly moving fresco cycle there (*c.* 1305). In addition, the quasi-imperial political movements established by Pope Boniface VIII at the turn of the 14th century may also have prompted Giovanni to return to more overtly Classical quotations.

Giovanni's return to the classical spirit

From 1302 to 1310 Giovanni again worked in Pisa, this time for a pulpit for the cathedral. In this pulpit, now badly reconstructed after having been disassembled, the relief style is considerably more docile than that of the Pistoia reliefs. Although a decidedly Gothic tiering of the narrative appears for the first time at Pisa, the decorative motifs, column capitals, and freestanding caryatids (a sculptured figure used as a column) show a new severity of style and a renewed interest in direct copying of Roman sculpture. These developments parallel aspects not only of Giotto's painting but of contemporary French sculptors as well.

Giovanni's last recorded work was a tomb sculpture for Margaret of Luxembourg in Genoa in 1311 (fragments now in the Palazzo Bianco). He was last recorded in Siena in 1314, and it is presumed that he died shortly thereafter. If, as is clear from his work in Siena, Giovanni was Italy's only Gothic sculptor, it is also true that he never lost sight of the heritage of Rome that underlies all of the artistic thinking of central Italy. While at times the Antique style may seem to submerge beneath his fascination for contemporary Gothic forms, nonetheless Giovanni, like his father, continuously insisted on a reintegration of antique forms and the Antique style into his sculp-

ture. Thus the Pisani created in their work a focus on the antique past that led ultimately to the revivals of the 15th century now commonly known as the Renaissance.

MAJOR WORKS

GIOVANNI PISANO: Fontana Maggiore (with Nicola Pisano) (1278; Perugia, Italy); external decoration of the Baptistery, Pisa (1278–85; Pisa, Italy); sculptural decoration of the facade, Siena Cathedral (1284; Siena, Italy); pulpit (1297–1301; S. Andrea, Pistoia, Italy); pulpit (1302–11; Cathedral, Pisa); tomb of Margaret of Luxembourg (originally in S. Francesco di Casteletto, Genoa, but now destroyed, 1311; fragments in Palazzo Bianco, Genoa; Palazzo Rosso, Genoa).

NICOLA PISANO: pulpit (*c.* 1255–60; Baptistery, Pisa); pulpit (1265–68; Siena Cathedral).

BIBLIOGRAPHY. The most comprehensive writings on the Pisani in English are by J. POPE-HENNESSY, *Italian Gothic Sculpture* (1955); and J. WHITE, *Art and Architecture in Italy, 1250 to 1400* (1966), both of which give monographic discussions of the individual works of art. Long articles by M. WEINBERGER on Nicola in the *Encyclopedia of World Art*, vol. 10, col. 641–647 (1965), and by J. POPE-HENNESSY on Giovanni, *ibid.*, vol. 6, col. 357–365 (1962), are models not only for their review of scholarly opinions and attributions, but also for the comprehensive bibliographies that they include. M. WUNDRAM also catalogs recent publications in his article "Toskanische Plastik von 1250–1400," *Zeitschrift für Kunstgeschichte*, 21:243–270 (1958).

E. BERTAUX in *L'Art dans l'Italie méridionale* (1904), is still important for his early discussion of Nicola's Apulian connections. G.H. and E.R. CRICHTON carried this discussion into English in *Nicolo Pisano and the Revival of Sculpture in Italy* (1938), but their arguments lack focus and oftentimes substance as well. C. GNUDI, *Nicola, Arnolfo, Lapo* (1948), is important for his discussion of Nicola's studio (in Italian). C. SEYMOUR, JR., "Invention and Revival in Nicola Pisano's 'Heroic Style'," *Studies in Western Art: Acts of the Twentieth International Congress of the History of Art*, vol. 1, pp. 207–226 (1963), reviews recent literature for Nicola and gives cogent political reasons for Nicola's classicizing style; he also carries the heroic mode of Nicola's sculpture into the 15th century. W.R. VALENTINER's article on Nicola's Apulian connections, "Studies on Nicola Pisano," *Art Quarterly*, 15:9–36 (1952), is still useful.

(J.T.Pa.)

Pissarro, Camille

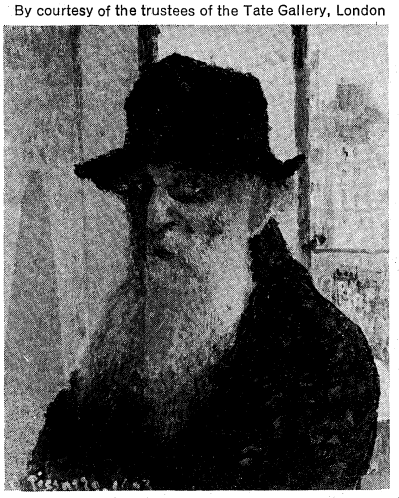
Camille Pissarro was the only Impressionist painter who participated in all eight of the group's exhibitions; his kindness, warmth, wisdom, and encouraging words cast him in a fatherly role to struggling younger artists—Claude Monet, Auguste Renoir, Paul Cézanne, and Paul Gauguin—who were exploring new means of personal expression. Despite financial hardships that continued until he reached his 60s, Pissarro never lost faith in the new art, believing that "one must be sure of success to the very end, for without that there is no hope!"

Pissarro was born July 10, 1830, in St. Thomas, Danish West Indies, son of a prosperous Jewish merchant, Abraham Gabriel Pissarro, and Rachel Manzano-Pomié. At the age of 12 he left home for studies in Paris, where he showed an early interest in art. Returning to the West Indies after five years to work in his father's store, he began making sketches of the exotic island and its people. Because he was unable to obtain his father's permission to study art, he ran away to Caracas in 1853 and remained there for two years with the Danish painter Fritz Melbye. Finally, Pissarro's father relented, and in 1855 he returned to France. His earliest canvases, dating from this period, are figure paintings and landscapes of the tropics and of the French countryside; although broadly painted, they show the careful observation of nature that was to remain a characteristic of his art throughout his life.

Earliest canvases

The uninspired academic teaching at the École des Beaux-Arts, where he was enrolled, led Pissarro to seek out the painter Camille Corot, who permitted Pissarro to call himself Corot's "pupil" at a Salon exhibition in 1864. At this time Pissarro was also attracted to the rural, sentimental paintings of the Barbizon artist Jean-François Millet and to the works of Gustave Courbet, the leading proponent of everyday Realism. During the 1860s Pissarro participated in the famous Parisian Café Guerbois discussions, in which artists and writers exchanged ideas, and worked with the younger painters Renoir and Monet. To escape the Franco-Prussian War, in 1870 Pissarro fled to England; there he and Monet, who had also fled France, visited the museums, where they viewed British landscape paintings. It was in London that Pissarro married Julie Vellay, formerly his mother's maid, who had already borne him two of their seven children.

When Pissarro returned to France in 1871, he found his house in Louveciennes looted and a great number of his paintings destroyed. Soon he was to look for another house in Pontoise. (Because it was costly to live in Paris, Pissarro, like several of his painter friends, lived in villages not far from the city.) His surroundings formed the theme of his art for some 30 years and were always carefully chosen: "I require a spot that has beauty!" At Pontoise he was joined by Cézanne in 1872, and the two of them painted out of doors, even in the middle of winter.



Pissarro's paintings are never dramatic; on the contrary, his leading motifs during the 1870s and 1880s are simply houses, factories, trees, haystacks, fields, labouring peasants, and river scenes. Forms do not dissolve but remain firm, and colours are strong; during the latter part of the 1870s his comma-like brushstrokes frequently recorded the sparkling scintillation of light, as in "Orchard with Flowering Fruit Trees, Springtime, Pontoise" (1877). Although his paintings were sold by the dealer Paul Durand-Ruel, who represented several of the Impressionists, Pissarro continued to experience financial hardships, which he described in letters to his eldest son, Lucien; this remarkable correspondence began in 1883 and lasted for 20 years.

Motifs during the 1870s and 1880s

In some of the letters to his son, Pissarro expressed dissatisfaction with his own work. Preoccupied by problems of style and technique, he eagerly embraced the Neo-Impressionist theories of Georges Seurat, whom he met in 1885 through the painter Paul Signac. Seurat's technique, consisting of meticulously painted small dots of juxtaposed colours, was adopted by Pissarro; for about five years he painted in this "divisionist" manner, a style which made his works unpopular with dealers, collectors, and even his old fellow artists. Overwhelmingly discouraged by their continuing state of poverty, Madame Pissarro considered drowning herself and their two youngest children. Finally, Pissarro abandoned the style, not, however, because of the opposition he met but because "it was impossible to be true to my sensations and consequently to render life and movement, impossible to be faithful to the effects, so random and so admirable, of nature. . . . " At about this time, also, there was an estrangement from Paul Gauguin, who had formerly worked at his side but now was involved with the new Symbolist movement.

A large and successful retrospective exhibition of Pissar-

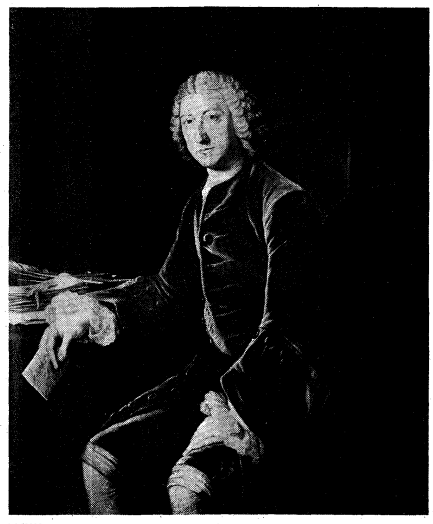
Late works

ro's paintings was held by Durand-Ruel in 1892, giving the artist greater financial stability, although by this time he was troubled by a chronic eye infection that frequently made it impossible for him to work out of doors. Both in 1893 and 1897 he took hotel rooms in Paris from which he painted 24 canvases of the city's streets by day and by night, in sun, rain, and fog. During the 1890s he also did a series of river scenes in Rouen, likewise depicting the various effects of nature. From 1900 until his death in Paris on November 13, 1903, Pissarro continued working, mainly in Paris, Éragny, Dieppe, and Le Havre, with freshness of vision and increasing freedom in his technique. More than 1,600 works, consisting of oils, gouaches (a method of painting with opaque watercolours prepared with gum), temperas, pastels—and even paintings on fans and on porcelain—as well as nearly 200 prints, give testimony to the high quality of Pissarro's half century of work.

MAJOR WORKS

"The Hermitage at Pontoise" (*c.* 1867; Justin K. Thannhauser Collection, New York); "Still Life" (1867; Toledo Museum of Art, Ohio); "Jallais Hill, Pontoise (La Côte du Jallais, Pontoise)" (1867; Metropolitan Museum of Art, New York); "Louveciennes, the Road to Versailles" (1870; Emil G. Bührle Collection, Zürich); "Lower Norwood, London, Snow" (1870; National Gallery, London); "Crystal Palace, London" (1871; Henry J. Fisher Collection, Greenwich, Connecticut); "Quarry Near Pontoise" (1874; Kunstmuseum, Basel, Switzerland); "The Little Bridge" (1875; Städtische Kunsthalle Mannheim, Mannheim, West Germany); "Orchard with Flowering Fruit Trees, Springtime, Pontoise" (1877; Louvre, Paris); "The Red Roofs, View of a Village in Winter" (1877; Louvre); "Peasant Girl with a Stick" (1881; Louvre); "The Cafe au Lait" (1881; Art Institute of Chicago); "Towpath at Pontoise" (1882; Durand-Ruel Collection, Paris); "Île Lacroix, Rouen—Effect of Fog" (1888; Philadelphia Museum of Art); "Paris, the Boulevard Montmartre at Night" (1897; National Gallery, London); "Boulevard des Italiens, Morning, Sunlight" (1897; National Gallery of Art, Washington, D.C.); "Place du Théâtre Français" (1898; Minneapolis Institute of Arts, Minnesota); "Rue de l'Épicerie, Rouen—Morning, Gray Weather" (1898; Durand-Ruel Collection, Paris); "The Church of Saint-Jacques, Dieppe—Morning, Rainy Day" (1901; Nate B. and Frances Spingold Collection, New York); "Louvre from Pont Neuf" (1902; Sterling and Francine Clark Institute of Art, Williamstown, Massachusetts); "Bridge at Bruges" (1903; City Art Gallery, Manchester, England).



BIBLIOGRAPHY. A most useful annotated bibliography of the artist appears in JOHN REWALD, *The History of Impressionism*, rev. ed., pp. 637–39 (1961). A good biographical study that includes colourplates and a selected bibliography is JOHN REWALD, *Camille Pissarro* (1963). Indispensable for the study of the artist's work is the critical study and catalog by LUDOVIC RODOLPHE PISSARRO and LIONELLO VENTURI, *Camille Pissarro: son art—son oeuvre*, 2 vol. (1939). Its extensive bibliography lists over 500 publications. Pissarro's graphic works were cataloged by LOYS DELTEIL, *Le Peintre-Graveur illustré*, vol. 17, *Camille Pissarro, Alfred Sisley, Auguste Renoir* (1923). For the artist's own writings see CAMILLE PISSARRO, *Letters to His Son Lucien*, ed. with the assistance of LUCIEN PISSARRO by JOHN REWALD (1943).

(Mi.V.)

Pitt, William, the Elder

William Pitt the Elder (later the 1st earl of Chatham), who dominated the British government during the Seven Years' War (1756–63), is often regarded as the greatest British statesman of the 18th century. He held effective directing power of government for no more than five years, but in that period (1756–61) his energy, vision, and practical ability in conducting the war secured the transformation of his country into an imperial power. Though the rest of his life was politically active, it seems by comparison to be either a preparation for that burst of national and personal glory or an aftermath of it, for his formation of another ministry in 1766 was clouded by an illness that compelled his withdrawal two years later.

Background and education. Pitt was born in London on November 15, 1708. His mother, Lady Harriet Villiers, daughter of Viscount Grandison, belonged to the Anglo-Irish nobility; his father, Robert Pitt, member of

William Pitt, the Elder, painting from the studio of W. Hoare, 1754. In the National Portrait Gallery, London.

Parliament, was the son of Thomas ("Diamond") Pitt, governor of the East India Company's "factory" at Madras, India, where he made a vast fortune and secured one of the world's largest diamonds (sold in 1717 to the regent of France). "Diamond" Pitt had returned from India with a despotic temper made devilish with spleen and gout; he quarrelled violently with his wife and declared war on "that hellish confusion that is my family," but he treated his grandson William with affection. Father Robert was mean and cantankerous, and the Villiers blood was notoriously unstable. William inherited the gout, as well as a haughty temper and a strain of manic depression not understood at the time but politely called "gout in the head."

Such was the background and the smoky, explosive inheritance that was suddenly to blaze into genius. But William's passionate temper and Pitt truculence had to be disciplined, so he was sent to Eton College, where he acquired social polish and learned to be aloof and yet agreeable, to be politely insolent. Delicate health and the early onset of gout deprived him of field sports and hunting, but he learned to ride with a good seat and take his port wine, and he enjoyed the select company of clever and well-connected friends—the two Grenvilles (one to be Earl Temple; the other, George, to be first minister to George III), George Lyttelton, Charles Pratt (to become a follower of Pitt and, as the 1st Earl Camden, a member of his 1766 ministry), and other men who would later become influential in politics, as well as Henry Fielding, author of *Tom Jones*. But Pitt hated the brutal harshness of Eton and determined to have his own sons educated at home. He continued his education at Trinity College, Oxford, but left after a year without taking a degree. He then spent several months at the University of Utrecht in the Netherlands, probably studying law.

Education

His classical education made him think, act, and speak in the grand Roman manner. His favourite poet was Virgil, and he never forgot the patriotic lessons of Roman history; he constantly read Cicero, the golden-tongued orator who could yet lash offenders with his indignation. Later, in Parliament, his organ-like voice could be distinctly heard outside the House. This voice, perfect timing, and splendid gestures were worthy of David Garrick, the greatest actor of the day and a personal friend; Pitt's lean, tall, commanding figure, combined with a Roman beaky nose and hawklike eyes—large and gray but turning black when he was roused—overwhelmed all onlookers. To his countrymen he was to become a divine portent, a voice from the Delphic oracle, with the mind of Julius Caesar. Frederick II the Great of Prussia was to call him a "true Roman."

For the present, possessed of a mere £100 a year, he nevertheless rejected the church, a younger son's last re-

sort as a career. While he was vegetating on a small family property in Cornwall, which he called a "cursed hiding-place" in one of his many letters to his adored sister and confidante, clever Nan (Ann) Pitt, help came from a politically powerful millionaire nobleman, Lord Cobham, who lived in splendour in a palatial mansion and vast park at Stowe, in Buckinghamshire, to which William and his friends paid visits. Cobham sent William abroad on "The Grand Tour" of Europe (only France and Switzerland were visited, however) and later bought him a cornetcy—a commission—in his own regiment of horse (1731).

Early political career. In 1735 Pitt was offered one of the "pocket" boroughs his brother controlled, Old Sarum in Wiltshire, and entered Parliament. He belonged to the small group known as "Cobham's cubs" and the "boy patriots," the connection of family friends and place hunters whom Cobham was mobilizing to oppose the ministry of Sir Robert Walpole (later the 1st earl of Orford). Walpole had governed England since 1720, monopolizing patronage, and had—they thought—become too ready to compromise in foreign affairs for the sake of peace. The "patriots" joined other discontented Whigs such as John Carteret (later Earl Granville) and William Pulteney (later the 1st earl of Bath) to rally opposition forces behind Frederick Louis, prince of Wales, who was vehemently estranged from his father, King George II.

Attack on Walpole

There were no formal political parties in the 18th century, and political power, together with the financial opportunities it brought, was a gift of patronage from a handful of landowning family oligarchies and from the monarch himself; nor was there a formal opposition in Parliament, and opposition to the king's ministry was regarded as factious and even traitorous. Pitt's maiden speech in Parliament was so critical of the ministry that it provoked Walpole to deprive him of his military commission, to "muzzle this terrible young cornet of horse."

In 1737 the Prince of Wales made Pitt one of his court officials with a salary of £400 a year. He was still a relatively poor dependent of a powerful Whig clan but already showed an independence of mind and a readiness to appeal to public opinion outside Parliament that were new in English political life: when Walpole dismissed him from his cornetcy, he ostentatiously drove about London in a one-horse chaise to underline his poverty. His talents as an orator had already become clear. He repeatedly referred to the "voice of England," which had to be sought outside Parliament because Parliament was so packed with placemen and sinecurists. He claimed to speak for the commercial interests and even for the colonies overseas, the latter scarcely represented in the Commons. He was using arguments that carried far beyond the close interests of the Whig families; but he made lasting and valuable friendship with the rich sugar planter-aldermen of the City of London in his opposition to Walpole's cautious handling of the disputes with Spain over West Indian trade.

Walpole at last fell from power in 1742 and was replaced by a ministry that included his old colleagues Thomas Pelham-Holles, the 1st duke of Newcastle, and Philip Yorke, the 1st earl of Hardwicke, with Carteret as secretary of state. Pulteney was silenced by the grant of a peerage. The "boy patriots," of whom Pitt was the acknowledged leader, were still excluded from power. They opposed Carteret even more vigorously than they had Walpole. In the War of the Austrian Succession (1740–48), Pitt, a former warmonger, now vigorously opposed the sending of men and subsidies to the Continent to check the French by protecting Hanover (the king's territory in Germany) and condemned Carteret as a "Hanover troop minister": for this he was never forgiven by his sovereign. Pitt insisted that French power should be opposed at sea and in its colonial possessions, not on the Continent. When Carteret was forced to resign in 1744, Newcastle and his brother Henry Pelham took office and wanted to include Pitt in their ministry, but George II refused to accept him, though he did accept Cobham, Lyttelton, and Grenville. It was at this time that Pitt first appeared in Parliament swathed in bandages, on crutches, and with a huge gout boot on his foot, parading his illness. But, in the Jacobite rising of 1745 (the Forty-five Rebellion), Pitt gained new stature as the one effective statesman.

Opposition of George II to Pitt

In February 1746, the King agreed to appoint Pitt joint vice treasurer of Ireland at £3,000 a year, and two months later he became paymaster general of the forces; he bowed very low as he kissed the King's hands, but George II wept with rage. The post of paymaster was one of the most sought after in government, with ample opportunity for corruption. There was an outcry from Pitt's friends, who suspected he had been bought, but he proceeded to show both his contempt for moneymaking and his integrity as an honest but comparatively poor man by ostentatiously refusing to take for himself any more than the official salary of more than £4,000 a year: he put the interest that paymasters before had appropriated to themselves, together with the accounts of the paymaster's funds, into the Bank of England and won the people's hearts again. He introduced many reforms into the administration, and, though he supported the Pelhams' alliance with Hanover (which was a change of tack), he tried also to strengthen British naval power.

A legacy of £10,000 from the old Duchess of Marlborough at this time, left to Pitt "for the noble defence he has made for the support of the laws of England, and to prevent the ruin of his country," enabled him to indulge in more lavish expenditure and generosity. He spent a good deal on landscape gardening and bought a new property near London. At this time, after a furious quarrel, he became estranged from his sister Nan, who had been his hostess for many years.

When Henry Pelham died in office in 1754, Pitt hoped for advancement, but, after much reshuffling and intrigue, Newcastle and Henry Fox (later 1st Baron Holland) abandoned him for the sake of expediency. He then became ill and retired to a new house at Bath, groaning "I wish for nothing but a decent and innocent retreat, not to afford the world the ridiculous spectacle of being passed by every boat that navigates the river." An invalid and an aging bachelor, he suddenly fell in love with Lady Hester Grenville, became engaged at once, and was married by November 1754. She was 33 and he 46, but she adored him, possibly from the times in her childhood when he had visited Stowe with her brothers. She was attractive, clever, patient, and eminently practical—particularly about money, arranging mortgages, satisfying creditors, and pouring away her own fortune, in his last years of grandiose extravagance, to protect him from disillusionment. It proved to be an ideally happy marriage with a well-ordered, loving home and family ("the infantry" Pitt called them); later he was to be found making hay with them at Hayes Place, his house in Kent, going for picnics, and chasing butterflies. He magically became healthy and happy, ready for his last big parliamentary fight for high office. But first, because of his attacks on Newcastle's ministry, he was dismissed, penniless, from the pay office in 1755. His brother-in-law Earl Temple helped with an annuity of £1,000.

Marriage to Lady Hester Grenville

Leadership during Seven Years' War. The outbreak of the Seven Years' War gave Pitt his supreme opportunity for statesmanship. The war began with heavy losses and considerable confusion of policy. The popular demand for Pitt became irresistible, and he declared, "I am sure I can save this country, and nobody else can." In November 1756 he formed a ministry that excluded Newcastle, with the Duke of Devonshire as its nominal head. In June 1757 Newcastle returned to office on the understanding that he should control all the patronage and leave Pitt to conduct the war.

Pitt determined that it should be in every sense a national war and a war at sea. He revived the militia, re-equipped and reorganized the navy, and sought to unite all parties and public opinion behind a coherent and intelligible war policy. He seized upon America and India as the main objects of British strategy: he sent his main expeditions to America, to ensure the conquest of Canada, and supported the East India Company and its "heaven-born general," Robert Clive, in their struggle against

the French East India Company. He subsidized and reinforced the armies of Frederick the Great of Prussia to engage the French on the Continent, while the British Navy harassed the French on their own coasts, in the West Indies, and in Africa. Choosing good generals and admirals, he inspired them with a new spirit of dash and enterprise. His hand, eye, and voice were everywhere. By 1759, the "year of victories," Horace Walpole, man of letters and son of Sir Robert Walpole, wrote with reluctant admiration, "Our bells are worn out threadbare with ringing for Victories." Pitt, the "Great Commoner," was known and feared throughout the world. This resolute and concerted policy was too much for Bourbon France, and, by the terms of the Treaty of Paris in 1763, Great Britain remained supreme in North America and India, held Minorca as a Mediterranean base, and won territory in Africa and the West Indies.

The Treaty of Paris

Pitt had given Britain a new empire besides preserving and consolidating the old. But, before the war ended, he had been forced to resign. In 1760 George III came to the throne resolved, as was his chief adviser, the Earl of Bute, to end the war. When Pitt failed to persuade his colleagues to declare war on Spain to forestall its entry into hostilities, he resigned in October 1761. He alone was not tired of war. He never considered its carnage or the ruin facing a bankrupt country. He had tended to concentrate the whole conduct of government into his own hands and worked with furious energy. His haughty and aloof manner, which alienated so many of his colleagues, and his high-handed treatment of affairs had earned him respect and admiration but little friendship. When his resignation was accompanied by a peerage for Hester and an annuity to her of £3,000, there was again an outburst of abuse and scurrility. Just as when he had accepted the pay office, this acceptance of a peerage and a pension for his wife seemed to be the result of a political bargain. As rewards for his immense services they were meagre enough, but it was some measure of his unique reputation for high-minded disinterestedness that his accepting them should provoke so much bitter disillusionment. His effigy was burned in the city, and Hester was reviled as Lady Cheat'em. Pitt attacked the terms of the Treaty of Paris as an inadequate recognition of Great Britain's world-wide success. But, though his popular appeal was soon restored, his career as war minister was over.

Last years. Pitt fell back on his gout and his gardening. In 1765, an admirer left him a splendid new estate at Burton Pynsent in Somerset, where he could plant avenues of noble trees. He was frequently at Bath, where they stood up in the Pump Room when he drank the water. He now had the attacks of "gout in the head" that led to bouts of insanity.

When Bute resigned in 1763, he was succeeded by George Grenville, and Pitt's attacks on the administration completed a breach between the two brothers-in-law. Pitt was becoming a champion of liberty, condemning the high-handed action taken by the ministry against a member of Parliament, John Wilkes, whose paper, the *North Briton*, had attacked the King's speech at the opening of Parliament and who eventually had to flee abroad. Inactive in 1764 and 1765, Pitt re-entered the stage in January 1766 to deliver a passionate plea for imperial liberty on behalf of the American colonists who had resisted the Stamp Act and to demand that act's repeal. In July the King asked him to form a ministry drawn from all sections of the houses of Parliament. Pitt's judgment and wisdom were impaired at this time, and, never having paid attention to manoeuvring among political connections, he found it difficult to form a coherent ministry. It was a fiasco rightly called a "tessellated pavement" by his political opponent Edmund Burke. Pitt himself chose the secondary post of lord privy seal, for which he was created earl of Chatham, but this meant abandoning the House of Commons and the possibility of influencing it directly by his oratory there. The "Great Commoner" retired to the Lords and fell ill for another two years, leaving a rudderless government, under the luckless Duke of Grafton and Charles Townshend, to abandon his policies. Engulfed in a black fit of insanity, Chatham withdrew completely and in 1768 resigned office. He acquired a group of followers in the House of Commons and, in an alliance with Lord Rockingham's group of opposition Whigs, offered a threat to Lord North's ministry, but this opposition was, in the end, without results.

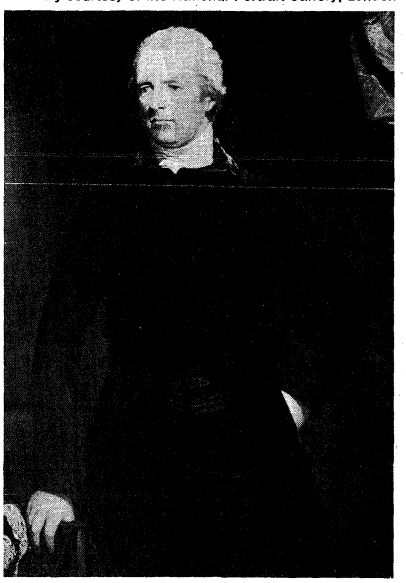
Defense of the American colonists

Chatham's last years were clouded by illness, yet he was to reappear in the House of Lords—with ever greater difficulty—as an elder statesman. He continued to plead for generous treatment of the American colonists though he did not wish to grant them independence, partly for fear of their falling into the hands of France; in 1775 he hurriedly introduced a bill designed to suspend repressive measures at Boston and to maintain the legislative authority of Parliament over the Colonies while using the Continental Congress established at Philadelphia as a body for assessing the monetary contributions of each colony. Although the bill was summarily rejected, it indicates how Chatham would have handled the American problem. His last speech, against any diminution of an empire based on freedom, closed a political career that had become devoted to a reconciliation of imperial power with constitutional liberty. Chatham died at Hayes on May 11, 1778, falling back into the arms of his son William who was reading to him the passage in Homer's *Iliad* on Hector's farewell. He was buried in Westminster Abbey with all the funeral pomp he could have desired and with public grief.

BIBLIOGRAPHY. LORD MACAULAY'S review (1834) of Rev. FRANCIS THACKERAY'S *History of the Right Honourable William Pitt, Earl of Chatham* in his *Essays and Lays of Ancient Rome* (1884, reprinted 1954), brilliant but dated; J.H. PLUMB, *Chatham* (1965), a short, interesting, readable, and up-to-date account; LORD ROSEBERY, *Chatham: His Early Life and Connections* (1910), long, but worth digging into; O.A. SHERRARD, *Lord Chatham: A War Minister in the Making*, 3 vol. (1952–58); and W.C.B. TURNSTALL, *William Pitt, Earl of Chatham* (1938), both scholarly and detailed.

(V.M.W.)

Pitt, William, the Younger



One of the most notable prime ministers of British history, Pitt the Younger, who held office from 1783 to 1801 and from 1804 to 1806, has nevertheless been more highly regarded by posterity than by his contemporaries. Certainly, his political precocity was as obvious in his own time as to later historians; entering Parliament at the age of 21, he became prime minister at 24. But his meteoric rise to power was made possible by the irreconcilable political splits and personal animosities of the period and by George III's determined participation in politics. It was undoubtedly to Pitt's advantage that one of his most brilliant contemporaries, Charles James Fox, had hopelessly antagonized the King by attacking the crown's influence and had also alienated his own natural supporters by his coalition (April–December 1783) with a reactionary politician, Lord North. Pitt's outstanding gifts of oratory were also recognized by his colleagues; even in the late 18th century, the classic age of brilliant British parliamentary debates, he again and again demonstrated his power to dominate the House of Commons. But because of his extreme shyness and his total inability to court popularity, he made little personal impact on his colleagues or the public, and many of his abilities remained unnoticed. It was, therefore, left to the historians of a later age to assert his greatness. Constitutionalists, who could view his work and position in perspective, claimed that his premiership constituted a significant development in the history of the office of prime minister (a title that Pitt himself would never accept), while others have regarded him as a reviver of Toryism. He is also thought of as a great war leader.

Meteoric rise to power

Early life. William Pitt was born at Hayes, Kent, on May 28, 1759, the second son of William Pitt, 1st earl of Chatham, a famous statesman of the mid-18th century, whose energy contributed much to Britain's successful prosecution of the Seven Years' War (1756–63) with France. His mother was Lady Hester Grenville, sister of George Grenville (who headed the government from 1763 to 1765). Both because he was extremely delicate

and because his father disliked public schools, he was educated at home. A precocious boy, he went to Pembroke Hall, Cambridge, at the age of 14. Because of persistent ill health, he made use in 1776 of the antiquated privilege that allowed noblemen's sons to graduate without examination. Left, after his father's death in 1778, with an income of less than £300 a year, he was called to the bar in 1780 and joined the western assize circuit. In September 1780, because of his youth, he failed to secure election to Parliament for Cambridge University but four months later was provided with a seat for Appleby in Westmorland, on condition that he should resign it should his views and those of his patron diverge. Appleby was one of the many pocket boroughs that, before the Reform Act of 1832, were virtually in the control of some great landowner who could ensure that his nominee won the election. Pitt made a very successful maiden speech and, in March 1782, when it was clear that a new ministry would soon be formed, announced with astonishing self-confidence that he had no intention of accepting a subordinate position. He did, in fact, refuse a vice treasurership of Ireland, offered to him by the next prime minister, the Marquess of Rockingham.

William Pitt the Younger, oil painting by John Hoppner (1758–1810). In the National Portrait Gallery, London.

Under Lord Shelburne, who succeeded as prime minister in July 1782, Pitt became chancellor of the exchequer. With Shelburne's consent, Pitt, in February 1783, sought a compact with Charles James Fox, who had gone into opposition, but Fox absolutely refused to serve under Shelburne. According to his contemporary biographer, his former tutor and friend George Tomline, Pitt then replied that he had not come there to betray Lord Shelburne. This interview marked the beginning of the long political duel between Pitt and Fox and also rapidly brought to an end Shelburne's ministry, since Fox now surprisingly allied himself with Lord North, a politician who had always been willing to work in accordance with the King's wishes, and defeated Shelburne. King George III, unwilling to accept the coalition that would give office to Fox, whom he hated, invited Pitt to form a government; but Pitt declined, knowing he would not have a majority in the House of Commons, and the King had to commission Fox and North. To embarrass the new government, which, under the nominal premiership of the Duke of Portland, consisted of an admixture of reformers and anti-reformers, Pitt brought forward the question of parliamentary reform, with which he had already once, a year earlier, concerned himself. He suggested no extension of the franchise but recommended measures to prevent bribery and to make the representation more realistic. Although his resolutions were defeated, reformers now looked to him, rather than to Fox, as their parliamentary leader.

Loyalty to Lord Shelburne

Pitt's first ministry, 1783–1801. In December 1783, after the defeat in the House of Lords of Fox's East India Bill, George III at once took the opportunity to dismiss the coalition and asked Pitt to form a government. Pitt clearly did not take the premiership as the King's tool, for his first step was to try, on his own terms, to include Fox and his friends in the new ministry. But Fox would not consent to join a government from which his ally Lord North would have been excluded.

When Parliament reassembled in January 1784, the government was at once defeated by 39 votes on a virtual motion of censure, but Pitt refused to resign, and George III was prepared to abdicate rather than again surrender to the Fox–North coalition. Pitt admitted that his situation was without precedent but denied that he was prime minister through backstairs influence. He hung on, and gradually the coalition's majority in Parliament began to crumble; many members, fearing the loss of their seats at a general election, went over to Pitt's side during February and March, doubtless in the hope that he would gain a majority in the existing house sufficient to make a dissolution unnecessary. By March 8 the majority against him was one vote, and on March 25 Parliament was dissolved.

No 18th-century government lost a general election, and Pitt's success in 1784 was never a matter of doubt. The "influence of the Crown" ensured that the new House of Commons was chosen by the Treasury. The statement of Pitt's early-20th-century biographer J. Holland Rose that Pitt "never stooped to associate with jobbers" is no longer accepted. Patronage and corruption gave Pitt a majority, and secret service money was used to pay election bills. Although public opinion aided Pitt in the open constituencies, it is nevertheless misleading to say that he was "the choice of the people"; he was merely the dispenser of royal patronage. Pitt himself was returned for the University of Cambridge; only once again (1790), at subsequent elections, did he have to stand a contest.

Financial policy. When Pitt became prime minister, the national credit was seriously impaired by the heavy cost of the recent American Revolution. The debt was about £250,000,000, a staggering amount for those days. Pitt imposed new taxes to wipe out the deficit, checked smuggling by reducing the high duties that encouraged it, and reduced frauds in the revenue by establishing an improved system of auditing accounts. He also simplified the whole range of customs and excise duties, bringing them into a single consolidated fund, out of which all classes of public creditors were to be paid. In 1786 he introduced a sinking fund on a new principle: an annual surplus of £1,000,000 was to be appropriated to the purchase of stock and allowed to accumulate at compound interest for 28 years, by which time the income from it would amount to £4,000,000 a year. In 1792 another act provided that a sinking fund of 1 percent should be attached to every new loan, which would thereby be redeemed within 45 years. The system worked reasonably well in peacetime because there was an annual surplus of revenue, but, after the outbreak of war in 1793, the government redeemed debt bearing a low interest by fresh borrowing at a higher rate of interest.

Pitt's fiscal policy revealed the influence of the ideas of the political economist Adam Smith, author of *The Wealth of Nations* (1776). In 1785 Pitt tried to bring about the commercial union of the British Isles; Ireland was to purchase the advantage of complete free trade with England and the Colonies by an annual contribution to the cost of defense. But the opposition of British traders caused the plan to be modified in such a way as to compel the Irish to reject it.

Problems with India, Canada, and Australia. Fox's East India Bill had been defeated, but the problems it was designed to solve remained. Britain's increased possessions in India made it necessary for the administration there to be supervised by the government rather than be left in the hands of the commercial East India Company. Pitt, therefore, introduced his own East India bill, which was passed in the summer of 1784. He set up a new

government department, the Board of Control, to supervise the directors of the company. He also ended an inappropriate division of authority in India by making the governor general supreme over the subordinate governments of Bombay and Madras. In 1786 a supplementary act increased the authority of the governor general over his own council. Warren Hastings, governor general of Bengal since 1773, returned home in 1785, having greatly strengthened British power in India, only to undergo the ordeal of an impeachment (trial in Parliament) for his conduct. Pitt honestly believed that there was a case against Hastings and, determined that the British name should be freed from the suspicion of injustice or oppression in the government of Oriental peoples, supported the demand for an inquiry. But those who conducted the impeachment acted with unwarrantable rancour; the trial dragged on for seven years (1788–95) and, although Hastings was finally acquitted, the expenses almost ruined him.

Impeachment of Warren Hastings

Another imperial problem with which Pitt had to deal was that of the future of Canada. By the Constitutional Act of 1791 the then province of Quebec was divided into a predominantly French province of Lower Canada and a predominantly English province of Upper Canada. Pitt, who was in office when men were first transported to Australia, never regarded that country as anything more than a convict settlement.

Foreign policy and war with France. Pitt's foreign policy was only moderately successful. In 1788 he made alliances with Prussia and with Holland, aimed at restricting French influence. But, in effect, the alliance served only one useful purpose: Prussia's diplomatic support enabled Pitt in 1790 to triumph over the Spanish without having to go to war in the Nootka Sound dispute, when the Spanish attacked English ships at what is now Vancouver Island. Thus, the Spanish claim to a monopoly of trade and settlement on the western seaboard of North America was finally destroyed. Pitt's intervention in eastern Europe, however, bore no such marks of triumph. Catherine II of Russia, at war with Turkey, was bent on establishing her supremacy in the Black Sea. In March 1791 Pitt sent her an ultimatum demanding the restoration to the Sultan of all conquests except the Crimea. But his policy of bolstering up the effete Turkish Empire was supported neither by the entire Cabinet nor by public opinion, and the government, badly shaken, had to reverse its policy.

Although the British government clung to neutrality as long as possible, in face of the European wars started by the leaders of the French Revolution, war proved in the end unavoidable. It was not the execution of the French king Louis XVI in January 1793 that made a continuation of peace impossible but was the provocative French decrees of November and December 1792, which authorized their armies to violate neutral territory and which promised military assistance to any European people wishing to depose its rulers. The French, confident of victory after their successes against the Austro-Prussian forces and believing that England was ripe for revolution, declared war on England and Holland on February 1, 1793. Pitt refused to intervene to restore the French monarchy. He fought to protect Britain's vital commercial and colonial interests.

The French Revolution had revived the agitation for parliamentary reform, dormant since a bill introduced by Pitt in 1785 had been defeated. But the cause of reform was soon discredited because its advocates were thought to approve of the violence in France. The unwise demonstrations of the radicals caused the government to have recourse to repressive legislation. In May 1792 a proclamation against seditious publications was issued; and the Habeas Corpus Act, which normally prevented the detention of persons without trial, was suspended in 1794 and remained so until 1801.

Suspension of Habeas Corpus

The crisis over Ireland. The French Revolution had disastrous repercussions in Ireland, too, creating new hatreds to exacerbate the old religious feuds and a rebellion in 1798. As early as 1792 Pitt had held that an ultimate union of the two countries was the only solution of the Irish religious problem; the events of 1798 convinced him that union was most urgently necessary. Large-scale corruption carried the measure through the Irish Parliament, but opposition from Pitt's Cabinet and particularly from the King prevented him from carrying his supplementary proposals—Catholic emancipation and state provision for Catholic and Dissenting clergy. As a result, Pitt resigned on February 3, 1801, and his friend Henry Addington (afterward Viscount Sidmouth), formed a government. The crisis again drove the King insane, and after his recovery in March he accused Pitt of having caused his illness. Pitt replied that he would never again press the Catholic question during the King's reign.

Addington's ministry, 1801–04. Patriotic motives induced Pitt to support the new ministry, but for several months during the session of 1802–03 he never attended Parliament, living in Walmer Castle, where, holding the ancient office of warden of the Cinque Ports, he organized a local volunteer force. In March 1803 Addington invited Pitt to join the government, but Pitt made it clear that he would return only as prime minister. War broke out again in mid-May 1803, and by 1804 Pitt was becoming increasingly critical of the government's financial polity and its measures to meet the growing danger of invasion. Addington's majority fell steadily, and he decided to resign. On April 30 Pitt was informed that the King wished him to plan a new ministry. Pitt replied on May 2 that a nonparty government was desirable but fell in with the King's determination that Fox be excluded and also renewed his pledge not to reintroduce measures for Catholic relief.

Pitt's second ministry, May 1804–January 1806. Pitt's second ministry was weaker than the first, for the Addington group, as well as others, went into opposition. The Third Coalition against Napoleon's France, an alliance with Russia, Sweden, and Austria engineered by Pitt, collapsed after the battles of Ulm and Austerlitz in 1805, and the year closed in disaster, in spite of Nelson's victory at Trafalgar in October, which ended the invasion threat and ensured Britain's naval supremacy for the rest of the war. Pitt's health, never robust, was now failing. He made his last public speech at the Guildhall in London on November 9, 1805. The Lord Mayor proposed his health as "the saviour of Europe." He replied,

> I return you many thanks for the honour you have done me. But Europe is not to be saved by any single man. England has saved herself by her exertions, and will, as I trust, save Europe by her example.

By January 15, 1806, some of his colleagues were determined to force him to resign as the only means of saving his life, and the King was thinking about his successor. He died on January 23, 1806, at Putney and was buried in Westminster Abbey on February 22. A motion for a grant of £40,000 to pay his debts was unanimously carried in the Commons. Earlier (1801), his friends had raised £12,000 in order to relieve him from embarrassment. The famous inscription under his monument in the Guildhall, composed by the statesman George Canning, records that "dispensing for near 20 years the favours of the crown, he lived without ostentation, and he died poor." Careless to a fault about money and engrossed with public affairs, he allowed his large official income to be squandered by servants and tradesmen.

Private life and character. Though eloquent and forceful in Parliament and Cabinet, Pitt made no impact in society and altogether lacked the common touch. He was always notably withdrawn. He never married, and no wholly convincing explanation has ever been put forward of the insuperable obstacle that, at the eleventh hour, prevented him marrying Eleanor Eden, daughter of Lord Auckland. In his career, women played an astonishingly insignificant part. He had few friends; an increasing loneliness, characteristic even when he was a young man, was the self-chosen feature of his private life. Even members of the government complained of his inaccessibility. In 1801 his resignation from office caused extraordinarily little sensation; a contemporary wrote that "nobody speaks of him; no addresses, no subscriptions, no stir of any kind any where." Long before his death, bodily in-

Pitt's personal inaccessibility

firmities, increased by his excessive addiction to port, curtailed his working day. In appearance he was tall and thin, with exceptionally bright eyes and a prominent nose.

Pitt's experience was remarkably limited. He never set foot in Scotland or Ireland; the greater part even of England was unknown to him. He was once in France—for a few weeks. He never came into touch with men of letters or original thinkers; in his official patronage he neglected literature, science, and the arts. Even his friend William Wilberforce, the anti-slavery campaigner, was struck by his ignorance of human nature and his exaggeratedly favourable estimate of men and of political prospects. He was long overconfident of success in every cause he espoused; in the end only the weight of ill-health and Napoleon's great victories of 1805 began to shatter his optimism. Although at first connected with the movement for parliamentary reform, he made no attempts to reintroduce the issue after the failure of his bill in 1785. He made no effort to deal with the social problems caused by the Industrial Revolution; and in all his long years of office, nothing was done to reform the barbarous criminal law, the harsh game laws, prison administration, and local government.

But, to be fair, little was done in these matters until the third decade of the 19th century. Moreover, many of Pitt's limitations stemmed from the real if not apparent misfortune of his becoming premier when little more than a boy. If he had had time to broaden his mind with varied experience and to know his fellowmen, he might have governed the country with more mature views and a greater store of practical wisdom. Nevertheless, by reason of his superb debating powers he dominated the House of Commons, even in that age of notable oratory. His conduct in Parliament had a mixture of prudence, firmness, and transcendent ability never before seen and hardly ever again surpassed.

Historical importance. The constitutional significance of Pitt's career has often been misunderstood. He was not a prime minister of the modern type. At no time was he the leader of a well-organized, coherent party commanding a majority of the House of Commons, which itself owed its existence to the will of the electorate. He was not at all the choice of the nation; he was the nominee of the King, and he retained office only as long as he retained the King's confidence. He had to resign in 1801 because his Irish policy was not acceptable to George III. Even though the inadequacy as a wartime prime minister of his successor, Henry Addington, made Pitt's return to office almost inevitable three years later, Pitt did not return on his own terms but on the King's. He was more dependent on the King's favour than on the support of the House of Commons. His most serious crisis came in the winter of 1788–89, when, during George III's madness, Pitt lost the all-important support of the crown. Had the dissolute Prince of Wales, who favoured the opposition, become regent, Pitt would have been dismissed. Without the support of the crown, neither he nor anyone else could remain long in office. Moreover, there were obvious limitations to his absolute authority in the Cabinet, where colleagues opposed him on all the great questions of the day. And, finally, Pitt had to deal with a sovereign of narrow intellect and with intense and irrational prejudices—though, indeed, these were shared by a great many of George III's subjects.

Although Pitt's supremacy in the Cabinet has often been exaggerated, the necessity for a prime minister who would supervise and coordinate the work of the various departments and possess the chief confidence of the king was never again questioned after his ministries. When the question of his returning to power had been discussed in 1803, he asserted to Viscount Melville that it was absolutely necessary

Pitt's view of the prime ministry

> that there should be an avowed and real minister, possessing the chief weight in the council and the principal place in the confidence of the king. . . . Power must rest in the person generally called the first minister, and that minister ought . . . to be the person at the head of the finances.

Pitt's achievement of this status, while depending upon his forcefulness of character, was only made possible by his very long tenure of office. His total of 19 years in power exceeded by almost seven years the tenure of office, earlier in the 18th century, of Sir Robert Walpole, often regarded as "the first" British prime minister, and that of Lord North, nearer Pitt's own time. In the early 19th century, Lord Liverpool was nominally the head of the administration for 15 years but was never the dominant personality in his cabinets.

It is sometimes claimed that Pitt emerged as the leader of a new Tory Party. Certainly, as a minister who accepted the royal prerogative, he represented the traditions of the Tory, or Court, Party, as distinct from those of the Whigs, who sought to dictate to the crown the choice of its servants; but he was far from being a great party leader commanding the votes of a majority in the House of Commons. He had a personal following of little more than 50. In spite of persistent efforts, great speeches, and the support of powerful and eloquent members, he failed to pass a slave trade abolition bill, a parliamentary reform bill, and Catholic relief bills. Had he led a homogeneous party, this legislation would have been carried; but his supporters always deserted him when he was advocating reforms that either their prejudices or their vested interests opposed.

A cartoon of World War II depicted Pitt and Lloyd George, the prime minister during part of World War I, helping Winston Churchill to climb up and join them on a plinth for famous war leaders. Into this role, too, Pitt's long tenure of office helped posterity to mold him; he was in power during the eight years (1793–1801) of the French Revolutionary Wars and during two years (1804–06) of the Napoleonic Wars. Yet military historians have often severely criticized Pitt for the unprepared condition of the British armed forces in 1793, for his failure to mobilize the country's manpower during the war's progress, and for allowing such military resources as the country did possess to be wasted in ruinous enterprises. Forty thousand troops, sent to capture the French West Indies in the mistaken impression that the French economy would be seriously affected by the loss of the sugar islands, died of yellow fever there. The Duke of Wellington later declared that it was Pitt's great misfortune that he had no one to advise him about the conduct of the war. But alliances formed by Britain were the basis of the great coalitions that waged war against Revolutionary and Napoleonic France. Pitt was the architect of the first three coalitions, those of 1793, 1798, and 1804–05. His steadfast resolution despite all setbacks and his undoubted patriotism justly made him recognized at the time as his country's "guardian angel" and gave rise to various stories associated with him, such as that which alleges that he died murmuring of the plight of his country.

BIBLIOGRAPHY. PHILIP HENRY STANHOPE, 5th Earl Stanhope, *Life of the Right Honourable William Pitt*, 2nd ed., 4 vol. (1862; new ed., 3 vol., 1879), is written in fine literary style and contains some important letters. The standard large-scale biography has been that of J. HOLLAND ROSE: *William Pitt and National Revival* (1911), *William Pitt and the Great War* (1911), and *Pitt and Napoleon* (1912). JOHN EHRMAN, *The Younger Pitt*, vol. 1 (1969), ends at 1789. When completed, Ehrman's biography will replace Rose. Of shorter biographies, the best is LORD ROSEBERRY, *Life of Pitt* (1891, reprinted 1969). PHILIP W. WILSON, *William Pitt, the Younger* (1930), is a semi-popular short life. DONALD G. BARNES, *George III and William Pitt, 1783–1806* (1939), has long been the standard treatment of the political roles of the King and Pitt. New information and interpretations require modification of some views. ALAN F. FREMANTLE, *England in the Nineteenth Century*, 2 vol. (1929–30), is a detailed political history. *The Later Correspondence of George III*, ed. by ARTHUR ASPINALL, vol. 1–5 (1962–70), includes a generous selection of the King's letters (1783–1810) but needs to be supplemented by other correspondence at certain points; *The Correspondence of George, Prince of Wales, 1770–1812*, also ed. by ARTHUR ASPINALL, vol. 1–8, (1963–71), is useful on the parliamentary opposition. Both series have valuable prefaces and footnotes.

(A.As.)

Pius II, Pope

Pope Pius II (Aeneas Silvius Piccolomini) was both an outstanding humanist and pope in his era (15th century). In various ecclesiastical and civil posts he played an important role in European politics before becoming pope. As pope he tried to unite Europe in a grand crusade against the Turks. He recorded the vicissitudes of his life in his many writings in flowing Latin prose.

Pius II, bronze medal by Andrea Guacialoti (1435–95). In the Samuel H. Kress Collection, National Gallery of Art, Washington, D.C.

From cardinal's secretary to pope

Aeneas Silvius was born October 18, 1405, at Corsignano (later Pienza), near Siena, Italy, into a noble family in very reduced circumstances. He acquired his humanistic education by assiduous work under unfavourable conditions. To earn a living he became secretary to Cardinal Domenico Capranica and went with him to the Council of Basel, a meeting of bishops concerned with church reform (1431–37), which was already at loggerheads with Pope Eugenius IV. With Cardinal Niccolò Albergati he visited many European countries on a diplomatic mission. On returning to Basel in 1436, he became an official of the council, which gave him opportunities to show his great skill as an orator. He became secretary to the antipope Felix V, elected on November 5, 1439, by the remnant of bishops at Basel, who refused to obey Pope Eugenius' order to transfer the council to Ferrara and Florence. As representative of the Basel remnant at the Diet (imperial assembly) of Frankfurt, he attracted the attention of Frederick III of Austria, who invited him to Vienna (1442) and made him imperial poet laureate and his private secretary. Thereupon, he broke his connection with the antipope in 1445 and was absolved of the ban of excommunication that he had been under. A serious illness is said to have led him to amend his dissolute life (he was the father of several illegitimate children). In Frederick's name he proposed to end the rivalry between the papal council at Florence and the rebellious council at Basel by summoning a third council but could persuade neither Eugenius nor the bishops at Basel. Hitherto a layman, Aeneas received sacred orders in 1446. He next managed to calm the storm raised by Eugenius' deposition of two of the German archbishop electors and was chiefly responsible for reconciling the German princes with the Pope and for Frederick's withdrawal of support for the council at Basel.

Made bishop of Trieste by the new pope, Nicholas V, in 1447, he continued his successful mediation between the German states and the Holy See, explaining in a "letter of retractation" his change of role from supporting Basel to being advocate of the papacy. He was transferred in 1449 to the see of Siena, where he was still able to be of service to King Frederick by negotiating his marriage with a Portuguese princess and his coronation as Holy Roman emperor in Rome by Nicholas V (1452).

Nicholas' successor, Calixtus III (1455-58), made Aeneas cardinal-priest of Sta. Sabina as a reward for negotiating peace with Alfonso V, king of Aragon and Naples, and persuading him to cooperate in the crusade against the Turks that Calixtus was energetically promoting. On Calixtus' death Aeneas Silvius was elected pope as Pius II (August 19, 1458). As pope he had one main purpose: to organize a grand crusade to drive back the Turks, who, having captured Constantinople in 1453, were threatening to overrun the rest of Europe. He summoned the Christian princes to a congress in Mantua to study and meet the danger. When he arrived on the appointed day, June 1, 1459, he was alone. Very gradually some came but only to squabble for advantages to themselves.

Abortive crusade against the Turks

The patient diplomacy of the Pope achieved little. A condition for success was to restore peace to the West. In Italy, Pius slowly regained control of the Papal States. His negotiations with France for the repeal of the Pragmatic Sanction of Bourges (of 1438, which made France largely independent of the papacy in ecclesiastical jurisdiction) failed with King Charles VII but succeeded with his son Louis XI (1461). The Greek cardinal Bessarion was sent to Germany (1460) to promote the crusade, but local feuds and wars blocked his efforts. He was equally unsuccessful in Vienna and returned to Rome in the following year but had some success later in Venice. Wars in the Tyrol and discord in Bohemia increased the general unrest. A lull in some hostilities and promises of support from the emperor Frederick and Philip the Good, duke of Burgundy, encouraged the intrepid but sick Pope to proclaim in October 1463 a crusade, which he himself would lead. Pius left Rome on June 18, 1464, for the rendezvous of the armies in Ancona, an Adriatic seaport on the east coast of Italy, where he arrived to find nearly no one. Two Venetian ships arrived on August 11. Pius died during the night of August 14–15. His heart was interred at Ancona, still facing as it were, the infidel East. His body was taken to Rome and there buried in St. Peter's; it was transferred to the church of S. Andrea della Valle when the new St. Peter's was being built.

Pius' achievements

Pope Pius II's great knowledge of conditions in Germany and elsewhere inspired a scheme of wide church reform, but the political conditions of the time and the resistance of the various vested interests rendered its application impossible. He did what he could, particularly by encouraging the movements toward strict observance of the rules of life within religious orders. On the whole, he created worthy cardinals, and on January 17, 1460, he issued a bull condemning appeals from a pope to a general (ecumenical) council of the church. A voluminous writer about the events he had participated in, he wrote also general history and geography, poetry, and at least one scurrilous novel (*The Tale of Two Lovers*). As pope he was a patron of humanists but not to excess either in the use of money or in being complacent about their morals.

BIBLIOGRAPHY

Writings: Pius II's complete works, *Opera omnia*, ed. by M. HOPPERUS, were printed in 1551. Other collections are *Orationes politicae*, ed. by J.D. MANSI (1755–59); and *Opera inedita*, ed. by J. CUGNONI (1883).

English translations: His novel *De duobus amantibus* was much translated (first Eng. trans., *The Goodly History of the . . . Ladye Lucres of Scene in Tuskan*, 1560); new Eng. trans., *The Tale of Two Lovers*, by F. GRIERSON (1929). "The Commentaries of Pius II," ed. by F.A. GRAGG and L.C. GABEL, were published in *Smith College Studies in History*, vol. 22, 25, 30, 35, and 43, abbreviated into the autobiographical account *Memoirs of a Renaissance Pope* (1959). The *De gestis Concilii Basiliensis commentariorum libri II*, ed. by D. HAY and W.K. SMITH (1967), was written in 1440 supporting conciliarism.

Lives: B. PLATYNA, *Vita Pii II in RIS* (Rerum italicarum scriptores), vol. 3, pp. 246–263, by a contemporary curial official; R.J. MITCHELL, *The Laurels and the Tiara: Pope Pius II, 1458–1464* (1962); G. PAPARELLI, *Enea Silvio Picollomini, Pio II* (1950).

Pius V, Saint and Pope

An ascetic and reformer who inaugurated one of the most austere periods in the history of the Roman Catholic Church, Pius V, pope and saint, succeeded in rooting out

the last vestiges of Protestantism in Italy. Pius V was born Antonio Ghislieri on January 17, 1504, at Bosco in northern Italy. He came from a poor family and was a shepherd until the age of 14, when he became a Dominican friar. His first important appointment was as inquisitor, a high office of the Inquisition, then the Roman Catholic Church's judicial system for discovering, examining, and punishing heretics. Ghislieri's methods, prompted by excessive zeal, provoked such opposition from his bishop's officials as well as his chapter that he was recalled in 1550. The chief inquisitor in Rome, Giovanni Pietro Carafa, convinced of his value, sent him on a mission to Lombardy and, in 1551, appointed him commissary general of the Roman Inquisition. When Carafa became pope (as Paul IV), Ghislieri was made bishop of Nepi and Sutri (1556), cardinal (1557), and finally grand inquisitor of the Roman Church (1558). He was continued in this office by Pius IV, whom, however, he antagonized by his censoriousness and obstinacy. After the death of Pius IV, the adherents of strict religious rules, led by Cardinal (later St.) Charles Borromeo, the nephew of Pius IV, had no difficulty making him pope (January 7, 1566). Retaining his ascetic mode of life, Pius immediately began the work of reform. Decrees and ordinances were issued rapidly; the papal court became a model of sobriety; prostitutes were driven from the city or confined to a certain quarter; penalties were fixed for Sunday desecration, profanity, and animal baiting; clerics holding benefices were required to spend definite periods in their administrative districts; members of convents were compelled to live in strict seclusion according to their vows; instruction in the catechism, the short manual outlining the principles of Catholicism, was ordered. A new catechism appeared in 1566, followed by an improved breviary (the daily prayers for clergy and nuns [1568]) and an improved missal (a book containing the prayers and responses for celebrating the mass [1507]). The use of indulgences—*i.e.*, the remission of temporal punishment due for sin—and dispensations from vows was restricted, and the whole system of penance reformed.

Reform activity

Pius V, contemporary medallion. In the coin collection of the Vatican Library.

Pius was an avowed enemy of nepotism. Though it is true that he made one nephew cardinal, he was allowed to have no influence, and the rest of the family was kept at a distance. By the constitution *Admonet nos* (March 29, 1567), he forbade the reinvestiture of fiefs—those landed estates held under feudal tenure that were intended to revert to the Holy See—and bound the cardinals by oath to observe it. In March 1569 Pius ordered the expulsion of the Jews from the States of the Church, though for commercial reasons they were allowed to remain under humiliating conditions in Rome and Ancona. In February 1571 the Humiliati, a corrupt monastic order of Milan, was suppressed on account of an attempt upon the life of the archbishop, Cardinal Borromeo.

The rules governing the Inquisition were sharpened; old charges, long suspended, were revived; rank offered no protection but rather exposed its possessor to fiercer attack. None was pursued more relentlessly than the intellectuals, among whom many of the Protestant doctrines had found acceptance. Princes and states withdrew their protection of heretics and courted the favour of the Holy See by surrendering distinguished offenders. Philip II of Spain in 1566 surrendered Bartolomé de Carranza, the Spanish theologian and former confessor to Queen Mary of England, and Cosimo de Medici in 1567 gave up Pietro Carnesecchi, the Florentine heretic who had been suspected even during Paul IV's papacy (receiving two years later as a reward the title of grand duke of Tuscany). In March 1571 the special Congregation of the Index, a list of books condemned as dangers to faith and morals, was established distinct from the Inquisition, and hundreds of printers took flight to Switzerland and Germany. The regret of Pius was that he had sometimes been too lenient. He encouraged Philip II of Spain to use the most ruthless tyranny to preserve his Dutch subjects in the Catholic faith and sent troops to France to help Catherine de Médicis repress the Huguenots; he protested against the tolerance shown by the Holy Roman emperor Rudolf II.

Establishment of the Index

In all this work, Pius confirmed Borromeo's belief that a spiritually minded pope was above all else necessary if the decrees of the Council of Trent (1545–63) that were intended to rebut Protestant doctrines and to reform Catholicism were to be put into practical effect. The moral standing of the papacy was greatly raised, and its effectiveness was immensely increased by the obliteration of heresy in Italy, and the morale of the church was much improved by the universal insistence on interpreting church doctrine according to the precepts established at the council. Yet it is open to doubt how much of this improvement was due to Pius' continuous use of the Inquisition. Some of the credit belongs to the new generation of higher and lower clergy in the several provinces whose attitude was so different from that of their predecessors. The council left him to finish the reform of the missal and breviary, but he left the medieval canon virtually unchanged, as it remained until 1970.

Moreover, Pius' policy had practical disadvantages. It took too little account of the wishes of secular rulers at a time when their support was essential for the defense of the church against heresy. He excommunicated Elizabeth I of England and declared her an usurper (February 25, 1570) without possessing the means to enforce his judgment, and he antagonized not only England but Spain, France, and the Holy Roman Empire as well. Much more successful was his organization of a crusade against the Turks, which resulted in a decisive naval victory of Lepanto (October 7, 1571). He made October the month of the rosary because of his victory. Pius died on May 1, 1572, and was canonized by Clement XI in 1712. His feast day is May 5.

BIBLIOGRAPHY. The fullest biography is F.A.P. DE FALLOUX, *Histoire de St. Pie V*, 2 vol. (1844). Slighter biographies (*Vita di Pio V*) are two that appeared soon after his death: GIROLAMO CATENA (1586) and GIOVANNI ANTONIO GABUZIO (1605). There is a study of the Pope's policy towards France by C. HIRSCHAUER, *La Politique de St. Pie V en France 1566–1572* (1922). H. DANIEL-ROPS, *Une Ère de renouvenu: la Réforme catholique* (1955; Eng. trans., *The Catholic Reformation*, 1962), has a good section on Pius V.

(I.F.B./D.Wo.)

Pius IX, Pope

Pius IX, Pope (Giovanni Maria Mastai-Ferretti), also known as "Pio Nono," was pope from 1846 to 1878, the longest pontificate in history. It had far-ranging effects for the development of the Roman Catholic Church during the period from the mid-19th to the mid-20th century. It was in his pontificate that the papacy lost control of the papal states, the dogma of the Immaculate Conception was declared, the Syllabus of Errors of 1864 was issued, the First Vatican Council was convened, and the doctrine of Papal Infallibility was authoritatively defined.

Prepontifical life. Pius IX was born on May 13, 1792, at Senigallia, Italy, the fourth son of Girolamo Mastai-

Pius IX.
Felici

Ferretti, gonfalonier (standard-bearer) of Senigallia, and the countess Caterina Solazzi. He first came into prominence as archbishop of Spoleto from 1827 to 1832, a time of revolutionary disturbance. He was made bishop of the important diocese of Imola in 1832, but it was not until 1840 that he received the hat, as cardinal priest of SS. Piero e Marcellino, the delay being generally ascribed to the disquiet caused by his liberal views. He was not, in 1846, the most prominent liberal candidate likely to succeed Gregory XVI; but it took the conclave only two days to determine his election (on June 16, 1846) and so prevent that of the conservative Luigi Lambruschini. He took the name of Pius in deference to the memory of Pius VII, who had been his friend and who had, like him, been bishop of Imola. The choice was in some sense prophetic, for "Pio Nono," as his predecessor had done, began his career as a supporter of liberal ideas only to learn from bitter experience that liberals often tended to be anticlerical. In 1846, however, all this lay in the future and Europe was agog at the unusual spectacle of a liberal pope.

Early reign. The new pope was confronted by a difficult situation. All Europe, save perhaps Metternich of Austria, considered that the papal states stood in urgent need of reform. A memorandum drawn up in 1831 by the French, Austrian, Russian, and Prussian ambassadors in Rome (with the support of the British representative in Florence) had suggested that councils should be elected to assist in local government, that a central body, composed partly of elected representatives, should control finance, and that the dominant position held by the clergy in the administration and in the judicial system should be terminated. Liberal opinion clung to these measures as absolutely essential throughout the pontificate of Gregory XVI. In addition, the papacy was constantly under attack by Italian nationalists as one of the instruments through which Austria maintained its domination over the peninsula.

Pius recognized that the papal administration, if not so corrupt and despotic as its opponents asserted, was inefficient and intolerant, but he was sufficiently Italian to resent Austrian interference. Above all, he saw the need for the papacy to possess a greater measure of popular support. Yet he was never a revolutionary. He believed that the interests of the church must always come first, and he appreciated that the conservative Catholic powers such as Austria were entitled to consideration for the practical support that they had given the church in the past. That he should eventually disappoint his revolutionary supporters is not surprising, and Pius himself was early aware of this possibility. A criticism more substantial than that of betrayal of the liberal cause is that he chose to depart from the traditional policies of his predecessors without possessing any definite plans for avoiding the pitfalls that must surround the paths of a pope endeavouring to ally himself with liberalism and nationalism. Pius wasted no time. He declared a general political amnesty on July 16, 1846, and followed it by a number of practical reforms, including a reorganization of the criminal procedure. Some financial reforms of an administrative character came next, and the censorship was mitigated. Finally came Pius' most daring innovations, the political reforms announced in 1847. The council of ministers became a cabinet of departmental heads of which only the secretary of state was of necessity to be a cleric, it was to be advised by a council of 24 elected members, and a municipal government was established for Rome that included an elected representative body. At the same time, the papacy brought support to the cause of Italian nationalism when Pius ordered the Austrian government to withdraw from Ferrara the reinforcements sent to its garrison there and opened negotiations with Piedmont for a national customs union.

Papal responses to Austrian domination of Italy

The revolution of 1848. The year of revolutions, 1848, began with revolution in Sicily; soon all Europe was ablaze and Pius was faced with demands, both liberal and nationalist, much beyond what he had been prepared to grant. On March 14 he was compelled to grant a constitution establishing a two-chamber parliament with full legislative and fiscal powers subject only to the pope's personal veto. On March 23 Charles Albert of Sardinia (Piedmont) declared war on Austria. For a time Pius continued to endeavour to steer a middle course, claiming in his address to the cardinals of April 29 that he was a disinterested spectator of the revolutionary activities sweeping Italy and that his program of reform was merely the fulfillment of the program long pressed upon the papacy by the powers. In the atmosphere of the time such sentiments were judged as displaying absolute hostility to the national cause, and the papacy was never again able to appear in Italy as anything other than a bulwark of reaction.

To prevent revolution from breaking out in Rome itself, Pius consented to the appointment of popular ministries, but none of the appointees were able to control the situation. A steadily deteriorating situation culminated in the assassination of one of them, Pellegrino Rossi, on November 15. A radical ministry was appointed under Emanuele Muzzarelli and Giuseppe Galletti, and when the Swiss guards were disbanded the pope was a virtual prisoner. On November 24–25, with the aid of the French and Bavarian ambassadors, he fled to Gaeta in the kingdom of Naples. In his absence, elections were held for a constituent assembly; and this, on February 9, 1849, declared the temporal power at an end and a democratic republic to be established. The papacy thereupon issued a formal appeal to the rulers of France, Austria, Spain, and Naples, but not Piedmont, for assistance. Although it was generally considered that the pope's restoration could take place only with some sort of undertaking to maintain constitutional government in the papal states, and although Louis-Napoleon, the newly elected president of France, was in favour of such a policy, Pius held out against any concessions and asserted his determination to exercise his temporal power without any restrictions whatsoever. The upshot of a period of military and diplomatic manoeuvre on the part of France and Austria was the unconditional restoration of papal rule by the French general N.-C.-V. Oudinot on July 15. The revolution was over, and Pius himself returned to his capital on April 12, 1850.

The Roman question. It has often been asserted that Pius returned to Rome a changed man, that the former liberal had become a narrow reactionary. That his policy had changed there is no doubt, but his fundamental attitude remained the same. The interests of the church had always been his first concern, and he could never be an unconditional ally of nationalism or liberalism. He had been prepared to countenance both while they left the church intact, but experience had taught him that both led to revolution, which he had never been prepared to countenance. Furthermore, political concessions on his part had led to attacks on his spiritual power, and he considered that it could be protected only by his continued exercise of a temporal authority. Once these two aspects of his dominion had become indissolubly linked, it is easy

to see why Pius considered himself obliged to oppose any alteration of his position as a temporal ruler.

In 1846 Pius had considered that a new departure was necessary to meet the legitimate demands for reform within the papal states and perhaps also those for a change in the Italian system of states; he had experimented and failed, and he now considered that he could do no more. But the problems that he had tried to solve remained, and to substitute no policy at all for one that had failed was no answer. The new secretary of state, Cardinal Giacomo Antonelli—a layman, to whom diplomacy was now entrusted, since Pius recognized his own inadequacies in the field—considered throughout that, in endeavouring to retain the temporal sovereignty untouched, he was fighting a losing battle, but that he had no practical alternative to a policy of inaction. So, not for the first time in history, the papacy was a spectator while events changed the map of Europe.

Role of papal secretary of state

Most of the administrative reforms carried out immediately after Pius' accession remained, and the papal territories benefitted from the general increase in European prosperity after 1850. But constitutional government was never restored; the amnesty granted on the pope's return was so riddled with exceptions as to be worthless; and to all expressions of national sentiment the papacy was utterly hostile. It was not that papal government was tyrannical but that it formed an absolute barrier in the way of Italian unification upon which politically minded Italians were set. So relations with Piedmont, where Count Camillo Cavour became chief minister in 1852, grew steadily worse. What began as a dispute over the terms of a new concordat took on a much more serious aspect when Cavour found it politically expedient to encourage anticlerical feelings during the passage of a law in 1855 dissolving a large number of religious houses. Certain of papal opposition, Cavour began in the same year his plans to achieve Italian unification under the leadership of Sardinia-Piedmont alone. At Plombières in 1858 he agreed with Napoleon III to combine to eliminate Austria from the Italian peninsula and so to settle the fate of Italy between them. Pius declared his neutrality in the war which broke out in April 1859, fearing that the victory of either of his protectors would leave him at its mercy. The Austrian defeat and the armistice of Villafranca resulted in the pope's losing control over the Romagna but nowhere else. Sporadic negotiations for the establishment of an Italian confederacy under the presidency of the pope went on during the winter of 1859–60, but the pope's refusal to contemplate the loss of any part of his dominions brought them to an end. In January 1860 Cavour (who had resigned in protest against the armistice) returned to power, possibly as a direct consequence of the pope's intransigence, and agreed with France to cede Savoy and Nice in return for a free hand everywhere in Italy except at Rome itself. The newly raised papal army was defeated at Castelfidardo on September 18, and the papal states were quickly overrun. French troops protected the Patrimony of St. Peter, which alone among his dominions still remained in the pope's hands.

The loss of temporal power

For ten more years the remnant of the temporal possessions were retained by virtue of the presence of a French garrison at Rome. Cavour himself was favourable toward an agreed settlement of the Roman question on the basis of a continuing papal sovereignty over all the states of the church but with its exercise entrusted to the king of Italy. A start was made to begin negotiations, but then the pope suddenly withdrew. In less than a year Cavour had died (June 1861), and it was clear that the pope would be able to hold his remaining territories just so long as Napoleon III was willing and able to maintain the French garrison in Rome. When the Franco-German War broke out that was no longer possible. On Sept. 20, 1870, Italian troops occupied the city; and in October a plebiscite was held in which an overwhelming majority of the votes cast were for the incorporation of Rome in the kingdom of Italy. Pius remained for the rest of his days a prisoner, as he regarded himself, in the Vatican. He refused any intercourse with the Italian government, so that their relations rested upon a law passed by the Italian parliament in November. The sovereignty of the pope was declared to be untouched by the loss of his dominion in compensation for which he was to receive an annual sum of money. He was to be entitled to conduct his own diplomatic relations with other powers and to have exclusive authority within the Vatican itself and a small district around it. In the rest of Italy, church and state were to be separated. So, though the papacy did not formally recognize the fact until the concordat of 1929, the Roman question had been settled.

Ultramontanism. Important as the events just described were for the papacy, the doctrinal developments of Pius' pontificate, which spring directly out of these political disasters, constitute its most significant contribution to papal history. Ultramontanism began with Joseph de Maistre, as a reaction against Gallicanism and against Josephinism, seeking to free the church from the chains of secular control by binding it more closely with the papacy. H.-F.-R. de Lamennais developed it by suggesting that the church would benefit from a general increase in political freedom. Gregory XVI condemned Lamennais's teaching because he saw that freedom might mean freedom to deny religion altogether. Pius IX decided in 1846 to experiment with liberalism but later became convinced that Gregory XVI had rightly suspected it. Nevertheless, if Italy taught Pius one lesson, developments in France, where the church prospered more under the liberal regime of Louis-Philippe than it had under the clerical Charles X, suggested quite the opposite conclusions to the liberal Catholics there, whose spokesman was Charles de Montalembert. On the other hand, the coming of the Second Empire stimulated the party led by Louis Veuillot, whose Ultramontanism was of the older sort, completely divorced from liberalism and seeking freedom for the church in an authoritarian state that would guard it against revolution.

For a period after 1850, Pius' policy took little heed of either brand of Ultramontanism. Antonelli followed the paths of Consalvi, Pius VII's secretary of state, in seeking to procure more favourable concordats with Catholic rulers. Most important was that with Austria (1855), the home of Josephinism; and others were concluded with Spain (1851, 1859), with Portugal (1857), with Württemberg (1857), with Baden (1859), with Nassau (1861), and with a number of Latin-American states (1852–62). Such agreements might be politically valuable but were no defense against intellectual anticlericalism; and Pius became increasingly convinced that the real danger to the church lay in the modern secular ideas that the liberal Catholics were endeavouring to incorporate into its doctrines. The events of 1860 finally convinced him that the notion of a "free church in a free state," as dear to Montalembert as it was to Cavour, was a snare. The encyclical *Jamdudum Cernimus* (March 18, 1861) denounced not only Piedmontese aggression but all modern political doctrines, which, it said, encouraged non-Catholic religions, allowed full freedom to attack the church in print, and sought always to undermine the authority of the church. The risorgimento not only convinced Pius that liberalism in the church must be destroyed but also placed the liberal Catholics in the difficult position of appearing to support those who had caused him so much distress. In every way the ground was being cleared for a new departure. The alternative to Montalembert's doctrine was no longer an unconditional attachment to the principles of the *ancien régime* but a new kind of Ultramontanism, asserting the need for concentrating church authority in the pope's hands. The ground was being prepared for the first Vatican Council and the doctrine of papal infallibility.

Pius' attack on liberalism

But first the strong liberal party in the Catholic Church had to be defeated. In 1863 Montalembert was invited to address a large Catholic congress at Malines, and he took the opportunity to defend the concept of a free church in a free state and to condemn intolerance in principle, citing as an example the revocation of the Edict of Nantes. Pius was content in reply to point out that on these two points he was running counter to authoritative pronouncements of Pius VI and Gregory XVI. This was sufficient to deter Montalembert from accepting a second invitation to Malines in 1864, but his supporter F.-A.-P. Dupanloup

proved an able substitute. Meanwhile, at a congress at Munich in 1863, J.J.I. von Döllinger had pleaded for the right of a scholar to pursue independent inquiry. It was clear to everyone that the church stood in need of authoritative pronouncements about its relations with the state and with modern society, and discussion began about the possibility of calling an ecumenical council for this purpose. But once again the Roman question intervened decisively in the struggle.

On Sept. 15, 1864, the French and Italian governments came to an agreement whereby the French garrison was to be withdrawn from Rome within two years. In fact, it was not finally withdrawn until the outbreak of the Franco-German War, but the conclusion of the September convention was sufficient to make Pius decide to take immediate action against liberalism. On Dec. 8, 1864, he issued the encyclical *Quanta Cura* with, attached to it, the famous *Syllabus* listing 80 of the "principal errors of our times." As the errors listed had already been condemned in allocutions, encyclicals, and other apostolic letters, the *Syllabus* said nothing new and so could not be contested. Its importance lay in the fact that it published to the world what had previously been preached in the main only to the bishops, and that it made general what had been previously specific denunciations concerned with particular events. Thus perhaps the most famous article, the 80th, stigmatizing as an error the view that "the Roman Pontiff can and should reconcile himself to and agree with progress, liberalism, and modern civilization," sought its authority in the pope's refusal, in *Jamdudum Cernimus*, to have any dealings with the new Italian kingdom. On both scores, the *Syllabus* undermined the liberal Catholics' position, for it destroyed their following among intellectuals and placed their program irrevocably out of court.

The *Syllabus*

Though Dupanloup tried to explain away the *Syllabus* by insisting upon its context and by stressing its purely negative aspect (thus, though the concept of toleration as the final and universal answer was condemned, it did not follow that intolerance was universally valid), the *Syllabus* nevertheless dealt a mortal blow at liberal Catholicism, which ceased after 1864 to be the main issue taxing Catholic controversialists. While some of Louis Veuillot's followers hoped that at the forthcoming council a positive statement of the orthodox doctrine of the position of the church in society would replace the negative denunciations of the *Syllabus*, the majority looked upon that battle as won and so turned to the question of defining the pope's infallibility, the keystone of the neo-Ultramontane program of centralizing the authority of the church in Rome so as to escape from the control of the secular state. Conversely, the former liberal Catholics were ranged in opposition to this project. When the council at last met, on Dec. 8, 1869, everything was ready for a decisive engagement.

The Vatican Council. In the doctrine of papal infallibility itself there was nothing new. It had been employed to define, on Dec. 8, 1854, the dogma of the Immaculate Conception, which asserted that the freeing of the Virgin Mary from all taint of original sin had occurred at the moment of her conception. The pope had previously made extensive inquiries among the bishops and other divines and there was little opposition to such an exercise of his undoubted prerogative. When, however, at a gathering of bishops and other dignitaries of the church in Rome in 1862 and again at another in 1867 it had been suggested that the doctrine of infallibility should be authoritatively defined, Dupanloup had led a successful opposition to the project. It was objected that such a definition was inopportune, tending to widen the breach between the church and modern society, and that it would present a one-sided view of the source of authority in the church; for while the pope possessed powers issuing directly from God, so too did the bishops, for instance, whose ordinary jurisdiction arose, not out of their nomination or institution (whether by the state or by the church) but equally from divine origin; so that the pope's powers ought not to be defined without reference to other aspects of the nature of the church. The criticism that must attach to Pius is that he allowed, even encouraged, the council to put aside discussion on the wider issue, which was its original program, in favour of the narrower definition. This was, of course, precisely what the Ultramontane party desired. The Ultramontanes, indeed, undoubtedly possessed the backing of by far the greater part of the church, partly because of the reaction engendered by the political misfortunes of the last decade, partly because of the immense prestige enjoyed by Pius as a result of his long and tragic pontificate, but to a larger extent because of the contemporary movement away from intellectualism and in favour of devotional religion. Pius himself was at the front of this movement and received strong support from the Jesuits, whose influence was most emphatically increasing.

The dilemma of the church

The first Vatican Council opened on Dec. 8, 1869, the day of the feast of the Immaculate Conception, which Pius chose for the majority of the important acts of his pontificate. The opposition, consisting of the German, French, and U.S. bishops, was strong enough to prevent a definition of the doctrines and nature of the church on the lines suggested by the *Syllabus*; but the Ultramontane party, led by Archbishops H.E. Manning (of Westminster) and V.A. Dechamps (of Malines) brought forward the question of infallibility, upon which their position was much stronger. Pius intervened decisively to alter the procedure of the council on Feb. 20, 1870, and again on April 29, and to make known his personal support for Manning and Dechamps. The outcome was to postpone all deliberation except that upon infallibility. The decisive vote came on July 13 when 451 voted for it, 88 against it, and 62 in favour of some amendment. Thereupon the minority left Rome and the final definition was carried on July 18 by 533 votes to 2 (see also OLD CATHOLIC CHURCHES). Infallibility was confined to those occasions upon which the pope made pronouncements *ex cathedra*; but these pronouncements were to take their authority from God and not from the consent of the church, and no mention was made of any other divine authority existing in the church except that of the pope. There is no doubt that this act secured the triumph of the Ultramontane party or that the decisive element in it was provided by Pius himself.

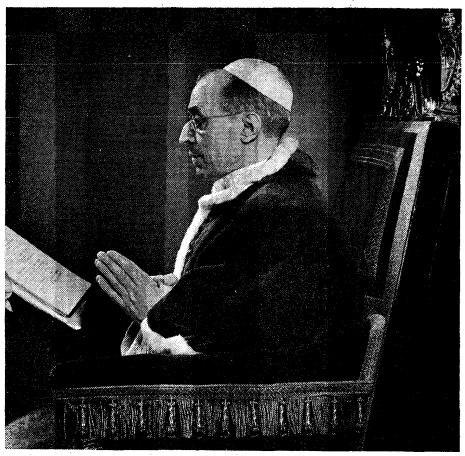
Definition of papal infallibility

Last years. Pius reigned for another eight years, during which he became further estranged from the Italian government and witnessed a general outbreak of anticlericalism in western Europe. In Germany this culminated in Bismarck's *Kulturkampf*, which Pius condemned in the encyclical *Quod Nunquam* of Feb. 5, 1875, leaving the solution of the problem to his successor. Pius died on Feb. 7, 1878, having seen in his long pontificate the creation of the modern papacy.

Evaluation of his pontificate. The exact responsibility of Pius for the events of his pontificate is still a matter for controversy. The result is clearer. Church and state were finally separated, authority in the church was centralized in Rome, and the church was ranged in opposition to the dominant political forces. On that score Pius was condemned by many contemporaries; the 20th century, however, was to see Italian nationalism develop into Fascism and revolutionary principles into Communism. Whether the separation of church and state reinforced anticlericalism or inoculated the church against its effects is less certain.

But perhaps the most damaging criticism of Pius is that he assumed almost the sole direction of events while never appreciating their significance. The great events of his pontificate occurred despite him rather than because of him. Thus he condemned in the *Syllabus* that very separation of church and state which it was the work of the first Vatican Council—to which for the first time the secular Catholic rulers were not invited—to secure. At one time or another Pius was served by the leaders of all the important movements of his century, by liberal cardinals like Pasquale Gizzi, by ecclesiastical statesmen like Antonelli, and by the ascetic Manning, a convert from Protestantism. Yet it is unfair to say that he changed his political principles; rather he never possessed any, save in his personal religious life, that were not rather naïve, and so he

was always open to be guided by experience. In view, however, of the benefit that has accrued to the church from the loss of the temporal power, it should at least be asked whether it was not Pius' determination to maintain it at all costs that contributed most to the temporal power's being lost.



BIBLIOGRAPHY. The best biography in English, *Pio Nono: A Study in European Politics and Religion in the Nineteenth Century* by E.E.Y. HALES (1954), was written avowedly to explain events from the viewpoint of Pius IX. It is a scholarly work, enriched with a bibliography covering not only the pontificate but the wider Italian and European context. FERNAND HAYWARD, *Pie IX et son temps* (1948), is the work of a French scholar, favourable to the Pope but showing much research. For a less favourable view, see *The Roman Question: Extracts from the Despatches of Odo Russell from Rome*, 1858–1870, ed. by NOEL BLAKISTON (1962). A.C. JEMOLO, *Chiesa e Stato in Italia negli ultimi cento anni* (1948), is a massive study, particularly strong in the study of ideas. ROGER AUBERT, *Le Pontificat de Pie IX* (1952), is thoroughly reliable, as is the same author's *Vatican I* (1964). ABBOT CUTHBERT BUTLER, *The Vatican Council*, 2 vol. (1930; new ed. by CHRISTOPHER BUTLER, 1 vol., 1962), based on correspondence with the English bishop Ullathorne, gives a good account of Pius' activity at the council. More specialized studies are *The Syllabus of Errors* by the American scholar, DAMIAN MCELRATH (1964); and *Pio IX e Leopoldo II* by GIACOMO MARTINA (1967).

Pius XII, Pope

Elected in March 1939, Pius XII (Eugenio Pacelli) was pope during World War II and during the years of postwar reconstruction. For 20 years he was a copious speaker and writer, and his ideas on international structures and reforms in liturgy and biblical studies were important, but his conduct during World War II has been the subject of controversy.

Pius XII.

Early life and career

Eugenio Pacelli was born in Rome on March 2, 1876. His family came from Tuscany and had supplied Vatican lawyers since 1819. Eugenio was educated at Roman day schools and studied for the priesthood at the Gregorian University there, though for reasons of health he soon lived at home, not at his college of Capranica. He was ordained in 1899. He was a successful student with a quick mind and an exceptional memory, although the theological formation then available at the Gregorian University was limited. It was in the subject of law that he made his mark and so passed into the Vatican Secretariat of State. There he rose rapidly and in 1917 was made archbishop and sent as nuncio—a diplomat—to the Bavarian Court to negotiate a concordat (a Vatican-state agreement). This done, he passed (1925) to Berlin with the same aim and remained there until he was named cardinal, by Pius XI, and recalled to Rome at the end of 1929 to become secretary of state. After ten years in this office, during which he travelled on papal missions to North and South America and to France, he was elected pope in the shortest conclave since 1623.

These experiences are crucial in assessing Pacelli's pontificate. He grew up in a home of deep piety and of devotion to the papacy but also in a Rome smarting from the loss of the papal states, a Rome still clerical, resentful, and suspicious of the secular world. He inherited a diplomatic tradition and technique centred on the principle of the concordat, which aims to preserve the church's privileges and freedom of action, even under regimes irreconcilable with Christian principles.

Fascism came to power in Italy (1922) during Pacelli's absence in Germany, and his brother, a lawyer, helped to fashion the concordat with the dictator Benito Mussolini—to achieve which the Catholic Popular Party and any chance of ousting Mussolini were sacrificed. This settlement of the Roman Question, which created the Vatican city state (1929), satisfied Pius XI's ambition and that of many Italians but created many problems for the next 30 years in Pacelli's life, both in relations with the increasingly hostile dictatorship and with the uneasy democracy that succeeded it after the war.

Twelve years in Germany had made Pacelli fluent in German and had given him great love for the Germans. A tireless and methodical worker, he admired such virtues in the Germans and had many German helpers in the Vatican. But his deep knowledge of German affairs precluded illusions about Nazism, and the concordat with Hitler's Germany (1933), largely his work, was (he often said) a calculated risk, aimed at preserving a platform for Catholic life and ministry in a hostile German society.

His part in the anti-Nazi encyclical *Mit brennender Sorge* (1937; "*With Burning Sorrow*") his dozens of other notes and memoranda to the German Government as secretary of state, his frigid and outspoken reception of the Nazi foreign minister Joachim von Ribbentrop in Rome, his bitter reproach of the Austrian Cardinal Theodor Innitzer's weakness in face of the Austro-German *Anschluss*—the union of Austria and Germany—in 1938, and finally the unfavourable German reception of his election as pope, all showed his true estimate of the German tyranny.

During the few months between his election and the outbreak of war, Pius XII turned his diplomatic gifts to preventing the catastrophe, but not in the spirit of appeasement—the Vatican had disliked the Munich Agreement (1938) by which Czechoslovakia was sacrificed to expanding German power by Britain and France. Pius especially strove to keep Italy neutral and was deeply saddened when he failed.

Significance of papal reign

The demands of war harmonized with Pius' austerity and immense capacity for work; they enhanced his exalted, almost dramatic, conception of his office. His untiring efforts to humanize war and to relieve suffering, anxiety, and grief, though they did not always receive Axis cooperation, have been generally applauded. In a notable series of Christmas broadcasts (1939–48), he looked firmly toward the postwar future and to the opportunities it would offer for a new order in which the international community would be given real expression, replacing the egoistic nationalism that had bred war.

There has been less agreement about Pius' conduct and utterance in relation to the war itself. Deeply conscious of paternal responsibilities that transcended nationalism, pledged to neutrality, obliged to condemn unchristian conduct and yet fearful of provoking reprisals on the defenseless—the Pope clearly suffered many agonies of indecision, aggravated by his dislike of strife. He has been charged with neglecting, in the interests of a calculated neutrality, to raise an authoritative voice in defense of the persecuted, Christian or Jewish. Others have claimed that protests would have aggravated Nazi policy without achieving any good result. Both approval and censure of his choices during these difficult years have often been facile and superficial: the deeper question may be asked whether the nuances, the hints, the oblique allusions of traditional diplomacy, which came naturally to him and which often seemed to him much clearer than they seemed to others, were any longer appropriate to the savagery and cynicism of a death struggle for world domination and of deliberate genocide. The problems of

a neutrality that is not completely silent are never wholly surmountable, since causes are not morally neutral.

Though Pius refused to be drawn into any crusade against international Communism, he enacted severe measures against Catholics collaborating with Communists (1946); and the precarious balance between Christian Democracy and the extreme left in postwar Italy led him to encourage the Catholic Action leader Luigi Gedda, whose meddling in politics embarrassed the parliamentary Christian Democratic Party. Premier Alcide De Gasperi's successful protest against this (1949) earned him disfavour at the Vatican. When Pius' failing health left power in the hands of a "bureaucracy" of cardinals, including the autocratic head of the Holy Office, Alfredo Ottaviani, clerical interference in Italian public life reached a high pitch.

Many of Pius' innumerable addresses to specialist audiences dealt with urgent moral problems; by the end of his life he was moving toward outright rejection of modern war and doubted the justification of a war deterrent policy. In the field of marital relations, he made a number of pronouncements about the "safe period" without carrying discussion of birth regulation substantially beyond the position of his predecessor. Nor did he advance Catholic thinking or policy in the ecumenical field, though slight concessions were made in 1949.

Perhaps Pius' greatest utterance was the encyclical *Divino Afflante Spiritu* (1943; "With the Help of the Divine Spirit"), which gave fresh impetus and direction to Catholic biblical studies. These studies had been hampered by the inquisitorial atmosphere persisting since the days of crisis under Pius X over Modernism—a movement that sought, among other things, to apply modern methods of historical criticism to both the Bible and the life of Christ, but was vitiated by arbitrary philosophical assumptions. The encyclical welcomed most of the techniques of modern biblical scholarship.

Mediator Dei (1947; "Mediator of God") was a similar charter for the liturgical movement; he aimed at restoring a community character to public worship but mistrusted extravagant experiment. More conservative and suspicious views prevailed in *Humani Generis* (1950; "Of the Human Race"), touching on theological tendencies.

Pius' later ill health accentuated his solitary bent, increased the power of his conservative curia—the papal administrative bureaucracy—and aroused misgivings in some countries, not least in France, where Roman handling of the worker-priest problem—by sending worker-priests, who had been sharing the work and living conditions of labourers in order to extend their ministry, back to traditional religious tasks—caused deep resentment. When he died, at Castel Gandolfo in 1958, respectful mourning was worldwide, but Rome, showed few signs of the revolution in church life around the corner. Though he was gifted and deeply spiritual, history is unlikely to place him among the great creative popes.

BIBLIOGRAPHY. J.O. SMIT, *Pope Pius XII* (Eng. trans. 1951); OSCAR HALECKI and J.F. MURRAY, *Pius XII: Eugene Pacelli, Pope of Peace*, rev. ed. (1954); and N. PADELLARO, *Portrait of Pius XII* (Eng. trans. 1956), are conventionally laudatory and are works written in Pius' lifetime. English translations of two works of C. FALCONI, *The Popes in the 20th Century from Pius X to John XXIII* (1968), and *The Silence of Pius XII* (1970), assume an impartial manner but are basically hostile to Pius. R. HOCHHUTH, *The Representative* (Eng. trans. 1963), is a bitterly hostile caricature. Other works include: S. FRIEDLANDER, *Pius XII and the Third Reich: A Documentation* (Eng. trans. 1966); J. Pizarro, Francisco

Francisco Pizarro, the Spanish conqueror of the Inca empire of Peru, a man personifying an epoch that saw the extension of Spanish power to the greater part of the Caribbean and Central and South America, possessed in full the qualities of physical strength, valour, cunning, and leadership that were essential to conquest. With only 180 men, he landed in Peru, ascended the Andes, and captured the seats of Inca power in the cities of Cajamarca and Cuzco.

Francisco Pizarro, engraving by Crispijn van de Passe (1560–1637).
By courtesy of the Metropolitan Museum of Art, New York, Whittelsey Fund, 1951

Early life

Pizarro was born about 1475 in Trujillo, Spain, a small town some 130 miles (209 kilometres) southwest of Madrid. The illegitimate son of Captain Gonzalo Pizarro and Francisca González, a young girl of humble birth, he spent much of his early life in the home of his grandparents. According to legend he was for a time a swineherd, a not unlikely possibility since this was a common occupation of boys in that region. He doubtless participated in local manorial wars and, when these were ended, very probably went to fight in Italy. Certainly in 1502 he went to Hispaniola (modern Haiti and Dominican Republic) with the new governor of the Spanish colony.

Pizarro had little inclination toward the settled life of the colonizer, and in 1510 he enrolled in an expedition of the explorer Alonso de Ojeda to Urabá in Colombia. He appears to have been marked out as a hard, silent, and apparently unambitious man who could be trusted in difficult situations. Three years later, acting as captain, he participated in an expedition led by the explorer Vasco Núñez de Balboa that was credited with the discovery of the Pacific. From 1519 to 1523 he was mayor and magistrate of the newly founded town of Panamá, accumulating a small fortune.

Discovery of Peru. It was not until 1523, when he was some 48 years old, that Pizarro embarked upon the adventure that was to lead to his lasting fame. In partnership with a soldier, Diego de Almagro, and a priest, Hernando de Luque, he made preparations for a voyage of discovery and conquest down the west coast of South America. The initial period of exploration took place from 1524 to 1527, during which time Pizarro and his men endured many hardships. After eventually sighting a raft occupied by what appeared to be civilized Indians dressed in manufactured cloth, they decided to send Almagro back to Panama for reinforcements. The new governor of Panama, however, sent back orders that the expedition be abandoned in order that no more lives be lost. At this point Pizarro is reputed to have drawn a line on the ground with his sword, inviting those who desired wealth and glory to cross it. The "famous thirteen" who did cross the line continued their exploration of the coast as far as 9° S, obtaining distinct accounts of a great Indian empire as well as many Inca artifacts. They christened the new land Peru, probably a corruption of the name of a coastal river, the Virú.

Finding the Governor of Panama still opposed to their now promising enterprise, the explorers decided that Pizarro should go to Spain to ask Charles in person for permission to undertake conquest. Sailing in the spring of 1528, Pizarro was in Seville at the same time as Hernán Cortés, conqueror of Mexico, and was able to win Charles over to his scheme. He was decorated, granted a

coat of arms, and, in July 1529, made governor and captain general of the province of New Castile for a distance 600 miles south of Panama along the newly discovered coast. Pizarro was invested with all the authority and prerogatives of a viceroy, and Almagro and Luque were left in subordinate positions. All the famous thirteen received substantial rights and privileges in the new territories.

The conquest. Joined by four of his brothers, Pizarro sailed for Panama in January 1530 and by January of the following year was ready to set off for Peru. He set sail with one ship, 180 men, and 37 horses, being joined later by two more ships. By April they had made contact with emissaries of Atahuallpa, emperor of the Incas, who was residing near the city of Cajamarca with an army of about 30,000 men. Somewhat scornful of Pizarro's small force, the Inca accepted a proposal that the two leaders meet in that city.

Capture of Atahuallpa

Arriving on November 15, Pizarro immediately set up his artillery and sent his brother Hernando and another Spaniard to request an interview. After a day of tense waiting, Atahuallpa, borne on a litter, entered the great square of Cajamarca with an escort of between 3,000 and 4,000 men, who were either unarmed or carrying short clubs and slings beneath their tunics. Pizarro sent out a priest, Vicente de Valverde, to exhort the Inca to accept Christianity and Charles V as his master. Atahuallpa disputed both the religion and the sovereignty of the Spaniards and, after examining a Bible offered by the priest, flung the book to the ground. Valverde reported these events to Pizarro, who immediately ordered an attack. The astonished Incas were cut down from all sides, Pizarro himself seizing Atahuallpa.

Pizarro was now faced with the problem of maintaining his position until reinforcements could arrive from Panama. Atahuallpa was held as hostage and failed to win his release though he fulfilled a promise to fill the chamber in which he was held with gold and silver. Accused of ordering the execution of his brother Huascar, a rival for the title of Inca, and of plotting to overthrow the Spaniards, Atahuallpa was put to death by strangulation on August 29, 1533. With news of Atahuallpa's death, the Inca armies surrounding Cajamarca retreated; and Pizarro was able to progress towards Cuzco, the royal capital, which was occupied without a struggle in November 1533. The Spaniards declared Manco Capac, Huascar's brother, as Inca.

For the remainder of his life, Pizarro was engaged in consolidating the Spanish hold on Peru and in defending his and his brothers' share of the spoils. A certain enmity and rivalry developed between him and Almagro as a result of Pizarro's overriding powers from the king of Spain. This contravened a solemn agreement between the original three partners that the spoils of the expedition should be shared equally. Almagro at one stage seized Cuzco but was persuaded by Pizarro to depart for Chile, over which he had been granted extensive powers by the King. Disappointed by the poverty of that country, however, he returned to Peru, where he was made prisoner and later executed by Pizarro's brother, Hernando.

Pizarro himself was in Lima, a city that he had founded in 1535 and to which he devoted the last two years of his life. Almagro's former adherents had grouped around Almagro's son in Lima, where they were confined and watched. Suspecting that they were to be eliminated, they decided to move first, attacking Pizarro's palace on June 26, 1541. Pizarro died that day a protracted death, drawing a cross of his own blood on the ground, kissing it, and crying "Jesus" as he fell.

BIBLIOGRAPHY. Although not strictly concerned with Pizarro's actual life story, WILLIAM H. PRESCOTT, *History of the Conquest of Peru*, 2 vol. (1847); and SIR CLEMENTS R. MARKHAM, *A History of Peru* (1892), are two classic accounts of the Pizarro brothers' exploits. Modern appraisals of the Pizarros' feat include HAMMOND INNES, *The Conquistadors* (1969); and the magazine HORIZON, *Pizarro and the Conquest of Peru* (1970), both lavishly illustrated; MANUEL BALLESTEROS GAIBROIS, *Francisco Pizarro* (1940) and *Descubrimiento y conquista del Peru* (1963); JOHN HEMMING, *The Conquest of the Incas* (1970); LOUIS BAUDIN, *La Vie de François Pizare* (1930); and CLIFFORD SMYTH, *Francisco Pizarro and the Conquest of Peru* (1931), a narrative.

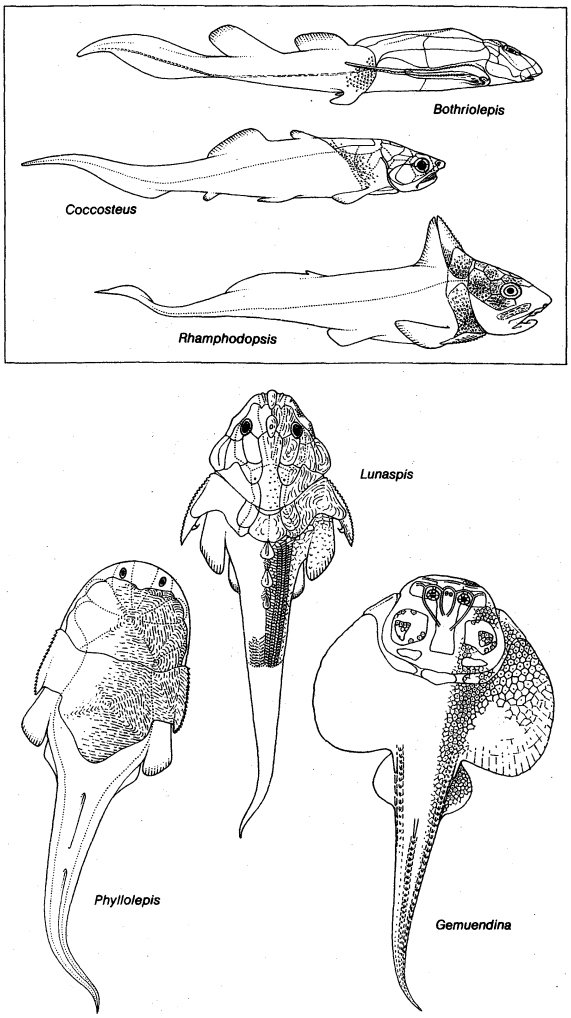
Placodermi

The Placodermi are an extinct class of fishes characterized by an armour consisting of a head shield and a trunk shield, the two often connected by a paired joint in the neck region. Placoderms existed throughout the Devonian Period (345,000,000–395,000,000 years ago), but only two species persisted into the succeeding Carboniferous Period which began about 345,000,000 years ago. During the Devonian they were a dominant group, occurring in all continents except South America in a variety of marine and freshwater sediments. Most were small or moderate in size, but a few may have reached a length of four metres (13 feet). Their origin is unknown, though it is possible that they shared a common ancestor with the sharks, skates, and rays. It is also possible that they died out leaving no descendants; it has been argued that one order, the Ptyctodontida, gave rise to the modern Holocephali (chimaeras and their allies).



Natural history. Fossils of the earliest known Placodermi, the Arctolepida, are found in freshwater stream deposits. Later members of this suborder were mainly freshwater inhabitants, though a number lived in the sea. The other suborder of Arthrodira, the Brachythoraci, were mostly marine forms, especially in the Upper Devonian. The Petalichthyida and Rhenanida were exclusively marine, the Phyllolepida only freshwater. Although the other two orders occurred in both habitats, the Ptyctodontida lived mostly in the seas and the Antiarchi mostly in freshwaters. One antiarch fossil shows evidence of both lungs and gills, probably an adaptation to life in poorly oxygenated freshwaters.

The earliest placoderms were heavily armoured, bottom-dwelling (benthic) fishes; they were poor swimmers. Many later forms became highly specialized for this type of life, as is well shown in some Arctolepida, which had a lengthened trunk shield and spinal plates, and in the Antiarchi, in which the shield was lengthened and flattened, the eyes and nostrils were in a dorsal position, and the pectoral fins, attached to the anterior end of the trunk shield, just behind the head, were jointed appendages adapted for crawling. The most striking benthic adaptation occurred in Gemuendinida, which superficially resembled modern rays; it is doubtful, however, that they swam by undulating their enlarged pectoral fins, as do the modern rays. The broad, flat-bodied Phyllolepida were adapted for life on stream bottoms. Petalichthyida and Ptyctodontida probably also lived near the bottom. Certain Brachythoraci became adapted for fast swimming between the surface and the bottom (*i.e.*, were nektonic).

Feeding habits

Sluggish, benthic placoderms with small ventrally (*i.e.*, on the lower side) placed mouths (Arctolepida, Petalichthyida) presumably fed on bottom detritus and small invertebrates. One of the Antiarchi, *Bothriolepis*, was a mud-grubber, as is revealed by the preserved contents of its intestine. The Gemuendinida had an anteriorly placed mouth suitable for feeding on small benthic invertebrates. Many Ptyctodontida had heavy, blunt jaw plates adapted for crushing hard-shelled invertebrates, and many Brachythoraci must have been predators—that their wide gape enabled them to swallow smaller fishes has been proved by the stomach content of some fossils. Other Brachythoraci had sharp jaw plates suitable for slicing pieces from larger prey. Some placoderms may have been herbivorous (plant eaters), but this has not been demonstrated.

Form and function. The most striking feature of Placodermi gives them their name; that is, their armour of dermal, or skin, bones, which were formed into a head shield and a trunk shield. The arrangement of bones is so different from that of modern fishes with bony skeletons that it is unlikely that the bones of the two groups have similar origins (*i.e.*, are homologous). For this reason the bones of placoderms have been given distinct names. Although the arrangement of bones differs in each order, it is possible that all placoderms were derived from a common ancestral type. The trunk shield, sometimes

Representative placoderms.
By courtesy of E.A. Stensio

called the dermal shoulder girdle, primitively had a median (*i.e.*, along the body midline) dorsal bone, two median ventral bones, and anterior and posterior pairs of lateral (*i.e.*, toward the sides) and ventral bones, joined by characteristic paired spinal plates. In many placoderms a hinged joint developed between the head and trunk shields, permitting considerable elevation of the head. The presence of an ossified, or bony, endocranium (*i.e.*, the skeleton surrounding the brain and sense organs) in some placoderms has provided detailed information of its structure in some placoderm types. The skeleton of the jaws and gills is not well-known in any placoderm. An enlarged hyomandibular bone supported the jaw articulation of Rhenanida and Ptyctodontida, but this bone is unknown in Arthrodira, in which the jaw hinge is fused to the so-called postsuborbital bone. Structures known as the palatoquadrates and Meckel's cartilages supported bones with teeth, crushing plates, or slicing edges. The gills, situated under the posterior part of the endocranium, were covered laterally by opercula (gill covers) and opened on either side by a slit behind the head shield.

In most placoderms the vertebral column lacked centra (an ossification of the central portion). Neural (dorsal) and hemal (ventral) arches and spines were commonly present on the vertebrae; vertebrae near the head were often fused to form a synarcual element that articulated with the endocranium.

The body behind the trunk shield was probably covered by scales in primitive placoderms; in most known forms these have been reduced or lost, and placoderms with fully scaled posterior regions have been found only in a few Rhenanida, Petalichthyida, and Antiarchi. The tail fin was tapering and whip-like in some, in others was upturned (heterocercal). Arthrodira, Ptyctodontida, and Antiarchi had one or two dorsal fins; Rhenanida and Petalichthyida had only enlarged dorsal scales. The presence of an anal fin in some Brachythoraci is suggested by an internal skeletal plate.

Fin structure

Paired pectoral fins are known in very few Placodermi; their structure can often be inferred from information provided by supporting skeletal elements. Some authorities consider long-based pectoral fins as primitive, but within the Placodermi such fins are found only in otherwise highly specialized Brachythoraci and Gemuendinida. The pectoral fins of the former had as many as 25 basal elements (supportive structures at the base); the latter had very large, raylike pectoral fins, each with an elongated basal plate and three series of radials, or supportive bones in the fins. More primitive Arthrodira (Arctolepida), as well as Ptyctodontida, Stensioellida, and probably Petalichthyida, had narrow-based pectoral fins with only three basal elements in some cases. Within the Arthrodira the long-based pectoral fin evolved from a narrow-based one. The most specialized pectoral fins, which occurred in the Antiarchi, were long, oarlike appendages covered with small plates, and had a complex articulation at the shoulder region and usually at midlength. These fins may have evolved from spinal plates such as occur in most other placoderms.

Paired pelvic fins occur in most Placodermi, but their presence is often indicated only by an ossified pelvic girdle. Rhenanida had relatively small, long-based, flaplike pelvic fins. The antiarch, *Bothriolepis,* had paired "frills" at the posterior end of the trunk shield; these may have been modified pelvic fins. In the Ptyctodontida, the pelvic fins differed in the two sexes; the females had large, scale-bearing pelvic fins, and the males had claspers that probably were used for internal fertilization.

Classification. *Distinguishing taxonomic features.* The major groups of placoderms are distinguished by a number of characters, the most important of which are the pattern of the dermal bones of the head and trunk shields, and the presence or absence of tesserae (minute, superficial plates) between the bones. The proportions of the head and trunk shields are significant, as are the positions of the eye orbits and the nasal openings. The structures of the pectoral fins and of related parts of the trunk shield are also important.

Annotated classification. In 1966 A.S. Romer, an American vertebrate paleontologist, published a classification of Placodermi on which the classification below is based. The dagger (†) is used to indicate the fact that the entire class is extinct and known only from fossils.

†CLASS PLACODERMI

Devonian to Lower Carboniferous (340,000,000–395,000,000 years ago). Head and trunk (or shoulder) region covered by a shield of dermal bones; the 2 shields often connected by a pair of joints in the neck region; a pair of spinal plates typically connect the lateral and ventral parts of the trunk shield; shield formed of bone, usually ornamented by tubercles (knobby prominences) or ridges of dentine (the predominant substance of teeth) or semidentine.

Order Arthrodira (Euarthrodira)

Lower Devonian to Lower Carboniferous; dermal bones of head and trunk shields, including cheek and gill covers, well developed and typically ornamented with tubercles; cranium not elongated posteriorly; 1 pair of paranuchal plates (head bones); lateral and ventral trunk shield with anterior and posterior series of bones; orbits lateral, nasal openings anterior; 2 pairs of upper and 1 pair of lower dermal jaw bones; marine and freshwater.

Suborder Arctolepida

Lower Devonian to Lower Carboniferous; lateral trunk shield not reduced; spinal plates usually large; pectoral fins narrow-based.

Suborder Brachythoraci

Lower to Upper Devonian; lateral part of trunk shield reduced; spinal plates reduced or absent; pectoral fins moderate to long-based.

Order Petalichthyida

Lower to Upper Devonian; roof of cranium greatly elongated posteriorly, with 2 pairs of paranuchal plates; orbits dorsal; cheek region covered with scales; trunk shield short, due largely to reduction in size of posterior plates; caudal fin unknown; no dorsal or anal fins; marine only.

Order Phyllolepida
Upper Devonian; body dorso-ventrally flattened; cranial roof short and broad with a very large median bone nearly surrounded by 5 pairs of small marginal elements; trunk shield broad and moderately long, lacking posterior bones on the sides; bones ornamented with more or less concentrically arranged ridges; freshwater only.

Order Ptyctodontida
Middle Devonian to Lower Carboniferous; cranial roof short, cheek bones reduced or absent, gill covers scaled; 1 pair of upper and 1 pair of lower shearing or crushing tooth plates; trunk shield short, lacking posterior bones; pectoral fins narrow-based, pelvic fins sexually dimorphic, with those of males having claspers; 2 dorsal fins and a long tail that tapers to a point; marine and freshwater.

Order Antiarchi
Lower to Upper Devonian; strongly armoured; adapted to bottom living; shields flattened ventrally; head short with distinctive dermal bone pattern; mouth ventral with small transversely placed jaws; orbits close together on top of head and nasal openings slightly in front of them; trunk shield long with 2 median dorsal bones; pectoral fins long, oarlike appendages articulated in shoulder region and usually jointed at midlength; body rarely covered with scales; 1 to 2 dorsal fins; tail with upper lobe larger than lower; almost worldwide in freshwater and sometimes in marine deposits.

Order Rhenanida
Lower to Upper Devonian; larger skull plates typically separated by fields of tesserae; trunk shield short; marine only.

Suborder Radotinida
Lower Devonian; a well-developed rostrum (blunt beak) anterior to the nasal openings, which are near the midline dorsally; eye orbits lateral.

Suborder Gemuendinida
Lower to Upper Devonian; flat-bodied, raylike fishes with much enlarged pectoral fins; orbits dorsal and nasal openings between them near midline; mouth terminal.

Suborder Stensioellida
Lower Devonian; poorly known forms with resemblances to Rhenanida; nasal openings probably ventral.

Critical appraisal. There is considerable difference of opinion among authorities about the interrelationships of the various orders and suborders. This may be attributed in part to incomplete knowledge of their structure, and in part to different emphases given to characters in the various classifications. The classification above is conservative in that it gives equal ordinal rank to each major group, and it implies no special close relationship among them. In another widely used classification, the Rhenanida and Antiarchi are considered to be so divergent that they are regarded as superorders; the remaining orders are grouped together as the superorder Arthrodira, and the order Euarthrodira is used to unite the Arctolepida and Brachythoraci. A different classification, based primarily on the structure and presumed evolutionary development of the pectoral fins, shoulder girdle, and spinal plates, is founded on the "fin-fold" theory of the origin of paired fins—according to which a long-based pectoral fin is primitive, and a narrow-based fin is specialized. This classification has not been widely accepted because it is completely opposed by the manner in which placoderm fossils are distributed in the geological strata, or layers.

Future studies may demonstrate special relationships among some of the following orders: Arthrodira, Petalichthyida, Ptyctodontida, and Rhenanida. The Phyllolepida and Stensioellida are too poorly known to permit satisfactory conclusions about their position in the classification.

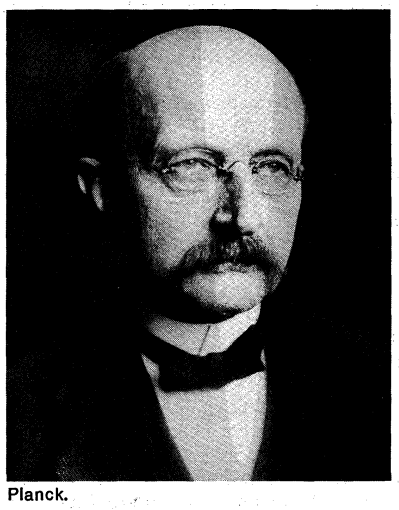
(R.H.D.)

Planck, Max

The beginning of the 20th century saw the development of two theories that brought about fundamental changes in physics and have gained significance far beyond this discipline: the quantum theory and the theory of relativity. The first of these, the quantum theory, was established at the turn of the century, on December 14, 1900, when a German physicist, Max Karl Ernst Ludwig Planck, at a meeting of the German Physical Society in Berlin, announced his sensational theoretical research into radiation and absorption by a black body, defined as a body that absorbs all the radiation that falls on it. In order to explain the distribution of radiant energy emitted from a black body at a given temperature, it was necessary for him to postulate that energy can exist only as quanta in multiples of an elementary quantity, now designated as Planck's constant (h). From that time on, a predominant role has been played in an ever-increasing number of fields by the new fundamental constant h, the quantum of action, introduced into physics by Planck, and it has proved to be of vital importance to the theory of structure of atomic dimensions. Thus Planck's discovery was to influence physics and the related sciences to a much higher degree than he himself could ever imagine.



An especially interesting point about the way in which Planck's new concept came into being is that Max Planck was the furthest from having a revolutionary mind. He was one of the conservative scientists of the classical epoch, and in thermodynamics he did not even recognize the probability interpretation, advocated at that time chiefly by an Austrian physicist, Ludwig Eduard Boltzmann. He felt compelled to use this particular statistical method only when he saw no other possibility of providing a theoretical basis for the correct radiation formula that he intuitively conceived.

Early life

Max Planck was born on April 23, 1858, in Kiel, Schleswig, West Germany, but he was descended from a South German family. He spent his school days and his first years of studies at the University of Munich. There he came into close contact with the many aspects of artistic life and developed an inclination toward music that was so strong that it made him hesitate about whether or not to devote himself completely to it.

Among Planck's teachers in his later years of study in Berlin were the famous physicists Hermann Ludwig Ferdinand von Helmholtz and Gustav Robert Kirchhoff. He made extraordinarily rapid progress in his studies and, at the age of 21, now back in Munich once more, he was awarded his doctor's degree in physics *summa cum laude*. The following year he became a lecturer at the University of Munich. His subject, theoretical physics, was at that time not well represented, and he first had to struggle for its authorization.

EB Inc.

Planck.

In 1885 Planck was called as extraordinary professor to the University of Kiel, where he married his first wife, Marie Merck, the daughter of a Munich banker. After the death of his wife, he married her niece, Marga von Hoesslin, the daughter of the Munich painter Georg von Hoesslin, in 1911, and this union lasted until his death.

When Kirchhoff died, Max Planck was called in 1889 as his successor to the University of Berlin, where—from 1892 onward as an ordinary professor—he spent 37 years at the Friedrich Wilhelm University delivering his brilliant lectures, and where he carried out his most important scientific activities.

In Berlin, Planck was able to devote himself unreservedly to many unsolved problems of physics. His preference was for thermodynamics, and here again he attempted to explain how energy is distributed according to wavelength in the so-called black-body radiation of a cavity. At that time there was a formula introduced by the German physicist Wilhelm Wien, for the distribution of energy, which corresponded with experiments in the short wavelength region. Berlin scientists had carried out new measurements of the black-body radiation with longer wavelengths and had found agreement with a theory that Lord Rayleigh, an English physicist, had prepared in 1900, which is still known as Rayleigh's radiation formula.

Planck succeeded first of all in obtaining, by skilful combination of the formulas of both Wien and Rayleigh, a new relationship in full agreement with the measurements taken over all wavelengths of the electromagnetic spectrum. This formula, which has since become famous as Planck's radiation formula, was announced by Planck on October 19, 1900, at a meeting of the German Physical Society, although he was not then able to give a theoretical basis for the formula. Then, in the short space of two months before the end of 1900, he succeeded in making a complete theoretical deduction, at the cost, however, of renouncing fundamental principles of classical physics and of introducing quanta of energy.

Planck's formula

Because of this break with classical physics, the quantum theory was at first rejected by many physicists. Most of them considered it to be an ad hoc hypothesis invented only to prove the correct radiation formula. It was only with the triumph of Niels Bohr, a Danish physicist, who in 1913 calculated for the first time the position of the special lines of a spectrum with the aid of the quantum theory, that the theory became a spectacular success.

Planck took little part in the further rapid development of the quantum theory that reached a pinnacle in the '20s by the efforts of the physicists Werner Karl Heisenberg, Erwin Schrödinger, Paul Adrien Maurice Dirac, and others in formulating quantum mechanics. Planck, on the contrary, frequently spoke out against the new ideas to which he, of course, had personally given the incentive, but which had now become much more revolutionary. Thus, Planck, to the end of his life, belonged to the group of older physicists who recognized the successes of the younger generation but who refused to see anything conclusive in their theoretical constructions.

In the meantime, Planck had taken on countless new fields of activity and honorary offices. In 1912 he became Permanent Secretary of the Section of Mathematics and Natural Science of the Prussian Academy of Science, of which he had been a member since 1894. He was also foreign member of the Royal Society of London and of other societies. In recognition of his services to the advancement of physics by the discovery of energy quanta, he was awarded the Nobel Prize for Physics in 1918. From 1930 he was president of the Kaiser Wilhelm Society of Berlin, which has borne his name since the end of World War II as the Max Planck Society.

Awarded Nobel Prize

But Planck also showed wide interests in fields other than physics. He occupied himself particularly with philosophical and religious problems, to which he devoted several publications.

During the National Socialist regime in Germany, Planck considered it his duty to stay in his native country, and he endeavoured repeatedly to prevent injustice to others. In 1944 his Berlin home was destroyed by bombing; and in the same year, July 20, his son Erwin was arrested for his implication in the plot to assassinate Hitler and was executed six months later. After World War II, Max Planck spent the last years of his life in Göttingen. He died there on October 4, 1947, at the age of 89.

(W.Br.)

Planet, Minor

The minor planets, sometimes called asteroids, form a distinct and numerous class of very small objects in the solar system. They revolve around the Sun in orbits that nearly all lie between Mars and Jupiter. The existence of these tiny bodies, most of which are only a few kilometres across, challenges every theory of the origin of the solar system. Their discovery illustrates the scientific progress of the early 19th century. J.D. Titius in 1766 proposed and J.E. Bode in 1772 popularized what is known in astronomy as the Titius-Bode Law, for which the physical basis is still not understood. One takes the sequence of numbers (0, 3, 6, 12, 24, 48, 96, 192, 384, 768, etc.), adds 4 to each, and divides each by 10; the result represents the average distance of each of the then-known major planets from the Sun relative to the Earth's distance (one astronomical unit, abbreviated a.u.) quite well; namely, Mercury 0.4, Venus 0.7, Earth 1.0, Mars 1.6, (missing planet 2.8), Jupiter 5.2, Saturn 10.0, and a supposed next planet 19.6. Sir William Herschel's discovery of Uranus in 1781 strongly supported belief in this "law," because the planet's actual distance agreed quite well at 19.2 a.u. with the predicted value. The later discoveries of Neptune in 1846 at an actual distance of 30.1 a.u. and of Pluto in 1930 at 39.5 a.u. did not fit the so-called law, and one also notices that 0 is not one-half of 3.

Titius-Bode law

Nonetheless, in the last years of the 18th century in the hope of finding the missing planet at 2.8 a.u., Baron von Zach organized a group of 24 astronomers to search the sky. This task required that hand-drawn sky charts be prepared for all stars down to an agreed limit of faintness. Then on subsequent nights a region of the actual sky must be observed and compared in every detail with its chart, in the hope that an object would appear to view that had not been there before. The expected motion of such a planet would be about 30 seconds of arc per hour, so that an actual discovery (as contrasted with a missing star on the chart) could be readily established.

History of discoveries. Ironically, the first discovery was not made by a member of the organized group but by Giuseppe Piazzi at Palermo, Sicily, on the night of Jan. 1, 1801. He continued his observations until February 11, when illness interrupted. No one else was aware of his discovery, and so the new planet was "lost" as it receded behind the Sun. C.F. Gauss (1777–1855) brilliantly attacked the problem of computing an orbit from a few observations and laid down principles for tracking a newly discovered object, which have not been improved upon to this day. Using Gauss's predictions, Zach and Heinrich W.M. Olbers rediscovered the little planet, which had been named Ceres by Piazzi after the goddess of fertility, who was also the patron goddess of Sicily. The size of the orbit agreed exactly with Bode's Law. The object was disappointingly small, and no observable diameter could be discerned. Hence the term asteroid (meaning starlike) came into use, but it is a misnomer since these objects are not stars, and they do not remain in constellations but wander around the sky as the planets do.

About three months later Olbers discovered another small planet, which he named Pallas; in 1804 another, named Juno, was discovered by Karl Harding at Lilienthal, Germany; and finally in 1807 Olbers found a fourth member of this group, which he called Vesta. All the first four had similar orbits, and this immediately led to the theory that

the planet that was "required" by Bode's Law at this distance from the Sun either had been broken into fragments or had never completely accreted into one body, according to the nebular hypothesis of Laplace (1749–1827). As a group, these four new orbits had larger eccentricities and inclinations than the major planets, the averages being 0.165 and 16.4° as compared with 0.071 and 3.2°. It was at first thought that the four fragments completed the group, and the search seems to have been abandoned until 1830 when K.L. Hencke renewed it. In 1845 he discovered a fifth minor planet and named it Astraea. After that the annual rate of discovery increased until it reached about 10 by 1890, by which time 300 were known.

Role of photography. The introduction of astronomical photography in 1891 provided a turning point, and the invention of the "blink" comparator proved to be of enormous value in the search for more. Two photographic plates are taken of exactly the same region of the sky, with the exposures separated in time by a few hours or a day. The plates are mounted in the comparator so that an optical path from the same part of either plate may be reflected into the observing eyepiece by flipping a small mirror back and forth. When properly aligned, the background stars appear to be identical on both plates, but an object that has moved will appear in nearby but different positions, and it will "blink" at the observer as he intermittently observes one plate or the other. Afterward the rectangular positions on the plates must be measured accurately with respect to those surrounding stars that can be found in star catalogs. The process of computing the position of the minor planet on the sky from these measures is called the plate-reduction.

"Blink" comparator

The rate of discovery thus increased greatly, although many of the objects were observed over too short a period of time for their orbits to be well determined. The German astronomers participated extensively in this work. After Gauss's work in the computation of orbits, that of J.F. Encke, P.A. Hansen, J. Bauschinger, and others followed. By 1930 the work was concentrated under G. Stracke at the Astronomisches Rechen-Institut in Berlin-Dahlem, where all observations were collected, orbital elements were computed, and predictions were prepared for the observers. M. Wolf, at the Königstuhl Observatory at Heidelberg, exploited the new photographic method, using the 41-centimetre Bruce camera built especially for this work and donated by Catherine Bruce of California. He made 582 new discoveries during his lifetime, and his successor, K. Reinmuth, made 980. Other leading discoverers included C. Jackson at Johannesburg (392), G. Newjmin in the Crimea (379), and E. Delporte at Brussels (214). By 1940 about 7,500 discoveries had been made; 1,564 planets had received permanent numbers; and the predictions of their favourable observing positions were published each year. It is estimated that there are about 50,000 minor planets in the solar system that could be observed with existing telescopes.

Identification and rediscovery. There is no simple way to identify any particular minor planet except by the agreement of its position and motion with that predicted for it from its orbital elements, and by the brightness that is predicted on the basis of previous observations and relative distances. Thus the required amount of computations continually increased. To have accurate predictions after many years, it is necessary to compute the gravitational attraction of each of the major planets upon each minor planet and the perturbing effects of this upon each set of orbital elements. There have been serious proposals that astronomers should abandon studying the minor planets completely. Some astronomers have referred to them as "the vermin of the sky." But the discovery of planet (433) Eros in 1898 showed the importance of further studies and the work has gone on.

In 1900–01 and again in 1930–31, Eros approached within 23,000,000 kilometres of the Earth and thus provided an opportunity to determine a more accurate value of the solar parallax and the astronomical unit, the distance from the Earth to the Sun. The possibility of finding other objects of scientific interest was the basis of continued observations.

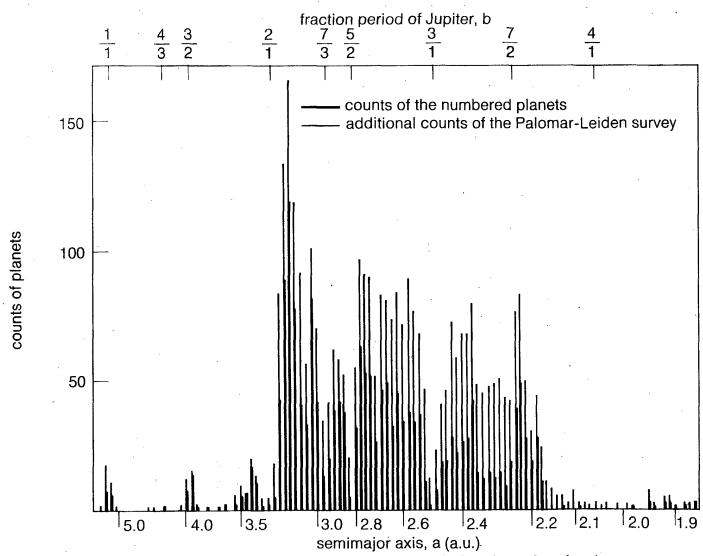
Notable groups and minor planets. The discovery of planet (588) Achilles in 1908 represented the first of at least 30 known Trojan planets. They remain in positions that form nearly an equilateral triangle with respect to the Sun and the largest major planet, Jupiter. They are examples of the stable triangular solution of the three-body problem (see MECHANICS, CELESTIAL). The discovery of (1221) Amor in 1932 marked the first of a series of "close-approach" planets, which may pass even nearer to the Earth than Eros and nearer to the Sun than the Earth. Then followed Adonis in 1936, Hermes in 1937, (1566) Icarus in 1949, (1620) Geographos in 1951, and others. On June 12, 1968, Icarus approached within 6,800,000 kilometres of the Earth, and it provided the first opportunity for observations by radar. Recently J. Schubart has determined the solar parallax from the observations of (1221) Amor, as it has been observed during five close passages near the Earth since its discovery. Icarus has the most eccentric elliptic orbit ($e = 0.83$) of all the known minor planets, the smallest semimajor axis ($a = 1.08$), and it passes closest to the Sun (28,000,000 kilometres). Hidalgo (944) has the largest semimajor axis (5.82), the highest inclination (42.5°), and it ranges in distance from 2.0 to 9.5 astronomical units from the Sun. Both were discovered by W. Baade.

First radar observation

Results from modern survey. World War II produced a hiatus of nearly ten years in minor planet research. In 1947 the Minor Planet Center was established at the Cincinnati Observatory in Ohio; the work had previously been coordinated at Berlin and later at Heidelberg in Germany. An intensive observing program was instituted at the Goethe Link Observatory of Indiana University, Brooklyn, Indiana, for the purpose of reobserving those minor planets that had deviated widely from their computed positions over the intervening years. Nearly 5,000 sky photographs were obtained between 1950 and 1965, and more than 19,000 positions of minor planets were observed. Simultaneously there were rapid developments in electronic computers, and these were fully exploited at Cincinnati and elsewhere to carry out the necessary computations of orbital elements, perturbations, and predictions. An annual volume containing the ephemeris of each numbered planet near its opposition from the Sun is published by the Institute of Theoretical Astronomy in Leningrad.

G.P. Kuiper and his collaborators conducted a survey of the sky with the 25-centimetre telescope at the McDonald Observatory during 1950–52 to photograph systematically all minor planets to the limit of 16.5 magnitude. They obtained 3,255 observations, only 25 percent belonging to new objects. In 1960 the 122-centimetre Schmidt telescope of Palomar Observatory (now part of Hale Observatories) was used to photograph a statistical sample of the sky, 18° by 12°, reaching the 20.5 magnitude. These 96 large plates were blinked and measured by C.J. Van Houten and I. Van Houten-Groeneveld, yielding 12,000 observations of 2,100 objects. The results of this statistical sample have been extrapolated to provide an estimate for the whole sky.

The naming of minor planets. The prerogative to choose the name of a new minor planet has been traditionally assigned to the discoverer. Consecutive numbers are now assigned to the planets whose orbits are accurately known, and the names of modern discoveries are submitted to the International Astronomical Union for approval.



The feminine mythological names adopted for the early discoveries have been supplemented by other classes of names, usually feminine, occasionally with a contrived feminine ending. The names usually honour some individual or place.

Minor planet (12) was named Victoria in 1850 after the queen of England; (250) Bettina after Baroness Rothschild who subsidized the discovery; (323) Brucia was the first minor planet discovered with the telescope donated by Miss Bruce; (1486) Marilyn was named after Paul Herget's daughter. There is a long list of curious hybrids, such as the names of famous astronomers with attached feminine suffixes, (784) Pickeringia, (1000) Piazzia, (1001)

Gaussia. There are acronyms; for example, initials from Reinmuth's eight discoveries spell G. Stracke, honouring a fellow astronomer; (849) Ara, discovered in the U.S.S.R., commemorates the American Relief Administration's help during the famine of 1922–23. Many planets are named after flowers.

Exceptions to the rule of femininity include certain groups or single planets with unusual orbital characteristics such as the Trojan and Apollo groups, and (1620) Geographos was named in recognition of the National Geographic Society subsidy of the Palomar Observatory's photographic sky survey. Fittingly, the planet known to come closest to the Sun is (1566) Icarus.

Statistics of minor planets. The inclinations of minor planets are clustered around a maximum near 5°, but they are fairly well distributed from 0° to 16°, with about 10 percent still above this range. The eccentricities have a maximum near 0.17, and few exceed 0.30. The dominant feature of the distribution of the mean distance from the Sun is the existence of gaps, discovered by Daniel Kirkwood in 1866 when only 88 planets were known. The most prominent one is at the point where the period of revolution is in the exact ratio of 2:1 with the period of Jupiter; others are at 3:1, 5:2, and other simple integral ratios. This phenomenon is believed to be due to the perturbations produced by Jupiter when the minor planet is in resonance with it, although no rigorous mathematical or statistical proof has ever been given. Curiously, at the ratios 1:1 and 3:2 there are concentrations of minor planets. The formula $\log N = 0.39m - 3.3$ closely represents the number of minor planets, within an interval of one magnitude centred on m, that have this mean opposition magnitude. To eliminate the effects of varying distances, one computes the absolute magnitude, g, that the planet would have if it were one unit from the Sun and the Earth. This brightness then depends upon the true diameter and the albedo or reflecting efficiency of the surface. The latter is found to be about 7 percent, the same as the Moon, although for Vesta it is four times that amount. The diameters can be observed for only a few of the largest objects: Ceres is 785 km, Pallas is 490 km, Juno is 190 km, and Vesta is 400 km. The diameter in kilometres for fainter objects may be computed from the formula $\log d\ (\text{km}) = 3.7 - 0.2\ g$. If $g = 20$, the object is only 0.5 km in diameter. The total mass of all the minor planets is probably less than one-thousandth of the mass of the Earth, but the density is not accurately known. The number of planets having a given diameter shows a discontinuity around $g = 11$ or a diameter of 30 km.

Distribution of minor planet distances from Sun. Semimajor axis, a, is average distance of planet from Sun; b stands for the ratio of the minor planet orbit period to the Jupiter period (see text).

Precise photoelectric observations of the brightness of some minor planets show variations that may be due to rotation, irregular shape, and/or differing albedo over the surface. In 1931 Eros was observed to be very elongated, with a maximum diameter of 30 km. The Trojan planet (624) Hector is believed to be nearly cylindrical, with a length of 110 km, a diameter of 40 km, and a rotation period of 6.9 hours. Such series of observations are difficult to obtain, but the known cases indicate that the axes of rotation are distributed at random in space. The known periods of rotation lie mostly between five and eight hours. Eugene Rabe has shown that this is consistent with the periods of revolution of infinitesimal particles about each other and with their gradual accretion.

Rabe has also shown that if the planet Jupiter was formerly about 20 times as massive as it now is, then its former satellites could have escaped the gravitational field of Jupiter and wandered into the present positions of the Trojans. The known Trojans range in size from 100 km to 3 km. Analysis of the three-body problem indicates that they can remain in these stable periodic orbits with slow swings back and forth along it (librational amplitudes) of nearly 60° from the triangular points for an indefinitely long time.

Origins of minor planets. In order to study the past history of the minor planets, Hirayama Seiji devised in 1918 an approximate method for removing the long-term oscillations of the elements that are induced by the major planets. The results of his calculations allowed him to identify certain families of minor planets, each of which appears to have come from some single point in space at a former time, presumably as the product of the fracturing of a larger parent body. Such an analysis can be carried backward with validity for only a few tens of millions of years, or less than 1 percent of the age of the solar system. The same method has been extended by D. Brouwer (1951), James Arnold (1969), and the Van Houtens (1970). There is not complete agreement on the details, but in general the family members have smaller diameters than the average of all the minor planets taken together, and they constitute about 30–40 percent of the total population. Once a larger body is broken into fragments, the probability of future collisions is increased because of the greater total cross-sectional area that the particles present. Thus the process would continue indefinitely, and in part this could lead to the formation of the meteors. Edward Anders (1965) has undertaken to "reconstitute" the parent bodies from the present identifiable families. He conjectures that if this process could be carried out a second time at a much earlier and now unrecognizable state of the solar system, then only a few relatively large minor planets would have been present.

Hirayama families

In spite of the evidence in support of such a theory of the past history of minor planets, G.P. Kuiper, H. Alfvén, the late E.W. Brown, and others have been inclined to a theory that the process of accretion is continuously at work and that there is a dynamical "focussing" mechanism that produces such similarity of elements, in combination with the Kirkwood gaps. The average density of material per unit of volume in the region of the minor planets is about 10^6 lower than in the region of the interior major planets. Thus the process of accretion is far from being completed. Considering the discontinuity that has been found in the count according to diameters, one is led to conclude that the accretion process is still in operation for the larger objects and that the collisional process is responsible for the smaller ones. But the effects of magnetohydrodynamic forces and the solar wind may preclude the possibility of any precise description of the past conditions of the minor planets on the basis of universal gravitation alone.

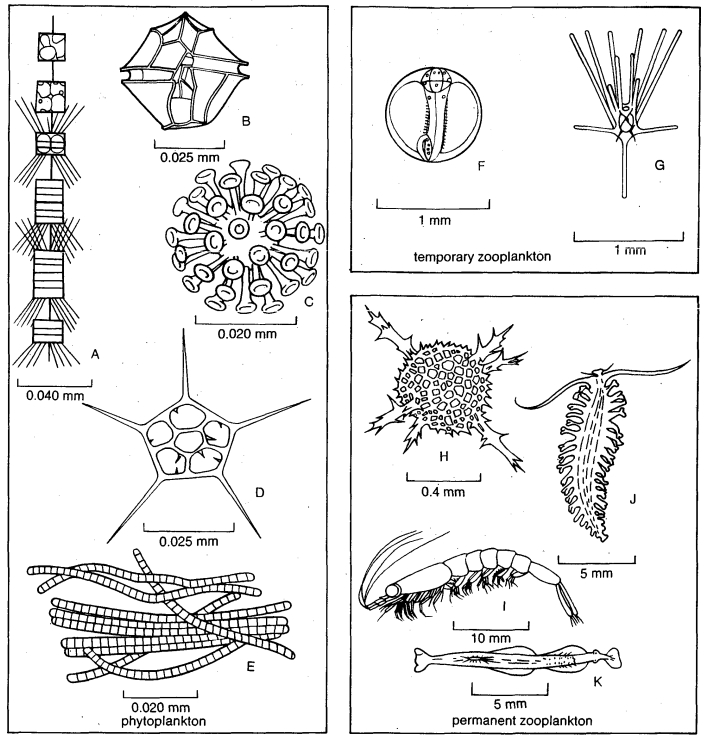
(P.H.)



Plankton

Plankton is a collective term for organisms that live suspended in the sea and in bodies of fresh water around the world. These organisms drift about either because they are nonmotile or because they are too small or too weak to swim effectively against the currents. Plankton is rich in algae, bacteria, and protozoans but includes also crustaceans, mollusks, and coelenterates, as well as representatives from almost every other phylum of animals. Plankton is distinguished from the nekton, which is composed of strong-swimming animals, and the benthos, which includes sessile, creeping, and burrowing organisms on the sea floor. Large floating seaweeds (for example, *Sargassum*, which constitutes the Sargasso Sea) and various related multicellular algae do not belong to the plankton but to the pleuston. Organisms resting or swimming on the surface film of the water are called neuston (*e.g.*, the alga *Ochromonas*).

Plankton is the productive base of both marine and fresh water ecosystems, providing food for larger animals and indirectly for man, whose fisheries depend upon plankton. The vast resource of plankton is only beginning to be developed and exploited by man. It may in time be the chief food supply of the world, in view of its high biological productivity and wide extent. It has been demonstrated on several occasions that large-scale cultures of algae are technically feasible. The unicellular green alga *Chorella* has been used particularly in this connection. Through ample culture conditions production is directed toward protein content greater than 50 percent. Although this protein has a suitable balance of essential amino acids, its low degree of digestibility prevents practical utilization. Phytoplankton may become increasingly important in the space age as a source for food and for gas exchange. The carbon dioxide released during respiration of the crew would be transformed into organic substances by the algae, while the oxygen liberated during this process would support human respiration.

The kinds of plankton. The plantlike community of plankton is called phytoplankton, and the animallike community is zooplankton. This convenient division is not without fault, for strictly speaking, many planktonic organisms are neither clearly plant nor animal but are better described as protists. Using size as a criterion, plankton can be subdivided into macroplankton, microplankton, and nannoplankton, though no sharp lines can be drawn between them. Macroplankton can be collected with a coarse net, and morphological details of individual organisms are easily discernible. These forms, one millimetre or more in length, ordinarily do not include phytoplankton. The microplankton (also called net plankton) is composed of organisms between 0.05 and 1 mm in size and is a mixture of phytoplankton and zooplankton. The lower limit of its size range is fixed by the aperture of the finest cloth used for plankton nets. The nannoplankton (dwarf plankton) passes through all nets and consists of forms of a size less than 0.05 mm. Phytoplanktonic organisms dominate the nannoplankton.

Phytoplankton. The chief components of marine phytoplankton are found within the algal groups and include diatoms, dinoflagellates, and coccolithophorids. Silicoflagellates, cryptomonads, and green algae are found in most plankton samples. Fresh-water phytoplankton, usually rich in green algae, also includes diatoms, blue-green algae, and true flagellates (see ALGAE).

Representative Types of marine plankton.
(A) Diatom *(Thalassiosira)*. (B) Dinoflagellate *(Gonyaulax)*. (C) Coccolithophorid *(Discosphaera)*. (D) Silicoflagellate *(Distephanus)*. (E) Blue-green alga *(Trichodesmium)*. (F) Flounder eggs with embryo. (G) Pluteus larva of sea urchin. (H) Radiolarian. (I) Crustacean *(Euphausia)*. (J) Annelid *(Tomopteris)*. (K) Arrowworm *(Sagitta)*.

Important marine phytoplankton

The diatoms range in size from two μ ($1\ \mu = 1/1{,}000$ mm)—*e.g.*, small *Nitzschia* and *Fragilaria* species—to large representatives 1 or 2 mm long—*e.g.*, *Thalassiothrix longissima, Rhizosolenia styliformis.* Some live as individuals (*e.g., Corethron, Coscinodiscus*), but the majority form chains (*e.g., Chaetoceros, Skeletonema, Thalassiosira, Asterionella*). Some of the diatoms (*e.g., Corethron, Chaetoceros*) have their shells drawn into long hairs that greatly improve floating. Most diatoms are nonmotile; but many, particularly benthic or bottom-dwelling forms, are capable of gliding motions. The diatom shell, or frustule, is composed of hydrated amorphous silica. Such shells have formed great fossil deposits known as diatomaceous earth.

The dinoflagellates range in size from a few μ (*e.g.*, small *Gyrodinium*) to 0.2 mm (*e.g., Ceratium*). Most of the species are photosynthetic, but many nonphotosynthetic forms are known (*e.g., Peridinium decipiens, Noctiluca*). Dinoflagellates are motile organisms with two flagella. One drives the organism forward, while the other is responsible for a rotating motion. A dinoflagellate directs its swimming according to both light intensity and direction (phototaxis). Under natural conditions in quiet bodies of water, it may perform diurnal vertical migrations that serve to adjust its position toward light and a greater rate of photosynthesis. Swimming also helps the organism stay above the light (or photosynthetic) zone. Improved flotation has been achieved in some species through the development of spectacular arrangements of "wings." Such features are particularly noticeable in species found in tropical waters. In temperate regions dinoflagellates are typical members of summer and autumn phytoplankton. They produce most of the bioluminescence seen during that time. One of the best known bioluminescent organisms is *Noctiluca*, a nonphotosynthetic dinoflagellate that migrates to the surface at night. Other bioluminescent dinoflagellates are *Ceratium* and *Gonyaulax*. Off the west

coast of California, *Gonyaulax polyedra* causes the "red tide" and the pronounced bioluminescence accompanying it. The flash seen at night around footprints close to the water during "red tides" is caused by the same organism. *Gonyaulax* bioluminescence, more intense during the night than in daylight, has a diurnal rhythm with a period of about 24 hours. Dinoflagellate bioluminescence is most pronounced in warmer regions, where it has a spectacular intensity in some areas; for example, in the offshore waters of Puerto Rico (see BIOLUMINESCENCE). Several species of dinoflagellates are poisonous. Off the west coast of Florida and in the Gulf of Mexico, red water, caused by *Gymnodinium brevis*, has been associated on occasion with enormous numbers of dead fish. In many other areas extensive losses of fish have occurred in connection with red tide. Dinoflagellates of several genera (*Gymnodinium, Exuviaella, Gonyaulax, Prorocentrum*) are responsible. Shellfish poisoning off the west coast of California is caused by the dinoflagellate *Gonyaulax catenella* and by another *Gonyaulax* species in the Bay of Fundy (Nova Scotia). Poisons isolated from these dinoflagellates are among the most powerful known in nature. Typically, dinoflagellates exist in marine environments, although vast numbers of *Glenodinium sanguineum* may cause red discoloration of inland lakes, especially in alpine regions.

Coccolithophorids vary from 5 to 50 μ in size and thus are part of the nannoplankton. These algae are covered by variable numbers of calcified plates (coccoliths) of different shapes. Most of them are ellipsoidal; but coccoliths in the shape of rhombuses, trumpets, or spines are not uncommon. The coccolithophorids are classified according to the shape and the elaborate microstructure of their coccoliths. In many cases the electron microscope must be used for identification. Coccoliths are found in enormous numbers in marine bottom sediments. The coccolithophorids are motile, with two flagella, and typically are found in tropical and temperate regions of the open sea. One species (*Coccolithus huxleyi*), however, is common in coastal areas, particularly fjords, where it occurs sporadically in vast numbers (as high as hundreds of millions per litre), giving the water a milky greenish appearance (green water). A few coccolithophorids also occur in fresh water.

Important fresh-water phytoplankton

Green algae, common in fresh-water plankton, are found more rarely in marine environments. Some are motile (*e.g., Chlamydomonas, Haematococcus*), and many of the motile forms occur in colonies (*e.g., Gonium*). Several nonswimming green algae have developed structures that enable them to float on the surface of the water; these include branching and embedding of organisms in a gelatinous mass of considerable size (*e.g., Staurastrum*). Blue-green algae are present in most samples of fresh-water phytoplankton. At times tremendous populations of *Aphanizomenon flos-aquae* float on the surfaces of lakes, completely covering the water (water bloom). Although blue-green algae are usually absent from marine waters in temperate and polar areas, one genus, *Trichodesmium*, frequently appears in tropical regions. The reddish colour of *Trichodesmium erythraeum* is caused by a photosynthetically active pigment, phycoerythrin. This blue-green alga floats on the surface of the water, aided by a mechanism involving its gas vacuoles, and sometimes causes red discoloration of the water. The Red Sea owes its name to this alga.

Other microflagellate representatives of the phytoplankton undoubtedly play a significant role in the primary production of oceans and inland waters. True flagellates (*e.g., Euglena*) are common in fresh-water plankton. Vast, nearly pure populations of *Euglena* sometimes occur in highly polluted areas.

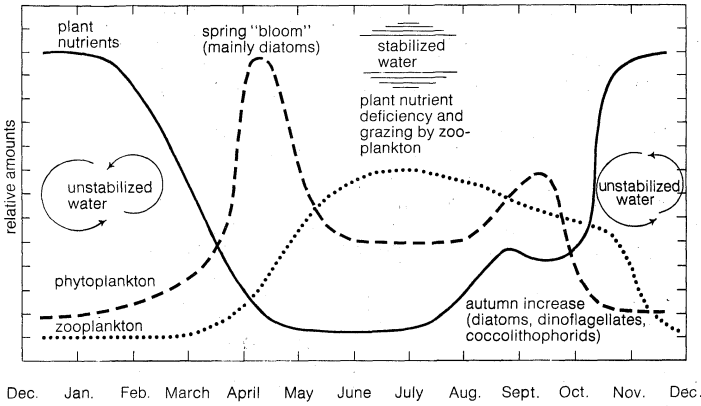
Temporary and permanent zooplankton

Zooplankton. The zooplankton is divided into two groups. Temporary plankton consists of planktonic eggs and larvae of members of the benthos and nekton; permanent plankton includes all animals that live their complete life cycles in a floating state. The temporary plankton, particularly abundant in coastal areas, is characteristically seasonal in occurrence, though variations in spawning time of different species ensure its presence in all seasons. Representatives from nearly every phylum of the animal kingdom are found in the permanent plankton. Among the protozoans, planktonic foraminiferans and radiolarians are so abundant and widespread that their skeletons form the bulk of bottom sediments over wide ocean areas. They are absent in fresh water. The ciliate protozoans are represented mainly by the tintinnids, which are between 20 and 640 μ in size and sometimes occur in vast numbers. Among the planktonic coelenterates are the beautiful siphonophores (*e.g., Physalia*, the "Portuguese man-of-war"), and the jellyfishes. Planktonic ctenophores, called "combjellies" or "sea walnuts," are also common. Fresh-water rotifers may be present in plankton in vast numbers during the warmer seasons. A group of organisms found at all latitudes, in surface water and at great depths, are the marine arrowworms (*e.g., Sagitta*), important planktonic predators. Oysters, mussels, other marine bivalves, and snails begin life as planktonic larvae. The wing snails (Pteropoda) spend their entire life cycles as plankton.

Crustaceans are the most important members of the zooplankton. They are the marine counterparts of insects on land; noteworthy is the fact that on land, as in the sea, the arthropods are the most diverse and numerous of all animal phyla. The copepod *Calanus finmarchicus* is important as food for the herring, and the euphausid *Euphausia superba* is the main food source for blue and fin whales in the Antarctic Ocean. Whalebone whales migrate to waters where spawning of these crustaceans occurs; and the rapid growth of these large mammals, feeding entirely on plankton, is impressive.

There is a pronounced tendency for zooplankton to perform diurnal vertical migrations in both lakes and the sea. This migratory behaviour varies with stages in the life cycle, seasons of the year, latitude, hydrographic structure, and meteorological conditions. Generally, the animals ascend toward the surface at sunset from daytime depths. At midnight, if there is no optical stimulus (*e.g.*, moon, artificial light), some of the animals return to the daytime depths, then approach the surface once again just before dawn. As the sun rises, all descend to their daytime level.

Bacteria and fungi. Bacteria and fungi found in water belong by definition to plankton, but because of special techniques required for sampling and identification, they usually are considered separately. These organisms are important in the transformation of dead organic materials to inorganic plant nutrients. Some of these marine and fresh-water micro-organisms (including blue-green algae) fix molecular nitrogen from water containing dissolved air, forming ammonia or related nutrients important for phytoplankton growth. Although little is known about the extent of nitrogen fixation, bacteria and fungi always are found in water samples. A peculiar situation exists in the Black Sea where water below 130–180 metres contains hydrogen sulfide and no oxygen. Under these conditions only bacteria are found.



Productivity of plankton. *General features.* The productivity of an area is dependent upon the availability of nutrients and water stability conditions. Currents that flow near continents are important to plankton production in an area. The California Current (a continuation of the Kuroshio Drift from Japan) causes an outland transport of water and combines with a compensating nutrient-rich current along the coast of California to make this area highly productive. The same situation exists along the west coast of southern Africa, which is influenced by the Benguela Current, and off the west coast of South America, influenced by the Peru Current. One of the poorest oceanic areas, the Sargasso Sea, is supplied with water through the North Equatorial Current. Originating at the coast of Africa, the waters are depleted of nutrients as they flow toward the Sargasso Sea. Unstabilized water masses in shallow areas (*e.g.*, Bay of Fundy, Nova Scotia), where phytoplankton is always in the light zone, have high primary production.

Dependence on availability of nutrients and sunlight

In the sea an adequate supply of nutrients, including carbon dioxide, enables phytoplankton and benthic algae to transform the light energy of the sun into energy-rich chemical components through photosynthesis. The bottom-dwelling algae are responsible for about 2 percent of the primary production in the ocean; the remaining 98

percent is attributable to phytoplankton. Most of the phytoplankton serves as food for zooplankton, but some of it is carried below the light zone. After death, this phytoplankton undergoes chemical mineralization, bacterial breakdown, or transformation into sediments. Phytoplankton production usually is greatest from five to ten metres below the surface of the water. Too high light intensity and/or the lack of nutrient in the upper regions may be the causes for this sub-optimal photosynthesis. Although bacteria are found at all depths, they are most abundant either immediately below great phytoplankton populations or just above the bottom. Zooplankton is used directly as food by fish (*e.g.*, herring) or mammals (*e.g.*, whalebone whales); however, several food chains usually have been passed before plankton is available as food for human consumption. Since each step in the chain is calculated as a 90 percent loss of the original energy obtained from the sun, there is considerable energy lost as the number of components in the food chain increases (see BIOSPHERE).

The oceanic cycle. The conditions in northern temperate regions serve as an example of an annual plankton cycle. The growth of phytoplankton is dependent upon

Annual plankton cycle in temperate regions of the Northern Hemisphere.

adequate amounts of required nutrients and light. Temperature is not a critical factor because species with low temperature optima prevail during cold seasons and in low temperature areas. During the cold winter months, the nutrient situation is excellent in northern temperate oceans, but low light levels and complete mixing of water masses (*i.e.*, unstabilized water), which in the North Atlantic prevails down to several hundred metres, combine to keep the phytoplankton population below the light zone. As a result, no photosynthesis occurs and primary production is impossible. During spring the upper water masses are warmed by the sun; this results in lighter water layers on top of colder, heavier ones (*i.e.*, stabilized water). The phytoplankton remain within the light zone; nutrients are available; and a burst in phytoplankton population, consisting of diatoms (*i.e.*, spring diatom bloom), occurs. The high population level falls quickly because the phytoplankton are consumed by zooplankton whose numbers now increase. As dead organisms and feces sink, the upper water masses become depleted of plant nutrients, resulting in moderate production during the summer months. During the autumn months, cooling of nutrient-poor surface water layers makes them heavier and results in their mixing with deeper water rich in nutrients; an autumn increase in phytoplankton of short duration occurs. As the mixing of water masses extends far below the light zone during winter, primary production again diminishes. In polar regions only one summer maximum occurs, while in tropical areas the production is either uniform or irregular throughout the year.

Plant Breeding

In its modern form, plant breeding involves the application of genetic principles to produce plants that are more useful to man. This is accomplished by selecting plants that man finds desirable, economically or aesthetically, by controlling the mating of the selected individuals and by selecting desirable individuals among the progeny. These processes, repeated over many generations, can change the hereditary makeup and value of a plant population far beyond the natural limits of previously existing populations. This article emphasizes the application of genetic principles to the improvement of plants; the biological factors underlying plant breeding are dealt with in the article HEREDITY.

Historical background

Plant breeding is an ancient activity of man, dating back to the very beginnings of agriculture. Probably soon after the earliest domestications of cereal grains, man began to recognize degrees of excellence among the plants in his fields and saved seed from the best plants for planting new crops. Such tentative selective methods were the forerunners of early plant-breeding procedures.

The results of early plant-breeding procedures were conspicuous. Most present-day varieties are so modified from their wild progenitors they are unable to survive in nature. Indeed, in some cases, the cultivated forms are so strikingly different from existing wild relatives that it is even difficult to identify their ancestors. These remarkable transformations were accomplished by early plant breeders in a very short time from an evolutionary point of view, and the rate of change was probably greater than for any other evolutionary event.

Scientific plant breeding dates back hardly more than 50 years. The role of pollination and fertilization in the process of reproduction was not widely appreciated even 100 years ago, and it was not until the early part of the 20th century that the laws of genetic inheritance were recognized and a beginning was made toward applying them to the improvement of plants. One of the major facts that has emerged during the short history of scientific breeding is that an enormous wealth of genetic variability exists in the plants of the world and that only a start has been made in tapping its potential.

PLANT-BREEDING GOALS

The plant breeder usually has in mind an ideal plant that combines a maximum number of desirable characteristics. These characteristics may include resistance to diseases and insects; tolerance to heat and frost; appropriate size, shape, and time to maturity; and many other general and specific traits that contribute to improved adaptation to the environment, ease in growing and handling, greater yield, and better quality. The breeder of fancy show plants must also consider aesthetic appeal. Thus the breeder can rarely focus attention on any one characteristic but must take into account the manifold traits that make the plant more useful in fulfilling the purpose for which it is grown.

Increase of yield. One of the aims of virtually every breeding project is to increase yield. This can often be brought about by selecting obvious morphological variants. One example is the selection of dwarf, early maturing varieties of rice. These dwarf varieties are sturdy and give a greater yield of grain. Furthermore, their early maturity frees the land quickly, often allowing an additional planting of rice or other crop the same year.

Another way of increasing yield is to develop varieties resistant to diseases and insects. In many cases resistant varieties have been the only practical method of pest con-

trol. Perhaps the most important feature of resistant varieties is the stabilizing effect they have on production and hence on steady food supplies. Varieties tolerant to drought, heat, or cold provide the same benefit.

Modifications of range and constitution. Another common goal of plant breeding is to extend the area of production of a crop species. A good example is the modification of grain sorghum since its introduction to the United States about 100 years ago. Of tropical origin, grain sorghum was originally confined to the southern Plains area and the Southwest, but earlier maturing varieties were developed until grain sorghum is now an important crop as far north as North Dakota.

The influence of mechanized agriculture

Development of crop varieties suitable for mechanized agriculture has become a major goal of plant breeding in recent years. Uniformity of plant characters is very important in mechanized agriculture because field operations are much easier when the individuals of a variety are similar in time of germination, growth rate, size of fruit, and so on. Uniformity in maturity is, of course, essential when crops such as tomatoes and peas are harvested mechanically.

The nutritional quality of plants can be greatly improved by breeding. For example, it is possible to breed varieties of corn (maize) much higher in lysine than previously existing varieties. Breeding high-lysine maize varieties for those areas of the world where maize is the major source of this nutritionally essential amino acid has become a major goal in plant breeding.

In breeding ornamentals, attention is paid to such factors as longer blooming periods, improved keeping qualities of flowers, general thriftiness, and other features that contribute to usefulness and aesthetic appeal. Novelty itself is often a virtue in ornamentals, and the spectacular, even the bizarre, is often sought.

EVALUATION OF PLANTS

The appraisal of the value of plants so that the breeder can decide which individuals should be discarded and which allowed to produce the next generation is a much more difficult task with some traits than with others.

Qualitative characters. The easiest characters, or traits, to deal with are those involving discontinuous, or qualitative, differences that are governed by one or a few major genes. Many such inherited differences exist, and they frequently have profound effects on plant value and utilization. Examples are starchy versus sugary kernels (characteristic of field and sweet corn, respectively) and determinant versus indeterminant habit of growth in green beans (determinant varieties are adapted to mechanical harvesting). Such differences can be seen easily and evaluated quickly, and the expression of the traits remains the same regardless of the environment in which the plant grows. Traits of this type are termed highly heritable.

Quantitative characters. In other cases, however, plant traits grade gradually from one extreme to another in a continuous series, and classification into discrete classes is not possible. Such variability is termed quantitative. Many traits of economic importance are of this type; *e.g.*, height, cold and drought tolerance, time to maturity, and, in particular, yield. These traits are governed by many genes, each having a small effect. Although the distinction between the two types of traits is not absolute, it is nevertheless convenient to designate qualitative characters as those involving discrete differences and quantitative characters as those involving a graded series.

Quantitative characters are much more difficult for the breeder to control, for three main reasons: (1) the sheer numbers of the genes involved make hereditary change slow and difficult to assess; (2) the variations of the traits involved are generally detectable only through measurement and exacting statistical analyses; and (3) most of the variations are due to the environment rather than to genetic endowment; for example, the heritability of certain traits is less than 5%, meaning that 5% of the observed variation is caused by genes and 95% is caused by environmental influences.

It follows that carefully designed experiments are required to distinguish plants that are superior because they carry desirable genes from those that are superior because they happen to grow in a favourable site.

METHODS OF PLANT BREEDING

Mating systems. Plant mating systems devolve about the type of pollination, or transferal of pollen from flower to flower (see POLLINATION). A flower is self-pollinated (a "selfer") if pollen is transferred to it from any flower of the same plant and cross-pollinated (an "outcrosser" or "outbreeder") if the pollen comes from a flower on a different plant. About half of the more important cultivated plants are naturally cross-pollinated, and their reproductive systems include various devices that encourage cross-pollination; *e.g.*, protandry (pollen shed before the ovules are mature, as in the carrot and walnut), dioecy (stamens and pistils borne on different plants, as in the date palm, asparagus, and hops), and genetically determined self-incompatibility (inability of pollen to grow on the stigma of the same plant, as in white clover, cabbage, and many other species).

Other plant species, including a high proportion of the most important cultivated plants such as wheat, barley, rice, peas, beans, and tomatoes, are predominantly self-pollinating. There are relatively few reproductive mechanisms that promote self-pollination; the most positive of which is failure of the flowers to open (cleistogamy), as in certain violets. In barley, wheat, and lettuce the pollen is shed before or just as the flowers open; and in the tomato pollination follows opening of the flower, but the stamens form a cone around the stigma. In such species there is always a risk of unwanted cross-pollination.

Control of breeding

In controlled breeding procedures it is imperative that pollen from the desired male parent, and no other pollen, reaches the stigma of the female parent. When stamens and pistils occur in the same flower, the anthers must be removed from flowers selected as females before pollen is shed. This is usually done with forceps or scissors. Protection must also be provided from "foreign" pollen. The most common method is to cover the flower with a plastic or paper bag. When the stigma of the female parent becomes receptive, pollen from the desired male parent is transferred to it, often by breaking an anther over the stigma, and the protective bag is replaced. The production of certain hybrids is, therefore, tedious and expensive because it often requires a series of delicate, exacting, and properly timed hand operations. When male and female parts occur in separate flowers, as in maize, controlled breeding is easier.

A cross-pollinated plant, which has two parents, each of which is likely to differ in many genes, produces a diverse population of plants hybrid (heterozygous) for many traits. A self-pollinated plant, which has only one parent, produces a more uniform population of plants pure breeding (homozygous) for many traits. Thus, in contrast to outbreeders, self-breeders are likely to be highly homozygous and hence true breeding for a specified trait.

Breeding self-pollinated species. The breeding methods that have proved successful with self-pollinated species are (1) mass selection; (2) pure-line selection; (3) hybridization, with the segregating generations handled by the pedigree method, the bulk method, or by the backcross method; and (4) development of hybrid varieties.

Mass selection. In mass selection, seeds are collected from (usually a few dozen to a few hundred) desirable appearing individuals in a population, and the next generation is sown from the stock of mixed seed. This procedure, sometimes referred to as phenotypic selection, is based on how each individual looks. Mass selection has been used widely to improve old "land" varieties, varieties that have been passed down from one generation of farmers to the next over long periods.

An alternative approach that has no doubt been practiced for thousands of years is simply to eliminate undesirable types by destroying them in the field. The results are similar whether superior plants are saved or inferior plants are eliminated: seeds of the better plants become the planting stock for the next season.

A modern refinement of mass selection is to harvest the best plants separately and to grow and compare their progenies. The poorer progenies are destroyed and the seeds of the remainder are harvested. It should be noted that selection is now based not solely on the appearance of the parent plants but also on the appearance and performance of their progeny. Progeny selection is usually more effective than phenotypic selection when dealing with quantitative characters of low heritability. It should be noted, however, that progeny testing requires an extra generation; hence gain per cycle of selection must be double that of simple phenotypic selection to achieve the same rate of gain per unit time.

Mass selection, with or without progeny test, is perhaps the simplest and least expensive of plant-breeding procedures. It finds wide use in the breeding of certain forage species, which are not important enough economically to justify more detailed attention.

Pure-line selection. Pure-line selection generally involves three more or less distinct steps: (1) numerous superior appearing plants are selected from a genetically variable population; (2) progenies of the individual plant selections are grown and evaluated by simple observation, frequently over a period of several years; and (3) when selection can no longer be made on the basis of observation alone, extensive trials are undertaken, involving careful measurements to determine whether the remaining selections are superior in yielding ability and other aspects of performance. Any progeny superior to an existing variety is then released as a new "pure-line" variety. Much of the success of this method during the early 1900s depended on the existence of genetically variable land varieties that were waiting to be exploited. They provided a rich source of superior pure-line varieties, some of which are still represented among commercial varieties. In recent years the pure-line method as outlined above has decreased in importance in the breeding of major cultivated species; however, the method is still widely used with the less important species that have not yet been heavily selected.

Exploitation of sports

A variation of the pure-line selection method that dates back centuries is the selection of single-chance variants, mutations or "sports" in the original variety. A very large number of varieties that differ from the original strain in characteristics such as colour, lack of thorns or barbs, dwarfness, and disease resistance have originated in this fashion.

Hybridization. During the 20th century planned hybridization between carefully selected parents has become dominant in the breeding of self-pollinated species. The object of hybridization is to combine desirable genes found in two or more different varieties and to produce pure-breeding progeny superior in many respects to the parental types.

Genes, however, are always in the company of other genes in a collection called a genotype. The plant breeder's problem is largely one of efficiently managing the enormous numbers of genotypes that occur in the generations following hybridization. As an example of the power of hybridization in creating variability, a cross between hypothetical wheat varieties differing by only 21 genes is capable of producing more than 10,000,000,000 different genotypes in the second generation. At spacings normally used by farmers, more than 50,000,000 acres would be required to grow a population large enough to permit every genotype to occur in its expected frequency. While the great majority of these second generation genotypes are hybrid (heterozygous) for one or more traits, it is statistically possible that 2,097,152 different pure-breeding (homozygous) genotypes can occur, each potentially a new pure-line variety. These numbers illustrate the importance of efficient techniques in managing hybrid populations, for which purpose the pedigree procedure is most widely used.

Pedigree breeding starts with the crossing of two genotypes, each of which have one or more desirable characters lacked by the other. If the two original parents do not provide all of the desired characters, a third parent can be included by crossing it to one of the hybrid progeny of the first generation (F_1). In the pedigree method superior types are selected in successive generations, and a record is maintained of parent–progeny relationships.

The F_2 generation (progeny of the crossing of two F_1 individuals) affords the first opportunity for selection in pedigree programs. In this generation the emphasis is on the elimination of individuals carrying undesirable major genes. In the succeeding generations the hybrid condition gives way to pure breeding as a result of natural self-pollination, and families derived from different F_2 plants begin to display their unique character. Usually one or two superior plants are selected within each superior family in these generations. By the F_5 generation the pure-breeding condition (homozygosity) is extensive, and emphasis shifts almost entirely to selection between families. The pedigree record is useful in making these eliminations. At this stage each selected family is usually harvested in mass to obtain the larger amounts of seed needed to evaluate families for quantitative characters. This evaluation is usually carried out in plots grown under conditions that simulate commercial planting practice as closely as possible. When the number of families has been reduced to manageable proportions by visual selection, usually by the F_7 or F_8 generation, precise evaluation for performance and quality begins. The final evaluation of promising strains involves (1) observation, usually in a number of years and locations, to detect weaknesses that may not have appeared previously; (2) precise yield testing; and (3) quality testing. Many plant breeders test for five years at five representative locations before releasing a new variety for commercial production.

Bulk-population breeding

The bulk-population method of breeding differs from the pedigree method primarily in the handling of generations following hybridization. The F_2 generation is sown at normal commercial planting rates in a large plot. At maturity the crop is harvested in mass, and the seeds are used to establish the next generation in a similar plot. No record of ancestry is kept. During the period of bulk propagation natural selection tends to eliminate plants having poor survival value. Two types of artificial selection also are often applied: (1) destruction of plants that carry undesirable major genes and (2) mass techniques such as harvesting when only part of the seeds are mature to select for early maturing plants or the use of screens to select for increased seed size. Single plant selections are then made and evaluated in the same way as in the pedigree method of breeding. The chief advantage of the bulk population method is that it allows the breeder to handle very large numbers of individuals inexpensively.

Backcross breeding

Often an outstanding variety can be improved by transferring to it some specific desirable character that it lacks. This can be accomplished by first crossing a plant of the superior variety to a plant of the donor variety, which carries the trait in question, and then mating the progeny back to a plant having the genotype of the superior parent. This process is called backcrossing. After five or six backcrosses the progeny will be hybrid for the character being transferred but like the superior parent for all other genes. Selfing the last backcross generation, coupled with selection, will give some progeny pure breeding for the genes being transferred. The advantages of the backcross method are its rapidity, the small number of plants required, and the predictability of the outcome. A serious disadvantage is that the procedure diminishes the occurrence of chance combinations of genes, which sometimes leads to striking improvements in performance.

Hybrid varieties. The development of hybrid varieties differs from hybridization in that no attempt is made to produce a pure-breeding population; only the F_1 hybrid plants are sought. The F_1 hybrid of crosses between different genotypes is often much more vigorous than its parents. This hybrid vigour, or heterosis, can be manifested in many ways, including increased rate of growth, greater uniformity, earlier flowering, and increased yield, the last being of greatest importance in agriculture.

By far the greatest development of hybrid varieties has been in maize, primarily because its male flowers (tassels) and female flowers (incipient ears) are separate and easy to handle, thus proving economical for the production of

hybrid seed. The production of hand-produced F_1 hybrid seed of other plants, including ornamental flowers, has been economical only because greenhouse growers and home gardeners have been willing to pay high prices for hybrid seed.

Recently, however, a built-in cellular system of pollination control has made hybrid varieties possible in a wide range of plants, including many that are self-pollinating, such as sorghums. This system, called cytoplasmic male sterility, or cytosterility (Figure 1), prevents normal

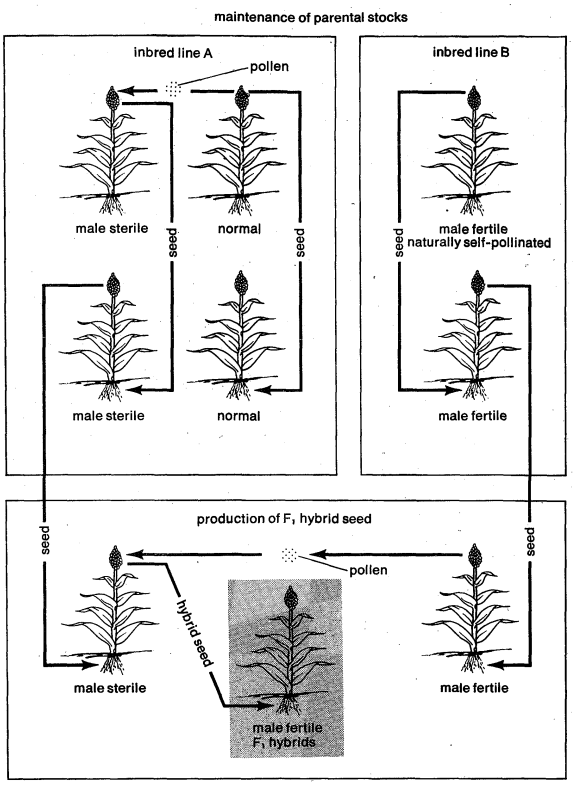

Figure 1: Production of hybrid seed in sorghum using cytoplasmic male sterility.

maturation or function of the male sex organs (stamens) and results in defective pollen or none at all. It obviates the need for removing the stamens either by hand or by machine. Cytosterility depends on the interaction between male sterile genes $(R+r)$ and factors found in the cytoplasm of the female sex cell. The genes are derived from each parent in the normal Mendelian fashion, but the cytoplasm (and its factors) is provided by the egg only; therefore, the inheritance of cytosterility is determined by the female parent. All plants with fertile cytoplasm produce viable pollen, as do plants with sterile cytoplasm but at least one *R* gene; plants with sterile cytoplasm and two *r* genes are male sterile (produce defective pollen).

The production of F_1 hybrid seed between two strains is accomplished by interplanting a sterile version of one strain (say A) in an isolated field with a fertile version of another strain (B). Since strain A produces no viable pollen, it will be pollinated by strain B, and all seeds produced on strain A plants must therefore be F_1 hybrids between the strains. The F_1 hybrid seeds are then planted to produce the commercial crop. Much of the breeder's work in this process is in developing the pure-breeding sterile and fertile strains to begin the hybrid seed production.

Breeding cross-pollinated species. The most important methods of breeding cross-pollinated species are (1) mass selection; (2) development of hybrid varieties; and (3) development of synthetic varieties. Since cross-pollinated species are naturally hybrid (heterozygous) for many traits and lose vigour as they become purebred (homozygous), a goal of each of these breeding methods is to preserve or restore heterozygosity.

Mass selection. Mass selection in cross-pollinated species takes the same form as in self-pollinated species; *i.e.*, a large number of superior appearing plants are selected and harvested in bulk and the seed used to produce the next generation. Mass selection has proved to be very effective in improving qualitative characters, and, applied over many generations, it is also capable of improving quantitative characters, including yield, despite the low heritability of such characters. Mass selection has long been the most important method of breeding cross-pollinated species and still is a major method, especially in the economically less important species.

Hybrid varieties. The outstanding example of the exploitation of hybrid vigour through the use of F_1 hybrid varieties has been with maize. The production of a hybrid maize variety (Figure 2) involves three steps: (1) the selection of superior plants; (2) selfing for several generations to produce a series of inbred lines, which although

Production of hybrid corn

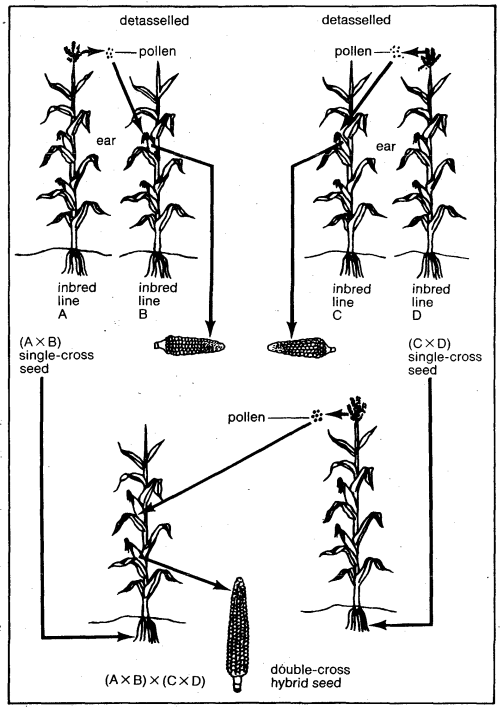

Figure 2: The crossing of inbred lines of maize (corn) to produce single crosses and the crossing of single crosses to produce double-cross hybrid seed.

different from each other are each pure breeding and highly uniform; and (3) crossing selected inbred lines. During the inbreeding process the vigour of the lines decreases drastically, usually to less than half that of field-pollinated varieties. Vigour is restored, however, when any two unrelated inbred lines are crossed, and in some cases the F_1 hybrids between inbred lines are much superior to open-pollinated varieties. An important consequence of the homozygosity of the inbred lines is that the hybrid between any two inbreds will always be the same. Once the inbreds that give the best hybrids have been identified, any desired amount of hybrid seed can be produced.

Pollination in maize is by wind, which blows pollen from the tassels to the styles (silks) that protrude from the tops of the ears. Thus controlled cross-pollination on a field scale can be accomplished economically by interplanting two or three rows of the seed parent inbred with one row of the pollinator inbred and detasselling the former before it sheds pollen. In practice most hybrid corn is produced from "double crosses," in which four inbred lines are first crossed in pairs (A × B and C × D) and then the two F_1 hybrids are crossed again (A × B) × (C × D). The double-cross procedure has the advantage that the commercial F_1 seed is produced on the highly productive single cross A × B rather than on a poor-yielding inbred, thus reducing seed costs. In recent years cytoplasmic male

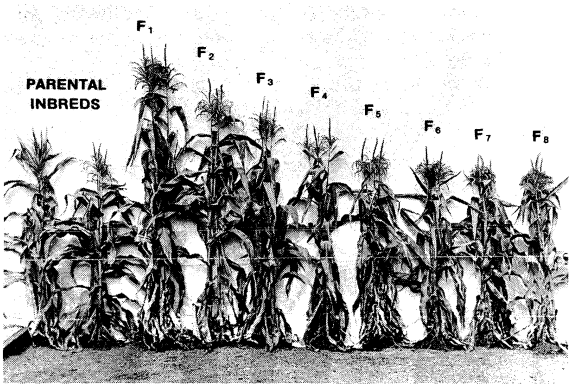

Figure 3: *Heterosis followed by decline in vigour in maize.* Representative plants of the two parental inbreds are at left. To their right are vigorous F_1 hybrids and the F_2 through F_8 selfed generations. The decline in vigour from F_1 through F_8 is similar to that observed when plants from open-pollinated varieties are self-pollinated.
D.F. Jones, *Genetics*, no. 9 (1924)

sterility, described earlier, has been used to eliminate detasselling of the seed parent, thus providing further economies in producing hybrid seed.

Much of the hybrid vigour exhibited by F_1 hybrid varieties is lost in the next generation. Consequently, seed from hybrid varieties is not used for planting stock but the farmer purchases new seed each year from seed companies.

Perhaps no other development in the biological sciences has had greater impact on increasing food supplies of the world than hybrid maize. Hybrid varieties in other crops, made possible through the use of male sterility, have also been dramatically successful and it seems likely that use of hybrid varieties will continue to expand in the future.

Synthetic varieties. A synthetic variety is developed by intercrossing a number of genotypes of known superior combining ability—*i.e.*, genotypes that are known to give superior hybrid performance when crossed in all combinations. (By contrast, a variety developed by mass selection is made up of genotypes bulked together without previous testing of performance in hybrid combination.) Synthetic varieties are known for their hybrid vigour and for their ability to produce usable seed for succeeding seasons. Because of these advantages, synthetic varieties have become increasingly favoured in the growing of many species, such as the forage crops, in which expense prohibits the development or use of hybrid varieties.

Distribution and maintenance of new varieties. The benefits of superior new varieties obviously cannot be realized until sufficient seed has been produced to permit commercial production. Although the primary function of the plant breeder is to develop new varieties, he usually also carries out an initial small-scale seed increase. Such seed is called breeders seed. The next stage is the multiplication of breeders seed to produce foundation seed. Production of foundation seed is usually carried out by governmentally regulated seed associations or institutes. The third step is the production of certified seed, the progeny of foundation seed, produced on a large scale by specialized seed growers for general sale to farmers and gardeners. Certified seed must be produced and handled in such a way as to meet the standards set by the certifying agency (usually a seed association). Seed associations are also usually responsible for maintaining the purity of new varieties once they have been released for commercial production.

The distribution of new varieties developed by commercial plant-breeding companies is often through seed associations, but many reputable companies market their products without following the official certification process. In some countries, particularly in Europe, new varieties can be patented for periods up to 15 years or more, during which time the breeder has an exclusive right to reproduce and sell the variety.

Plant Internal Transport

Movement of water and nutrients takes place in plants, just as the bloodstream distributes nutrients throughout the body of animals. This internal movement, usually called transport, is necessary in all plants, even the most primitive ones, unicellular algae. Nutrients are taken up through the cell membrane, and certain substances may in turn be released into the surrounding water. Transport across membranes is fundamental and may be regarded as the basis for long distance transport (see MEMBRANE, BIOLOGICAL). Molecules are moved actively—*i.e.*, with the expenditure of energy—across a cytoplasmic membrane, from one compartment (*e.g.*, one cell) to another. Active transport

The importance of transport processes in plants increased as multicellular plants evolved and their tissues acquired specialized functions. In large marine algae, for example, carbohydrates (such as sugars) are transported over relatively long distances, from their site of formation in well-illuminated plant parts near the water surface to parts near the sea floor that receive only small amounts of light. As land plants developed, long-distance transport assumed a still more important role; in this case, not only are carbohydrates transported from the organs in which they are formed (the leaves) to other parts—such as reproductive organs (flowers and fruits), stems, and roots—but water and minerals must be transported to leaves, which are not submerged in water (as are those of most primitive plants) but are in a relatively dry air environment. Highly developed land plants, such as trees, have two types of tissues specialized for long-distance transport: the xylem and the phloem. Water and dissolved mineral nutrients ascend in the xylem (the wood of a tree, such as an oak or a pine) and products of photosynthesis, mostly sugars, move from leaves to other plant parts in the phloem (the inner bark of a plant).

Evolving land plants faced not only the problem of transport but also the problem of supporting their weight. Aquatic plants are supported by their buoyancy in water. Even large seaweed do not need a rigid stem; flotation devices such as gas-filled bladders hold them upright and enable them to grow toward the water surface and obtain sufficient sunlight for photosynthesis. On land, a rigid, self-supporting structure is necessary for plants; this structure, the xylem, consists of tiny rigid tubes through which water and dissolved mineral nutrients can move. The rigidity of the tubes within a stem is sufficient to make it self-supporting.

THE TWO MAIN TRANSPORT SYSTEMS, XYLEM AND PHLOEM

Land plants take up water from the soil through the roots; the few rare exceptions, such as some plants of the Peruvian desert that grow in dry soil, rely on adaptations that enable them to obtain water from the air. In most plants, then, water ascends through the xylem, the tiny capillaries of the woody stem tissue, into all plant parts but primarily into the leaves, from which it is transpired (evaporated) into the air. In this way, the mineral nutrients are transferred from the soil to all above-ground plant parts.

Plants living in humid habitats, such as the small and primitive mosses and liverworts, do not have a well-developed xylem. Similarly, water plants that have returned from land to an aquatic habitat during evolution have a reduced xylem; such plants, which have readapted to an aquatic environment, are not woody, because they need neither water-conducting tissues nor a self-supporting structure. On the other hand, tall land plants such as trees and vines (lianas) have the most highly developed long-

distance transport systems. Vines differ from trees in that their xylem serves primarily for water conduction; they depend, for the most part, on other plants for support. Certain vines are of great length (several hundred feet) and have extremely highly developed tissues for transporting water and nutrients.

Most of the material that comprises a plant's dry weight is a consequence of photosynthesis, in which light energy is converted into chemical energy used to synthesize organic substances. Carbon dioxide from the air and water, which the plant takes from the soil, are utilized during photosynthesis, which occurs mostly in green plant parts —especially the leaves (see PHOTOSYNTHESIS). Since plants shed their leaves either continuously or periodically but still increase in size, it is clear that many photosynthetic products must be transported out of the leaves and carried to all other plant parts; this process takes place primarily in the phloem.

The discovery of the functions of xylem and phloem (wood and bark) was made following that of the circulation of blood in the 17th century. By the early 19th century, it had been established that water ascends from roots into leaves through xylem and that photosynthetic products descend through phloem. Experiments now called girdling experiments were performed, in which a ring of bark is removed from a woody plant. Girdling or ringing does not immediately interfere with upward movement of water in the xylem, but it does interrupt phloem movement. In some plants surgical removal of phloem is difficult; in this case phloem may be killed by using steam (steam girdling). Xylem conduction is normally not affected by such treatment, and movement in the two transport tissues can thus easily be distinguished. Girdling experiments, however, are not entirely foolproof. The question as to whether or not mineral nutrients can ascend in the phloem illustrates the kinds of difficulties that may be encountered. Much smaller amounts of mineral nutrients reach the leaves in girdled plants than in ungirdled ones. From this observation it might be concluded that some nutrients ascend in the phloem of ungirdled trees; girdling, however, interrupts the flow of sugars into roots. Roots are thereby starved and take up fewer mineral nutrients; the reduced flow of mineral nutrients to the leaves of girdled plants can thus be explained as a secondary effect.

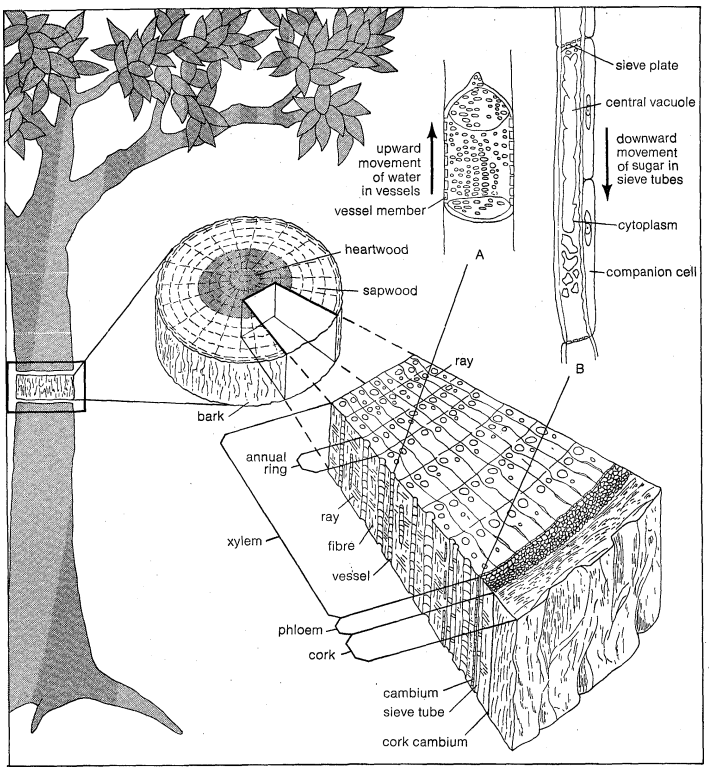
Girdling experiments

It was once widely believed that flogging a fruit tree increases the crop. The rational explanation of this is simple: flogging a tree damages the phloem; *i.e.*, it girdles the tree, perhaps partially. Girdling increases the sugar concentration of the leaves by restricting downward transport to the roots and may thus directly or indirectly stimulate flowering or, if done after fruit-set, may increase fruit size.

STRUCTURAL BASIS OF TRANSPORT

Cell-to-cell transport. Two features of plant cells differ conspicuously from those of animal cells. In plant cells the protoplast, or living material of the cell, contains one or more vacuoles, which are vesicles containing aqueous cell sap. Plant cells are also surrounded by a relatively tough but elastic wall. Water entering the vacuole by osmosis (*i.e.*, movement of water across a membrane into regions of lower water concentration, such as cell interiors, which normally contain dissolved substances) expands the protoplast and consequently the cell wall until the internal pressure is balanced by the elastic counterpressure of the wall. Spaces between and within cell walls are sufficiently large to permit water to flow around all cells. The space available for free water flow is called apoplast. Water in apoplast originates from the roots and contains nutrients taken up by them. Nutrients enter a cell by crossing the outer cytoplasmic membrane.

Because mature cell walls are dead structures, metabolic activities—the chemical reactions of living systems—occur within protoplasts. Substances can enter a protoplast by cytoplasmic connections between neighbouring cells (plasmodesmata) or by active transport mechanisms requiring energy and a group of enzymes called permeases. Plasmodesmata penetrate neighbouring cell walls at areas called pits. Some substances pass out of cells into the apoplast and are transported by energy-requiring processes into the protoplast of another cell.



Structure of xylem and phloem. *The xylem.* Cell-to-cell transport takes place in all multicellular plants, but it is a slow process; the higher plants evolved the specialized tissues, xylem and phloem, for rapid long-distance transport. The woody tissue, xylem, contains highly specialized cells for water conduction. The cells are long and reinforced by strong, woody walls; their protoplast breaks down and dissolves after wall growth is completed, so that the entire inside of the cell becomes available for rapid water conduction. In other words, the water-conducting cells of xylem are dead when functional. In the more primitive conifers the xylem consists largely of spindle-shaped cells called tracheids, which have a diameter around 40 microns (.04 millimetres or about 0.0016 inch) and a length of about three millimetres (about 0.12 inch). Flowering plants have a more highly specialized xylem, in which the mechanical function and the water conduction function have been separated during evolution. Tracheids, the primitive conducting cells, have evolved to form fibres for mechanical strength and vessels for water conduction. Vessel elements are barrel-like cells with widths of up to 0.5 millimetres (or about 0.02 inch) in some plants. Vessel elements are arranged end-to-end; their end walls are partly or wholly dissolved, and rows of such cells thus form long capillaries (tubes), up to several metres in length. These tubes are the vessels.

Conducting units—tracheids in conifers and vessels in flowering plants—have overlapping ends that are laterally connected by means of numerous pits. Pits are "windows" in the walls consisting of a thin wall membrane through which water but not an air–water interface (a bubble) can easily pass from one conducting unit to the next. Numerous vessels of limited length thus provide a certain protection against injury: that is, since water pressures in the xylem are often well below zero (*i.e.*, the water is under tension), air will be sucked into any injured xylem vessel and spread immediately throughout it but cannot pass through the wet pit membranes into the uninjured units. Damage is thus confined to the units that are injured and cannot easily spread; in addition, the smaller the conducting unit, the more confined is the damage. Plants with large, highly efficient vessels are much more vulnerable to injury, as is evident, for example, from the vulnerability of the elm, which has large vessels, to the Dutch elm disease, in which the water-conduction vessels are injured by beetle activity and fungal growth. In general, both the less efficient but safer coniferous wood and the more highly efficient but more vulnerable wood of flowering plants have been successful during evolution. Very tall trees occur in both groups; *e.g.*, *Sequoia* among the conifers and *Eucalyptus* among the flowering plants.

The phloem. The conducting elements of the phloem underwent evolutionary changes somewhat similar to those of the xylem. The conducting elements of conifers, called sieve cells, are similar in shape and dimensions to tracheids. They do not have a woody wall, however, and they are alive at functional maturity even though their cytoplasm may be highly specialized and the cells have usually lost their nucleus during development. In flowering plants the conducting elements in the phloem, called sieve elements, are arranged end-to-end to form sieve tubes, a name derived from the sievelike end walls through which passage of food from one cell to the next occurs. Sieve cells and sieve elements are almost invariably accompanied by special companion cells believed to control, to a certain extent, the metabolism of the nucleus-free conducting cells.

Phloem cells

Vascular tissue. In primary tissues, such as leaves, strands of phloem and xylem run parallel, forming conducting bundles. These form a network of veins that can be seen when a leaf is held against a light. Xylem sap from the stem enters a leaf through the petiole (leaf stalk) and spreads throughout the leaf blade in the xylem part of the conducting bundles, or veins. Photosynthetic products enter the phloem tissues of the veins, and they are

transported from the leaf through the phloem of the petiole.

Throughout most of the plant, xylem and phloem channels run more or less in an axial, or longitudinal, direction, although this path may not be precisely parallel with the stem axis. In most stems of monocotyledonous plants —flowering plants with one seed leaf, such as lilies, grasses, palms—the tissue is primary; *i.e.*, it is formed entirely by the growing shoot tip. Because such plants have no cambium tissue in their stems, they have no secondary growth and thus show relatively little increase in stem diameter. The conducting tissue consists of narrow strands, containing both xylem and phloem, distributed throughout the plant. A single crosswise section through the stem of a coconut palm may contain 20,000 vascular bundles, which are connected into a complex network by numerous cross connections; if the stem is injured, alternate pathways of transport are available.

Tree stems of both conifers and dicotyledonous plants (flowering plants with two seed leaves, such as oaks, maples, elms) contain a cell layer called the vascular cambium that gives rise to secondary xylem and phloem. With each season's secondary growth, the stems increase in diameter. Xylem is formed as a woody cylinder on the inner side of the cambium layer near the centre of the stem. The vessels are deposited by the cambium as a complex network in such a way that an injury to the stem interrupts the local flow of water, but water continues to flow around the injury. Phloem is formed toward the outside of the stem from the cambium layer, forming the inner, conducting bark. The conducting phloem layer remains very thin, less than 0.5 millimetre, and is renewed each year. Older phloem serves only for food storage. Conducting and storing phloem comprise the living bark.

Both xylem and phloem have limited longevity. The oldest phloem layers are the outermost—the dead bark of the stem surface. The yearly amounts of xylem visible in cross sections of stems as distinct rings are known as annual rings. The oldest xylem layers (*i.e.*, the oldest annual rings) are in the dead central core, or heartwood, of the woody stem, which can often be recognized by its darker coloration. The lighter coloured sapwood is living and functions as storage tissue and, especially in the outermost sapwood, as conducting tissue; the younger annual rings comprise the sapwood. In some highly specialized tree species with large vessels (such as some oaks, ashes, and others) only the very outermost growth ring functions in water conduction. Conducting tissues seldom run straight along a tree stem; usually they are arranged in a helical or spiral pattern, sometimes called the spiral grain of a tree. The angle of the spiral arrangement usually changes from year to year; the path of water up a tree stem may therefore be very complicated if more than one growth layer acts as a conducting tissue. Functionally, the effect of the variable spiral grain is to distribute water to all parts of the tree from any root.

Ray tissue

An important tissue in the stems of conifers and dicotyledonous trees is the ray tissue. Rays, small strands of radially running tissue, are continuous from the stem centre through the xylem and phloem and serve for radial conduction and storage of starch. No rays are present in monocotyledonous stems, however; more or less radially running bundles that originally connected the stem with leaves, which have fallen from lower stem parts, serve the same purpose.

Gas exchange and transport in leaves. Although some transpiration (evaporation) of water occurs from the surfaces of all leaf cells, most of it takes place through special structures called stomata; these structures are pores whose openings are controlled by a flexible pair of cells called guard cells. The movement of guard cells is controlled so that they open during daylight hours and close at night or under conditions of excessive water stress. The stomatal opening not only permits the escape of water vapour but also allows carbon dioxide to enter leaves for photosynthesis. Photosynthesis ceases as night falls, and excessive water loss is prevented by stomatal closure.

Most water, which is taken up by roots and ascends into leaves, is lost by transpiration. Transpiration is necessary for two reasons. One is the necessity of keeping stomata open throughout the daylight hours for the entry of carbon dioxide. The second is the fact that xylem sap is very dilute; *i.e.*, it contains much water. In order for sufficient quantities of soil nutrients to be accumulated in leaf cells, large amounts of water must be transpired.

Stomata are very efficient in transpiring water. Water molecules that emerge from such a small pore can escape without interference in all radial directions. (From an open surface water molecules can escape only in a straight line because of mutual interference of neighbouring molecules.) Thus, water can evaporate through a multiperforate membrane (with many pores) almost as efficiently as from an open water surface of equal size even though the total area of all the pores is extremely small. The advantage of the multiperforate membrane is that the size of the pore opening can be controlled.

Xylem sap entering leaves from the stem spreads out into the xylem tissues of all veins and from vein ends into the walls of other leaf cells. Thus surrounded by xylem sap, leaf cells live in an environment not unlike that of algal cells in water. Solutes—dissolved nutrients—brought up from roots can be taken up from the xylem sap into the cell interior. Any solute not actually used by the leaf cells can either be transported to the leaf surface or transferred into the phloem to be returned to the plant body for use in other plant parts; certain substances of no value to the plant are deposited in the form of crystals, sometimes in special crystal cells along the phloem path.

Movement of gases in leaves

Leaf tissue is very spongy—*i.e.*, the cells are surrounded by an abundance of communicating gas spaces. Water evaporates from cell walls into the gas space, diffuses into the stomatal cavity, and then moves into the air through the stomatal pore between the guard cells. Within the gas spaces of the leaf, gases presumably move by diffusion and perhaps, as leaves are moved about by wind, by convection.

The bark of the stem also contains stomata when young and secondary structures of similar function—openings in the bark called lenticels—when older. Very young stems are usually green and function somewhat like

leaves; *i.e.*, they photosynthesize and transpire. Photosynthesis in older stems is negligible although transpiration continues. Transpiration through lenticels takes place in the summer, but closure of lenticels largely prevents transpiration in the winter.

Uptake of water and mineral nutrients from the soil. Water uptake from the soil by root cells is passive, in that water may be pulled into the root by low xylem pressure and also follows osmotic gradients caused by the mineral nutrients, which are taken up actively (*i.e.*, with the expenditure of metabolic energy) across root cell membranes. As the mineral nutrients—the ions (charged components) of inorganic salts—are taken up, they are largely incorporated into organic molecules. Thus, the solutes in xylem sap are mostly complex organic substances, sometimes of a specific nature; for example, nicotine synthesis takes place in the roots of tobacco plants, where nitrogen is incorporated into compounds that have moved to the roots through the phloem as sugars. If a tomato shoot is grafted onto a tobacco rootstock, nicotine-containing tomato leaves are formed. On the other hand, a tobacco shoot grafted onto a tomato rootstock results in a plant with nicotine-free tobacco leaves. Many other specific nitrogen-containing substances originate in the roots; in most plants, however, nitrogen is transported to the leaves from the roots in the form of compounds known as amino acids and amides.

The major chemical elements needed by a plant are: carbon, hydrogen, oxygen, phosphorus, potassium, nitrogen, calcium, iron, and magnesium; in addition, many others are required in very small amounts. A lack of any element may result in deficiency diseases. A few elements taken up by plants are of no nutritive value and usually are eliminated (*e.g.*, sodium chloride) or crystallized (*e.g.*, silica), sometimes by deposition in special cells.

The plant is able to control to some extent the substances that enter. If equal amounts of sodium and potassium are available to roots of plants, and the amount of the two elements inside the plant is analyzed, less sodium is likely to be found than potassium, which is a vital nutrient. The structural basis for the control of uptake of substances into roots is the so-called Casparian strip, a conspicuously thickened wall area of one cell layer around primary roots; it prevents excess soil solution from being pulled directly into the central part of the root where the xylem is located. As a result, the soil solution has to pass through a cell barrier in which uptake can metabolically be controlled. After nutrients are inside living root cells and have been converted to appropriate compounds, the latter are released into the xylem and move to above-ground parts.

Casparian strips

XYLEM TRANSPORT

Quantitative aspects. The sum of the cross-sectional areas of all the branches of a tree approximately equals that of the stem; this means that the total amount of conducting tissue remains about the same from roots to leaves. In terms of water movement, the velocity of movement might be expected to be uniform throughout the entire axial system of stem, branches, and twigs. Because some trees (*e.g.*, oaks) have thick twigs, however, the velocity of water movement is greater in the stem than in the twigs at any time. Similarly, in tree species with slender branches (such as birches), the reverse is true. Normally the proportion of xylem to leaves supplied by that xylem is greater in plants growing in dry habitats than in plants found in wet ones and may be as much as 700 times greater in certain desert plants than in aquatic plants and herbs of relatively humid forest floors. The leaves of dry-habitat plants thus are more richly supplied with water-conducting xylem tissue than are those of moist habitats.

The velocity of sap movement in trees varies throughout a 24-hour period. During the night, especially a rainy night, sap flow may stop; velocity increases with daylight, peak rates being found in the early afternoon. Peak velocities correlate with vessel size; the rate of sap flow in trees with small vessels is about two metres (seven feet) per hour; that in trees with large vessels, about 50 metres (160 feet) per hour. The energy required to lift water in both cases is comparable; in large-porous trees water simply moves faster through fewer and larger vessels.

Mechanism of sap ascent. It was demonstrated about 1900 that living cells of the stem are not responsible for water movement. It is now generally recognized that water in the xylem moves passively along a gradient of decreasing pressures. Under certain special conditions water is pushed up the stem by root pressure. This may be the case with herbaceous (nonwoody) plants in the greenhouse under conditions of ample water supply and little transpiration. In nature, these conditions may be met in early spring before the leaves emerge, when the soil is wet and transpiration is low. Under such conditions, water movement is caused by active uptake of ions (charged particles) and by the entry of water from the soil into the roots. Most of the time, however, water is pulled into the leaves by transpiration. A gradient of decreasing pressures from the base to the top of a tree can be measured, even though pressures are low.

A vacuum pump cannot pull water to a height of more than ten metres (about 33 feet). Since many trees are far taller than 33 feet, the mechanism by which they move water to their crowns has been sought. Is it possible for trees to pull water into their crowns along a decreasing pressure gradient or do they employ some other mechanism? If trees pull water, that in the xylem would have to be held on the tracheid and vessel walls by adhesion, and water molecules would have to hold together by cohesion. The hypothesis that water is pulled upward along a pressure gradient during transpiration has been called the cohesion theory. Two critical requirements of the cohesion mechanism of sap ascent are: (1) sufficient cohesive strength of water and (2) existence of tensions (*i.e.*, pressures below zero) and tension gradients in stems of transpiring trees.

The cohesion theory of sap ascent

Although the tensile strength of water is very high, an excessive pull exerted on a water column will break it. The tallest trees are about 330 feet (100 metres) high. A nonmoving water column at an atmospheric pressure of one atmosphere at the base of the tree is exposed to a pressure of minus nine atmospheres (*i.e.*, a tension of nine atmospheres) at the top. Calculations show that, under conditions of peak flow at midday, this gradient increases by about 50 percent; in other words, a transpiring sequoia would have a pressure in the xylem of minus 14 atmospheres at the top if the basal pressure is one atmosphere. If the pressure at the base is minus ten atmospheres because of dry soil, however, the pressure at the top drops to minus 25 atmospheres.

It has now been shown that negative pressures and gradients of negative pressures do exist in trees with an ingeniously simple device called the pressure bomb. A small twig is inserted in a container (the pressure bomb), its cut stump emerging from a tightly sealed hole. As pressure is applied to the container and gradually increased, water from the xylem emerges from the cut end as soon as the pressure being applied is equal to the xylem tension that existed when the twig was cut. This method has been used to measure gradients of negative pressures in trees; the cohesion theory thus would seem to explain the sap-ascent mechanism.

PHLOEM TRANSPORT

Quantitative aspects. Products of photosynthesis, primarily sugars, move through phloem from leaves to growing tissues and storage organs. The rate at which these substances are transported can be measured in various ways; *e.g.*, as velocities in distance traveled per unit time or as mass transfer in (dry) weight transported per unit time. Velocities appear to be graded—*i.e.*, some molecules move faster than others within the same channel. Peak velocities of molecules usually are of the order of 100 to 300 centimetres (40 to 120 inches) per hour. Average velocities, more difficult to measure but significant in mass-transfer considerations, are lower.

Velocity of phloem transport

Mass transfer can be measured by weighing a storage organ, such as a potato tuber or a fruit, at given time intervals during its growth. Mass transfer per cross-sec-

tional area of conducting tissue is referred to as specific mass transfer and is expressed as grams per hour per square centimetre of phloem or sieve tubes. With a given specific mass transfer, the velocity with which a liquid of a certain concentration flows can be calculated; in dicotyledonous stems, for example, specific mass transfer is between ten and 25 grams per hour per square centimetre of sieve tube tissue at times of peak performance. In certain tree species the sieve tubes can be tapped to obtain an exudate. The concentration of this exudate, multiplied by the measured average velocity, is of the same order of magnitude as specific mass transfer, indicating that liquid movement through sieve tubes could account for transport.

Much of the experimental work on phloem transport now is done with the aid of radioactive substances; radioactive carbon dioxide administered to an illuminated leaf is incorporated into sugar during photosynthesis and carried from the leaf. The velocity of this movement can be measured by determining the arrival of radioactivity at given points along the stem. Whole plants, as long as they are reasonably small, can be pressed against photographic film after the conclusion of a similar experiment, and the photographic image will indicate the portions to which radioactive sugar has moved.

Mechanism of phloem transport. The mechanism of phloem transport has been studied by plant physiologists for many years. A number of hypotheses have been put forth over the past years, but none is entirely satisfactory. One fundamental question is whether sugars and other solutes move en masse as a flowing solution or whether transport takes place independently of the solvent water. The phenomenon of exudation from injured sieve tubes supports the first possibility, which has been further supported by a discovery involving aphids (phloem-feeding insects); when aphids are cut away from plants while feeding, their mouthparts remain embedded in the phloem. Exudate continues to flow through the mouthparts; the magnitude of the rate of this exudation indicates that transport within the sieve tube to the mouthparts occurs as a flow of solution.

Evidence against solution flow is the movement of substances in opposite directions through a section of phloem at any one given time. This, however, has never been convincingly demonstrated in just one sieve tube. On the other hand, unsuccessful attempts have been made to find simultaneous movement of sugars and water along a phloem path in order to demonstrate solution flow.

Mass flow

Mass-flow hypotheses include the pressure-flow hypothesis, which states that flow into sieve tubes at source regions (places of photosynthesis or mobilization of storage products) raises the osmotic pressure in the sieve tube; removal of sugars from sieve tubes in sink regions —*i.e.*, those in which sugars are removed for growth and storage—lowers it. Thus a pressure gradient from source to sink is established in sieve tubes that would allow solution flow. The electroosmotic hypothesis postulates that solution is moved across all sieve plates (areas at which individual sieve elements end) by an electrical potential that is maintained by a circulation of cations (positively charged chemical ions), such as potassium. Transport hypotheses postulating solute movement independent of solvent water include the spreading of solute molecules between two liquid phases and the active movement of molecules by a type of cytoplasmic movement that is frequently referred to as cytoplasmic streaming.

TRANSPORT AND PLANT GROWTH

Storage and circulation. It is important to realize that the plant, with its two transport systems, xylem and phloem, is able to move any substance to virtually any part of its body; the direction of transport is usually opposite in the two systems, and transfer from one system to the other takes place easily. An exception is transport into flowers and certain fruits, in which flow in each system is unidirectional.

Numerous substances move from roots to mature leaves through xylem and are transferred from the leaves, together with sugars, through the phloem to other plant parts. In the autumn months in temperate regions, plants store most of the products resulting from photosynthesis during the summer months in structures such as stems, bulbs, and tubers and mobilize it in the spring when new growth begins. A few plants, such as some tropical monocotyledons (certain palms, for example), store food for many years for use at the time of flowering and fruit-set at the end of their life-span.

Transport of growth-regulating substances. Plant hormones, or growth regulators, are effective in very small amounts; they induce or enhance specific growth phenomena. Because the site of hormone synthesis is different from its place of action, hormones must be transported before they can exert their effects. There are several groups of plant hormones; each has different effects on plant growth. The best known plant hormones are the auxins, the most common of which is called indole acetic acid. Auxins are formed in young, growing organs, such as opening buds, and are transported away from tips of shoots toward the base of the plant, where they stimulate the cells to elongate and sometimes to divide. Responses to gravity and light are also under auxin control. Auxin moves to the lower side of a leaning stem; cells on the lower side then elongate and cause the stem to bend back to a vertical position. Response to gravity in many roots is the opposite of that in shoots; the same mechanism of auxin distribution is responsible, but roots react to different quantities of the hormone than do shoots. Similar auxin distributions are responsible for phototropic responses—*i.e.*, the growth of plant parts such as shoot tips and leaves toward light. In certain cases auxin may be destroyed on the illuminated side.

Auxin transport

Auxin is not normally transported through vascular tissue; moreover, transport is polar—*i.e.*, it takes place along the stem from tip to base, regardless of the stem's position. Velocities of transport are of the order of five to ten millimetres (0.2 to 0.4 inch) per hour, and transport requires the expenditure of metabolic energy. There is evidence that most growth hormones can be transported through xylem or phloem, but, at least in the case of auxin, the transport mechanism is specific.

Hormone transport is also involved in the stimulation of flowering. In some plants, flowering is triggered by short or long days. The receptor of this stimulus is in the leaves. A chemical substance, probably a flowering hormone of as yet unknown nature, then moves to the shoot apex and causes a transformation of the vegetative growing point into a flowering shoot.

Many growth-correlating phenomena are effected by transported hormonal stimuli. A vigorously growing terminal (topmost) shoot may inhibit lateral buds lower down from growing out and may force later branches to bend down. If the terminal shoot is removed, laterals grow out and topmost lateral branches bend upward. In leaning trees with secondary tissue (wood), the cambium produces compression wood on the lower side (in conifers) or tension wood on the upper side (in dicotyledons) in response to a hormone; the stem responds by pushing (in conifers) or pulling (in dicotyledons) itself upright. Transport of growth-regulating substances is thus largely responsible for the characteristic shape of each plant species (see also HORMONE).

BIBLIOGRAPHY. The following three books contain extensive bibliographies through which the reader will find his way into every aspect of the literature: K. ESAU, *Plant Anatomy*, 2nd. ed. (1965), an excellent college-level textbook on anatomy, with chapters on xylem, phloem, leaves, and roots; M.B. WILKINS (ed.), *The Physiology of Plant Growth and Development* (1969), a graduate-level book, containing chapters on transport of nutrients, growth regulators, mineral uptake, photosynthesis, and movement of stomata; M.H. ZIMMERMANN and C.L. BROWN, *Trees: Structure and Function* (1971), a profusely illustrated college-level tree physiology textbook, discussing xylem and phloem transport as well as growth correlations in trees. For continuing reviews, the reader is also referred to the *Annual Review of Plant Physiology* and to supplement volumes to the *Handbuch der Pflanzenphysiologie (Encyclopedia of Plant Physiology)*.

(M.H.Z.)

Plasma State

The plasma state of matter is unique like the solid, liquid, and gaseous states, and is sometimes referred to as the fourth state of matter. A plasma is an electrically conducting medium, in general consisting of negatively charged electrons, positively charged ions (atoms or molecules that have lost one or more of their electrons), and atoms or molecules or both. Its properties depend on the collective behaviour of the particles, as distinct from the individual; and the number of positive charges is almost equal to the number of negative charges. Nearly all the matter in the universe exists in the plasma state, occurring predominantly in this form in the Sun and stars and in interstellar space. Auroras, lightning, and welding arcs are also plasmas; plasmas exist in neon and fluorescent tubes, the crystal structure of metallic solids, and in many other phenomena and objects.

A plasma may be produced in the laboratory by heating a gas to an extremely high temperature, which causes such vigorous collisions between its atoms and molecules that they dissociate into electrons and ions. Plasmas may be partially or completely ionized. A completely ionized hydrogen plasma, consisting solely of electrons and protons (hydrogen nuclei), is less complex than a mixture of atoms or molecules and so is the most elementary aggregation of matter known. In certain circumstances, a plasma obeys the laws of magnetohydrodynamics, the study of the behaviour of electrically conducting fluids in the presence of electric and magnetic fields.

Relation to laws of magneto-hydro-dynamics

DEVELOPMENT OF PLASMA PHYSICS

The modern concept of the plasma state is of recent origin, dating back only to the early 1950s. Its history is interwoven with many disciplines. Three basic fields of study have made unique contributions: electrical discharges, magnetohydrodynamics, and kinetic theory.

Interest in electrical-discharge phenomena may be traced back to the beginning of the 18th century, with three English physicists, Michael Faraday in the 1830s and Joseph John Thomson and John Sealy Edward Townsend at the turn of the 19th century, laying the foundations of the present understanding of the phenomena. Irving Langmuir introduced the terminology plasma in 1923, while investigating electrical discharges. In 1929 he and Levi Tonks, another physicist working in the United States, used the term to designate those regions of such a discharge in which certain oscillations of the negatively charged electrons could occur. They called these oscillations plasma oscillations, their behaviour suggesting that of a jelly-like substance. Not until 1952, however, when two more United States physicists, David Bohm and David Pines, first considered the collective behaviour of electrons in metals as distinct from that in ionized gases was the general applicability of the concept of a plasma fully appreciated.

The collective behaviour of charged particles in magnetic fields is implicit in magnetohydrodynamic studies, the foundations of which were laid in the early and middle 1800s by Faraday and André-Marie Ampère of France. Not until the 1930s, however, when new solar and geophysical phenomena were being discovered, were many of the basic problems of the mutual interaction between ionized gases and magnetic fields considered. In 1942 Hannes Alfvén, a Swedish physicist, introduced the concept of magnetohydrodynamic waves.

Kinetic theory

These two separate approaches—the study of electric discharges and the study of the behaviour of charged particles within magnetic fields—were unified by the introduction of the kinetic theory of the plasma state, which holds that plasma, like gas, consists of particles all in random motion. In 1905 the Dutch physicist Hendrik Antoon Lorentz applied the kinetic equation for atoms (the formulation by the Austrian physicist Ludwig Eduard Boltzmann) to the behaviour of electrons in metals. Various physicists and mathematicians in the 1930s and 1940s developed the plasma kinetic theory further to a high degree of sophistication, and since the early 1950s interest has increasingly focussed on the plasma state itself. Space exploration, the development of electronic devices, a growing awareness of the importance of magnetic fields in astrophysical phenomena, and the quest for controlled thermonuclear (nuclear-fusion) power reactors all have stimulated such interest. Problems remain for the theory of plasma state, especially involving the simultaneous solution of James Clerk Maxwell's electromagnetic equations determining electric and magnetic fields and kinetic equations determining statistical behaviour of plasma particles.

GENERAL CONCEPTS

Although a gas normally acts as an electrical insulator, at sufficiently high temperatures it becomes a conductor. Increased thermal agitation of the molecules and atoms causes them to become ionized as they collide, disintegrating into electrons and positively charged entities called ions. At sufficiently high electron densities an ionized gas becomes a plasma. A basic property of a plasma is its electrical quasi-neutrality; that is, the numbers of negative charges and of positive charges per unit volume of plasma are approximately equal. At sufficiently high electron densities such quasi-neutrality is inevitable. Any excess concentration of either charge would lead to the development of large electrostatic restoring forces resulting from the attraction between opposite charges. Just as a weight on a spring will bob up and down about its rest position, any general displacement of the electrons as a group with respect to the positive ions leads to oscillation of the electrons as a whole about an equilibrium state. These movements were the plasma oscillations studied by Langmuir and Tonks.

Plasma properties and parameters. In general, a plasma is a complex mixture of many different particle types, each distinguishable by its mass and charge and with all particles in rapid thermal motion. The basic properties of a plasma as matter are essentially independent of its chemical properties; they are determined primarily by conservation of energy and momentum laws and by the behaviour of the electrons. The study of the extremely complex interactions among the vast numbers of particles requires the use of statistical methods. Number densities or number per unit volume (n) and kinetic temperatures (T) are defined for each type of particle present. The average kinetic energy per particle is 1.5 times Boltzmann's constant (k) and the kinetic temperature, or $\frac{3}{2}kT$. As in a gas, kinetic pressures are defined as equal to the number density times Boltzmann's constant times temperature, or nkT. In thermodynamic equilibrium, all temperatures are the same as that of the enclosure, and (ignoring particle interactions) the sum of the kinetic pressures is the force per unit area exerted on the enclosure. A basic classification of plasmas can be made in terms of the electron-number density (n_e, the number of electrons per unit volume), the electron temperature (T_e), and the degree of ionization, or the fraction of the plasma ionized. One of the most important parameters associated with a plasma is the Debye length, a concept similar to that introduced in 1923 by the chemists Peter W. Debye and Walter K.F. Hückel in their theory of strong electrolytes (compounds that ionize easily and conduct electricity). In a plasma the Debye length is the maximum distance over which a large difference in the number of positive charges and negative charges can occur. It is equal to a constant times the square root of the ratio of the electron temperature to the electron number density; that is, $h = 69(T_e/n_e)^{1/2}$, in which the Debye length h is given in metres, n_e is the number per cubic metre, and T_e is given in degrees Kelvin. For distances appreciably greater than the Debye length, quasi-neutrality must exist, whereas for distances less than the Debye length an individual positively charged ion can exert a force on an electron. This phenomenon leads to a quantitative definition of a plasma: an ionized gas is a plasma provided the physical dimensions of the gas are much greater than the Debye length. For disturbances on a scale greater than the Debye length, the plasma behaviour is macroscopic, or collective; whereas, on a scale smaller than the Debye length, individual particle behavior can occur.

The basic properties of plasma

When the plasma is not in equilibrium and, especially, when it contains electrical currents (*i.e.*, general motion of the electrons relative to the ions), the particle interactions within a sphere having a Debye radius are best accounted for in terms of equivalent binary collisions. That is, it is possible to add together the many simultaneous interactions between particles within such a sphere in such a way that they may be represented as a series of discrete events between two particles only. The number of such events is called the collision frequency.

Another important measure used in plasma physics is the angular frequency (ω_p) of the plasma oscillations noted by Langmuir and Tonks; it is equal to the average thermal speed of the electron divided by the Debye length, giving a value proportional to the square root of the electron density number, or $\omega_p = 56\sqrt{n_e}$ radians per second.

Elastic and inelastic collisions. In any gas, separate collision frequencies are defined for collisions between all different particle types and all different types of collisions. The total collision frequency for a particular particle type is the sum of these separate frequencies. Two basic types of collisions exist: elastic and inelastic; in an elastic collision, the kinetic energy of colliding particles remains the same after a collision as before; in an inelastic collision, a fraction of the kinetic energy is transferred to the internal energy states of the colliding particles. In an atom, for example, the electrons have certain allowed (discrete) energies and are said to be bound. In a collision a bound electron may be raised from a low to a high energy state, or excited. This, however, can occur only by the expenditure of kinetic energy and only if the kinetic energy exceeds the difference between the two energy states. If the energy is sufficient, a bound electron may become a free electron, and the atom is said to be ionized; the minimum, or threshold, energy required to free an electron is called the ionization energy. Inelastic collisions may also occur with positive ions if electrons are still attached to them. In general, only collisions of electrons and photons (electromagnetic radiation particles) with atoms and ions are significant in these inelastic collisions; ionization by a photon is called photo-ionization.

Collisions defined

A molecule also has discrete energy states, which may be excited by particle collisions. At sufficiently high energies of interaction, the molecule can dissociate into atoms or into atoms and atomic ions. Again, collision of electrons and photons with molecules may cause ionization, producing molecular ions. In general, the reaction rate for inelastic collisions is similar to that of chemical reactions. At sufficiently high temperatures, the atoms are stripped of all electrons and are bare atomic nuclei, and at temperatures of about 1,000,000° K (degrees Kelvin) or greater, nuclear reactions can occur—another form of inelastic collisions. When such reactions lead to the formation of heavier elements the process is called thermonuclear fusion; excess mass is transmuted into kinetic energy (that of motion), and kinetic energy is gained instead of lost.

Radiation from plasmas. Elastic collisions occur between all particles, a fraction of the energy and momentum of one particle being exchanged with the other. The amount of energy exchanged depends on the mass ratio of the colliding particles. On the average, the energy exchanged between one particle type and another is proportional to the temperature difference and the collision frequency. In basically elastic collisions of electrons with ions, however, all of the energy is not exchanged; some is radiated; such radiation is called *bremsstrahlung* (German: "braking radiation") and is associated with the deceleration of electrons in a collision. The power (energy per unit of time) radiated is proportional to the square root of the electron temperature, the radiation being emitted as a continuum of wavelengths.

A similar process occurs in a magnetic field. In such a field an electron gyrates about a magnetic line of force in a helix, a configuration similar to a so-called spiral staircase, the frequency of rotation being called the cyclotron frequency. Charged particles moving in an arc or circle radiate energy, and when an electron moves in a helix about a magnetic line of force, an electromagnetic wave is radiated. At low electron energies an electron radiates at integral multiples of the cyclotron frequency, and at the highest energies the radiation becomes a continuum of frequencies, called synchrotron radiation, a phenomenon associated with similar processes in a synchrotron particle accelerator.

Synchrotron radiation

Other forms of radiation met with in plasma physics include line and recombination radiation. The lifetime of an atom or ion in an excited state is only about 1/100,000,000 of a second. When an electron goes from a high to a low energy state, a photon is emitted, with its frequency proportional to the energy difference between the two states. This emission is called line radiation because the photon would be observed as a line in a spectrometer. In another process, a free electron can be captured by an ion, followed by the emission of a photon; this is called radiative recombination, the associated radiation being a continuum of frequencies with a low frequency cutoff.

Emitted radiation may be absorbed and re-emitted from one atom or molecule to another, and depending on the processes, frequency changes can occur. If the distance travelled after emission and before absorption is small, compared with the dimensions of the plasma, the plasma is said to be optically thick. In this case, the spectrum of the radiation emitted from the surface is characteristic of an ideal blackbody (which emits radiation at the same rate as it absorbs it) and a blackbody temperature may be assigned; the power radiated is proportional to the fourth power of the blackbody temperature. If, however, the absorption distance is large compared with the plasma dimensions, the plasma is said to be optically thin, and the spectrum of the radiation emitted is characteristic of the individual types of radiation—in general, a function of the electron temperature.

BASIC PLASMA PHYSICS

Plasma formation. Apart from solid-state plasmas, such as those in metallic crystals, plasmas do not usually occur naturally at the surface of the earth. For laboratory experiments and technological applications, therefore, plasmas must be produced artificially. Because the atoms of such alkalies as potassium, sodium, and cesium possess low ionization energies, plasmas may be produced from these by the direct application of heat at temperatures around 3,000° K. In most gases, however, before any significant degree of ionization is achieved, temperatures in the neighbourhood of 10,000° K are required. Because all substances melt at temperatures far below that level, so far no container can withstand an external application of the heat necessary; therefore, any heating must be supplied internally by applying an electric field to the gas to accelerate and scatter all of the free electrons, thereby heating the plasma. Because of their small energy exchange in elastic collisions, electrons can be raised to much higher temperatures than other particles. As long as the rate of loss of electrons exceeds their rate of production, however, a plasma cannot take form.

Artificial production of plasmas

For plasma formation a sufficiently high electric field must be applied, its exact value depending on geometry and the gas pressure. An equilibrium state is reached when the electrical power input is balanced by energy losses to the outside. The electric field may be set up via electrodes or by transformer action, which is induced by a changing magnetic field. Laboratory temperatures of about 10,000,000° K with electron densities of about 10^{19} per cubic metre have been achieved by the transformer method. Extremely high temperatures, but relatively low-density plasmas, have been produced by the separate injection of ions and electrons into a mirror system (a plasma device using a particular arrangement of magnetic fields for containment). Other methods have used the high temperatures that develop behind a wave that is moving much faster than sound to produce what is called a shock front; lasers have also been employed.

Effects of magnetic and electric field. *Individual particle description.* The behaviour of a plasma may be described at different levels. If collisions are relatively infre-

quent, it is useful to consider the motions of individual particles. A magnetic field exerts a force on a charged particle only if the particle is moving, the force being at right angles to both the direction of the field and the direction of particle motion. In a uniform magnetic field, (B), a charged particle, gyrates about a line of force with an angular frequency equal to the magnetic field strength times the ratio of the charge of a particle (q) to its mass (m), or, $\omega_c = Bq/m$, charges of different sign rotating in opposite directions; in this equation, ω_c is the rate of gyration, or the cyclotron frequency.

The radius of the orbit is called the Larmor radius (r_L) and is equal to the product of the particle mass and the component (v) of the particle velocity in a plane perpendicular to the magnetic field divided by the product of its charge and the magnetic field—*i.e.*, $r_L = mv/qB$. The centre of the orbit is called the guiding centre. The particle may also have a component of velocity parallel to the magnetic field and so traces out a helix when the motion of the guiding centre is uniform. If a uniform electric field (E) is applied at right angles to the direction of the magnetic field, the guiding centre drifts with a uniform velocity of magnitude equal to the ratio of the electric to the magnetic field (E/B), at right angles to both the electric and magnetic fields. Should the electric field alternate in time, the problem is even more complex. If, however, such an alternating electric field varies at the same frequency as the cyclotron frequency, the guiding centre will remain stationary and the particle will be forced to travel in an ever-expanding orbit. This phenomenon is called cyclotron resonance and is the basis of the cyclotron particle accelerator.

Cyclotron resonance

The motion of a particle about its guiding centre constitutes a circular current. As such, the motion produces a dipole magnetic field not unlike that produced by a simple bar magnet. Thus, a moving charge not only interacts with magnetic fields but also produces them. Therefore, interactions between particles caused by their motions must also be considered. The direction of the magnetic field produced by a moving particle, however, depends both on whether the particle is positively or negatively charged and on the direction of its motion. If the motion of the charged particles is completely random, the net associated magnetic field is zero. On the other hand, if charges of different sign have an average relative velocity (*i.e.*, if an electrical current flows) then a net magnetic field over and above any externally applied field exists. The magnetic interaction between charged particles is therefore of a collective, rather than of an individual, particle nature.

Statistical and fluid descriptions. At a higher level of description than that of the single particle, kinetic equations of the Boltzmann type are used. Such equations essentially describe the behaviour of those particles about a point in a small-volume element, the particle velocities lying within a small range about a given value. The interactions with all other velocity groups, volume elements, and any externally applied electric and magnetic fields are taken into account.

At a still higher level of description, equations of a fluid type may be derived from the kinetic equations; they express the conservation of mass, momentum, and energy per unit volume, with one such set of equations for each particle type. Total conservation equations may be obtained from these by a process of summation from the equations of each particle type. For instance, the derived thermal-energy equation states that the rate gain of thermal energy is equal to the work done by pressure forces plus heating from electrical currents less losses from radiation and heat conduction. The total heat flux —that is, the thermal energy transported across a unit area of the plasma in a unit of time—is the sum of each term for each particle type present.

Determination of plasma variables. The basic variables useful in the study of plasma are number densities, temperatures, electric and magnetic field strengths, and particle velocities. In the laboratory and in interplanetary space, both electrostatic (charged) and magnetic types of sensory devices called probes help determine the magnitudes of such variables. With the electrostatic probe, ion densities, electron and ion temperatures, and electrostatic potential differences can be determined. Small search coils and other types of magnetic probes yield values for the magnetic field; and from Maxwell's electromagnetic equations, the current and charge densities and the induced component of the electric field may be found.

Furthermore, in the laboratory, the absorption, scattering, and excitation of neutral and high-energy ion beams are helpful in determining electron temperatures and densities; in general, the refraction, reflection, absorption, scattering, and interference of electromagnetic waves also provide ways to determine these same variables. As an example, a powerful but difficult technique for such measurements is based on the scattering of a laser beam by plasma electrons. Aside from the above methods, much can be learned from the radiation generated and emitted by the plasma itself; in fact, this is the only means of studying cosmic plasma beyond the solar system. The various spectroscopic techniques covering the entire continuous radiation spectrum determine temperatures and identify such nonthermal sources as those producing synchrotron radiations.

Ion temperatures can be determined by measuring the widths of spectral lines on a spectrographic plate; their widths vary with thermal motions, a phenomenon called Doppler broadening. Velocities of plasmas in space are measured by Doppler shifts; that is, the spectral lines of radiation from receding bodies shift to lower frequencies, and vice versa. From the frequency of line radiation, researchers can identify elements, map the distribution of particles in plasmas, and determine their electron temperatures. Spectral lines are affected also by magnetic fields, and thus magneto-optical effects can determine such fields.

Doppler measurements of plasmas

Fluid-like behaviour. *Plasma waves.* An important parameter in plasma physics is the magnetic Reynolds number, the value of which depends on electrical resistivity of the plasma and the velocity of the particles. The Reynolds number is named for the British physicist Osborne Reynolds, who devised a measure of the critical velocity at which a flowing fluid changes its character. When the magnetic Reynolds number is much greater than one, resistance effects can be ignored and the magnetic lines of force are said to be frozen to (or to move with) the plasma. Because of this phenomenon certain interesting types of waves, called magnetohydrodynamic waves, occur at low frequencies. Generally, in a wave, the plasma particles oscillate about an equilibrium position, and their energy and momentum are transferred from one to another either by collisions or by interaction with electric and magnetic fields. Two fundamental types of wave motion can occur: longitudinal, like a sound wave, in which particle oscillation is in a direction parallel to the direction of wave propagation; and transverse, like a surface water wave, in which particle oscillation is in a plane perpendicular to the direction of wave propagation. In both types a wave may be characterized by a speed of propagation (u), a wavelength (λ), and a frequency (ν) related by an expression in which the velocity is equal to the product of the wavelength and frequency, namely, $u = \lambda\nu$. At low frequencies, on twanging or disturbing a line of force, a transverse wave called an Alfvén wave propagates parallel to the magnetic field with a velocity that depends on the particle density and the magnetic field strength. It is equal to the magnetic flux density (B) divided by the square root of the particle density (ρ) times the permeability of free space (μ_0); that is to say, $B/\sqrt{\mu_0\rho}$. A sonic wave that is an ordinary longitudinal sound wave can also propagate parallel to the magnetic field. Perpendicular to the magnetic field a different type of longitudinal wave called a magneto-sonic wave can occur.

Alfvén waves

In these magnetohydrodynamic transverse and longitudinal waves the plasma behaves as a whole, and the speeds are independent of wave frequency when the frequency is low; as in any fluid, excessive speeds can produce shock waves. At higher frequencies, however, the separate behaviour of ions and electrons causes the wave

velocities to vary with frequency. The Alfvén wave splits into two components, referred to as the fast and slow Alfvén waves, which propagate at different frequency dependent speeds. At still higher frequencies these two waves (called the electron cyclotron and ion cyclotron waves, respectively) cause electron and cyclotron resonances (synchronization) at the appropriate resonance frequencies. Beyond these resonances, transverse wave propagation does not occur until frequencies, called cutoffs, comparable with the plasma frequency, are reached, when the usual kind of electromagnetic wave may propagate.

For propagation of a transverse wave perpendicular to a magnetic field, two transverse modes of wave vibration exist. One corresponds to the electric field oscillating parallel to the magnetic field. This wave behaves as though there were no magnetic field present and is referred to as the ordinary wave. Propagation occurs only if the frequency is greater than the plasma frequency (ω_p); an electromagnetic wave with a lower frequency is reflected by the plasma. The other wave, in which the electric field is perpendicular to the magnetic field, is affected by the magnetic field and is called the extraordinary wave. It has several resonance and cutoff frequencies. At low frequencies it is a fast Alfvén wave, and at high frequencies it is a normal electromagnetic wave.

The speed of an ordinary longitudinal sonic wave at high frequencies also becomes frequency dependent and is referred to as the ion-acoustic wave, a resonance occurring at a frequency determined by electrostatic oscillations of the ions. Beyond this frequency no sonic wave propagates parallel to a magnetic field until the frequency reaches the plasma frequency, above which electroacoustic waves occur. The wavelength of these waves at the critical frequency (ω_p) is infinite, the electron behaviour at this frequency being the plasma oscillations of Langmuir and Tonks. Even without particle collisions, waves shorter than the Debye length are heavily damped; that is, their amplitude is rapidly decreased with time. This phenomenon, called Landau damping (after the Soviet physicist Lev Davidovich Landau), arises from the fact that some electrons always have the same velocity as the wave. As they move with the wave, they are accelerated and thus extract energy from the wave, damping it in the process. In the absence of truly energy-dissipative mechanisms, such as collisions, and in suitable circumstances, after the initial wave has damped away, an echo having related wave characteristics can be detected in the plasma.

Landau damping of wave amplitude

Containment and instabilities. Magnetic fields are used to contain high density, high temperature plasmas, such fields exerting pressures and tensions on the plasma. An equilibrium configuration is reached only when at all points in the plasma these pressures and tensions exactly balance the pressure from the motion of the particles. A well-known example of this is the pinch effect observed in specially designed equipment. If an external electric current is imposed on a cylindrically shaped plasma and flows in parallel to the plasma axis, the magnetic forces cause the plasma to constrict, or pinch. An equilibrium condition is reached for a temperature proportional to the square of the electric current. This phenomenon implies that any temperature may be achieved by making the electric current sufficiently large, the heating resulting from currents and compression. In practice, however, since no plasma can be infinitely long, serious energy losses occur at the ends of the cylinder; and also, major instabilities develop in such a simple configuration.

In general, there are two basic methods of eliminating or minimizing end losses from an artificially created plasma: the production of toroidal plasmas and the use of magnetic mirrors (see NUCLEAR FUSION). A toroidal plasma is essentially one in which a plasma of cylindrical cross section is bent in a circle so as to close on itself. For such plasmas to be in equilibrium and stable, however, requires special magnetic fields, the largest component of which is a circular field parallel to the axis of the plasma; any currents must be produced by transformer action.

A useful way of describing the confinement of a plasma by a magnetic field is by measuring containment time (τ_c), or the average time for a charged particle to diffuse out of the plasma; such time is different for each type of configuration. Various types of instabilities can occur in plasma. These lead to a loss of plasma and a catastrophic decrease in containment time. The most important of these instabilities is called magnetohydrodynamic. Although an equilibrium state may exist, it may not correspond to the lowest possible energy. The plasma, therefore, seeks a state of lower potential energy, just as a ball at rest on top of a hill (representing an equilibrium state) rolls down to the bottom if perturbed; the lower energy state of the plasma corresponds to a ball at the bottom of a valley. In seeking the lower energy state, turbulence develops, leading to enhanced diffusion, increased electrical resistivity, and large heat losses. In toroidal geometry, circular plasma currents must be kept below a critical value called the Kruskal–Shafranov limit, otherwise a particularly violent instability consisting of a series of kinks may occur.

Kruskal–Shafranov limit

Another class of instabilities is called drift wave, or universal. Spatial changes in density, temperature, or magnetic fields permit an abnormal number of particles with speeds equal to those of certain plasma waves. In an inverse manner to Landau damping, such waves grow by absorbing energy from the particles, and thus instabilities develop. A third basic type, dissipative instability, is associated with collisions between particles. Although a completely stable system appears to be virtually impossible, considerable progress has been made in devising systems that eliminate the major instabilities. Temperatures of the order of 10,000,000° K at densities of 10^{19} particles per cubic metre and containment times as high as 1/50 second have been achieved. The containment, however, is basically inefficient for practical use.

Applications. The most important practical applications of plasmas lie in the future, largely in the field of power production. The major method of generating electrical power has been to use heat sources to convert water to steam, which drives turbogenerators. Such heat sources depend on the combustion of fossilized fuels, such as coal, oil, and natural gas, and fission processes in nuclear reactors. A potential source of heat might be supplied by a fusion reactor, with a basic element of deuterium–tritium plasma; nuclear fusion collisions between those isotopes of hydrogen would release large amounts of energy to the kinetic energy of the reaction products (the neutrons and the nuclei of hydrogen and helium atoms). By absorbing those products in a surrounding medium, a powerful heat source could be created. To realize a net power output from such a generating station—allowing for plasma radiation and particle losses and for the somewhat inefficient conversion of heat to electricity—plasma temperatures of about 100,000,000° K and a product of particle density times containment time ($n\tau_c$) of about 10^{20} seconds per cubic metre are necessary. For example, at a density of 10^{20} particles per metre cubed, the containment time must be one second. Such figures have still to be reached, although there has been much progress.

In addition to its generation of power, a fusion reactor might desalinate seawater. Approximately two-thirds of the world's land surface is uninhabited, but only one-half of this because it is arid. The use of both giant fission and fusion reactors in the large-scale evaporation of seawater could make irrigation of such wastes economically feasible.

Another possibility in power production is to eliminate the heat–steam–mechanical energy chain. One suggestion depends on the dynamo effect. If a plasma moves perpendicular to a magnetic field, an electromotive force, according to Faraday's law, is generated in a direction perpendicular to both the direction of flow of the plasma and the magnetic field. This dynamo effect can drive a current in an external circuit connected to electrodes in the plasma, and thus electrical power may be produced without the need for steam-driven rotating machinery. This process is referred to as MHD (magnetohydrodynamic) power generation, and has been proposed as a method of extracting power from certain types of fission reactors.

Current from dynamo effect

The inverse of the dynamo effect, called the motor effect, may be used to accelerate plasma. By pulsing cusp-shaped magnetic fields in a plasma, for example, thrusts proportional to the square of the magnetic field can be achieved. Motors based on such a technique have been proposed for the propulsion of craft in deep space. They have the advantage of being capable of achieving large exhaust velocities, thus minimizing the amount of fuel that must be carried.

Provided the current is not too large, a glow discharge occurs between two electrodes at pressures of one thousandth of an atmosphere or thereabouts. Such glow discharges are responsible for the light given off by neon tubes and such other light sources as fluorescent lamps that operate by virtue of the plasmas that they produce in electric discharge. The degree of ionization in such plasmas is usually low, but electron densities of 10^{16} to 10^{18} electrons per cubic metre can be achieved with an electron temperature of 100,000° K. The electrons responsible for current flow are produced by ionization in a region near the cathode, most of the potential difference between the two electrodes occurring there. This region does not contain a plasma, but the region between it and the anode, or positive electrode, does.

Use in radio switching devices

Other applications of the glow discharge include electronic switching devices; and it and similar plasmas produced by radio frequency techniques can be used to provide ions for particle accelerators and act as generators of laser beams. In increasing the current through a glow discharge, a stage is reached when the energy generated at the cathode is sufficient to provide all the conduction electrons directly from the cathode surface, rather than from gas between the electrodes. Under this condition the large cathode potential difference disappears and the plasma column contracts. This new state of electric discharge is called an arc. Compared with the glow discharge, it is a high-density plasma and will operate over a large range of pressures. Arcs are used as light sources for welding, in electronic switching, for rectification of alternating currents, and in high-temperature chemistry. By running an arc between concentric electrodes and injecting gas into such a region, a hot, high-density plasma mixture is ejected, called a plasma jet; it has many chemical and metallurgical applications.

NATURAL PLASMAS

Extraterrestrial. It has been suggested that the universe originated as a violent explosion about 10,000,000,000 years ago and initially consisted of a fireball of completely ionized hydrogen plasma. Irrespective of the truth of this, there is little matter in the universe now that does not exist in the plasma state. The observed stars are composed of plasmas, as are interstellar and interplanetary media and the outer atmospheres of planets. Man's knowledge of the universe has come primarily from studies of electromagnetic radiation emitted by plasmas and transmitted through them; and, since the 1960s, from space probes within the solar system.
