but it is unlikely that they date to a time much earlier than the early Buddhist period.

The connection between these cultures and that of the modern Veddas has yet to be determined. The rock paintings in the caves, with depictions of elephants and riders, would be part of these stone cultures. It is equally possible that they are the work of the Veddas in more recent times.

No remains of the Neolithic or Chalcolithic cultures

General ethnic composition of Sri Lanka.

that spread through peninsular India in the 2nd millennium BC, with their distinctive painted pottery and ground stone axes, had been found in Sri Lanka by the 1970s.

That there was an extension of the South Indian Iron Age into the island is attested to by the finds of megalithic remains, stone cist graves, and circles, mainly in the north, and of terra-cotta elephant-shaped sarcophagi and of urn burials in the North Western Province. There, typical black and red pottery, sometimes with scratched owners' marks, has been found. These marks included some that resemble letters of the early Brāhmī inscriptions of India and Sri Lanka (from the 3rd century BC), and the discovery of similar black and red pottery in the lowest levels of Anuradhapura suggests that this invasion, probably of Tamil-speakers, may not have been earlier than the popularly believed colonization of Sri Lanka by North Indian settlers.

The problem of population growth

Demography. The high potential for growth of the population is indicated by the fact that over 40 percent of it is under 14 years old. In 1971 there were about 6,500,000 males and 6,200,000 females. The population density per square mile, which was about 140 in 1900, had risen to about 400 in the early 1960s and was nearly 502 in 1971. Life expectancy, which was about 42 years in 1946, had risen to about 58 by 1953 and to 66 in 1967. It is estimated that the 1971 population of about 13,000,000 will have increased to about 18,000,000 by 1983, and that it may increase to approximately 26,000,000 by the year 2000.

The birth rate remained approximately constant at 32 per thousand per annum during the 1960s, but decreased to 29 per thousand in the early 1970s. The death rate, as a result of better health conditions, has decreased from about 22 per thousand in 1945 to about 8 per thousand in 1970. The rate of increase of the population is thus about 2.1 percent a year.

THE NATIONAL ECONOMY

A comparative view. Sri Lanka's economy is still precariously dependent upon the exports of its plantation products, which are subject to severe fluctuations in the world market prices as well as to the influence of other factors beyond national control, such as the development of substitutes, changes in people's tastes abroad, changes in manufacturing practices, or the conclusion of multilateral trade pacts. The necessity of diversifying the economy in the agricultural sector by reducing dependence upon imports, especially of food crops, and encouraging the domestic production of substitutes, and achieving a greater degree of industrialization has been partially realized in recent years. The country remains dependent, however, upon imports of rice, sugar, and other foods, as well as of clothing. The diversification of agriculture has been rendered inevitable by falling prices in the world market for tea and rubber—two of the mainstays of the export sector. Tea, rubber, and coconuts together earn about 90 percent of Sri Lanka's foreign exchange, while tea alone, as mentioned, accounts for more than 55 percent. The output of rice has been increased through achieving higher yields, and it is hoped that enough may soon be grown to make Sri Lanka self-sufficient in this respect. The Mahaweli Ganga scheme alone is adding nearly 1,000,000 acres to the area devoted to rice production. Yields are also being increased by irrigation, flood control, the use of artificial fertilizers, intensive cultivation, and the use of better seeds.

Mineral deposits

Natural resources. Mineral deposits include iron ore, ilmenite (iron titanate, a common black mineral), graphite, and gemstones. Iron ore deposits of high quality, suitable for electrosmelting and found at a shallow depth, have been located in the Ratnapura, Balangoda, Kalutara-Batigama, Matara-Akuressa, Matale, and Chilaw areas, all in central or southern Sri Lanka; they total about 7,000,000 tons. Ilmenite deposits in the form of beach deposits are located north of Trincomalee at Pulmoddai; they amount to about 4,000,000 tons. Additional deposits exist at Turrukovil, Pamunugama, and elsewhere. Deposits of monazite (the principal ore of thorium, used in alloys) are found with ilmenite in beach sands along the west coast. There is an extensive deposit of ilmenite at Pulmoddai and important concentrations of monazite at Beruwela and Induruwa. Rutile (titanium dioxide, used to coat welding rods), zircon (zirconium silicate, used to line furnaces), and garnet sand (used as an abrasive) also occur as beach deposits. Sri Lanka is famous for its almost inexhaustible deposits of high-grade graphite. It also possesses both a quantity and a variety of gemstones, including rubies, sapphires, star-stones, and cat's-eyes (gemstones that change in lustre or colour, like the eyes of a cat). Other mineral deposits include large quantities of kaolin (china clay); other clays used for making tiles, bricks, and pottery; an inferior quality of mica; quartz, which is used for glass-making; and limestone suitable for cement manufacture.

Source: Official government figures; UN.

Sri Lanka's lagoons and other coastal features are favourable for manufacturing salt from seawater by solar evaporation during the rainless period. Prospecting for oil is in progress, but so far without result.

In addition to the climate and soil, which favour such crops as tea and rubber, the forests constitute a substantial resource, although pure stands of timber are rare. Fish and other edible forms of marine life abound in the seas around the island.

More than 50 waterfalls, some perennial and of considerable size, are found in the hill country; in addition, major irrigation projects, such as those on the Gal Oya, Mahaweli, and Walawe rivers, are also capable of yielding much hydroelectric power.

Sources of national income. *Agriculture, forestry, and fisheries.* As mentioned, tea, rubber, and coconut products are the principal sources of foreign exchange earnings. Most of the people are subsistence farmers; rice is their staple food, although only two-thirds of the country's needs are met by domestic production. Agricultural production is hampered by the fact that farms are often fragmented and scattered. The government, however, is taking measures to consolidate holdings and is seeking to encourage production by means of guaranteed prices. About 40 percent of the tea-producing lands, 70 percent of the rubber-growing areas, and most of the coconut lands are in national hands; the remainder is owned by British companies. Some livestock is raised. There are about 1,600,000 cattle, about 720,000 buffalo, 585,000 sheep and goats, 110,000 pigs, and 6,900,000 chickens on the island. The government is sponsoring a reafforestation program. Local timber production consists mostly of logs and firewood for domestic consumption. Fisheries employ about 40,000 people. Sea fishing is the principal source of the catch, although some fish are caught in rivers. Pearl fishing, once of importance, has been unsuccessful in recent years.

Livestock

Mining. Graphite is the principal mineral export. Most of the ilmenite produced is exported to Japan. Stone quarrying employs about 9,000 people. The cement industry is based on the deposits of limestone in the northern part of the country. The production of salt is a government monopoly.

Manufacturing. Industries are still of minor importance, accounting for only about 10 percent of the gross national income. Several large-scale industries are engaged in the processing of agricultural produce. Cement, textile, leather, and ceramics industries are being developed. The paper industry uses domestic paddy straw, wastepaper, and imported pulp. Steel-rolling, plywood, and tire manufacturing industries are thriving. Industrial estates are being established to promote light industries. Foreign aid is being used to establish sugar-refining, petroleum-refining, chemical, and textile industries.

Energy. About 785,800,000 kilowatt-hours of electricity are generated, both by hydroelectric plants and by thermal plants, which are fuelled by imported oil. Distribution is confined to the cities—Colombo, Nuwara Eliya, Diyatalawa, Norton Bridge, Bandarawela—and some few villages.

Financial services. The Central Bank administers and regulates the country's banking and monetary system and issues the national currency. Commercial banks include three national banks and nine branches of foreign banks. Government-sponsored credit institutions include the State Mortgage Bank, the Agricultural and Industrial Credit Corporation, and the Development Finance Corporation. Savings institutions are the Post Office Savings Bank, the Savings Bank, the Insurance Corporation, and the Employees' Provident Fund.

Foreign trade. Sri Lanka's unfavourable balance of trade is exacerbated by its dependence upon agricultural products, which are subject to fluctuations in market value. Imports are largely rice and other foodstuffs, manufactured goods, raw materials, and machinery. Exports are usually destined for the United Kingdom, China, the United States, Australia, and South Africa. Imports are mainly from the United Kingdom, China, the United States, India, Australia, Japan, and West Germany.

Management of the economy. *The public sector.* The state sponsors a wide variety of industrial corporations, among them a cement works, a chemical factory, an industrial estates corporation that provides ready-made factory units to small industry, a pulp and paper mill, a mineral sands processing plant, an oil refinery, and a steel-rolling mill. The government also sponsors numerous small manufacturing plants as a means of increasing employment.

The private sector. Private industrial development is encouraged by such measures as a five-year tax exemption, duty-free raw materials, and tax relief on investment. Foreign investment is also encouraged; it occurs mainly in the manufacture of textiles, electric appliances, transport equipment, metal, and glass. More than one-third of private industry is engaged in the production of food, beverages, and tobacco products.

Taxation. The rate of taxation is high and continues to rise. Taxes levied include an income tax on individuals and companies, a tax on wealth, a capital gains tax, and various customs and excise duties. Deficit budgeting has become a permanent feature, due to increased governmental expenditure on welfare services. The deficit is partially made up by market and administrative borrowing and foreign aid in the form of grants and loans. The principal sources of aid are the United States and Canada; the largest loans have been made by the Soviet Union, the United States, and West Germany.

Foreign aid and loans

Trade unions and employer associations. There are over 1,400 trade unions, more than half of which are unions for public servants. Sri Lanka is represented in the International Labour Organization. Industrial disputes are settled by 12 labour tribunals. Employer associations include those for planters and manufacturers.

Tourism. A Ministry of Shipping and Tourism has been established and is helping to promote tourism from abroad, in cooperation with the private sector and with the participation of international airlines and foreign governments. A number of hotels have been established in Colombo, seaside resorts developed, and additional transport facilities supplied. The travel trade is already begining to show profits.

Transportation. *Road networks.* Sri Lanka has a good road system, although the roads are often uneven in quality. There are about 23,800 miles of surfaced roads, most of which are in the western lowland, the southern central highlands, and the Jaffna Peninsula in the north. There is also a ferry service from Mannar Island to Pāmban Island, India; it runs parallel to Adams Bridge.

Railways. There are 954 miles of railways, of which about 850 miles have a gauge of five feet six inches; the remainder are narrow gauge. The railways are owned and controlled by the government. They serve the flat, low country, the central hill areas, and the Kelani Valley in the southwest.

Port facilities. Colombo, the capital, possesses the principal port. Other ports are Trincomalee on the east coast and Galle on the south coast. Galle handles the overflow of commercial shipping from Colombo. Trincomalee is one of the finest and largest natural harbours in the world. It was formerly a British naval base and now handles some of the island's export trade.

Air transport. There is an international airport at Colombo. Air Ceylon maintains both international and domestic services, as well as a regular air service between Tiruchchirāpalli, India and the Jaffna Peninsula. The Indian Airlines Corporation operates regular flights to Colombo from Madras, Tiruchchirāpalli, and Trivandrum.

ADMINISTRATION AND SOCIAL CONDITIONS

The structure of government. *The constitutional framework.* Sri Lanka is an independent republic within the Commonwealth of Nations. The former 30-member Senate was abolished in September 1971, and under the terms of the 1972 constitution the House of Representatives was renamed the National State Assembly. There is a Cabinet, headed by the prime minister. There is a well-established public service that administers through various government departments and corporations. The head

The constitution of 1972

of the republic is represented by the president (formerly governor general). The basic constitutional document was, until it was superseded by the 1972 constitution, the Ceylon Independence Order in Council, which was issued in 1947.

Regional and local government. Sri Lanka is divided into nine administrative provinces; these in turn are subdivided into 22 districts, which constitute the principal rural administrative units. Local authorities consist of 10 municipal village councils, 76 town councils, 36 urban councils, and 510 village councils.

The political process. *Elections.* The present National State Assembly was elected in 1970 and consists of 151 popularly elected members and six members who were appointed by the governor general (now the president). Under the terms of the 1972 constitution, the elections of 1977 will begin a five-year election cycle and the appointed membership will be eliminated.

Parties. The principal parties are the Sri Lanka Freedom Party (SLFP), the United National Party (UNP), the Trotskyist Lanka Sama Samaja Party (LSSP), and the Ceylon Communist Party (CCP).

De facto political developments. In 1970 a left-wing coalition government, supported by the SLFP, the LSSP, and the CCP and headed by Mme Sirimavo Bandaranaike of the SLFP as prime minister, came to power. A Constituent Assembly to frame a republican form of constitution was subsequently convened.

The Supreme Court

Justice. The judicial system is elaborate, comprising the Supreme Court, district courts, magistrate's courts, courts of requests, and rural courts. The Supreme Court consists of the chief justice and ten puisne (junior) justices. The justices of the Supreme Court are appointed by the governor general, other judicial officers by the independent Judicial Service Commission. The common law of Sri Lanka consists of Roman–Dutch law, but aspects of English law have also been adopted, particularly in commercial matters. Customary law frequently operates in matters concerning the personal status of Kandyans (those living in the former kingdom of Kandy), Tamils, and Muslims. In civil and criminal matters, English procedure generally is followed; the penal code is based on that of India.

The armed forces. The armed services comprise the army, navy, and air force. The army and navy each have a regular force, a regular reserve, a volunteer force, and a volunteer reserve. Service is entirely voluntary; there is no conscription. The navy possesses a frigate, a number of small patrol boats, and smaller craft. The air force has a strength of about 1,700 men and possesses a number of aircraft, including jets, light transports, helicopters, and trainers.

Administration. *Education.* For purposes of education the island is divided into 14 regions, for each of which a director of education is responsible. Education is free, from kindergarten to university level. Almost all children between the ages of 6 and 11 attend school, and a high proportion continue until the age of 16 or 18. There are more than 9,600 schools, with a total enrollment of about 3,000,000 students. There are several technical and teacher training schools and colleges. The island's four universities are the University of Ceylon and the University of Colombo, both in Colombo; Vidyodaya University in Gangodawila; and Vidyalankara University in Kelaniya. In 1963 almost 80 percent of the males and 64 percent of the females were literate.

Health and welfare. Public health and medical care services are mostly planned and financed by the Ministry of Health, under which is the Department of Health, which is responsible for providing these services. There are more than 800 medical institutions, including about 330 hospitals and 332 central dispensaries. Campaigns are conducted periodically against tuberculosis, cancer, venereal diseases, malaria, and leprosy, but they have not been notably successful. In addition to Western medical facilities, Sri Lanka in recent years has revived the practice of traditional medicine, which is conducted under government auspices.

The Ministry of Social Services

The Ministry of Social Services is responsible for public assistance, the relief of distress, the care and welfare of the aged and infirm, the administration of workman's compensation, and the rehabilitation of antisocial persons. Rural development activities include training in the performance of community services and self-help programs. There is a vigorous cooperative movement that is especially active in agriculture, industry, and fisheries.

Housing. The Ministry of Housing and Construction is responsible for the national housing program and for town and country planning. The housing shortage is most acute in and around Colombo. The ministry has constructed over 1,000 units in the city and promotes private construction by the granting of loans and the acquisition of land for housing development. Housing plans are directed toward the provision of low-income units, the extension of sanitation facilities, and the clearance of city slums.

Police services. The police and prisons services are efficient and adequate. There are about 260 police stations, and the police service consists of almost 10,000 persons. Village headmen assist the police. There are 14 prisons.

Social conditions. *Wages and cost of living.* The Employees' Provident Fund and wages boards have been established to regulate labour conditions, including conditions of employment, wage rates, industrial safety, and related matters. Wage scales are reviewed periodically in relation to the cost of living index. Unemployment and rising living costs have, nevertheless, caused much labour and student unrest; the increase in the population has been the principal cause of these problems.

Health conditions. Tuberculosis, malaria, and filariasis (parasitic infestations of the blood or tissues) are serious health problems. Leprosy, venereal diseases, and intestinal disorders also occur with frequency. In an attempt to lower the high birth rate, family planning has become an integral part of maternal and child care programs.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. Sri Lanka has a rich cultural heritage reaching back to the 3rd century BC. Its artistic tradition centres largely on Buddhist and Hindu religious art and the dance-drama. During the British administration the arts suffered an eclipse, and since independence there has been a tendency to imitate Indian and Western art forms. The government, however, is aware of the importance of preserving traditional forms.

The state of the arts. There are three main forms of the national dance-drama. The *kōlam* (a Tamil word for costume) play is a masked dance-drama that is performed annually. The devil dance, an expression of pre-Buddhist beliefs in spirits, is a masked dance performed to alleviate misfortune or illness. Most important is Kandyan dance, the sophisticated national dance. It is performed by elaborately costumed dancers and deals with mythological, historical, and naturalistic themes. It is taught at the National Academy of Dance in Kandy.

The national dance-drama

Since independence there has been a movement to adapt traditional dramatic forms to the modern stage. Translations of foreign plays are also performed.

Examples of national sculpture, painting, and architecture are seen in the remains of ancient works. These include colossal Buddha images, temples (especially around Kandy), and temple paintings. Other surviving art traditions include ivory carving, metalwork, lacquered woodwork, and basketry.

Cultural institutions. The Arts Council and the Government College of Fine Arts play an important role in the revival of folk arts and crafts. The three national museums in Colombo, Kandy, and Ratnapura contain cultural and artistic collections. The Government Archives are in Colombo. Archaeological reserves, distributed throughout the island, include temples and cities.

Press and broadcasting. The press is free and independent. There are four main newspaper groups, which publish in Sinhala, Tamil, and English. The government publishes a gazette as well as its own weekly newspapers.

The Ceylon Broadcasting Corporation provides national, commercial, and educational broadcasting services; it is responsible to the Ministry of Information and

Broadcasting. Domestic programs are broadcast in Sinhala, Tamil, and English. There are also broadcasts to Southeast Asia and Europe. There is as yet no television.

PROSPECTS FOR THE FUTURE

The increase in population and the decline in living standards are major problems in contemporary Sri Lanka. In addition, the government confronts the task of fostering and strengthening the sense of national unity, a problem it is attempting to solve by instilling in the various communities a spirit of good-will and of mutual accommodation.

Attempts at population redistribution

Among the economic and social measures taken by the government have been attempts to relieve pressure on the land by a redistribution of population, to increase the area of land under cultivation, to increase the yield of fisheries, and to sponsor more education. At present, for example, the southwest part of the island and the northern peninsula, which comprise together only one-third of Sri Lanka's area, contain 80 percent of its population. Attempts are being made to move families out of this area and into the sparsely populated dry zone by providing irrigation, as in the Mahaweli Ganga scheme. Agricultural and land development schemes together account for nearly 30 percent of all current capital expenditure. Increased investment in fishing is likewise expected to step up production to over 200,000 tons of fish per year, thus reducing the present rate of expenditure upon imports of fish and fish products. The use of deep-sea trawling methods and of mechanized fishing craft has been increased, and fishery harbours and fish freezing plants have been established.

Although 14 percent of the government's budget is spent upon education, much of the education has been of the academic type, with emphasis on the humanities; as a result, a large body of educated unemployed have come into existence. Educated and unemployed youths have helped to contribute to disruptions of normal life from time to time, of which one of the most serious has been the revolutionary uprising that took place in 1971. Much will depend upon the emergence of a type of nationalism that, in facing the challenges of contemporary national problems, will draw upon the past rather than seek to return to it.

BIBLIOGRAPHY. The administration reports of the various government departments and corporations in Sri Lanka contain much information, as do the publications of the national Association for the Advancement of Science, the Medical Association, and such specialized publications as *Tropical Agriculturist, Industrial Ceylon,* and the *Ceylon Journal of Science.* E.K. COOK, *Ceylon,* rev. by K. KULARATNAM (1951), is a good general account, but information on the economy is dated. *A Concise Atlas Geography of Ceylon* (1971), is a helpful adjunct. Relevant chapters by B.H. FARMER in O.H.K. SPATE and A.T.A. LEARMONTH, *India and Pakistan,* 3rd ed. rev. (1967); and by K. KULARATNAM in S.P. CHATTERJEE (ed.), *Developing Countries of the World* (1968), also provide complementary material. H.A.J. HULUGALLE, *Ceylon* (1942), is a delightful general account in concise form. P.G. COORAY, *The Geology of Ceylon* (1969), is a comprehensive work. M.D. RAGHAVAN, *The Karāva of Ceylon* (1961); N.D. WIJESEKERA, *The People of Ceylon,* 2nd ed. (1965); and K. KULARATNAM, *Tamil Place Names in Ceylon Outside the Northern and Eastern Provinces* (1966), throw an objective light on myths and legends about the people and their origins. Recent and reliable information on the economy may be found in: the INDUSTRIAL DEVELOPMENT BOARD, COLOMBO, *Statistical Guide* (1960) and *Research and Industry* (1970); *Statistical Abstracts of Ceylon 1967–68* (1970); and the *Statistical Pocket Book of Ceylon* (1969).

(K.Ku.)

Ssu-ma Ch'ien

Ssu-ma Ch'ien (in Pin-yin romanization Si-ma Qien), astronomer, calendar expert, and the first great Chinese historian, was the author of the *Shih-chi* ("Historical Records"), the most important history of China down to the end of the 2nd century BC. He was the son of Ssu-ma T'an, the "grand historian" (sometimes translated as "astronomer royal") at the Han court during the period 140–110 BC. The office of grand historian combined responsibility for astronomical observations and for the regulation of the calendar with the duties of keeping a daily record of state events and court ceremonies.

Early career

Ssu-ma Ch'ien was born at Lung-men. His date of birth is unknown. In view of his later achievements, the year 145 BC seems most likely. After travelling extensively in his youth, he entered court service. In 111 BC he accompanied a military expedition into the southwest of China, and in 110 BC he was a member of the Emperor's entourage when the latter visited Mt. T'ai to conduct the sacrifices symbolizing the dynasty's authority. In the same year, his father died, and after the mandatory period of mourning he was appointed in 108 BC to succeed him in the post of grand historian.

In 105 he was among those responsible for a complete reform of the Chinese calendar, a reform prompted by the Han emperor Wu Ti's inauguration of what was to be a "new beginning" to the Han dynasty. At about the same time, Ssu-ma Ch'ien began to undertake the unfulfilled ambition of his father to write a definitive history of the Chinese past, an ambition strengthened by his belief that under Wu Ti the Han had reached a peak of achievement that deserved to be recorded for posterity. Before his history was completed, however, Ssu-ma Ch'ien deeply offended the Emperor by coming to the defense of a disgraced general. Ch'ien was arraigned for "defaming the Emperor," a capital crime. Either because the Emperor felt him too valuable a man to lose or because Ch'ien himself requested a reprieve so that he could complete his history, he was castrated instead of executed.

By courtesy of the National Palace Museum, Taipei

Ssu-ma Ch'ien, ink and colour on silk by an unknown artist.

Wu Ti later relented, and Ssu-ma Ch'ien again rose in the Imperial favour, becoming "palace secretary" (*chung-shu-ling*). But he remained bitterly conscious of the shame he had suffered and lived a retiring life, devoting himself to the completion of his great masterpiece. He died *c.* 85 BC.

Structure and content of *Shih-chi*

The *Shih-chi* is his great claim to fame. There had, of course, been many histories before Ssu-ma Ch'ien's time. The keeping of court chronicles was already an established practice under the earlier dynasties. One such work, the *Ch'un Ch'iu* ("Spring and Autumn [Annals]") of the petty state of Lu, was said to have been the work of Confucius. It had achieved status as a canonical book largely because of its ethical judgments on the events which it recounts.

Ssu-ma Ch'ien denied that his work was in any way comparable to this great Classic. He termed himself not a "maker," like Confucius, but merely a "transmitter" of

past events. His great successor as historian of the Han, Pan Ku (AD 31–92), took him to task for his haphazard use of ideas from the various schools of philosophy and for his devotion to Taoism. But the ethical standards of Han Confucianism that Pan Ku and his contemporaries could take for granted had not in Ssu-ma Ch'ien's lifetime achieved the authority they had by the 1st century AD. Like most of his contemporaries, Ch'ien was an eclectic, employed at a court at which magic and the supernatural were still potent forces and where the state religious cult and accepted moral and political standards were still in a fluid state. Ssu-ma Ch'ien's moral judgments are, thus, not in accordance with any consistent theories.

His main achievement was that he reduced to an orderly narrative the complex events of the past, recorded in often contradictory sources deriving from the many independent states, each of which employed its own chronology. He organized these facts not, as in previous histories, simply as a chronologically ordered record but according to a new five-part plan. The "Basic Annals" gave a dated chronological outline centred around events at the court considered to have been the paramount power at the time. The following section consisted of chronological tables in which he attempted to clarify the confusion of the history of the various independent feudal kingdoms and to enable his reader to see at a glance what was happening in each of the states at any given time. The detailed accounts of each state were given in chapters entitled "The Hereditary Houses." A number of monographs dealt with various crucial aspects of government. These sections show Ssu-ma Ch'ien to have favoured the practical reformist statesmen who, in his own time, were formulating new policies for the increasingly centralized state, rather than the proponents of Confucian moral theories. The work ends with a collection of "Biographies" that deal with a variety of famous individuals, who are selected as exemplars of various types of conduct, and also with the affairs of the various foreign peoples, relations with whom were beginning to become increasingly important during the reign of Wu Ti.

Ssu-ma Ch'ien's aims and methods

Although the *Shih-chi* provided a model for the later dynastic histories, it differs from them in many ways. Its time span is far longer: such attempts to encompass the whole of human history were rare among later Chinese historians. Its source material, too, was far more varied. It incorporated not only the court annals of the Ch'in and the Han but also various earlier histories, parts of court chronicles of various feudal states, material from the canonical books and from the philosophical writings of all the schools, even historical romances. Neither is his subject matter exclusively court centred and "political," as were the later histories; it includes a far wider range of society, including businessmen and merchants, condottieri and bandits, actors and court favourites, good officials and bad.

He did not attempt to compose "objective" history but rather belonged unmistakably to the didactic Chinese tradition of history. He makes moral judgments on his characters. He also attempts to characterize them in types, recording an individual's exemplary deeds in one chapter and his misdeeds elsewhere. But the lessons he derives from history are varied and often mutually incompatible. He is much more notable for the critical attention he devotes to his sources. His acute critical comments are appended at the end of each chapter.

Finally, Ssu-ma Ch'ien is important not only as a historian but also as a master of racy, flexible Chinese prose. He has exerted a potent influence on later writers, particularly upon the early writers of narrative prose and fiction. Since Ssu-ma Ch'ien's time, his history has been acknowledged as the great historical masterpiece in Chinese, a standard against which all later histories would be measured and a model for large-scale historical composition, not only in China but in all Far Eastern countries influenced by the Chinese literary tradition.

BIBLIOGRAPHY. The standard study of Ssu-ma Ch'ien is the extremely perceptive work of BURTON WATSON, *Ssu-ma Ch'ien, Grand Historian of China* (1958), which gives a full critical analysis of Ssu-ma Ch'ien's works and also translates all the relevant biographical material from early sources. The historiographical methods and ideas of Ssu-ma Ch'ien are discussed in FRANK A. KIERMAN, *Ssu-ma Ch'ien's Historiographical Attitude As Reflected in Four Late Warring States Biographies* (1962). Further critical discussions are given in DERK BODDE, *Statesman, Patriot, and General in Ancient China: Three Shih chi Biographies of the Ch'in Dynasty, 255–206 B.C.*, rev. ed. (1967); and in the magisterial classical study of EDOUARD CHAVANNES, *Les Mémoires historiques de Sema-Ts'ien*, vol. 1 (1895). The latter work, in five volumes (1895–1905) translated the first 47 chapters of the *Shih-chi* with copious scholarly annotation. A sixth volume (1969) includes further translations by Chavannes and a bibliography of Western-language translations. Much of the remaining portion is translated in BURTON WATSON, *The Records of the Grand Historian of China*, 2 vol. (1961), which deals entirely with sections on the Han period.

(D.C.T.)

Stadium

The stadium is a unique form of structure with an exceptionally significant role in 20th-century construction technology. Basically, it is an enclosure that combines broad space for athletic games and other exhibitions with large seating capacity for spectators. The name derives from the Greek unit of measurement, the stade, the distance covered in the original Greek footraces (about 600 feet).

Classical stadiums. The first Greek stadiums were long and narrow and in the shape of a horseshoe, sometimes cut into the side of a hill, as at Thebes; Epidaurus; and Olympia, site of the Olympic Games, begun there in the 8th century BC. The Greeks also built hippodrome stadiums similar in layout but broad enough to accommodate four-horse chariot races, a feature of the Olympic Games as early as the 7th century BC.

Hippodrome stadiums

The design of the Greek stadium was taken over and improved on by the Romans, who built two types of stadiums: the circus and the amphitheatre. The circus was the Roman version of the hippodrome, a hairpin-shaped structure designed for chariot races. Down the middle of the arena ran a dividing wall, the spina, decorated with statues and obelisks; the racecourse ran around the spina. The largest, and doubtless the finest ever built, was the Circus Maximus in Rome, which in its principal form dated from the 1st century BC. Situated between the Palatine and Aventine hills, it measured 2,000 by 600 feet (610 by 190 metres) and is reputed to have held from 150,000 to 250,000 spectators. Rebuilt several times, it was ultimately demolished.

In contrast to the circus, the amphitheatre, one of the most characteristic of all Roman buildings, was completely enclosed on all sides. Intended for gladiatorial combats and other contests in which the precise dimensions of the field were of slight importance, the amphitheatre was designed to afford maximum seating capacity and optimum visual facility for spectators. The focus of the amphitheatre was on the relatively small arena, which drew its name from the Latin word for sand. The Romans built amphitheatres in all parts of their empire, but the classic example remains the Flavian Amphitheatre, or Colosseum, built in Rome in the latter half of the 1st century AD. Their possession of concrete enabled the Roman engineers to build this remarkable building as a self-supporting structure. To reinforce their joints they employed iron clamps, whose pillage in the Middle Ages at one time threatened the structure's stability.

Other notable Roman amphitheatres include those at Pompeii, Italy, and at Arles, France, the latter remaining the best preserved example of the form.

After the fall of Rome, amphitheatres survived for some time until the decline of the cities themselves terminated the spectacles they had held. Nearly two millennia passed before the form was revived, much smaller, usually temporary stands sufficing for such intervening spectatorial events as the knightly tournaments of the Middle Ages.

The renewal of large-scale spectator sports came about gradually in the 19th century with the growth of cities and the revival of interest in athletic contests; symbolically, the great impetus for the design of modern stadiums came from the revival of Olympic competition in 1896.

Maracaña Stadium, the municipal stadium in Rio de Janeiro, one of the world's largest, with a total capacity of 200,000 persons. The Maracañazinho, the smaller domed stadium behind it, can hold up to 40,000.
Manchete Press Agency—Pictorial Parade

Stadiums for modern Olympics. The stadium for the first modern Olympiad in Athens was a reconstruction of the ancient marble stadium built by Herodes Atticus on the site of an even earlier stadium. The Olympics since that time have provided a major focal point for the development of the modern stadium concept. In each four-year period since the first modern Olympiad, the host country has called on its most talented designers to erect a permanent stadium to mark the event. The first stadium of the modern genre was for the IV Olympiad in 1908 at Shepherd's Bush in London. The stands were partly roofed and the stadium seated over 50,000 people. Other Olympic stadiums of architectural note built before World War II include those at Stockholm (1912); Colombes, outside Paris (1924); Amsterdam (1927); and Berlin (1936). The Helsinki stadium, which was built for the XII Olympiad (1940, which was cancelled by the outbreak of World War II), was the scene for the XV Olympiad in 1952.

Other modern stadiums. Stadiums rivaling the size of those of ancient Rome were built in several cities in the first half of the 20th century, notably the vast Strahov Stadium, in Prague, completed in 1934 for the Sokol gymnastics exhibition and seating over 240,000 people. The municipal stadium in Rio de Janeiro has accommodated 200,000 people for football (soccer) games. Other stadiums seating over 100,000 include Hamden Park, in Glasgow (149,500); Wembley, in North London (126,000); Melbourne Cricket Ground in Melbourne, Australia (116,000); Tsentraly (Lenin) Stadium, in Moscow (103,000); Odsal Stadium in Bradford, England (102,500); Aztec Stadium, in Mexico City (100,000); and Soldier Field, Chicago (110,000).

Football stadiums

American football inspired a new type of stadium design, the elliptical bowl, first employed in the Yale Bowl at New Haven, Connecticut, in 1914, and repeated in several other stadiums, including the Rose Bowl, Pasadena, California, and the University of Michigan Stadium in Ann Arbor, Michigan, both seating 100,000. Because the bowl is entirely unsuited to the other principal U.S. sport, baseball, another type of American stadium has evolved, in which the aim is to supply maximum roofed seating capacity to protect spectators against the sun. A notable pioneer in this trend was triple-tiered Yankee Stadium, New York, built in 1923.

Design innovations. A basic difficulty of the roofed stadium was the interference with visibility by the columns supporting the roof. Dodger Stadium in Los Angeles was the first tiered stadium to provide column-free views from all seats (1959), followed by Shea Stadium in New York, which added field seat sections that rotate around the stadium to permit conversion from a baseball to a football arrangement (1964). Several other outstanding stadiums have been built for baseball, for example, Robert F. Kennedy Stadium, Washington, D.C.; Busch Memorial Stadium, St. Louis, Mo.; and Atlanta Stadium, Atlanta, Georgia.

The most significant development, however, was the Astrodome, built in Houston, Texas, the first major fully roofed stadium. Indoor stadiums of considerable size had been built previously, notably Madison Square Garden in New York (1890), and Chicago Stadium, Chicago (1928), capable of seating 21,000. For the 1960 Olympics in Rome, the leading Italian architect-engineer Luigi Nervi created the Roman sports complex, which included the Palazzetto dello Sport with a ribbed-dome roof. The Astrodome, however, was, by comparison, gigantic, with a seating capacity of 66,000 people around a large playing field. The dome, of transparent plastic panels supported by steel lattice, has a span of 642 feet and rises 208 feet above the playing field. The entire interior is air-conditioned. Under design or construction are several new stadiums (*e.g.*, at Kansas City, Missouri, and at Philadelphia) with roofs that can be slid out of the way in sunny weather.

An important new development was the application of flexible steel cables to span large roof dimensions. Cables contributed significantly to speed of construction, to lightness of roof, and to economy of construction cost in covered stadiums. In 1956 Lev Zetlin, a U.S. engineer, developed a rigid cable system since used on many arenas, the first constructed in Utica, N.Y., in 1959. A modern stadium with this system is being designed for Saudi Arabia and is also projected for designs for the Minnesota Vikings professional football team. The Saudi Arabian structure spans 720 feet and is covered with plastic bags under pressure. The Minnesota Viking design is saddle-shaped and has a 760-foot span.

Such cable systems can span large distances; a concept for a 200,000-capacity, covered baseball stadium has been developed by Zetlin. The lower portion of the stadium would contain a small city with all required services, including rapid transit trains that would move on ramps attached to the outside walls of the stadium. The cable roof would hold the walls together and relieve weight from spaces underneath.

The concept of an enclosed stadium and the desire for greater capacities have led toward the search for improved materials and construction techniques. Modern technology, including that developed in the aerospace

industry, already possesses techniques for covering spans of thousands of feet. Such is the potential of the modern stadium design concept that proposals to span all of Manhattan Island have been seriously discussed. It is by no means unrealistic to see today's roofed stadiums, with their arrays of restaurants, exhibition halls, and other auxiliaries, as the forerunners of completely roofed, weather-controlled cities.

(L.Z.)

Staël, Madame de

The brilliant personality of Madame de Staël, woman of letters, political propagandist, and conversationalist, epitomizes European thought and culture in her time, which spanned the final years of Louis XVI, the French Revolution, the Napoleonic era, and the Bourbon Restoration. Her writings include novels, plays, moral and political essays, literary criticism, history, autobiographical memoirs, and even a number of poems translated or imitated from the English 18th-century elegiacs, Goethe, and Schiller. Her chief literary importance was as a theorist of Romanticism. Chateaubriand saw in her *De la littérature* a "prospectus of Romanticism."

Giraudon

Madame de Staël, portrait by Jean-Baptiste Isabey, 1810. In the Louvre, Paris.

She was born Anne-Louise-Germaine Necker in Paris on April 22, 1766, of Swiss parents: her father was Jacques Necker, the Genevan banker who became Louis XVI's finance minister; her mother, Suzanne Curchod, the daughter of a French Swiss pastor, helped her husband in his career by establishing a brilliant literary and political salon in Paris.

The young Germaine Necker early gained a reputation for lively wit, if not for beauty. While still a child, she was to be seen in her mother's salon, listening to, and even taking part in, the conversation with that lively intellectual curiosity that was to remain her most attractive quality. When she was 16, her marriage began to be considered. William Pitt the Younger was regarded as a possible husband, but she disliked the idea of living in England. She was married in 1786 to the Swedish ambassador in Paris, Baron Eric de Staël-Holstein. It was a marriage of convenience and ended in 1797 in formal separation. There were three children: Auguste (b. 1790), who edited her complete works; Albert (b. 1792); and Albertine (b. 1796), who was allegedly fathered by Benjamin Constant.

Before she was 21, Germaine de Staël had written a romantic drama, *Sophie, ou les sentiments secrets* (1786), and a tragedy inspired by Nicholas Rowe, *Jane Gray* (1790). But it was her *Lettres sur les ouvrages et le caractère de J.-J. Rousseau* (1788) that made her known. There is in her thought an unusual and irreconcilable mixture of Rousseau's enthusiasm and Montesquieu's rationalism. Under the influence of her father, an admirer of Montesquieu, she adopted political views based on the English parliamentary monarchy. Favouring the Revolution, she acquired a reputation for Jacobinism. Under the Convention, the elected body that abolished the monarchy, the moderate Girondin faction corresponded best to her ideas.

Political views

Protected by her husband's diplomatic status, she was in no danger in Paris until 1793, when she retreated to Coppet, Switzerland, the family residence near Geneva. It was here that she gained fame by establishing a meeting place for some of the leading intellectuals of western Europe. Since 1789 she had been the mistress of Louis de Narbonne, one of Louis XVI's last ministers. He took refuge in England in 1792, where she joined him in 1793. She stayed at Juniper Hall, near Mickleham in Surrey, a mansion that had been rented since 1792 by French *émigrés*. There she met Fanny Burney (later Mme d'Arblay), but their friendship was cut short because Mme de Staël's politics and morals were considered undesirable by good society in England.

She returned to France, via Coppet, at the end of the Terror in 1794. A brilliant period of her career then began. Her salon flourished, and she published several political and literary essays, notably *De l'influence des passions sur le bonheur des individus et des nations* (1796), a treatise on the influence of the passions on happiness, which became one of the important documents of European Romanticism. She began to study the new ideas that were being developed particularly in Germany. She read the elderly Swiss critic K.V. von Bonstetten; the German philologist Wilhelm von Humboldt; and, above all, the brothers August Wilhelm and Friedrich von Schlegel, who were among the most influential German Romanticists.

But it was her new lover, Benjamin Constant, the author and politician, who influenced her most directly in favour of German culture. Her fluctuating liaison with Constant started in 1794 and lasted 14 years, although after 1806 her affections found little response.

At about the beginning of 1800 the literary and political character of Mme de Staël's thought became defined. Her literary importance emerged in *De la littérature considérée dans ses rapports avec les institutions sociales* (1800). This complex work, though not perfect, is rich in new ideas and new perspectives—new, at least to France. The fundamental theory, which was to be restated and developed in the positivism of Hippolyte Taine, is that a work must express the moral and historical reality, the *Zeitgeist*, of the nation in which it is conceived. She also maintained that the Nordic and classical ideals were basically opposed and supported the Nordic, although her personal taste remained strongly classical. Her two novels, *Delphine* (1802) and *Corinne* (1807), to some extent illustrate her literary theories, the former being strongly sociological in outlook, while the latter shows the clash between Nordic and Southern mentalities.

De la littérature

She was also an important political figure and was regarded by contemporary Europe as the personal enemy of Napoleon. With Constant and his friends she formed the nucleus of a liberal resistance that so embarrassed Napoleon that in 1803 he had her banished to a distance of 40 miles (64 kilometres) from Paris. Thenceforward Coppet was her headquarters, and in 1804 she began what she called, in a work published posthumously in 1821, her *Dix Années d'exil*. From December 1803 to April 1804 she made a journey through Germany, culminating in a visit to Weimar, already established as the shrine of

Goethe and Schiller. In Berlin she met August Wilhelm von Schlegel, who was to become, after 1804, her frequent companion and counsellor. Her guide in Germany, however, was a young Englishman, Henry Crabb Robinson, who was studying at Jena. The journey was interrupted in 1804 by news of the death of her father, whom she had always greatly admired. His death affected her deeply, but in 1805 she set out for Italy, accompanied by Schegel and Simonde de Sismondi, the Genevan economist who was her guide on the journey. Returning in June 1805, she spent the next seven years of her exile from Paris mostly at Coppet.

De l'Allemagne

While *Corinne* can be considered the result of her Italian journey, the fruits of her visit to Germany are contained in her most important work, *De l'Allemagne* (1810). This is a serious study of German manners, literature and art, philosophy and morals, and religion in which she made known to her contemporaries the Germany of the *Sturm und Drang* movement (1770 to 1780). Its only fault is the distorted picture it gives, ignoring, for example, the violently nationalistic aspect of German Romanticism. Napoleon took it for an anti-French work, and the French edition of 1810 (10,000 copies) was seized and destroyed. It was finally published in England in 1813.

Meanwhile Mme de Staël, persecuted by the police, fled from Napoleon's Europe. Having married, in 1811, a young Swiss officer, "John" Rocca, in May 1812 she went to Austria and, after visiting Russia, Finland, and Sweden, arrived, in June 1813, in England. She was received with enthusiasm, although reproached by such liberals as Lord Byron for being more anti-Napoleonic than liberal and by the Tories for being too liberal. Her guide in England was Sir James Mackintosh, the Scottish publicist. She collected documents for, but never wrote, a *De l'Angleterre:* (the material for it can be found in the *Considérations sur la Révolution française* [1818], which represents a return to Necker's ideas and holds up the English political system as a model for France).

On the Bourbon Restoration in 1814, Mme de Staël returned to Paris but was deeply disillusioned: the fall of Napoleon had been followed by foreign occupation and had in no way reestablished liberty in France. During the Hundred Days she escaped to Coppet and in September 1815 set out again for Italy. In 1816 she returned to spend the summer at Coppet, where she was joined by Byron, in flight from England after his unhappy matrimonial experience. A strong friendship developed between the two writers.

Mme de Staël's health was declining. After Byron's departure she went to Paris for the winter. Though poorly received by the returned *émigrés* and suspected by the government, she held her salon throughout the winter and part of the spring, but after April she was an invalid. She died in Paris on July 14, 1817.

Assessment

Mme de Staël's purely literary importance is far exceeded by her importance in the history of ideas. Her novels and plays are now largely forgotten, but the value of her critical and historical work is undeniable. Though careless of detail, she had a clear vision of wider issues and of the achievements of civilization. Her involvement in, and understanding of, the events and tendencies of her time gave her an unusual position: it may be said that she helped the dawning 19th century to take stock of itself.

MAJOR WORKS

Sophie, ou les sentiments secrets (1786); *Lettres sur les ouvrages et le caractère de J.-J. Rousseau* (1788; *Letters on the Works and Character of J.-J. Rousseau*, 1789); *Courte réplique à l'auteur d'une longue réponse* (1789); *Jane Gray* (1790); *Réflexions sur le procès de la Reine* (1793); *Réflexions sur la paix, adressées à M. Pitt* and *Réflexions sur la paix intérieure* (both 1795); *Recueil de morceaux détachés* (1795), including the first edition of the *Essai sur les fictions; De l'influence des passions sur le bonheur des individus et des nations* (1796; *A Treatise on the Influence of the Passions upon the Happiness of Individuals and of Nations*, 1798); *De la littérature considérée dans ses rapports avec les institutions sociales*, 2 vol. (1800; *A Treatise of Ancient and Modern Literature*, 1803, and *The Influence of Literature upon Society*, 2 vol., 1812); *Delphine*, 4 vol. (1802; *Delphine*, 3 vol., 1803); *Mémoires sur la vie privée de mon père*, first as preface to the *Manuscrits de M. Necker* (1804; later as separate book, 1818; *Memoirs of the Private Life of My Father*, 1818); *Corinne, ou l'Italie*, 2 vol. or 3 vol. (1807; *Corinna, or Italy*, 3 vol. or 5 vol., 1807); *De l'Allemagne*, 3 vol. (first edition suppressed 1810, republished 1813 and 1814; *Germany*, 3 vol., 1813); *Réflexions sur le suicide* (1813; *Reflections on Suicide*, 1813); *Zulma et trois nouvelles, precede d'un Essai sur les fictions* (1813; *Zulma and Other Tales . . .* , 1813); *Considérations sur les principaux événemens de la Révolution française*, 3 vol. (1818; *Considerations on the Principal Events of the French Revolution*, 1818); *La Doctrine des ultra-royalistes réfutée . . . ou Nouvelle réponse à la note secrète exposant les prétextes et le but de la dernière conspiration* (1818); *Dix Années d'exil* (1821; *Ten Years' Exile*, 1821); *Essais dramatiques* (1821), comprising *Agar dans le désert, Geneviève de Brabant, La Sunamite, Le Capitaine Kernadec, La Signora Fantastici, Le Mannequin,* and *Sapho; Des circonstances actuelles qui peuvent terminer la Révolution, et des principes qui doivent fonder la République en France* (1906). The first collected edition of the *Oeuvres complètes de Mme. la Baronne de Staël*, 17 vol. (1820–21), was supplemented by a collection of *Oeuvres inédites . . .* , 3 vol. (1821), and followed by another edition of the *Oeuvres complètes*, 3 vol. (1836). An edition of Madame de Staël's *Correspondance générale* was begun in 1960.

DIETRICH, 1890), the basic biography of Madame de Staël although its documentation is still incomplete; D.G. LARG, *Madame de Staël, la vie dans l'oeuvre (1766–1800)* (1924; Eng. trans. by V. LUCAS, 1926), and *Madame de Staël, la seconde vie (1800–1807)* (1928), the first comprehensive view of Madame de Staël both as a writer and as a historic figure; J.C. HEROLD, *Mistress to an Age: A Life of Madame de Staël* (1958), the best English-language introduction to Staëlian studies; A. LANG, *Une Vie d'orages: Germaine de Staël* (1958), a controversial and controverted biography, well worth reading; R. ESCARPIT, *L'Angleterre dans l'oeuvre de Madame de Staël* (1954), an analysis of Madame de Staël's description and analysis of English history, institutions, and customs; COMTESSE J. DE PANGE, *Le Dernier amour de Madame de Staël* (1944), and V. DE PANGE, *Madame de Staël et le Duc de Wellington* (1962), two studies evolved from family documents (the Countess of Pange is the great-granddaughter of Madame de Staël) that are essential to Staëlian studies.

(R.Es.)

Staging and Stage Design

Staging is the total concrete shape of a dramatic event; it embraces the arrangement of words, performers, dance, music, setting, costume, makeup, lighting, and properties for maximum theatrical effectiveness.

Role of staging and stage design in the performing arts

Through most of its history the theatre has encompassed all of the communal performing arts in a creative celebration of the richness of human activity and the aspirations of mankind. Each period has emphasized some forms and de-emphasized others, but the civilizations in which theatre has played a vital role in the lives of the people have marshalled the most varied tools of dramatic expression and did not separate text, music, and dance. In the healthiest of theatrical times, staging and design were not specialties handled by departmentalized experts; the direction of plays as a separate profession is a mid-19th-century innovation. Yet, Western audiences have become so thoroughly indoctrinated with the formulas of the literary drama of the late 19th and 20th centuries that most theatre of earlier periods and of the East are incomprehensible to them. The splintering of the components of theatre into serious drama, comedy, and farce or into the spoken word, dance, and music is a late development in theatrical history. This fragmentation is an outgrowth of the Age of Reason of 18th-century Europe, aggravated by the Industrial Revolution of the 19th century, and completed by the electronic age of the 20th century. It is difficult to project oneself into past times when theatre naturally embraced the word, dance, and music and dealt simultaneously with solemn and joyous human concerns. Because only dramatic texts survive, the prejudice in favour of the word is sanctified. Even the terminology in current use is conditioned by the small segment of theatrical history the vestiges of which are still prevalent. The word spectacle conjures up ostentatious display, gratui-

tous pageantry, and visual fireworks not proper to the dignified mounting of dramatic literature. Other labels attached to the nonliterary aspects of the theatrical event are equally revealing. "Divertissement" refers to a frivolous interpolation of music and dance in the interstices between the acts of weighty drama. "Decor" is the ocular icing. "Embellishments" refers to the settings and costumes, in fact, to all the physical appurtenances of the stage. "Staging" is the passive handmaiden, the interpretive servant, the midwife who tenderly deposits the dramatist's child on the boards of a public playhouse. Since contemporary theatre has shrunk to a marginal option in the life of the times and large integral functions of theatre have been siphoned off into the mass media, the mere semantics involved in explaining living theatre through the centuries becomes a problem.

In this article an attempt will be made to reverse the customary procedure of brushing off the primitive beginnings as quaint worship and childish play, of heralding the serious dramatics of the Greeks, and of progressing upward to the giants of modern realism. Instead, theatre will be considered as it has existed through most of its history—to wit, as a communal celebration. The article begins, therefore, with an extensive discussion of the history of staging practices, followed by theoretical analyses of shifting styles and other general aesthetic questions. Later, costuming and makeup and lighting receive separate attention. Technological aspects of sound are covered in the article ACOUSTICAL ENGINEERING. Though theatre housings are discussed insofar as they influence stage design, they are treated at greater length in another article, THEATRES AND STAGES. Related material will also be found in the articles THEATRICAL PRODUCTION; ACTING; and DIRECTING; as well as THEATRE, ART OF.

This article is organized as follows:

I. History of staging
Ancient Greece and Rome
Asian theatre
The Middle Ages
The Renaissance
The Baroque
The 19th century
The beginnings of modern theatre
Modern staging and design
II. Scenic design
Development of scenic design
Procedures
III. Stage lighting
Early forms of stage lighting

Light sources
Lighting controls
Contemporary lighting techniques
IV. Stage machinery
V. Theatrical costume design
Historical development
Contemporary costume-design procedures
VI. Theatrical makeup
Early development
Contemporary practices

I. History of staging

Origins of dramatic representation

Since the anthropological data on primitive drama is meagre, fanciful theories abound. One major misconception looks upon early rites as the tribe's excuse for emotional festivities and furious orgies, but research does not support the image of the childlike savage on colourful holiday from his routine chores. Sympathetic magic was a deadly serious, practical instrument for controlling the environment. The primitive's tools for influencing nature were not the same as the tools of technology, and the contemporary notion of theatre as a leisure-time safety valve should not be imposed on primitive ritual.

There is an apparent uniformity in the earliest development of dramatic representation, even among groups geographically and ethnographically separated from each other. The origins of drama seem to be religious, and the beginnings of religious rites often are in magic. When man feels that there are elements in his environment that he cannot control, he tends at first to believe that his ancestors are the spirits who hold a magical control. An offering of the first fruits of harvest was not only a thanksgiving but also insurance that their ancestors would bring them further harvests. These first fruits were offered ritually to the spirits of the dead, among the first nonreal forces man identifies. Corn and vegetable spirits and what are labelled "totemistic beliefs" are dependent on a belief in immortality, which may be the first collective idea shared by man. In the first stage, men pray to the dead and not to abstract spirits; in gratitude they make harvest offerings to the dead. It is only at a later stage that such generalizations as food gods appear, that man symbolizes his desires, transforming his ancestors into the shapes of universal spirits.

The earliest rituals were probably staged at regular intervals, often with the same members of a tribe playing the same roles. Men would imitate the behaviour of the spirits by wearing masks and costumes and dancing in certain patterns that were passed on from one generation to another. The second stage was reached when man passed from ritual incantation to developing his own myths about the spirits. In Western culture, the worshippers of Dionysus—the god of nature's procreative power and the ecstasy related to it—were the first group in ancient Greece to develop myths about their god. Whoever surrendered to the god forgot about himself and turned into another being. This belief in transfiguration explains why, from the beginning, the Dionysiac worshippers wore masks and disguises. It is commonly held that each year the worshippers became more complex in their celebration of Dionysus, until eventually they staged athletic contests, dances, and simple drama during their festivals.

Whatever the origin, the earliest phases of the theatre involved masks, costumes, and properties. Primitive societies tended to use the same piece of land for all rituals, although hunting tribes moved too often to have a particular sacred ground. A stage, and particularly scenery, came at a much later point in the development of drama. In all Western cultures, it seems that a permanent stage and scenery are introduced when drama starts to shift from a magical-religious institution to one that incorporates the lives of the members of the community.

ANCIENT GREECE AND ROME

Greece. During the earliest period of theatre in ancient Greece, when the poet Thespis—who is credited both with inventing tragedy and with being the first actor—came to Athens in 534 BC with his troupe on wagons, the performances were given in the agora (*i.e.*, the marketplace). The spectators sat on wooden stands until 498, when the stands collapsed and killed several members of the audience. Detailed literary accounts of theatre and scenery in ancient Greece can be found in *De architectura*, by the Roman writer Vitruvius, of the 1st century BC, and in the *Onomasticon*, of the next century, by the Greek scholar Julius Pollux. As they were writing several hundred years after classical theatre, however, it is questionable how accurate are their descriptions.

Little survives of the theatres in which the earliest plays were performed, but essential details have been reconstructed from the architectural evidence of the Theatre of Dionysus in Athens, which has been remodelled several times. The centre of the theatre was the original dancing place, the flat, circular space with the altar of Dionysus, called the *orchēstra*. In the centre stood a platform with steps (*bēmata*) leading to the altar (*thymelē*). Nearby was the temple out of which the holy image would be carried on festival days so the god could enjoy the plays.

The earliest theatres

Theatrical representations, coloured by religious sentiment, directed their appeal toward the total community, so that when these theatres were built, their first need was enough space for a large audience. In the beginning, entrance was free; after they started charging admission, poor citizens were given entrance money, since attendance was practically compulsory. It seems reasonable to assume that, because of the size of the theatres, there was a raised platform for actors to make them easier to see and to separate them from the chorus. In later times there was a high stage, with a marble frieze below and a short flight of steps up from the orchestra.

The earliest productions did not have a background building. The actors dressed in the *skēnē* (from which the word scene is derived), a small tent, and the chorus and actors entered together from the main approach, the *parodos*. The earliest properties, such as altars and rocks, could be set up at the edge of the terrace. This terrace, according to recent archaeological studies, was probably six feet (about two metres) above the level on which the earliest temple stood. The first extant drama for which a large building was necessary was Aeschylus's trilogy the *Oresteia*, produced in 458 BC. There has been a controversy among historians as to whether the *skēnē* was set up inside a segment of the orchestra or outside the edge of the orchestra. The *skēnē* was probably a long, simple building at the left of the orchestra terrace.

Origin of the scenic facade

In the first period of Greek drama, the principal element of the production was the chorus, the size of which appears to have varied considerably. In Aeschylus' *Suppliants*, there were 50 members of the chorus, but in his other plays there were only 12, and Sophocles increased it to 15. The size of the chorus, as the ritual element of drama diminished, became smaller in the 5th century. Since the number of actors increased as the chorus shrank, and the plots of the dramas became more complex, doubling of roles became necessary. On a completely open stage such substitutions were delayed, and the suspense of the drama was dissipated. Dramatic plausibility was also vitiated when gods and mortals, enemies and friends, always came from the same direction. The addition of a permanent scenic facade, with three doors, more than doubled the number of entrances and gave the playwright more freedom to build dramatic tension. About 425, a firm stone basis was laid for an elaborate building, called a *stoa*, consisting of a long front wall interrupted at the sides by projecting wings, *paraskēnia*. The spectators sat on wooden benches, which may have been arranged as a polygon or as a semicircle. The seats of honour were stone slabs with inscriptions on them assigning them to the priests. The upper rows were benches of movable planks supported by separate stones planted in the ground. The single wedge-shaped divisions were separated from each other by radiating aisles.

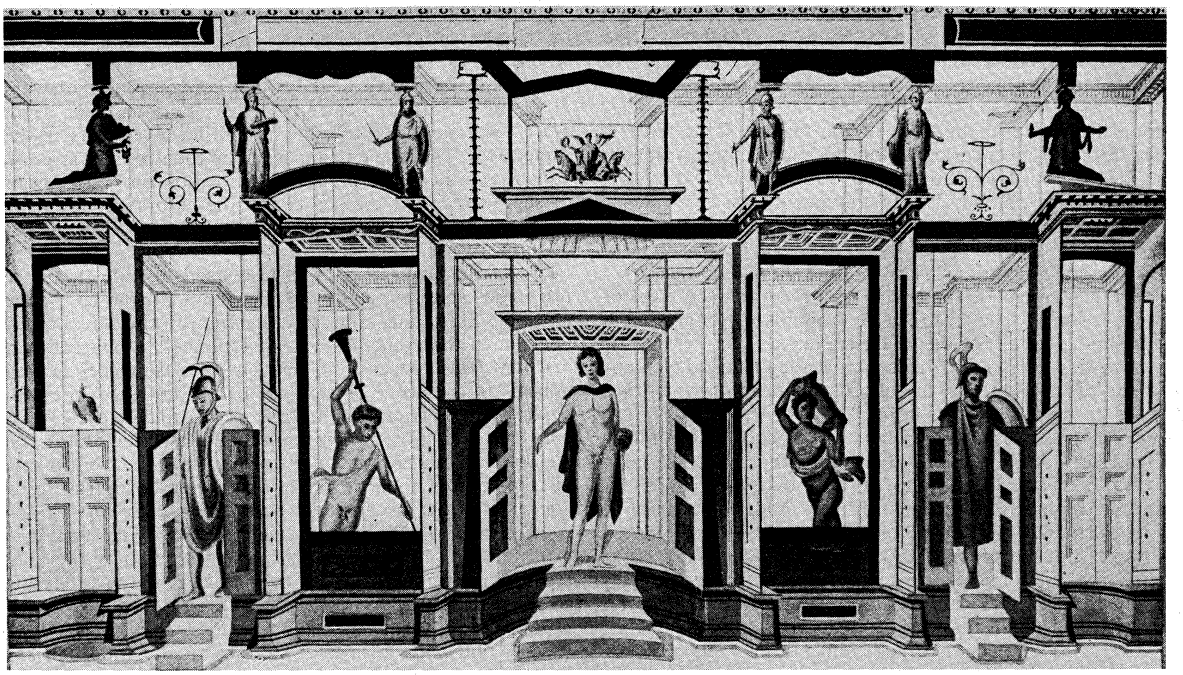
The background decoration was originally a temporary structure leaning against the front wall of the *stoa*. A wooden structure served as a skeleton, which was covered with movable screens. These screens were made of dried animal skins tinted red; it was not until Aeschylus that canvases in wooden frames were decorated according to the needs of a particular play. Aristotle credits Sophocles with the invention of scene painting, an innovation also ascribed by others to Aeschylus. It is notable that Aeschylus took an interest in staging and is credited with the classic costume design. Simple Greek scenery, however, was comparable with that of the 20th century; the impulse to visualize and particularize the background of the action became strong. Painted scenery was probably first used in production of the *Oresteia;* some 50 years afterward a second story was added to the wooden scene building. A wooden colonnade, or portico, the *proskēnion,* was placed before the lower story of the building. This colonnade, which was long and low, suggested the exterior of either a house, a palace, or a temple. Painted screens were set between the columns of the front of the *proskēnion,* and they indicated the locale rather than literally representing it.

The first painted scenery

In the beginning, scenery was probably altered slightly during the intermission between the four plays of a tetralogy or during the night between two of the festival days. By the latter part of the 5th century, scene changing was accomplished through the use of movable painted screens. Several of these screens could be put up behind one another so that when the first one was removed, the one immediately behind appeared. There are indications that in the theatre of Megalopolis, Greece, there were tracks coming out of a storeroom on the side, not only for movable screens but for a whole wooden scene building.

Soon after the introduction of the facade, plays were uniformly laid before a temple or a palace. To indicate a change of scene, the *periaktoi* were introduced. These were upright three-sided prisms set flush with the palace or temple wall on either side of the stage, mounted on wooden pegs, the sides painted to indicate different localities. There were several theatrical conventions that were observed in Greek theatre; one was that only the right *periaktos* was turned to indicate a different locality in the same town. The side entrances of the theatre, the *parodoi,* which were near the *periaktoi,* also took on conventions of significance. At the right one, the actors entered as if coming from the city or harbour; from the left, as if coming from the country.

The *periaktoi*



The permanent facade was also used to hide the stage properties and the machinery. Evidence for the use of the so-called flying machine, the *machina,* in the 5th century is given in the comedies of Aristophanes; a character in his play *Peace* ascends to heaven on a dung beetle and appeals to the scene shifter not to let him fall. The *machina* was a derrick. In the time of Euripides it was used conventionally for the epilogue. At that point the crane was used so that a god could descend from heaven to sort out the complications in the plot at the end of a tragedy, a convention that became known as a *deus ex machina*—"god from a machine." The lavish use of flying machines is testified to by the poet Antiphanes, who wrote that tragic playwrights lift up a machine as readily as they lift a finger when they do not have anything to say.

Wheeled platforms or wagons, called *ekkyklēma,* were used to show the results of actions in the interior of a house, such as wheeling out murdered people. It was, like the *periaktoi,* an expedient for open-air theatre, in which the possibilities for creating more realistic illusions were severely limited. Because of the tiered seats of the auditorium, a realistic picture of an interior scene under a roof could not be shown. So the Greeks, to represent the interior of a palace, for example, would wheel out a throne on a podium. These wheeled platforms were usually round, although recent archaeological evidence suggests that some may have been square. New machines were added in the Hellenistic period, by which time the theatre had almost completely lost its religious base. Among these machines was the *hēmikyklion,* a semicircle of canvas depicting a distant city, and a *stropheion,* a revolving machine, used to show heroes in heaven or battles at sea.

There was no one Greek theatre; the existing buildings, or those for which there is archaeological evidence, divide into four groups. The first is the pre-Aeschylean wooden theatres, which, though previously believed to have been circular, recent evidence suggests might have been trapezoidal. The second is the classical Athenian theatre of the 5th century BC. In all probability the classical wooden theatre with a stone foundation was of two stories. The upper story, the *episkēnion,* was primarily utilized for the stage machinery. The raised stage was probably called the *logeion,* the speaking place, although that word and *theologeion,* speaking place of divinities, have both been applied to the top of the *proskēnion* or first story of the scene building itself. The third group of theatres were the Hellenistic, built from the 4th century on, mostly in Greek territories. The Theatre of Dionysus in its present state is a product of 4th-century renovations, a rebuilding under the Roman emperor Nero in the 1st century AD, and alterations in the 3rd century AD. The last group was the Greco-Roman, found as Greek culture was fading and the Roman Empire spreading.

Rome. The development of the theatre, following the development of dramatic literature, was slower in Rome than in Athens. The essential distinction between Roman and Greek stage performances was that the Roman had no deep religious convictions. Despite the fact that the spectacles were technically connected with festivals in honour of the gods, the Roman audience went to the theatre for entertainment. The circus was the first permanent public building for spectacles, which included chariot races and gladiatorial fights. When Etruscan dancers and musicians were introduced in 364 BC, they performed in either the circus, the forum, or the sanctuaries in front of the temples. The players brought temporary wooden stands for the spectators. These stands developed into the Roman auditorium, built up freely from the level ground.

Distinctions between Roman and Greek theatre

The most important feature of the Roman theatre, as distinct from the Greek theatre, was the raised stage on which all the performers appeared. As every seat had to have a view of the stage, the portion occupied by the seating (*cavea*) was limited to a semicircle. The *orchestra*, immediately in front of the stage, seated distinguished visitors. As in Greek theatre, the scene building behind the stage, the *scaenae frons*, was used both as the back scene and as the actors' dressing room. The *scaenae frons* was no longer painted in the Greek manner but tended to have architectural decorations combined with luxurious ornamentation. The audience sat on tiers of wooden benches, *spectacula*, supported by scaffolding. There was no curtain; the back scene, with its three doors, faced the audience.

The *phlyakes* stages

When the popular comedies or farces of southern Italy were introduced to Rome, they came with their own distinctive type of stage—the *phlyakes* stage. Comedies in Italy were mimes, usually parodies of well-known tragedies, and the actors were called *phlyakes*, the gossips. They used temporary stage buildings of three main forms. One was the primitive low stage, a rough platform with a wooden floor on three or four rectangular posts. The second was a stage supported by low posts, covered with drapery or tablets; sometimes steps led up to a platform and a door was indicated. The third type was a higher stage supported by columns, without steps but usually with a back wall. The stages often had a short flight of five to seven steps in the centre, leading to the podium. The forewall, covered with drapery, was often decorated, and the background wall usually had objects hanging from it. The rear wall sometimes had other columns, besides the ones set at the corners, as well as doors and, in several cases, windows to indicate an upper floor. The door was usually behind a heavily decorated porch, with a sloping or gabled roof supported by beams and cross struts. Among the furnishings there were usually trees, altars, chairs, thrones, a dining table, a money chest, and a tripod of Apollo (*i.e.*, an oracular seat). This catalog demonstrates that the stage properties were simple, probably because the troupes wandered from town to town. The stage was set up in the marketplace in the smaller towns and in the *orchēstra*s of Greek theatres in the larger cities.

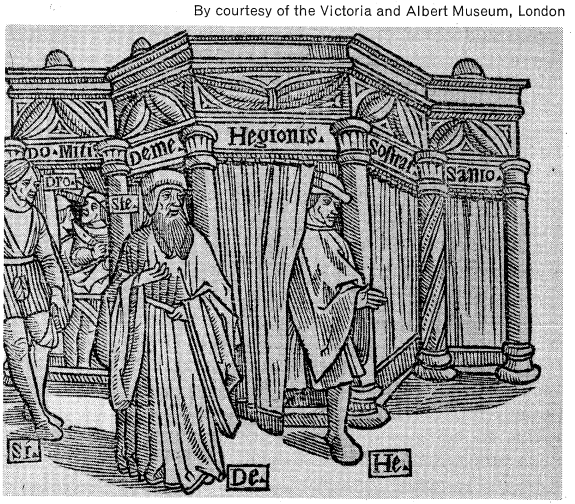
Coincident with the development of the *phlyakes* stages, and under the inspiration of Hellenistic colonists, the Romans began to build stone theatre buildings. A Hellenistic theatre was converted into a Roman one by making the following three fundamental changes: a deep stage was erected; the rear wall was made higher and decorated in Roman style with pillars, statues, and entablatures; and vaulted passageways replaced the open *parodoi*.

Roman stage conventions

The actors entered the playing space from one of the house doors or the side entrances in the wings. Among the stage conventions, the side entrance on the audience's right denoted the near distance and the one on stage right the farther distance. If a scene took place in a town, for instance, an actor exiting audience right was supposed to be going to the forum; if he exited to their left, he might be going to the country or the harbour. *Periaktoi* at the side entrances indicated the scenery in the immediate neighbourhood. If the play required a character to move from one house to another without bringing him on the stage, which represented the street, the actor was supposed to use the back door and the *angiportum* (*i.e.*, an imaginary street running behind the houses). Since interior scenes could not be represented on level ground, all action took place in front of the houses shown in the background. If a banquet was to be depicted, the table and chairs would be brought on stage for one scene and removed at the end of the scene. Costumes were formalized, but real spears, torches, chariots, and horses were used.

In the 1st century BC, theatre buildings and scenery became more elaborate. The invention of the arch and the use of concrete for vaulting allowed immense stone structures to be built on level ground. In 55 BC the first stone theatre was built, in Rome, by the general Pompey; the Roman writer Pliny wrote that it held 40,000 spectators and was used for "bloody shows," with 500 lions and 20 elephants killed at the grand opening. To fulfill the government policy of keeping the people entertained, theatres were built all over the Roman Empire. Many of the theatres were on flat sites, and the tiers of seats were supported by masonry, through which passages, called *vomitoria*, led from outside to the *orchestra* or to a corridor at the top of the auditorium. From there, by means of steps, a member of the audience could find his way to his seat.

The addition of the roof over the stage



A wooden roof was added over the stage, protecting actors and scenery from the weather. The auditorium was also covered by coloured linen awnings attached to fixed masts in the enclosing wall. The presence of the roof in some theatres led to two particular innovations. The first was that as it was now possible to cover the entire theatre

with an awning, it was being brought reasonably close to the indoor theatre. The second was the front curtain, the *aulaeum*, which was probably on a fixed frame that was dropped into a recess in the stage floor during the performance. There was also a second type of curtain, the *siparium*, used to cover parts of the facade behind the actors.

Setbacks in the development of the theatre building did occur, as when a stone theatre was actually demolished in a period of austerity because seats were thought to be unworthy of the stern simplicity of the Roman citizens. Preserved in Rome is the stone theatre of Marcellus, begun by Julius Caesar and finished by Augustus in 13 BC. Most important provincial towns had at least one theatre, and often a small covered theatre for inclement weather was constructed near the large open theatre.

In general, the history of the Greek and Roman theatre is so rich and varied that each successive period of European culture has found some aspect of it to use as an inspiration or model. Even the periods that resented the ancient theatre and its pagan overtones found some aspect to explore and use for their own. In the Middle Ages, for instance, although the tragedies and the theatre buildings of the Greeks and Romans were little known, the 2nd-century-BC Latin comedies of the Roman Terence remained alive. And the architectural writings of the 1st century AD of the Roman Vitruvius became the model for the theatre building of the later Renaissance and early Baroque periods.

ASIAN THEATRE

Although the emergence of Asian theatre was not simultaneous with that of ancient Greece and Rome, it merits discussion here rather than as an appendage to the history of Western drama. Asian theatre, to speak in generalities, is an appeal to both the senses and the inner eye of the audience. It is "magical" theatre in the most sophisticated sense of the word, exerting charm and power in a combination of realism and illusion. Perhaps the primary difference between Asian and Western drama stems from its attitude toward the spectator; Asian drama appeals to the varied sensibilities of its audience. It is the conjunction of emotional, intellectual, and spiritual influences and as such affects each spectator differently. Western drama hinges on finding a common denominator to manipulate its audience as a single body, whether it is composed of the Renaissance aristocracy or the 20th-century middle class. Asian drama, in contrast, allows a member of the audience to meet the theatre on an individual basis.

India. India is the point of origin for most of the theatre in Asia and had developed its dance and drama by the 8th century BC. According to Hindu holy books, the gods fought the demons before the world was created; and Brahmā asked the gods to re-enact the battle among themselves for their own entertainment. Once again the demons were defeated, this time by being beaten with a flagstaff by one of the gods. To protect theatre from demons in the future, a pavillion was built, and in many places in India today there are roofed platforms with a flagstaff next to the stage to mark the location of performances.

The myth of the development of dance drama was that Brahmā ordered the two elements combined; as a result, the words for "dance" and "drama" are the same in all Indian dialects. Early in Indian drama, however, dance began to dominate the theatre. By the beginning of the 20th century there were few performances of plays, though there were myriads of dance recitals. It was not until its political independence in 1947 that India started to redevelop the dramatic theatre.

In the 4th century a codification was written of the *śāstra*, or the staging conventions of the dance. It lists not only the costumes, makeup, gestures, and body positions but also any plots considered unsuitable, and it is the most complete document of stagecraft ever compiled. There is no scenery in Indian dance, although there are usually a few properties such as a three-foot-high brass lamp. A curtain is used, however, by troupes that dance *kathākali*, an ancient danced drama of southwestern India. The curtain itself is a cloth rectangle that is held between the stage and a large lamp by two stagehands.

The dancers perform a group of preliminary dances behind the curtain until an important entrance called "peering over the curtain." In this, a character fans the lamp by pulling the curtain in and out until the flames are spectacularly high. The dancer, still hiding his face, displays his hands and legs at the borders of the curtain. At the climactic moment the dancer pulls the curtain aside, displaying his awesome makeup, and the stagehands remove the curtain until the next dramatic entrance.

Classical Indian drama had as its elements poetry, music, and dance, with the sound of the words assuming more importance than the action or the narrative; therefore, staging was basically the enactment of poetry. The reason that the productions, in which scenes seem to follow in arbitrary order, seem formless to Westerners is that the playwright, even today, utilizes the symbolic language of simile and metaphor to fashion his drama. Because of the importance of the poetic line, a significant character is the storyteller or narrator, who is still found in most Asian drama. In Sanskrit drama the narrator was the *sūtra-dhāra*, "the string holder," who laid the scene, gave background information, and interpreted the actors' moods. Another function was performed by the narrator in regions in which the aristocratic vocabulary and syntax of the main characters, the gods and the nobles, was not understood by the majority of the audience. The narrator, first through the use of pantomime, later through comedy, made the story clear and offered a relief from the tension of the drama. In general, though, as everyone learned the stories after a number of years, the emphasis shifted to how passages were acted rather than on what was being portrayed.

The narrator's role

A new Indian theatre that started about 1800 was a direct result of the English colonization. With the addition of dance interludes and other Indian aesthetic values to Western theatre, India today is developing a national drama. Two examples of "new" theatre staging are the Prithvi Theatre and the Indian National Theatre. The Prithvi Theatre, a Hindī touring company founded in 1943, treats the stage as similar to a film. It utilizes dance sequences, incidental music, frequent set changes, and extravaganzas of movement and colour. The Indian National Theatre, founded in Bombay in the 1950s, takes an entirely different route to appeal to audiences; it gives performances all over India, in factories and on farms. Its themes usually involve a national problem, such as the lack of food, and the troupe's style is a mixture of pantomime and simple dialogue. They use a truck to haul properties, costumes, and actors; there is no scenery.

China. The most noticeable contrast between China and other Asian countries is that it produced virtually no dance. The classic theatre of the Chinese is called "opera"

because the dialogue is punctuated with arias and recitatives. Of the amazingly detailed written record of Chinese theatre, the first reference to opera was during the T'ang dynasty (618–907). The development of the opera style popular today took place during the Manchu rule of the 19th century. The Empress Dowager, the last hereditary ruler of China, was so enamoured of opera that she had a triple-deck stage constructed in the summer palace at Peking. Each level stood for either heaven, hell, or earth.

The most important individual in Chinese theatre of the 20th century, Mei Lan-fang, an actor and producer, was the first to apply to it academic principles of scholarship in reviving lost or forgotten masterpieces and opera forms. He restored historical accuracy and improved old costumes.

The Chinese theatrical performance

In general, Chinese theatrical performances start in the early evening and conclude after midnight. The performance itself consists of several plays and scenes from the best known dramas. The audience drinks tea, eats, and talks, and there are no intermissions. The stage itself has a curved apron, covered only by a square rug. On one side is a box for the orchestra, who play throughout the evening. There is neither a curtain nor any setting to speak of other than a simple, painted backdrop. This absence of scenery contrasts with the complicated and colourful costumes and makeup of the actors.

The behaviour of the audience differs from Western theatre in that its members stop talking to each other only at climactic moments. The actors are concerned with their movements only when they are at the centre of the stage; when they stand at the sides waiting for their parts, they drink tea and adjust their costumes in full view of the audience. An interesting interpretation of this behaviour was the view of the 20th-century German dramatist Bertolt Brecht that a Chinese actor constantly keeps a distance between himself, his character, and the spectator; his performance is always on a conscious level, with all his emotions transposed.

Property men walk around on stage setting up properties for the next play before the preceding one is finished. There are usually very few properties, only a table and a few chairs. A chair may act as a throne, a bench, a tower if an actor stands on it, a barrier if the heroine stands behind it, and so on. A curtain suspended in front of two chairs represents a bed. Doors and stairs are always suggested by pantomime; an actor always mimes opening a door and taking a high step when he "enters" a room.

There are a number of stage conventions; all entrances, for instance, are from a door stage left, and all exits through a door stage right. After a scene of combat, the man who is defeated exits first. Wind is symbolized by a man rushing across the stage carrying a small black flag. Clouds painted on boards are shown to the audience to represent either the outdoors or summer. Fire, however, is always represented realistically, either by the use of gunpowder or pyres of incense. The Chinese feel that the constant use of realism in Western drama atrophies the imagination.

China has few modern dramatists whose work is known abroad; from a designer's view there is one of note—T'ien Han, who after World War II wrote a 21-act tragedy called *Ballad of the Fair Women*. Its production involved the use of what the author named "synthetic propaganda," in which slides and motion pictures are combined with the drama.

Japan. Japan is the only country in Asia whose theatre has never undergone significant renovation in 1,300 years of continuous history. When an attempt is made to recreate the original production of a Greek tragedy or even a play by Shakespeare, its historical accuracy can only be an educated guess. In Japan, the traditions of stagecraft and costumes for both drama and dance have remained unaltered. Japanese staging is far more sophisticated than Western theatre; by the time of Shakespeare, for instance, the Japanese had already invented a revolving stage, trapdoors, and complex lighting effects.

Nō theatre

Although there are many kinds of theatre in Japan, the best known are the Nō and the Kabuki. Nō, the second oldest form of theatre, was developed by the late 1300s and first seen by Westerners in the 1850s. It developed from two sources: the first was the *dengaku*, a rice planting and harvesting ritual that was transformed into a courtly dance by the 14th century. The second source was the *sarugaku*, a popular entertainment involving acrobatics, mime, juggling, and music, which was later performed at religious festivals.

Two performers and adherents of Zen Buddhism in the late 1300s, Kan-ami and his son Zeami, combined the *sarugaku* elements with *kuse-mai*, a story dance that uses both movements and words. Soon *dengaku* elements were added, and the distinctive Nō style slowly emerged. Like the Zen ways of tea ceremony, ink drawing, and other arts, Nō suggests the essence of an event or an experience within a carefully delineated art form. There are scores of Nō theatres in Japan today, even though the design of a Nō theatre is so stylized that it is not usable for other types of performances. The Nō stage is a platform completely covered by a curving temple roof. The audience sits on three sides of the stage and is separated from the stage by a wide garden of gravel, plants, and live pine trees.

Masks are used, though they are restricted to the principal dancer and his companions. The male roles are made up in brilliant stiff brocades and damasks, perfect for the grandiose posturing of the actors. The female roles are played in bright flowered brocades. The outer robes of both sexes are of a fine-woven gauze, light and suitable for the gliding dances when sleeves and fans float in the air. Mask carving is an important art in Japan, and Nō masks add considerable beauty to the gorgeous traditional robes. Most costumes are based on the classic court hunting dress of the Heian (794–857) and Kamakura (1192–1333) periods.

A more detailed discussion of Nō staging practices will be found in the article NO THEATRE.

Kabuki staging techniques

Kabuki troupes, originally composed only of women, developed in the early 17th century. By the 1680s Kabuki had become an established art form, and curtains and scenery were introduced. Kabuki was first seen in western Europe during the latter part of the 19th century, but it was not until the 1920s that it was accepted there as something more than quaint. The Russian film director Sergey Eisenstein, after seeing the Kabuki troupe that toured the Soviet Union in 1928, interpreted it as a brilliant example of effects that could be achieved on film. Sound, movement, space, and voice functioned as elements of equal significance, not as accompaniments of each other. Kabuki staging devices were tried out in theatres in the Soviet Union, France, and Germany, and one Kabuki actor, in turn, brought back Russian techniques that influenced the Japanese theatre.

One Kabuki theatre in Tokyo is the largest legitimate theatre in the world, with a 91-foot- (28-metre-) wide stage and seating for 2,599 people. Running through the audience and connecting the stage with the rear of the auditorium is the platform runway, called the *hanamichi*. It is utilized for significant entrances and exits, processions, and dance sequences. Its purpose is to unite the actor and audience by moving the actor out of the decorative background. Originally there were two runways, with a connecting bridge at the rear of the auditorium. Because of economic pressure to seat more people and the influence of Western architecture, the second *hanamichi* was removed in the early 1900s. The runway cannot be compared to European or American central staging or use of theatre aisles because the Kabuki platform allows the actor to remain separate from the spectators.

The scenery for Kabuki may be as elaborate and complex as that found anywhere; the stage, for instance, may be a house, a forest, and a river simultaneously. Some settings are triple-level palaces, with the actors using all levels at once; others have only a simple backdrop similar to the Nō.

All of its costumes are of the period when Kabuki reached the peak of its perfection, during Edo times (1603–1868). Wigs and makeup carefully conform to classical tradition, enabling habitual playgoers to recognize the type of play and characters at a glance. Many of

the costumes are much exaggerated; all are designed to accentuate dramatic movement. Courtesans and heroes, for instance, wear stilts that raise them several inches off the ground.

Kabuki staging practices are discussed at greater length in the article KABUKI THEATRE.

Bali. Balinese theatre is included here as representative of theatre in the smaller nations of Asia, such as Thailand, Cambodia, Laos, Malaya, the Philippines, and Vietnam, in all of which drama consists almost exclusively of dance. Balinese dancing may take place anywhere; usually it is executed in front of a temple or a pavillion used for community meetings. The audience sits on three sides of the performers; if they are in a clearing, the audience sits in the round. The musicians, called the gamelan, sit on one side of the stage area. There are neither settings nor visible indications of scene changes; location is suggested by the dialogue or the facial expressions and gestures of the actors. A scenic "device" is employed at the beginning of each section of the dance; for instance, the dancer makes a gesture called "opening the curtain." The hands, palms out, are in front of the face; they separate on a diagonal line to reveal the figure, stopping only when the full, formal posture of Balinese dance is reached.

Balinese scenic "devices"

THE MIDDLE AGES

In terms of performances and theatres, Roman drama reached its height in the 4th century AD. Although it continued as a government-supported institution for 200 more years, it had already encountered difficulties that would lead to its demise. One of the two main sources of opposition was the growing Christian Church. From about AD 300 on, churches tried to dissuade Christians from going to the theatre, and in AD 401 the fifth Council of Carthage decreed excommunication for anyone who attended performances on holy days. Actors were forbidden the sacraments of the church unless they gave up their profession, a decree not rescinded in many places until the 18th century. An important contradiction, though, can be seen in an edict of Charlemagne (*c.* 814) stating that no actor could put on a priest's robe except under penalty of punishment or banishment. This indicates that mimes either were continuing their secular ridicule of the church or were endeavouring to pacify religious sentiment by the performance of "godly" plays.

The other main source of opposition that the Roman theatre could not stave off was the invasion of the barbarians from the north and east. Although by 476 Rome had been sacked twice, some of the theatres were rebuilt. The last definite record of a performance in Rome was in 533. Archaeological evidence suggests that the theatre did not survive the Lombard invasion of 568, after which state recognition and support of the theatre was abandoned. Theatre did, however, continue for a while in the Eastern Roman Empire, the capital of which was Constantinople. But by 692 the Trullan Council of the church passed a resolution forbidding all mimes, theatres, and other spectacles. Although the effectiveness of the decree has been questioned, historians, until recently, used it to signify the end of the ancient theatre.

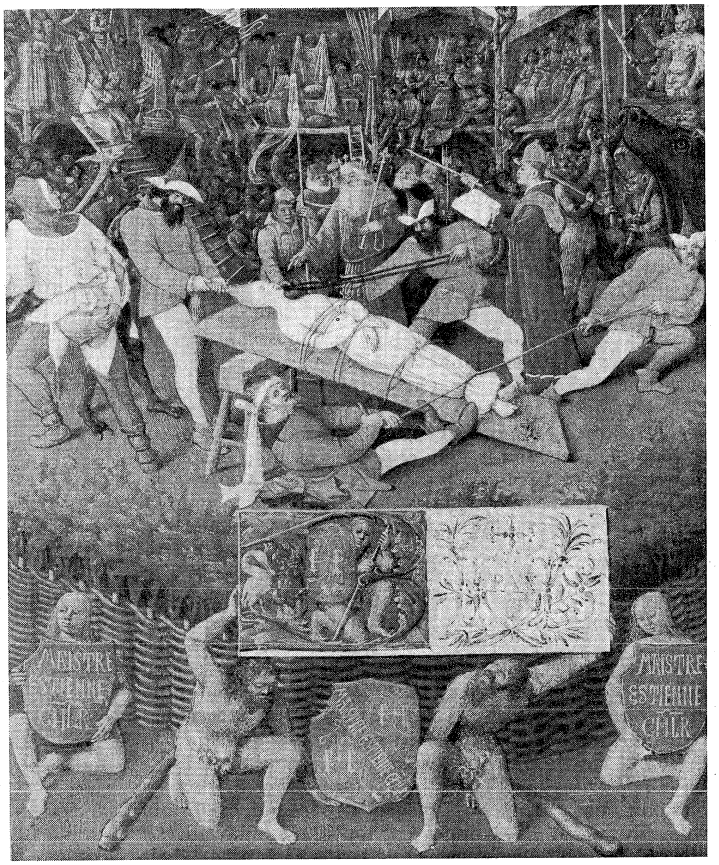
The assumption now is that although official recognition and support of performances were withdrawn and theatres were not used, some remnants of at least the mime tradition were carried on throughout the Dark Ages. Frequently during this period, the writings of Christians suggest that performers were familiar figures. For instance, two popular sayings were "It is better to please God than the actors" and "It is better to feed paupers at your table than actors." Apart from the mime tradition, one Roman playwright, Terence, retained his reputation through the early Middle Ages, probably because of his literary style. From a period between the 7th and 10th centuries comes a dialogue, "Persona Delusoris," between Terence and another character. This was probably a prologue either for a performance of one of Terence's plays or a comedy based on his work.

The beginnings of medieval European drama were in the tropes—embellishments of the liturgy that were sung in churches on Christmas and Easter; appearing by 1000, they consisted of short dialogues in Latin, originally sung antiphonally (*i.e.*, alternately between priest and choir). Later they were elaborated with more words, extra characters, and more acting. It is a reasonable assumption that the religious drama of the Middle Ages came into being through the desire of the church to make the gospel story more real to an illiterate congregation.

A number of staging conventions that evolved in the church were to continue throughout the Middle Ages. The playing area had two components; small scenic structures, called *mansions, sedes, loci,* or *domi;* and a general acting area, called a *platea, playne,* or *place.* The methods of staging from these first liturgical dramas to the 16th-century interludes can be divided into six main types. The first involved the use of the church building as a theatre. In the beginning, for Easter tropes, a tomb was set up in the north aisle. As dialogue was added, the entire nave of the church was used by the actors, and within this space different localities were indicated by *mansions.* A few *mansions* housed elaborate and numerous properties, particularly those for the Last Supper. Some *mansions* had curtains so that characters or objects might be revealed at the right moment or concealed at the end of an episode. Sometimes the choir loft was used to represent heaven and the crypt to represent hell.

The six types of medieval staging

The second type of staging evolved by the 12th century, as drama began to outgrow the capacity of the church to contain it. As long as the action was confined to the central theme, it could be played in an arrangement of *mansions* down the length of the nave. But as the subject matter extended to include both Old and New Testament history, the action was transferred to a stage outside the west door of the church. In 1227 Pope Gregory decreed the removal of what had become a show from holy ground to the marketplace or an open field. Simultaneously, there had begun a corresponding transition in the language in which the plays were presented: from Latin to the vernacular. When drama was first taken outdoors, the crucifix was placed at one end, no doubt where it would have appeared above the altar in the church. *Mansions* were placed alongside each other, their positions usually determined by memories of performances within churches.



A third type of staging was the so-called stationary setting, found outside of England, in which the audience accepted three conventions. One was the symbolic representation of localities by the *mansions;* the second was the placing of the *mansions* near each other; and the third was the use for acting purposes of such actual ground as was enclosed by or in front of each *mansion.* The ground-level area was the area for the actors, and the *mansions* were placed either in a straight or a slightly curved line. The fixed settings were probably impressive, as all of the scenery was visible simultaneously. Because of their scope, many of the plays were divided into parts separated by intermissions ranging from one to 24 hours. During the intermissions, *mansions* were changed. Also, some *mansions* might represent more than one location; the identity of the *mansions* was announced by the director before each segment of a play. It is difficult to know exactly how many *mansions* were used; in a play at Lucerne, Switzerland, in 1583, for instance, 70 different locations were indicated, though only about 32 mansions were actually used.

Mansions of heaven and hell

The two *mansions* almost always present were heaven and hell, set at opposite ends of the playing area. The earthly scenes were set in the middle, and the two poles were supposed to represent man's dual nature and the choices that faced him. In the 15th and 16th centuries, heaven was usually raised above the level of the other *mansions.* Sometimes heaven had a series of intricate turning spheres, with concealed torches, so that it would look as though golden light was emanating from it. As hell was supposed to be terrifying, it was built to be the complete opposite of heaven; some portions of it, for instance, were even below stage level. Sometimes hell was made to look like a fortified town, which was effective when Jesus Christ forced open the gates to free the cap-

tive souls. The entrance to hell was usually shaped like a monster's head and was called a hell mouth, from which came fire, smoke, noises, and the cries of the damned.

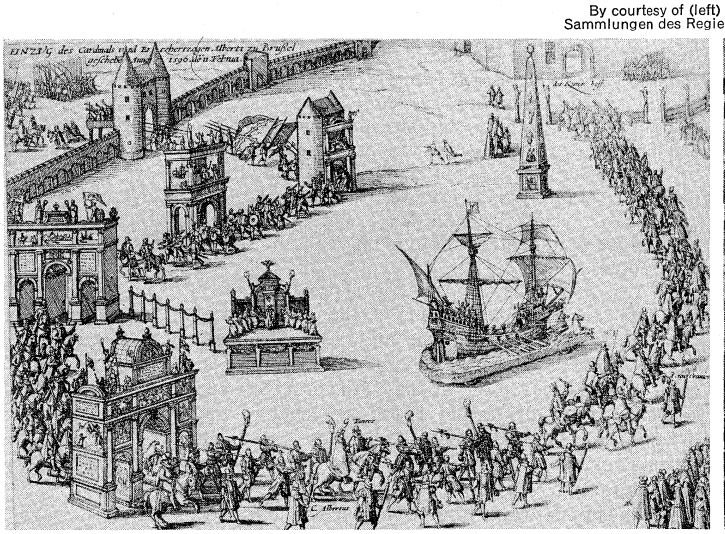
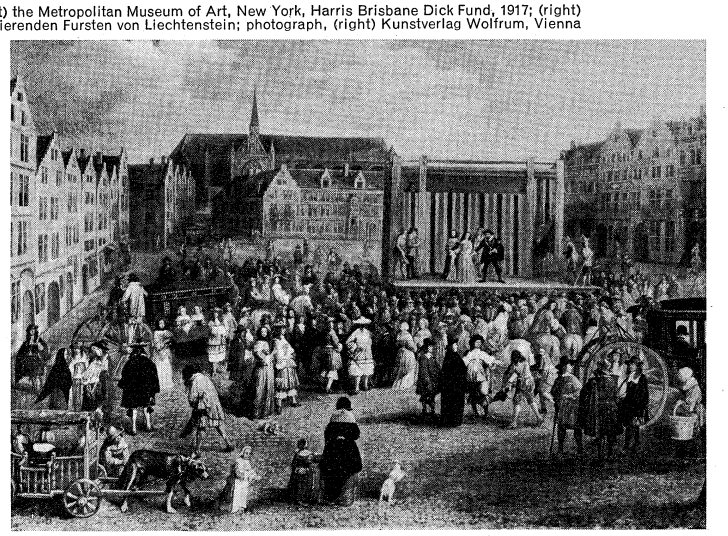
The fourth type of staging was in the round. In France and England particularly, still-standing Roman playhouses were used for drama, and the *mansions* were probably placed in a circle. The fifth type involved the use of the pageant, which was like the *mansion* that was used in fixed settings except that it had wheels. The upper level was the main acting area, and the pageant was often supplemented by a movable open platform set along side it. "Processional" staging was particularly popular in Spain, and continued until 1765. The wagons, called *carros,* on which the scenery was mounted were pulled next to platforms that had been erected in every town. The last type of staging, and the one of which the least is known, was the curtained platform. Itinerant professional actors who performed interludes toward the end of the Middle Ages required only a curtain behind them for staging.

Machinery for special effects

Special effects, which were very popular, became so complex and numerous by the 15th century that many scenes were added to take advantage of the machinists' abilities. Many effects involved flying; fixed settings were often placed against buildings on the top of which were pulleys and windlasses. Additional flying machinery was also hidden inside the heaven *mansion.* Angels flew between heaven and earth, souls released from limbo ascended, and devils and fire-spitting monsters flapped around. The machinery became so complex that 17 people were needed simply to operate the hell scenes at a theatre at Mons, Belgium. Trapdoors were used for sudden appearances, disappearances, and substitutions of dummies for actors in scenes of violence. In a production involving Barnabas' burning at the stake, the dummy was filled with bones and entrails to give off a realistic smell.



The morality plays, which first appeared in the 14th century, involved no scenery or complex properties. Although some were performed indoors, most were done outside on a stage that anticipated the English Elizabethan public theatre. A fixed facade was built at the rear of a large platform, and there were three openings at stage level that could be used to show interior scenes. A second level included similar openings, and a third level had a throne for the figure being honoured by the morality.



THE RENAISSANCE

Renaissance Italy. Just before 1500, Italian amateur actors were performing classical comedies on stages with no decoration except a row of curtained booths. By 1589, productions involving complex painted scenery and scene changes were being offered in Florence. And by 1650, Italy had developed staging practices that would dominate European theatre for the following 150 years.

The impact of the beginning of the Renaissance was felt differently in each country. The two forces moving Italian medieval theatre to change were the desire of the mercantile city-states to imitate the glories of ancient Rome and Greece (and in the process to escape liturgical constrictions) and the fact that Renaissance painters and architects, having discovered perspective, found that in

the theatre they could experiment beyond what had been possible in their studios. Toward the middle of the 15th century, scholars discovered the manuscripts of the 1st century AD of the Roman writer Vitruvius; one of these scholars, the architect and humanist Leon Battista Alberti, wrote *De re aedificatoria* (1452; first printed in 1485), which stimulated the desire to build something in the style of the classical stage. From 1537 to 1547 the architect Sebastiano Serlio published a work that concentrated entirely on the practical stage of the early 16th century.

In the beginning of the Renaissance, there were two distinct kinds of theatrical productions. The first was of the type presented by the Humanist Julius Laetus at the Roman Academy, a semisecret society he founded in the mid-15th century to revive classical ideals. In terms of staging, medieval-type *mansions* were placed next to each other to form a single large unit. There were, however, two elements not found previously: one was that the *mansions* were probably framed by decorative columns. This was the first movement toward the framework that would develop into the proscenium arch—the arch that encloses the curtain and frames the stage from the viewpoint of the audience. (The first permanent proscenium was built in the Teatro Farnese at Parma, Italy, in 1618–19, a temporary one having been constructed by Francesco Salviati 50 years earlier.) The second new element was that the *mansions*, by being linked, were treated as components of a general city street. In 1508 at Ferrara a background painted according to the rules of perspective was substituted for the mansions; the scene included houses, churches, towers, and gardens. In 1513 a production in Urbino had both a setting of a city and three-dimensional structures on the stage. There were towers on each side, in which the musicians played.

Origin of the proscenium arch

Serlio's treatise on the theatre had three especially significant items. The first was a plan for an auditorium and stage that assumed a rectangular hall, with spectators arranged in the same pattern as in the Roman cavea (*i.e.*, the tiered semicircular seating area of a Roman theatre), the difference being that the semicircle of the audience was cut short by the sidewalls. Second, his three types of stage designs, tragic, comic, and satiric, were the same as Vitruvius' classifications. Third, for the stage, he started with a Roman acting platform; but instead of the *scaenae frons*, he introduced a raked platform, slanted upward toward the rear, on which the perspective setting of a street was made up of painted canvases and three-dimensional houses. Since the perspective required that the houses rapidly diminish in size with distance, the actors were able to use only the front houses. Serlio used three types of scenes, all with the same basic floor plan: each required four sets of wings (*i.e.*, the pieces of scenery at the side of the stage), the first three angled and the fourth flat, and a perspective backdrop.

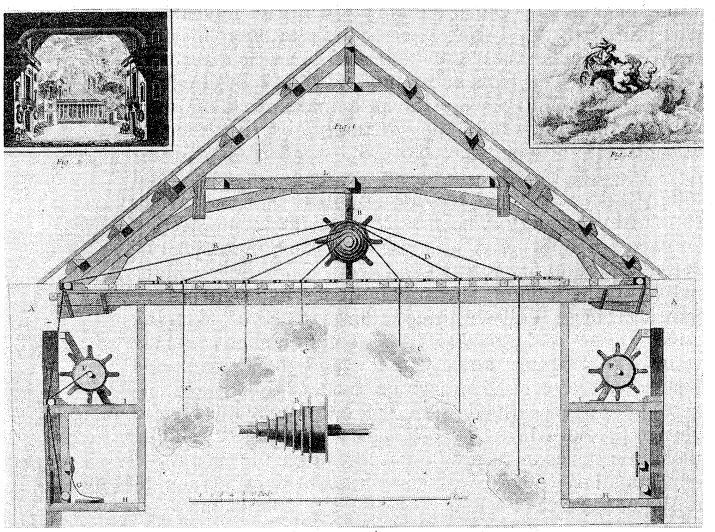
"Tragic Scene" by Sebastiano Serlio, a background in perspective for players who performed in front of this scene. Woodcut from *Architettura*, English edition, 1611.

Also in the latter half of the 16th century, intermezzi, entertainments totally unrelated to the play, were inserted between the acts. These grew out of Neoclassic divertissements for masked balls and banquets. The special effects and spectacle galore were the principal appeal of intermezzi, which grew until they virtually absorbed the full attention of the audience. Now the need to change settings rapidly for the alternating segments of plays and intermezzi encouraged the development of new devices for shifting scenery. The first solution to scene shifting adopted for intermezzi was derived from discussions of *periaktoi* found in Vitruvius. Nicola Sabbatini's "Manual for Constructing Theatrical Scenes and Machines," published in 1638, listed three main methods of changing scenery: one used *periaktoi;* the second manoeuvred new wings around those already there; and the third pulled painted canvas around the wings to conceal the previously visible surfaces. In addition, the author explains how to change the flat wings near the back of the stage by sliding them in grooves or turning them like pages in a book. All of Sabbatini's devices indicate a considerable simplification of Serlio's wings, for painted details have replaced the three-dimensional ones.

Development of wings



The final solution to scene changing required that flat wings replace the angled ones. The problem of transferring a perspective picture successfully to a series of flat wings was not solved until 1600. By 1650 angled wings were completely outmoded; at each wing position as many flats were set up, one behind the other, as there were settings. Scenery was changed by removing the visible wings to reveal the set behind. Grooves were made in the stage floor to support the flats and facilitate their movement. The background was painted on two flats, called shutters, which met at the centre of the stage; and cloths that could be rolled up were occasionally used.

The final step in scene shifting was introduced by Giacomo Torelli in 1641, when he perfected the chariot-and-pole system of scene changing. Slots were cut in the stage floor to support uprights. These poles, on which flats were mounted, were attached below the stage to chariots mounted on casters that ran in tracks parallel to the front of the stage. As the chariots rolled to the centre of the stage, they carried flats into view. An elaborate system of winches, ropes, and pulleys made it possible to change every part of a setting by turning a single winch. This invention, adopted by every European country except England and Holland, was the standard method of shifting scenery until the end of the 19th century.

The Italians were particularly taken with special effects and delighted in elaborating on medieval practices. Most of the special effects were associated with the intermezzi and involved the replacement of biblical characters of the Middle Ages by pagan deities. Flying machines with from one to 50 characters might be flying in any particular scene. According to Serlio, moving mechanical figures representing men, animals, and objects were cut out of pasteboard and drawn across a scene by invisible wires. In many productions clouds that engulfed the stage would hide the activity of lowering painted cloths and flats. The front curtain was used to conceal the scenery and increase amazement at the beginning of a performance. At first the curtain was dropped, but as this was hazardous, the roll curtain was soon adopted.

In spite of the interest taken in classical drama by the Italian aristocracy (with the overlay of exotica brought back by the merchant fleets), the movement was by no means a popular one, which explains why so few permanent theatres were built during the Renaissance. Audiences for the plays were comparatively small and could be accommodated comfortably in the large rooms of private palaces. One theatre of this time has survived and may be considered an expression of the architectural ideals of the period. It is the Teatro Olimpico at Vicenza, Italy, built from plans drawn by the influential architect Andrea Palladio and completed in 1584.

The theatre has a semi-elliptical auditorium that allowed a good view of the stage to all members of the audience and seated about 3,000 people. The lower floor of the auditorium was arranged as a series of curved

steps, encircled at the rear by a colonnade, the space between the columns forming boxes. Stairs led from the rear of the auditorium to the gallery. A semicircular acting space opened directly before the front row of seats, and beyond this forestage was the stage proper. The stage was set with the typical Renaissance scene; rows of houses forming three streets in forced perspective, the bare forestage serving as a public square.

Commedia dell'arte staging

Simultaneous with the theatre of the aristocracy was another that entertained the majority of the Italian population, the commedia dell'arte. The commedia became popular in the early 1500s and in the following 150 years swept over western Europe. It may have arisen from the Atellanae (*i.e.*, ancient popular farces played in Atella, a city near Rome). How it remained dormant for 1,000 years has never been adequately explained, particularly since the characters in the 16th century were the same as the earlier ones. There are no records of these masked, improvised farces being performed during the Middle Ages, although they probably were. At any rate, the persistence of the commedia is presumably due to the populace's love of the raw, earthy, satirical gang of scoundrels who made light of the court and their rarefied theatrics. Naples was a flourishing stand, where ridicule of the Spanish regime, which controlled the area, could be disguised by the vulgar doings of stock commedia characters. Each commedia troupe travelled constantly, either hiring large rooms, improvising stages outdoors, or performing on court stages. When perspective scenery and elaborate special effects were available, the troupes used them, but they were not a necessary ingredient of their productions (see also COMMEDIA DELL'ARTE).

Decades passed before the proscenium arch and decorated stage developed in Italy would influence the rest of Europe. In Renaissance Italy the existence of a small cultured aristocracy offered the ideal environment for the invention and growth of the new theatre. In England the Renaissance spirit discovered its characteristic medium in poetry rather than the visual arts; France, politically torn apart in the 16th century, had almost no cultural flowering; and Spain maintained its own national style.

The 16th and 17th centuries in France. In 16th-century France, most activity was associated with the Confrérie de la Passion, a Parisian organization set up for the performance of mystery cycles. In 1402 the company was granted permission to stage any mystery play, but by 1548 it had been forbidden to produce sacred mysteries, this satirical forum for the lower clergy having proved to be too much for the ecclesiastical authorities. They were granted, instead, complete control over secular drama, and they converted the Hôtel de Bourgogne into a theatre. The designs were all made up from sets of simulated houses painted on frames. What is unusual about these designs is the attempt to put so many houses representing different localities in the same stage area.

French *décor simultané* method of staging

In France, despite the number of critics seeking to hold to the classical "unities"—*i.e.*, the notion that a play should deal with only one action, set in one day, in one place—popular sentiment inspired plays involving many localities. Such a play could be presented by the use of curtains, by changing scenery, or by a third method, the *décor simultané*, which was utilized by Laurent and Mahelot, the designers for the Confrérie. Several localities were represented on the stage at the same time—each on a different portion of the stage—using angled mansions of wooden frames covered with canvas. When a play needed more *mansions* than could be fitted on stage at once, units were converted by removing the canvas coverings or by opening curtains to show an interior scene. Molière inherited a permanent town square set when he moved into the Petit-Bourbon in 1658.

The Elizabethan stage. During the early part of the 16th century, there were two distinct types of theatre in England. One was represented by small groups of professional actors who performed in halls, inns, or marketplaces. The location of a play was established by the words and gestures of the actors. As in the commedia dell'arte, these localities had little significance. The second type of theatre, found in the London area, was made up of amateurs, usually university students, performing for the royal court and assorted gentry. The audience and the actors were educated, acquainted with the classics, and knowledgeable about theatre in other countries, particularly France. The stage was probably set with buildings made of laths, covered with painted canvas, with cloud borders masking the upper part of the acting area.

The significant achievement of the Elizabethan stage was connected with the theatres of the professional acting groups, not the court theatre. During the second half of the 16th century, as they became successful, the troupes no longer needed to remain itinerant. In 1576 the first permanent public theatre, called simply the Theatre, was erected by the actor James Burbage. The building boom continued until the end of the century; the Globe, where Shakespeare's plays were first performed, was built in 1599 with lumber from the demolished Theatre.

The stage was a platform, as large as 40 feet square (more than 12 metres on each side), sticking out into the middle of the yard so that the spectators surrounded most of it. It was raised four to six feet (about one to two metres) and was sheltered by a roof, called "the shadow" or "the heavens." In most theatres the stage roof, supported by two pillars set midway at the sides of the stage, concealed an upper area from which objects could be raised or lowered. At the rear of the stage was a multilevelled facade with two large doors at stage level. There was also a space for "discoveries," probably between the doors. Historians disagree as to its function: either it was used only to locate scenes or scenes were actually performed there. Some scenes took place in a playing area on the second level of the facade, but again historians disagree as to which scenes they were.

Properties were occasionally carried onto the platform stage, but from extant lists it is obvious that they were few in number. Some properties were so cumbersome that they remained on stage throughout a performance. Smaller properties were probably revealed in the discovery space, and servants carried some properties on and off. It appears that the audience was not concerned by the scenic inconsistencies.

All of the theatre buildings were either round, square, or octagonal, with thatched roofs covering the sides. Spectators, depending on how much money they had, could either stand in the yard, which may have sloped toward the stage; sit on benches in the galleries that went around the greater part of the walls; sit in one of the private boxes; or sit on a stool on the stage proper.

The importance of this type of theatre was its flexibility. In some ways it was similar to earlier attempts to reconstruct the *scaenae frons* of the Romans; it had the facade

and the entrance doors. The Elizabethan theatre differed in that it had a platform that made movement possible in all directions instead of the long, narrow stage. The actors now had an inner stage to use, and even vertical action was possible by utilizing the upper stage level.

The Elizabethan playhouse, in its dynamic use of stage space, its predominantly formal approach to production, and its reflection of the new middle class ideology, represented a decided break with the classicism of the court-dominated spectacles; it broke the ground for the coming romanticism and naturalism. Shakespeare has always been considered the pivot for radical changes in theatrical thinking.

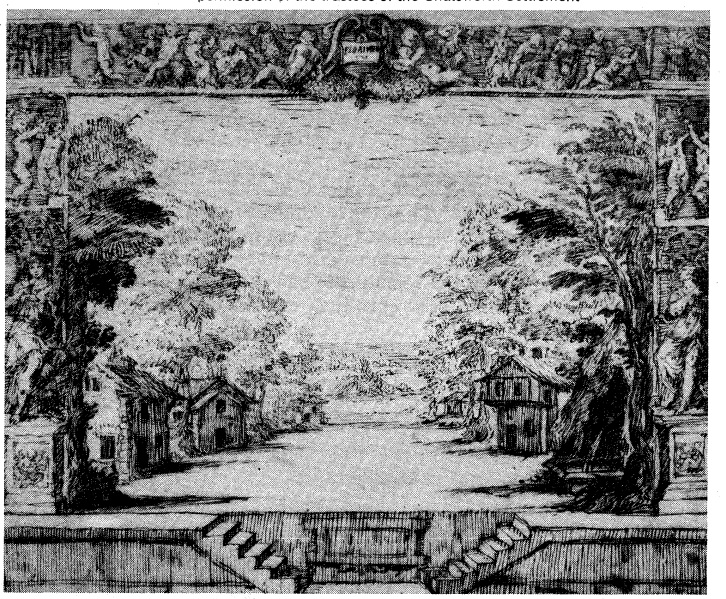
Spain's Golden Age. Religious drama developed during the Middle Ages only in northeastern Spain because the Moors occupied the remainder of the peninsula. During the 16th century, as Spain became the most powerful country in Europe, it started to develop a sophisticated theatre. Following an interest in classical drama and the introduction of printing came Juan del Encina, the founder of modern Spanish drama. Although the origin of professional players is obscure, actors were being paid as early as 1454. The popularity of the theatre mushroomed in the 1570s, and among the playwrights of this era were such masters as Lope de Vega, Cervantes, and Calderón de la Barca.

Staging based on the *corrales*

During this "Golden Age" in Spain, the theatre assumed a form more flexible than that of the Italian or French stages. The model was that of the *corrales*—courtyards enclosed by the backs of several houses—in which the earliest troupes had performed. The staging arrangements were almost identical to those in contemporary London. The stage itself was a raised platform, without a front curtain or a proscenium arch but with a permanent facade at the back. Stages were about 28 feet (nine metres) long and 23 to 30 feet (seven to nine metres) deep. The open platform was usually backed by a facade of two levels, with pillars dividing the lower level into three openings. The second level, basically a gallery, usually represented towers, city walls, or hills.

Spanish staging conventions, like those of the Elizabethan theatre, tended to be simple. To denote a change of location, an actor merely exited and re-entered. Three kinds of scenic background were utilized: the facade; the curtains concealing the facade, which were used when the location was not particularly important; and medieval-type *mansions,* which were sometimes erected on the main stage. As spectacle increased after 1650, painted flats with doors and windows were set into the facade in place of curtains. The *corrales* themselves, enclosing a square or rectangular courtyard, were unroofed until the 18th century, and when roofed a row of windows was added under the eaves. Benches were placed on the ground level and balconies set in the containing walls for wealthier patrons. A special boxlike gallery, called the *cazuela,* the "stewpot," was assigned to women spectators. And above the *cazuela* were galleries for members of the city government, the church, and the aristocracy.

THE BAROQUE



The combination of two innovations, the first opera in 1597 and the formulation of the laws of perspective in the 15th century, provided the foundation for the Baroque theatre, a period that would extend until the 19th century. During this era all countries were brought into the same orbit, although Italy remained the primary inspiration. The central emphasis of staging was on scenery for entertainment that differed from the classically inspired 16th-century dramas; now there were intermezzi, ballet, masques, and opera. New means of presenting spectacular visual effects were invented, and these encouraged the installation of more machinery in the theatre building. The result was that spectacle dominated all other aspects of production. The stage floor, which previously had extended only a few yards back from the proscenium arch, was now stretched farther from the auditorium.

England: the 17th and 18th centuries. The court masques served to introduce Italian staging to England and started the trend toward the proscenium-arch theatre that culminated in the disappearance of the facade stage by 1660. The masques were allegories designed to honour a particular person or occasion by comparing them favourably with mythological characters or situations.

Introduction of court masques in England

Inigo Jones, the foremost English architect of his time, was responsible for the productions of the masques and other entertainments at the English court from 1605 to 1640. He had visited Italy between 1596 and 1604 and was the individual most responsible for acceptance of Italian stage design in England. From his sketches it is known that Jones went through several phases in his designs, starting in 1604 with the *décor simultané,* mentioned above, in which different localities were represented on different portions of the stage. In 1605 he introduced simple perspective settings—two painted representations of houses with a painted back shutter. The same year he experimented with *periaktoi,* creating a globe, with no visible axle, that revolved to reveal eight dancers sitting inside.

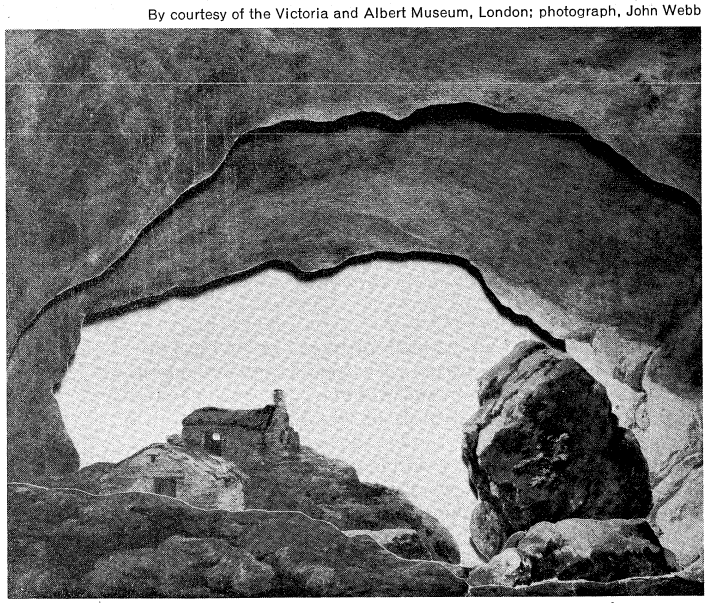
Devonshire Collection, Chatsworth. Reproduced by permission of the trustees of the Chatsworth Settlement

Stage designed by Inigo Jones in the Italian manner for a production of *Florimène,* 1635. In the Devonshire Collection, Chatsworth, England.

His masques all had painted proscenium arches, into which he set a falling curtain. By 1635 Jones designed a setting that utilized four angled wings, like Serlio's, and four shutters at the rear, three of which could be drawn to the sides in two parts. Jones's design for a masque in 1640 is considered the first design of the Baroque theatre. Four sets of side wings were placed on each side of the stage, each wing consisting of two flats. There were four shutters at the rear, with each dividing into two parts for easy removal. Each wing had either a header (*i.e.,* a horizontal unit that joins two upright wings, to form a flat arch) or a sky border (a horizontal piece of scenery, designed to look like the sky, which masks the space above the set). To give the illusion of distance, the side wings were made in exaggerated perspective, with each succeeding wing in significantly smaller scale than the one preceding. The disadvantage of using smaller sized flats toward the back of the stage was that if the actors stood too close to them the illusion would be destroyed. The actors were therefore restricted to the front of the stage. In successive decades, attempts were made to give the stage area greater depth by multiplying the number of flats on each side. In sum, with the exception of the chariot-and-pole system of scene changing, Jones introduced all of the major Italian developments into England.

Jones's first Baroque design

After Inigo Jones, English scenery practices and stage conventions were similar to those of Italy. Sets were changed by sliding them in grooves in the stage floor and overhead. Since the curtain was raised after the prologue



and remained up throughout the performance, all scene shifting was in view of the audience. It was not until 1750 that an "act drop" was used; previously, even intermezzi were performed in front of a full stage setting.

The development of spectacle was slow in England because members of the audience sat on the stage. Between 1700 and 1762 benches extended upstage from the proscenium and amphitheatrical seating was sometimes built across the back of the stage. Finally, in 1762, the distinguished actor David Garrick removed the spectators from the stage. As interest in spectacle increased, the scene painter became more important, and by the late 18th century each theatre had two or more permanent scene painters. In 1750 the actor-manager John Rich started to import from the Continent designers as eminent as the Italians Giovanni Servandoni and Giovanni Cipriani.

Loutherbourg's contributions

The best known designer around the end of the 18th century was Philip James de Loutherbourg, a painter; from 1771 he worked for Garrick as scenic designer at the Drury Lane Theatre in London and is credited with changing the orientation of design from the architectural to the landscape era, thus marking the end of the Baroque in England. He was one of the pioneers of the cut cloth, a double back cloth in which there was an opening in the one nearer the audience that revealed a vista painted on the back one. He also utilized transparent scenery; in one production he cut the moon out of the canvas back cloth, replaced it with gauze, and lit it from behind. The importance that Loutherbourg's landscape painting of the back cloth assumed is shown by the fact that the Drury Lane pantomime of 1779 was specially written for the scenery he had designed while on a trip to Derbyshire. His reproduction of actual places in England started a vogue for "local colour."

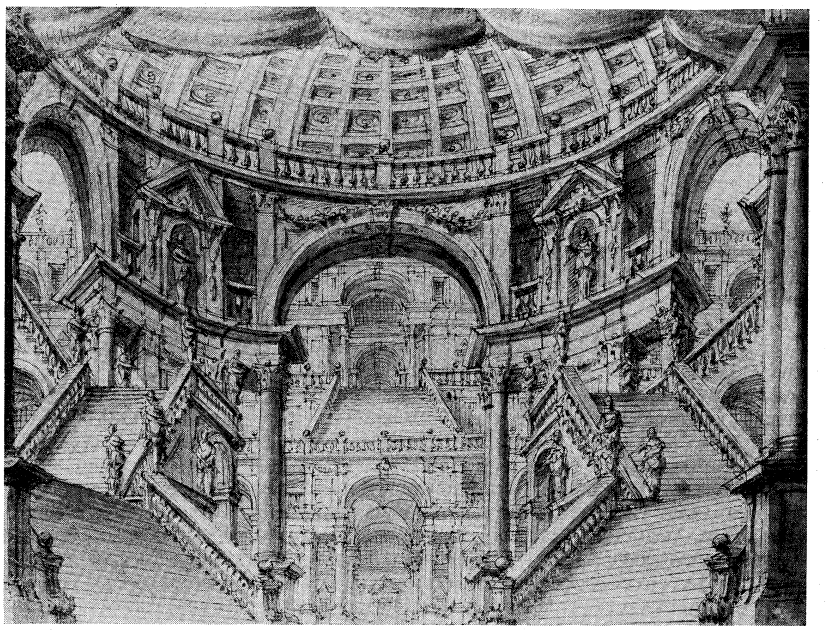
Philip James de Loutherbourg's model set for the pantomime "The Wonders of Derbyshire, or Harlequin on the Peak." In the Victoria and Albert Museum, London.

Loutherbourg was intrigued with miniaturization and invented a miniature theatre, the Eidophusikon, which consisted of nothing but scenic effects. He used miniature figures at the rear of the stage, which was six feet wide and eight feet deep, to represent soldiers in battle or marching. He was also a specialist in sound effects, such as waves, rain, hail, and gunfire. Loutherbourg's single most important contribution was that he achieved a unity of design because he directed both the scenery and the lighting and effects of a single production. At the beginning of the Baroque period in England, the three important theatres were the Drury Lane, the Lincoln's Inn Fields, and the Dorset Garden. Although each theatre was different from the others, they shared many significant details. The auditorium was divided into a raked pit, boxes, and galleries. There were two or three galleries, with the lowest partitioned into boxes and the upper one open. The theatres were small, each holding about 600 people. The stage included both a proscenium arch and an open platform in front of the proscenium. The stage was about 35 feet deep (11 metres), divided into equal parts by the arch. At either side of the apron were several doors, each with a balcony above it. These doors were the entrances for all the actors since the action took place on the apron and would continue to do so throughout the Baroque era. The floor of the stage was raked from the front of the apron to the back wall. There were grooves behind the proscenium for wings and shutters. Throughout the 18th century the theatre buildings grew larger, and the only other change was about 1700, when Christopher Rich, John's father and the manager of Drury Lane, removed one set of proscenium doors and shortened the apron.



Angled perspective designs

Italy in the 18th century. Significant changes in scenic design were made by Italy's Bibiena family, of whom the best known members were Ferdinando, Francesco, Giuseppe, Antonio, and Carlo. Around 1703, at Bologna, Ferdinando introduced angle perspective. Previously, stage design was based on one-point perspective using a single vanishing point, in which all lines appear to recede with distance toward one point at the centre of the background (as parallel railroad tracks might appear to meet in the distance to someone standing amid them). Bibiena, however, used perspective with two vanishing points; if this technique were used to render a large, flat building as seen from one corner of it, for example, the base and roof lines of one side extended into the distance would appear to meet at some point off to the right and those of the other side at another point off to the left. Furthermore, by locating these points quite low, Bibiena gave the structures the effect of immense size. Buildings, walls, or courtyards were placed in the centre of the set and vistas at the sides, and the scale of settings, which had previously been designed to make the scenery an extension of the auditorium, was altered. The front wings were painted as though they were only the lower part of a building. The result of these innovations was that Bibiena's sets seemed so large that they created a feeling of fantasy. Despite its apparent size, though, an angled-perspective setting required less stage space than one with a central alley. Many of the settings divided the stage into a foreground, for the actors, and a background, for distant objects. A drop, designed to resemble a series of arches or columns, often marked the rear of the acting area.

Another designer who developed the angled scene independently of Bibiena was Filippo Juvara, a major Italian architect of the early 18th century, who began his work, as did many artists of the period, with the decoration of court entertainments. Some of his most intriguing scenic designs, in terms of architectural fantasy, were executed for a marionette theatre owned by his patron. These designs are particularly helpful because Juvara usually included plans of the stage settings showing exactly how the wings were placed. Juvara's sets were basically curvilinear, leading the audience's eye to the foreground instead of the sides. In several sketches, he designed a permanent set with a large archway opening up to a series of vistas, which varied from a landscape to a perspective corridor. His designs foreshadowed the interest in landscape that was not to find its complete development until almost a century later.

Late 18th-century developments

In the second half of the 18th century, several new directions in thinking led to stylistic changes in scenery. One was the increased interest in history, spurred by the rediscovery of Pompeii in 1748. Scenery of classical ruins with vines rambling between the cracks became popular. Plays dealing with folk literature were produced with Gothic architectural settings. The most important new direction was that scenic designers introduced "mood," they started to emphasize light and shadow to create an atmosphere. The best known artist of this period was the Italian engraver Giambattista Piranesi, who executed more than 1,000 engravings of Roman ruins and prisons. He did not particularly apply himself to the theatre, yet

Drawing for an interior setting by Giuseppe Bibiena. In the Victoria and Albert Museum, London.

his designs were inspired by contemporary stage settings and were in turn themselves an inspiration for other designers. One admirer of Piranesi, for instance, brought to Poland a characteristically native modification of the Italian style.

Baroque theatre in France and Spain. Although Italian-style scenery was introduced to the French court before, it was not popular until after 1640. The first theatre in France with a permanent proscenium arch and a stage designed for flat wings was constructed in 1641 for Cardinal de Richelieu. In 1645 an Italian designer, Giacomo Torelli, popularly called "the great sorcerer," was imported by Richelieu's successor, Jules Cardinal Mazarin, to design for the new theatre, the Palais-Royal. Torelli's first assignment was an opera, for which he installed his chariot-and-pole system of scene shifting at the Petit-Bourbon. In 1646–47 Torelli remodelled the Palais-Royal to accommodate his invention. Pierre Corneille, the founder of French classical tragedy, was commissioned to write *Andromède* for the remodelled theatre. Although the play progressed through spoken episodes, each act provided an excuse for Torelli to introduce elaborate machinery, including the revolving stage. Until Torelli, the changing of scenery had marked a structural break in the dramatic presentation. Torelli put aside all previous methods, which were so distracting to the audience, and introduced set changes within, rather than at the ends of, the scenes. The audience was mesmerized by the scenery mysteriously changing while the action of an opera or ballet proceeded without interruption.

For the wedding of Louis XIV, in 1660, Gaspare Vigarani went to France from Italy to build the Salle des Machines, the largest theatre in Europe. It was 226 feet (69 metres) long, only 94 feet of which was occupied by the auditorium. Its stage, 132 feet (40 metres) deep, had a proscenium arch only 32 feet (ten metres) wide. One of Vigarani's machines, 60 feet deep itself, was used to fly the entire royal family and their attendants on stage for the finale. Vigarani was succeeded by his son, who was in turn followed by the Jean Berains, father and son. The Berains established a distinctly French style of design, emphasizing heavy lines, reverse curves, and encrusted ornamentation. Berain usually designed only one set for each act but used many machines and special effects. This combination of static scenery and dynamic machinery was to remain in vogue in French opera through the 18th

century. After 1682 the influence of the court on public theatre declined. After 1690 the King became so puritanical that plays were no longer encouraged.

In contrast to court opulence was the Comédie-Française, for which a theatre was built in 1689 from a converted tennis court. The stage was equipped for flat wings and shutters, but since scene changes were few, the machinery was minimal. The typical background for tragedies was the *palais à volonté* (literally "palace to order"), a neutral setting without particularized details. For comedy the typical scene was *chambre à quatre portes* ("room with four doors"), an informal interior. By 1700 Paris had two types of theatres—the Opéra, with its Baroque scenery and machines, and the Comédie-Française, which did not rely on spectacle.

The first true spectacle in a public theatre was the 1755 production of Voltaire's *Orphan of China*, with its supposedly accurate Chinese scenery and costumes. The *comédie-italienne*, permanently performing in Paris, introduced local colour and increased the use of spectacle. Giovanni Nicolò Servandoni, originally a Florentine who lived in Paris from 1724 to 1746, translated Italian styles to French taste. His use of perspective gave the illusion of space without falling back on the obvious geometry that characterized the High Baroque. He took over as director of the Salle de Machines, where his work in its turn influenced the designers of Italy and Germany. Throughout the 1700s, spectacle was utilized at the Opéra. Its best known designers included the painter François Boucher. And although many famous painters designed settings, there is still no comparison with the works of the Italians of this period. The financial problems of the theatres did much to prevent a forward thrust in French design. Ironically, the most sumptuous spectacle of the latter part of the 18th century occurred in France in 1794, after the Revolution: the National Convention decreed "The Festival of the Supreme Being," designed by the painter Jacques-Louis David and conducted by the revolutionary government leader Robespierre—Neoclassicism in the service of the Republic.

Until 1763 the theatre buildings remained unchanged. After that date they were built in the Italian style, with ovoid auditoriums and enlarged stages. By the 1780s, when the standing pit was abolished, all of the spectators were finally seated, off the stage. The seated pit was not to become accepted in France until the 19th century.

In Spain, during this period, theatre started the decline from which it has not yet recovered. It was not until 1598 that theatre performances were presented regularly at court. Although Italian-style scenery was used occasionally, it was not common until brought from Florence in 1626, by Cosimo Lotti, who staged many outdoor productions on the palace grounds. For one, he built a floating stage on a lake, and the special effects included a shipwreck, a water chariot drawn by dolphins, and the destruction of Circé's palace. This production was lit by 3,000 lanterns, and the spectators watched from gondolas. In 1640 Lotti built a permanent theatre, the Coliseo, which probably had the first proscenium arch in Spain. The next decade saw a decline in both court and public theatres. By 1650 the Coliseo was reopened, but its popularity had diminished by 1700. By the late 1600s Spain had lost most of its economic and political power, and its theatre through most of the Baroque was a watered-down version of Italian concepts.

Developments in northern Europe. One country outside the Italian influence during this period exhibited an interesting theatre plan. In 1638 Jacob van Campen, an architect, designed a theatre in Amsterdam that had no counterpart elsewhere in Europe. The auditorium was elliptical, with two tiers of boxes on one side. The opposite side had a stage facade with open balconies over the sides. The facade itself consisted primarily of pillars with cornices above them, and flat painted panels were set between the pillars. The panels themselves represented different localities, rather than a unified setting. The whole concept of these panels was probably directly derived from the simultaneous stage of the Middle Ages.

The constantly shifting politics of northern Europe, and particularly of Germany, in the 16th and 17th centuries was the primary cause for the late development of professional theatre in this region. Theatre in Germany owes its impetus to the English troupes that started touring the country in the early 17th century. At first, the English performed in courts, and by 1650 they were travelling across the country regularly. To attract the non-English-speaking audience, the troupes gradually inserted German phrases, speeches, and then whole scenes. As early as 1626, German actors were joining the troupes, and by 1680 English actors had completely disappeared. Because Germany was politically divided and there were no large cities, the troupes had to travel constantly to find new audiences. To attract the disparate spectators, a company might have as many as 100 plays in its repertory. These conditions combined to make it impossible to rehearse and mount plays with any great thought.

First Viennese opera house

Between 1650 and 1775 the aristocracy ignored public theatre in favour of opera. The first Viennese opera house was built in 1652 by Giovanni Burnacini and is similar to the courtyards of Italian Renaissance palaces in the two levels of its auditorium, framed by a double arcade of rounded arches. Italian influences were bound to be strong, since Italians played an important part in every aspect of theatre at the imperial court until 1770. The first performance at the Viennese opera house was of an Italian opera.

In the public theatre, the work of the manager Johann Friedrich Schönemann led to the establishment of the Hamburg National Theatre, the first noncommercial public theatre. This marked the beginning of a movement that gained force during the next decade and can be found even today in East German theatre. The prevailing attitude was that theatre is a cultural institution that, like museums, should be available to all citizens.

This movement toward permanence greatly influenced the evolution of staging in the 18th century. As audiences grew larger, and as cities developed, a troupe was able to reduce the number of plays in a repertory, and this in turn led to better productions. And as the theatre building grew in size and substance, the chariot-and-pole system of scene shifting was introduced. Interest in historical accuracy of sets and costumes was stimulated by the chivalric plays popular in the 1770s. During the next two decades dramatists were writing plays that relied on complex set pieces, including bridges and walls. Doors and windows were set up between the wings, marking the first development toward the box set—a set representing three walls of a room, the fourth being the proscenium.

Early Russian staging. Russian theatre can be traced back to the pagan rituals of the ancient Slavs, the later Christian festivals, and, in the Middle Ages, the mixed rituals of these two influences. As early as the 10th century there were mummers, called *skomorokhi*, probably itinerant comedians who performed in small towns and villages. Suffering the same fate as the actors of western Europe during the Dark and early Middle ages, the mummers were the victims of measures taken by the princes as well as the church. Their specialties were trained-animal acts, usually with bears, and puppet shows. The Greek Orthodox Church introduced some morality plays in Russia, but they were limited in scope and number. Since the mass was celebrated in the vernacular, the church did not need the aid of morality plays for the dissemination of its message. At the beginning of the 17th century, the only theatre using a literary text and a trained company was the school drama brought from Poland to the Ukraine.

The Tsar's theatre

In 1672 the first public performance of a play was offered in Moscow. A special theatre was built in the Tsar's residence; there seems to have been no scenery outside two fir trees on either side of the stage, although there was a sliding curtain. The Tsar (Alexis), who was so excited that he sat in the theatre for ten hours on the day of the first performance, paid for the founding of a theatrical school. The problem with the theatre during the next 80 years was precisely that it had been founded on the Tsar's order: it was attached to the court and subsidized by the aristocracy (who chose German direc-

tors); it assumed political overtones, and aimed at pleasing only the monarchy.

The beginning of change came in 1730, when an Italian group brought the commedia dell'arte, elaborate sets, and machinery to Moscow. During the next ten years, Italian opera and ballet were also introduced to Russia. Despite the success of foreign companies, the significant event was the birth of the national theatre in 1749. This enterprise was open to the public, and, although it was popular, lack of funds made it a weak rival to court theatre. Its impact lay in the fact that it introduced the concept of theatre to a large audience.

By the end of the 18th century, companies were touring the major cities, and privately owned theatres were being opened. In general, only the aristocracy patronized the theatre, and nobles established their own serf troupes. One prince, who owned 21,000 serfs, established his own ballet, opera, and dramatic companies. Owners occasionally rented their troupes for public performances, until the abolition of serfdom in 1861. Little is known of the staging of their productions beyond the fact that it was imitative of French and Italian theatre.

THE 19TH CENTURY

Theatre in France after the Revolution. Under Napoleon, French theatre was little different from that of the 1780s, specializing in Neoclassical drama. Popular drama, as performed by what were known as "boulevard theatres," introduced melodrama, a form that was to dominate theatre in the 19th century. Melodrama, in turn, by popularizing departures from Neoclassicism and capturing the interest of large audiences, paved the way for Romantic drama.

The dramatic debut of Romanticism is dated at 1830, when public pressure forced the Comédie-Française to produce Victor Hugo's *Hernani*. After a spirited opening at which Hugo's Bohemian claque overwhelmed the staid regular theatregoers, Romanticism was victorious and ruled the Parisian stage for 50 years. The grandiose bombast of Romanticism did not overturn the Baroque, it merely diluted it; the formal artificial structure was broken up into sentimental, melodramatic episodes depicting the distraught hero buffeted by an unfeeling world and the awesome elements. The melodramas introduced natural disasters that were significant to the plot, so that emphasis could be placed on special effects and spectacle. Dramatists also deliberately included exotic locales or examples of local colour, so that a variety of historical periods and fantastic sets would hold the attention of the audience. Throughout the 19th century, architectural perspective was replaced by neo-Gothic sentimentalization of nature. Painted Romantic scenery, in the style of Loutherbourg, was the rage in France.

Staging of romantic drama

The two important designers of this period were Louis-Jacques-Mande Daguerre, who was also the inventor of the daguerrotype, an early photographic technique, and Pierre-Luc-Charles Ciceri, the most important designer of this period. The panorama, a major scenic innovation, was invented in 1787 and first used on the London stage in 1792. The panorama was set up in a circular building in which the audience, sitting on a central platform, was totally surrounded by a continuous painting. Daguerre started his career as one of the first panorama painters. He went on to invent the diorama, in which the audience sat on a platform that revolved to show paintings on proscenium-like stages. Although the scenery remained stationary, Daguerre created the illusion of constant change by controlling the light on the semitransparent sets. The panorama became more popular than the diorama because it did not depend on the ability to alter stage lighting. Its shape, though, was altered to resemble the diorama, as it could not surround the audience in a standard theatre. The next development in spectacle was the moving panorama, in which a continuous scene was painted on a long cloth, hung from an overhead track, and attached at both ends to spools. When the spools were turned, the cloth moved across the stage so that the actors with their carriages, and other props could move from one location to another without changing wings and drops. The sky borders were dispensed with, and flats of architectural units or natural objects forming an arch were placed at the front of the stage, through which was seen a distant view painted on a curved panorama stretching across the back and sides of the stage.

Ciceri's importance arose from his abilities to depict local colour, ruins, and historical backgrounds. He founded the first scenic studio in Paris independent of a theatre, with specialists in various types of design. After the opening of the new Opéra in 1822, interest in spectacle was so great that promptbooks were published, describing scenery and special effects and how they could be adapted for theatres with less equipment.

Ciceri's contributions to staging

By the end of the 19th century, the process of scenic design and construction had become standardized. The director gave the requirements to the scenic designer, who made cardboard models. The scenery was constructed by the theatre's carpenters and then sent to a scenic studio for painting.

A number of changes were made in theatre architecture during this period. Theatre interiors, still decorated with Baroque ornamentation, were transformed from intimate playhouses for the aristocracy into huge auditoriums. Most of the private seats, such as boxes, were done away with in favour of benches. This change was in keeping with the egalitarian spirit of France after the Revolution. The larger theatre also made practicable the use of the chariot-and-pole method of scene shifting.

A significant factor was that whereas the Baroque scenic artist wanted his scenes to shift in front of the audience, the 19th-century designer used the curtain between acts. The setting was now seen as an image of reality to be revealed by the raising of a curtain, not a series of dazzling transformations. This spirit of treating the set as a picture became even stronger with the advent of the Realist school later in the century.

Scenic practices in Italy in the 19th century followed the same paths as in France. Although Italy continued to be a leader in opera, its influence in other countries declined, as did the demand for Italian scenic artists.

German Romanticism and Naturalism. The 19th century in Germany was a study in contrasts. The beginning decades saw the rise of Romanticism, which, 50 years later, was still strong, primarily in the figure of the composer Richard Wagner. The century's middle decades, of political and economic disillusionment before the unification of Germany, were conducive to the emerging Naturalist school, the philosophy of which was first personified by the Meiningen troupe, organized by the Duke of Saxe-Meiningen.

By the middle 1820s, after the defeat of Napoleon, the political turbulence in Germany led to municipal control over the theatre and strict censorship. Repertories were composed of "safe" classics and insipid new plays, resulting in competent but uninspired theatre. This competence was reflected in the staging. One of the few important designers of this period was Karl Friedrich Schinkel, who had been trained in both Italy and Germany. He introduced the diorama in Berlin in 1827, and it encouraged the extended use of moving and stationary panoramas and dioramas.

One true innovator during the first half of the 19th century was Ludwig Tieck, who advocated realistic acting on a platform stage. With the help of an architect, he tried to reconstruct an Elizabethan public stage. He also championed the open stage in the belief that pictorial realism destroys the true illusion of the theatre. Invited by William IV of Prussia to stage *Antigone* at the court theater in Potsdam in 1841, Tieck extended the apron in a semicircle over the orchestra pit and built a skene as the only background for the drama. In 1843 he adopted Elizabethan conventions to the proscenium theatre for a production of *A Midsummer Night's Dream*. Using the front part of the stage as a large open space, he built a unit in the rear consisting of two stairs leading to an acting area eight feet above stage level. The stairs framed an inner stage below the platform. He then hung tapestries at right angles to the proscenium, thus masking the sides of the stage. Although Tieck was universally respected, it was

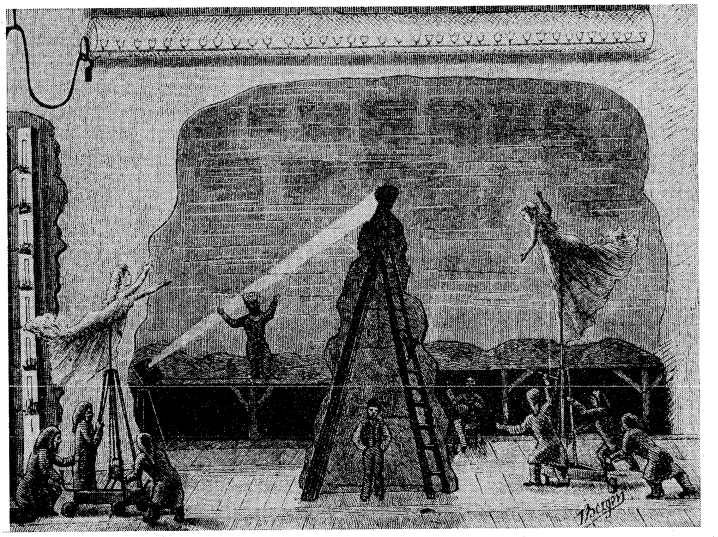
Innovations of Ludwig Tieck

not until the 1870s that widespread support was given to his innovations in staging. The works of Wagner and Saxe-Meiningen were responsible for this change in the public's attitude.

Wagner's works were the dramatic culmination of Romanticism and the contribution it was destined to make to modern theatre practices. German Romanticism was in great part a protest movement against the dominance of French Neoclassicism. Instead of structuring dramatic action according to fixed patterns of logical progression, the Romantics wanted dramatic structures born of human experience. This stress on what was to be called "organic form" was a protest against the received tradition of dramatic theory and staging practices. German Romanticism, also known as *Sturm und Drang* ("storm and stress"), which is generally attributed to the influence of the young Goethe at the end of the 18th century, turned to a revival of the Gothic style of the Middle Ages to escape Neoclassicism. The new middle class audiences identified with the lonely soul against the world—a sentimental world of windswept mountain crags and gloomy, moldering castles. The Baroque backdrop that enclosed the retreating wings of the formal stage was expanded to a large painting by a landscape artist.

Romanticism later broke into two camps. The first of these, called "historical Romanticism," held that history is continuous, and once its import has been grasped, the present can be recognized to be as "historical" as anything that occurred in the past. The second Romantic group, with which Wagner was associated, was concerned only with the use of history to reach absolute truths. Wagner believed that the study of history ultimately leads to prehistory and thus to transhistorical mythology, the realm of absolute truths. What is particularly interesting is that the first type, historical Romanticism, eventually found its home in the theatre in the Realist school. Wagner's myth-Romanticism faded by the late 1800s, although their personal contributions to staging exerted their influence well into the 20th century.

Wagner wanted to use myth to reunite modern man with the passion from which rationalism, the industrial process, and capitalism separated him. For him, the theatrical manifestation of the myth was the music drama, and he hoped to combine music, acting, stage space, design, and lighting to establish the primeval mood of myth. To house his music drama, Wagner designed a new opera house in Bayreuth, which opened in 1876. Although he did not invent it, Wagner established the practice of darkening the house lights so that the attention of the audience would be rivetted to the stage. He had the orchestra lowered into a pit, so that it became the hidden source of an enveloping sound. He did away with the box seats, from which the wealthier theatregoers had watched each other instead of the stage for hundreds of years.

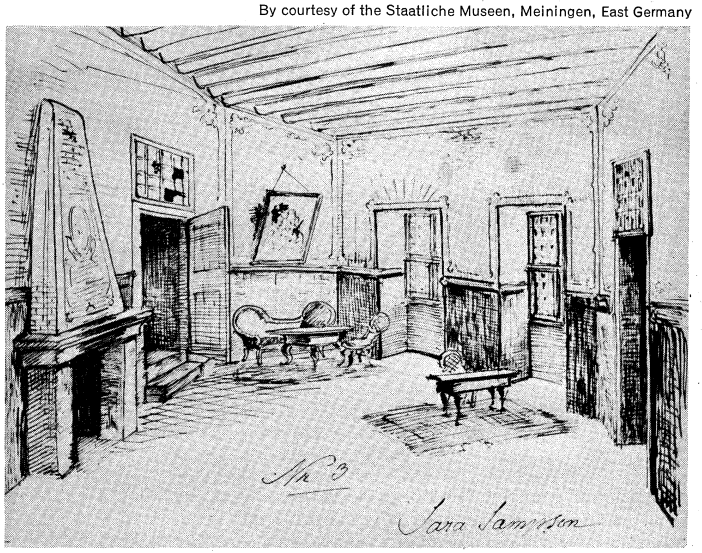


The stage itself was raked upward toward the rear, and the scenery was shifted by using the chariot-and-pole system. He introduced a system of steam vents to make a steam curtain to hide scene changes. In sum, he saw the theatre as a single instrument of which every part would function to move the audience from the commonplace to the mystical-mythical.

The Meiningen troupe

At the time Wagner was introducing his music drama, George II, duke of Saxe-Meiningen, began to take an interest in the theatre of his court. The theatre itself, built by his father in classical-revival style in 1831, had a facade decorated with pillars crowned by a Greek pediment. The building contained not only the auditorium and stage house but also an assembly hall for balls, banquets, and other nontheatrical festivities. Meiningen tried to create the illusion of reality with accurate spectacle and lifelike acting. He studied the distinctions between nations within the same historical period; the result was unprecedented historical accuracy. Meiningen also insisted on using authentic period furniture, and the success of his troupe led to the opening of theatrical supply houses. The Duke designed all scenery, properties, and costumes for his troupe. He saw a scene design as similar to an architectural design in that it directs whatever activity it shelters. He insisted on the continuous and direct relation between the design of a set and the actors' movements within it. Among his innovations was the abandonment of the practice of using only pastel colours for scenery; instead, he used richly coloured banners, foliage, and other devices instead of sky borders as overhead masking. Meiningen was one of the first designers to add to the plastic possibilities of a stage by breaking the surface of the stage floor into different levels. In one play, in which Roman generals go to negotiate with a German chieftain in his forest, the inaccessibility of the German was emphasized by fallen logs on the floor.

From 1866 to 1874 the troupe performed only in Meiningen; for the following 16 years it toured 38 cities in nine countries. It had enormous impact on the history of the theatre, as it achieved complete illusion in every facet of its productions. Saxe-Meiningen is considered the single most important influence on the directors who inaugurated 20th-century stagecraft; he introduced the pictorial mass grouping of crowds. He made every director conscious that scenery must be designed to fit the movements of actors; that lighting, properties, and costumes contribute to the creation of the visual mood; and that every detail of interpretation and stage business merits research, planning, and rehearsal. The Meiningen movement toward unified productions influenced such other major figures as André Antoine in France and Konstantin Stanislavsky in Russia, great apostles of realism and the



Wagner's staging techniques.

founders of modern theatre. Perhaps the reason that the Meiningen productions were more successful than Wagner's is that they sought not to create a passage to the world of absolutes on the stage but rather to present a world of illusion to which the theatre audience could relate directly.

Russian imperial theatre. Russian drama in the 19th century also got off to a slow start because of strict government censorship, particularly after 1825. This atmosphere was conducive, as in Germany, to the flowering of Romanticism, especially as manifest in patriotic spectacles. Melodrama, Shakespeare, and musical plays were the backbone of repertory until the 1830s. The best known plays of the new realistic school were those of Aleksandr Ostrovsky, Nikolay Gogol, and Ivan Turgenev.

Until 1882 the imperial theatres, under strict government controls, had a monopoly on productions in Russia's two major cities, Moscow and St. Petersburg. It was not until the monopolies were rescinded that public theatre was able to expand, although the state troupes, such as the Bolshoi in Moscow, continued to offer the most professional productions.

Through the 1850s each theatre had its own few stock settings. The box set had been introduced in the 1830s, but it was to take several decades to become popular. Realism began to dominate scenic design by the 1850s, particularly at the Maly Theatre. Archaeologically accurate settings started to appear in the 1860s, when one theatre hired an archaeologist to help the designer of Aleksey Tolstoy's *Death of Ivan the Terrible.* Previously, settings had followed the neutral style of the German designer Alfred Roller, whose pupils were the major designers for the state theatres. The unified production techniques exemplified by Meiningen were not to be seen in Russia until the Moscow Art Theatre flourished at the beginning of the 20th century.

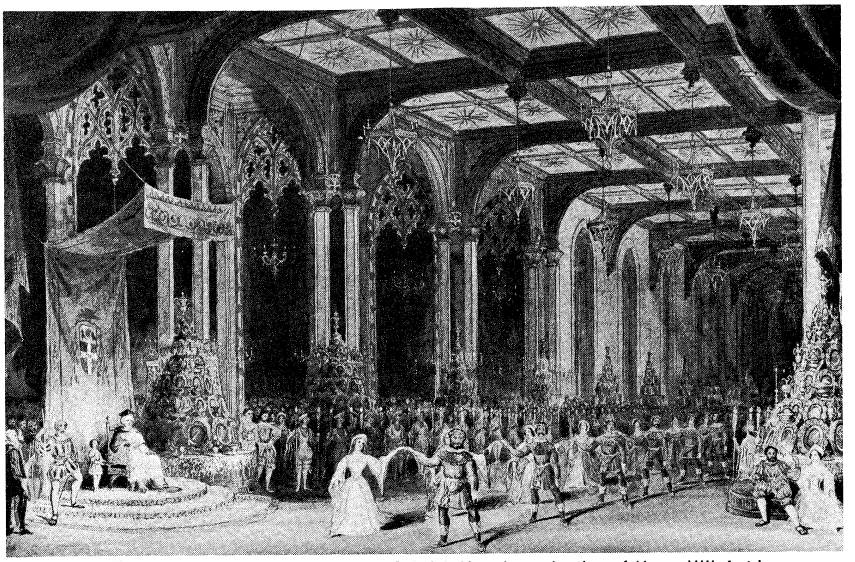
Victorian theatre. In 19th-century England, the audiences shaped both the theatres and the dramas played within them. The upper class favoured opera, while the working class, whose population in London alone tripled between 1810 and 1850, wanted broadly acted theatre with scenic wonders and machinery. And as the audience grew in number, the Georgian theatre building, which was small and intimate, began to disappear.

Designs of William Capon

In the early part of the 19th century, an important designer was William Capon. Influenced by Loutherbourg, he utilized raking pieces set at various angles and elaborate back cloths as an alternative to flats and wings. His sets were also large enough not to be overpowered by the larger theatres. One of Capon's sets, of a 14th-century cathedral, was 56 feet (17 metres) wide and 52 feet (16 metres) deep. His sets were historically accurate even though the practice of several designers independently decorating the same play was still in effect.

The productions of John Philip Kemble, the manager of first the Drury Lane and then the Covent Garden, marked the shift from Neoclassicism to Romanticism in English stage design. He put theatricality ahead of historical accuracy, as the audience demanded an increased use of spectacle with each passing year. As melodrama became more popular, the effects multiplied until, in an 1820 production of *King Lear,* the storm noises were so realistic that Lear could not be heard. In 1823 Kemble began to reverse this trend and started to use accurate sets and costumes for Shakespeare, and within 15 years archaeological accuracy was dominant.

Another important contributor to the history of staging was Lucia Vestris, an actress and manager at the Olympic Theatre. She controlled all the elements of a production and combined them into a single, integrated unit. She was also enamoured of spectacle and is credited with introducing the box set on the London stage. There is some evidence pointing to the use of a box set as early as 1794, but the first clear evidence of its use was by Mme Vestris in 1832. The sidewalls of rooms were built solidly from front to back so that the actors, instead of entering as usual between side wings set parallel to the footlights, came in through doors set on hinges. She treated the box set realistically, attaching knobs to doors and adding such touches as real books in bookcases.



By the 1840s, because of political conditions, many theatres were bankrupt. The next 20 years saw a gradual recovery, with few dramatic innovations in design. One important manager of this era was Charles Kean, a pictorial realist, whose first major attempt to insure accuracy in every production detail was made in 1852 with *King John.* In the following year, Kean gave the audience a printed list of the authorities he consulted to maintain the authenticity of each production. With the assistance of the designers Grieve, Telbin, and Lloyds, he mounted Shakespeare as lavishly as possible while at the same time emphasizing historical accuracy. In this he contrasted strongly with Samuel Phelps, whose Shakespeare productions at Sadler's Wells were simple in staging. Kean, with historical costumes, settings, and pageantry, almost buried his actors.

In the second half of the 19th century, burlesque, extravaganza, and musical drama held the largest audience appeal. The music hall also came into prominence, as incidental entertainment was separated from regular drama. In the period from 1860 to 1880, the theatre continued to expand, and the number of buildings alone increased 50 percent in the first ten years. The first manager of significance was Charles Fechter, who revived interest in the box set. He also discontinued entrances from the wings, heretofore a standard practice of actors even when the wings represented solid walls. Fechter also used a sinking stage, later perfected by the Germans, which allowed scene shifting to be handled in the basement.

The most important management team was that of Sir Squire Bancroft and his wife, Marie Wilton, at the Prince of Wales Theatre. Producing plays by Thomas W. Robertson, they succeeded in melding character and stage business. Spectacle was no longer embellishment but an emphasizing of realistic visual details. The Bancrofts' productions also finally won general acceptance for the box set; they were as accurate in modern plays as in Shakespeare; and they firmly anchored acting behind the proscenium arch. Theatre boxes had been replaced by open balconies, which no longer extended to the proscenium wall. This made it possible for the Bancrofts and others to lower the proscenium arch. In 1880 they even extended the arch across the floor of the stage to emphasize the picture frame. Modern, realistic interior settings were constantly used, and the acting was keyed to the settings. Although Fechter had employed realistic stage business as early as 1860, the Bancrofts were the first to standardize it and make it a tradition.

Trend toward realism

The greatest of the actor-managers was Sir Henry Irving, the manager of the Lyceum Theatre from 1878 to

"The Masque," painting by F. Lloyds, 1859, of Charles Kean's production of *Henry VIII*, Act I, scene 4. In the Victoria and Albert Museum, London.
By courtesy of the Victoria and Albert Museum, London

1901. The best known designers of the period, Craven and Harker, worked for Irving, who also hired archaeologists to aid in the accuracy of productions. He also imported Pre-Raphaelite easel painters: Sir Lawrence Alma-Tadema for *Cymbeline* and *Coriolanus* and Sir Edward Burne-Jones for *King Arthur*. After Irving saw the Meiningen performances in London in 1881, he modelled his Shakespearean productions on what he had seen. His most important staging innovation was to eliminate grooves for shifting scenery. In 1881 Irving introduced the "free plantation," a system by which scenery could be placed anywhere on the stage. Irving was also the first manager to use the front curtain to hide major scene changes, and he completely darkened the auditorium.

Technical innovations in staging methods

The widespread changes in staging methods during the 19th century were possible because of changes in architecture and the development of machinery. The complex scenery of the Victorian theatre required increased flying space about the stage, with a complicated counterweight system, and this in turn fostered one of the most popular features of the staging of this period. Flying, of actors as well as scenery, became an essential element in productions both of melodrama and of Shakespeare.

During this period the arrangement of the stage floor also changed to fit the requirements of spectacle. After 1850 the supporting joists of the stage were usually arranged so that the spaces between them could be used for lowering or raising scenery. Sometimes a vertical panorama would run from overhead through a cut. Floorboards laid over the joists could be moved to form "bridges" through which large set pieces could be raised or lowered.

The changes in stage floors made possible new scenic effects to meet the audience demand. The traps of the Elizabethan and Georgian eras, for instance, were greatly elaborated. The most famous trap was a "ghost glide," which made actors appear to rise from the earth and glide through space. The most lavish of the spectacles were Imré Kiralfy's *Nero* in 1890 and *Venice* the following year.

In the 1870s such three-dimensional scenic elements as platforms and steps became common. The trend was started by Edward Godwin, the father of Gordon Craig, in his sets for *The Merchant of Venice* in 1875. Probably from a desire to increase the number of three-dimensional pieces, Irving sought an alternative to the groove system of scene shifting. In its place, 135 people were hired to arrange and move the scenery. This development itself probably led directly to the removal of the raked stage, as the angled floor made it difficult to set up freestanding pieces. Another factor promoting three-dimensional pieces was that, after the introduction of gaslights, two-dimensional scenery tended to look tawdry under the new brightness. Irving, who was instrumental in accepting new developments in lighting, also introduced black masking pieces at the front of the stage to prevent light spill. Irving's importance to theatre is comparable to that of Saxe-Meiningen. His emphasis on pictorial realism was the high point of 19th-century English theatre, and this era was to continue until World War I.

Development of American theatre. The first record of a performance of a play written by an American was in 1690 at Harvard College. And the first permanent theatre, which was made of brick, was built in Philadelphia in 1766; it was imitative of English buildings in arrangement and general architecture. In 1752 Lewis Hallam, a member of a distinguished theatrical family, arrived with a troupe from England, thus marking the beginning of professional theatre in America. The theatre in America for the next 40 years was similar to English provincial theatre, with simple sets for easy travelling; there were as yet few cities that could afford a theatre. By the 1790s troupes were based in Boston, New York, Philadelphia, and Charleston, and many permanent theatres were being erected.

Early American theatre

The first decades of the 19th century brought not only multiplication of playhouses in the larger Eastern cities but also the extension of theatre to interior regions. The frontier spirit was embodied by Samuel Drake, who took the first company west (to Kentucky) in 1815. Drake designed an adjustable cut drop as a proscenium that could be set up in any large room. The front curtain was a roll drop, and three sets of wings (one each for exteriors, ornate interiors, and simple interiors) and six roll drops, including a garden, a street, and a wood, completed his scenic repertoire.

After 1825 New York City had higher standards of theatrical production and more theatre buildings than any other city in America. Although the audiences thought the theatres luxurious, they were in fact filthy and rat infested. They had little or no fire protection, and between 1820 and 1845, no less than 25 theatre buildings burned down. Although most productions used stock sets and props, occasionally an elaborate or specific set was added. Interest in historical accuracy was not a major production concern until 1830, when Charles Kean travelled with his Shakespeare troupe from England.

In 1849, within months after the Gold Rush, San Francisco started building the first of its many theatres. During the 1860s and 1870s it was a theatrical metropolis, in which vast sums were spent for European opera companies and legitimate theatre from the East Coast. Nothing noteworthy happened in stage design, however, as most troupes were geared for touring and needed only portable

scenery. Real changes came from New York, the only important centre for new ideas after the growth of the railways allowed touring companies to travel with full productions. Now it was finally possible to devote money and space to scenery and properties.

During the latter third of the 19th century, the general scenic trend was toward greater naturalism, with particular emphasis on local colour. The major design innovations came from the managers of troupes permanently based at a theatre. One such manager was Edwin Booth, whose new theatre, opened in 1869, introduced several new concepts. The most important innovation was that the stage floor was flat and had no grooves; elevators raised set pieces from the 50 feet (15 metres) of working space below the stage, and flying machines moved other pieces into the 76 feet (23 metres) of overhead space. Thirteen years before its introduction in England, the "free plantation" method of shifting scenery was used in an American theatre. In Booth's new theatre he abandoned the apron and used box sets almost exclusively.

Another important manager was Augustin Daly, who furthered the trend of realism. While the members of his troupe changed considerably during its three-decade history, it was the best example of the permanent stock company in the history of the American theatre. Daly stressed the unity of every production and controlled each element himself. His first success, *Saratoga*, by Bronson Howard, in 1870, was the first play to give a realistic picture of American life of the day.

American innovators: MacKaye and Belasco

Steele MacKaye, who also was active during this period, holds a unique place in theatre, as an actor, manager, playwright, inventor, and designer. In an age of mechanical inventions, producers were seeking a means of effecting scene changes that would not require an intermission. In 1879, MacKaye filed a patent for a "double stage," a feature he subsequently introduced in the Madison Square Theatre. He put the orchestra on top of and behind the proscenium arch and built an elevator platform on which the next scene might be set while a scene was being played below. The new scene was then merely lowered, with its own stage floor, to the appropriate level.

Among MacKaye's other mechanical innovations were a folding theatre chair with coatrack attached; a sliding stage; a theatre ventilation system; the first installation of an electric lighting system in a theatre (1885); devices to produce cloud, wave, and rainbow effects; the substitution of overhead lighting for footlights; and a process for fireproofing scenery. Some of his more grandiose schemes were never executed for financial reasons. For the Chicago Exposition of 1893, for example, he designed a "Spectatorium" for musico-spectacle-dramas; it called for a sky dome that encircled the stage, a curtain made of light, a sliding stage for scene changes, and an auditorium seating 10,000 people.

In 1896 six men formed the Theatrical Syndicate, which acquired almost complete control over American theatre. They were interested only in commercially profitable works, such as productions involving stars with large numbers of fans. The major opposition to the Syndicate came from David Belasco, a producer and playwright who had been educated in a monastery but ran away to join a circus. His aim as a producer was to bring complete realism to the stage, and it is difficult today to appreciate how spectacularly far he carried this attitude. In 1879, in his production of *The Passion Play*, the story of Jesus Christ from birth to Resurrection, he used a live flock of sheep to follow Joseph and Mary down the mountainside to Bethlehem. When the actor James O'Neill (the father of the playwright Eugene O'Neill), who played Christ, was dragged before Pontius Pilate and crowned with thorns, members of the audience fainted. And after the performance, when O'Neill walked around the city, people sank to their knees and prayed to him. The play aroused such religious frenzy that Jews were assaulted on the street outside the theatre, and a court injunction forbade further performances.

The power of the Syndicate was so great that in 1904 Belasco had to rent Convention Hall, in New York City, which had a leaky roof, for his productions. During the first performance there was a violent rainstorm, and the audience, including Admiral Dewey, had to sit through the last act holding umbrellas. Belasco's productions became so popular that the Syndicate was finally forced to compromise with him, thus breaking their stranglehold on the American theatre.

THE BEGINNINGS OF MODERN THEATRE

The new Naturalism. Ideologically, the drive to realize the full three-dimensionality of the stage was in accord with late-19th-century positivism—a mixture of science, Darwinism, sociology, and Socialism that postulated that the meaning of human character was to be found in its interaction with the physical, social, and economic environment. If such interaction is to be represented on stage, the production must create the atmosphere, as well as the appearance, of an environment. The plays of Henrik Ibsen and Émile Zola best captured the new Naturalism, and the man who did most to establish this movement in staging was André Antoine, who made his living as a clerk for the Parisian gas company.

Antoine's innovations

Antoine set up the Théâtre-Libre ("free theatre") in Paris in 1887 to produce the new Naturalist plays that were being censored by the French government, including the works of Ibsen, August Strindberg, Gerhart Hauptmann, and Henry Becque. The Théâtre-Libre became a testing ground for authenic production techniques, especially after Antoine saw the Meiningen troupe and Sir Henry Irving's company. He set out to reproduce environment in every detail—the "slice of life" school. In *The Butchers*, for instance, he hung animal carcasses on the stage. When he designed sets he arranged rooms as in real rooms and later decided which was the fourth wall to be removed.

Although Antoine insisted that furniture and props should be not only real but visibly used, he did not exclude the element of distinctive design. His schoolroom for *La Clairiere* was Naturalistic but included a formal patterning that in the objective view of Naturalism shouldn't be there. Though he did capture the fervour of the movement, Antoine's Naturalism has been overstressed.

Antoine's innovations did much to establish the principle that each play requires its own distinct setting. In 1906, as director of the state-subsidized Odéon Theatre, he produced classical plays in which he recreated theatrical conventions of the 1600s. What is significant was that he attempted to establish a realism based on past theatrical conventions instead of on architecture and dress.

The pattern of theatre reform set by France was repeated in Germany during the same period. Similar to the

Théâtre-Libre, the *Freie Bühne* ("free theatre") was founded in Berlin in 1889. Equally significant, a people's theatre, the *Freie Volksbühne*, was organized by a Socialist group in 1890. By 1900 the new realistic drama, including the works of Hauptmann and Arthur Schnitzler, had been accepted throughout Germany.

In England the rising realism was embodied in the plays of Henry Arthur Jones and Sir Arthur Wing Pinero. The first English independent theatre was organized by J.T. Grein, a native of Holland living in London. The founding producers included such eminent writers as George Moore, George Meredith, Thomas Hardy, Pinero, Jones, and William Archer. In the beginning Grein presented controversial continental plays, such as Ibsen's, but was unable to locate any daring English drama until he finally found his man in George Bernard Shaw. The Independent Theatre produced Shaw's first play, *Widowers' Houses*, in 1892. Shaw was a member of the Naturalist school, perhaps the only one with a sense of humour as well as a concern for ideas and social issues.

Russia also followed the pattern of the independent theatre movement as seen in France, Germany, and England. Although Russian playwrights had founded a realistic school of drama, theatrical productions were still similar to those of the 18th century. The Moscow Art Theatre, established by Stanislavsky and Vladimir Nemirovich-Danchenko in 1898, was the first independent theatre to emphasize theatrical production rather than censored or neglected plays. Its first play, Aleksey Tolstoy's *Fyodor Ivanovich*, accurately recreated 17th-century Russia and created a sensation. Stanislavsky sought to create the environment of a play only after visiting the actual place where the play's action occurred and after extensive research.

Reactions to realism. Between 1850 and 1900, the most famous group to oppose Naturalism were the Symbolists. The Belgian Maurice Maeterlinck was the chief theatrical spokesman for the group, which included artists from every medium. In theatre, the group was initially influenced by Ibsen's late plays and Wagner's theories about music drama. In their manifesto of 1886 they proposed that subjectivity, spirituality, and mysterious internal forces represent a higher form of truth than the objective observation of appearances. In 1890 the French poet Paul Fort set up the Théâtre d'Art to produce nonrealistic plays. Subsequently, the Théâtre de l'Oeuvre was organized in 1893 by Aurélien-Marie Lugne-Poe, who, guided by the belief that the spoken word creates the scenery, attempted to create a unity of style instead of an illusion of place and employed as designers such illustrious French painters as Henri de Toulouse-Lautrec, Maurice Denis, Odilon Redon, Edouard Vuillard, and Pierre Bonnard. Lugne-Poe's technique was typified in his production of Maeterlinck's drama *Pelléas et Mélisande*—no furniture or props were used, the stage was lit from overhead and most of the time it was in semidarkness, a gauze curtain was used so that the stage looked clouded in mist, and backdrops were painted in gray tones to convey a general air of mystery.

Appia and the music drama

The two important designers of the nonillusionistic movement were the Swiss Adolphe Appia and Gordon Craig. Appia assumed that the fundamental goal of a theatrical production was artistic unity. He concluded that there are three conflicting elements in a production —the moving three-dimensional actor, the stationary perpendicular scenery, and the horizontal floor. He recommended the use of three-dimensional units, such as platforms and steps, to enhance the actor's movement and create a bond between the horizontal floor and the vertical scenery. To unify the visual elements in a production, Appia advocated the use of light. He saw lights as changing in response to shifting emotions, moods, and actions, and he wanted to manipulate it as carefully as a musical score.

Since Appia designed few settings, and those only for Wagnerian operas, his influence spread primarily through his three books on staging and lighting design published from 1899 onward. He was brutually rebuffed by Wagner's widow, who considered Appia's projects for Wagnerian opera to be the work of a madman. In the Swiss educator Émile Jaques-Dalcroze, however, Appia found a collaborator whose rhythmic gymnastics realized the performer side of Appia's staging theories. In 1911, at Hellerau-Rähnitz near Dresden, they built a revolutionary theatre in which the stage and auditorium formed a single unified space with translucent walls that glowed with variable colouring. The acting areas, which were simple levels at the stage end of the rectangular enclosure, were a concrete expression of Appia's insistence on the primacy of the human body in movement.

Craig and the designer-director

Gordon Craig, the son of the English designer Edward Godwin and the actress Ellen Terry, started his career as an actor and became a designer at the turn of the century, just before the publication of the first of his many books on the theatre. Although he agreed with the major formulations of Appia, he disagreed with Appia's belief that the actor and the text are of prime importance. Craig held the director-designer to be supreme, and the essence of his designs was a revolt against the falseness of the realistic method. He created symbolic form and drew inspiration from Greek theatre. He substituted masses of light and shade for naturalistic detail and used imaginative statuesque shapes instead of illusionistic interiors, and he designed stages in various planes to aid movement. He dreamed of a theatre that would appeal to the emotions through movement alone, giving the audience a kinetic experience. He used curtains occasionally, but the primary and distinctive element in his work was the three-dimensional form.

Set design by Gordon Craig for the ghost scene in *Hamlet;* frontispiece from *Towards a New Theatre,* 1913, by Craig.

One of Craig's most interesting innovations was scenery made of screens with two-way hinges, which could be assembled in any shape and made in any size. The Abbey Theatre in Dublin was the first to use these screens; its director, the poet William Butler Yeats, was a great admirer of Craig. His work was similar to Appia's in that they both rejected detail and painted ornamentation. For both designers, light was used to create mood, not merely to illuminate the actors and certainly not to simulate nature. Craig's value to modern theatre has been debated. With his flamboyant rhetoric he hastened the end of archaeological painting and static stage pictures, and his campaign for the organic unity of production inspired new generations of theatrical craftsmen. On the debit side, his dismissal of the human being, the actor, has been called messianic arrogance; and his arid abstract shapes seemed interchangeable from drama to drama—the Russian painter-designer Léon Bakst called it northern pur-

itanism. His bombast provided too little guidance to concrete changes in the practicing theatre. In the long run, Appia, in his quieter, thorough fashion, was a more positive influence on contemporary staging.

Confrontations between actor and audience were the prime concern of Georg Fuchs, who founded the Künstler Theatre in Munich in 1907. He held that to be relevant, the theatre must reject the picture-frame stage and the Italianate auditorium. He proposed an indoor amphitheatre in which, on a projecting stage, the action could be thrown forward plastically into the audience. According to Fuchs, the stage designer should not try to produce an illusion of depth since depth is part of the theatre architecture and cannot be added by scenery. Fuchs's view was the culmination of the search for three-dimensionality that had passed through five essential stages since the 18th century. At first, an illusion of depth was achieved by painting perspective scenery on canvas; then the ground plan of the set was rearranged to envelop the actor with the set. The third phase was the introduction of objects for the actor to touch. With Appia and Craig there came the realization that an actor's movement shows up in contrast to inanimate objects, such as platforms and other masses. Fuchs introduced the final phase, in which the actor joins the place for playing to the area in which the audience also belongs. In Fuchs's theatre, designed by Max Littman, the acting area could be extended forward by covering over the orchestra pit, and the size of the stage opening could be changed by adjusting the inner proscenium, which had a door at stage level and a balcony above. The floor of the stage was divided into sections, each of which was mounted on an elevator so that it could easily become a platform. Four cycloramas, surrounding the stage, could be changed electrically.

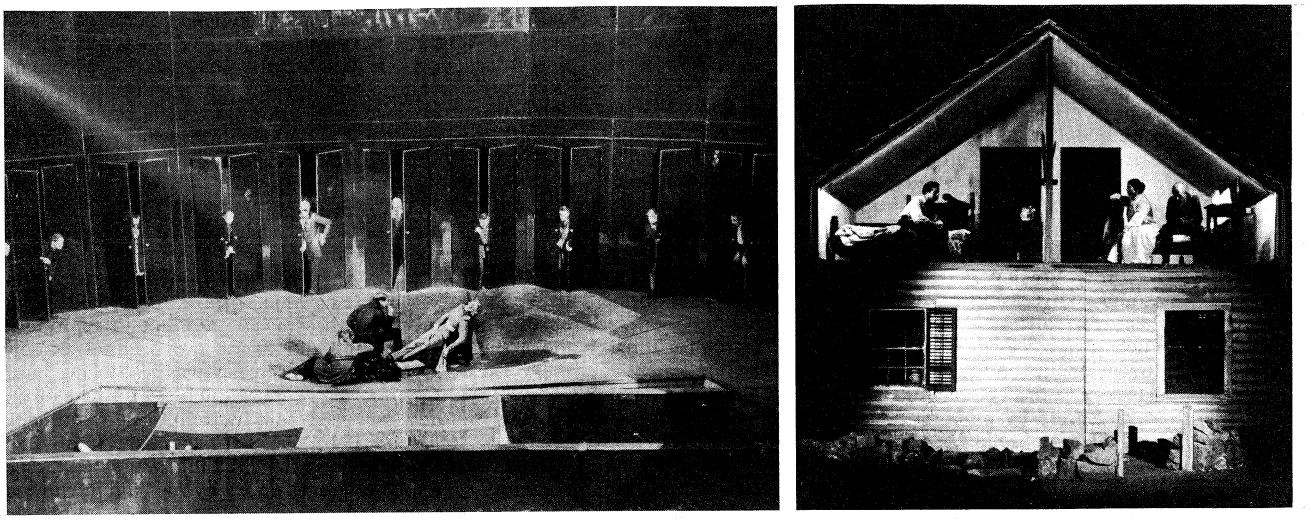
Search for the plastic stage

The next major director was Max Reinhardt, who started in 1893 as an actor at the Deutsches Theater, in Berlin, and later took it over. He initiated a series of productions that rapidly made Berlin one of the outstanding theatrical centres of Europe. While at the Deutsches, he experimented with staging at a cabaret and was strongly influenced by the advantages of an intimate atmosphere. In 1910 he staged *Oedipus Rex* in the Zirkus Schumann, an amphitheatre, in an attempt to recapture the union of actors and audience that had existed in classical Greek theatre. From 1915 to 1918 Reinhardt directed the Volksbühne Theatre, and 1919 he opened his own theatre, the Grosses Schauspielhaus, which had an open stage and every mechanical device known. This theatre was obviously derived from study of the Dionysian theatre at Athens, and he hoped that it would embody modern life as the arena had embodied the Greek community. Reinhardt was not a traditionalist, however (he showed a completely different approach when he converted a ballroom in Vienna into a formally designed intimate theatre); rather, he was a true eclectic who tried the whole gamut of theatrical invention, directing over 500 plays that represented every style. He believed that theatre, which had become shackled to literature, must be offered instead for its own sake. He re-examined the physical layout of the theatre building and the spatial relationship between the actors and the audience as part of his concept of theatrical style. Believing that the director must control every facet of a production, Reinhardt worked closely with his designers, Ernest Stern, Alfred Roller, Oscar Strnad, Emil Orlik, and the Norwegian Expressionist painter Edvard Munch. His productions usually centred on a particular motif or the staging conventions of a historical period. After beginning with a three-dimensional, drab naturalism, he adapted the indeterminate solids that Appia had inspired and then the decorative surface styles derived from contemporary art movements such as Art Nouveau, the Austrian Sezession, and Munch's Expressionism. He used unit settings with plugs (detachable parts of a setting that alter its appearance when in place), revolving stages that presented different facets of the same construction; he adapted the conventions of Oriental theatre; and he even totally renovated an auditorium interior for his production of *The Miracle* in 1911. He exerted a strong influence on the designers of the German expressionistic cinema as well as on stage artists. His eclecticism helped to reconcile the differences between conflicting movements by romanticizing the realistic and fleshing out the idealistic with solid structure.

Reinhardt's eclecticism

While most English productions during this period were in the realistic tradition, several steps were being taken toward nonillusionistic staging. One director, Sir Frank Benson, began by mounting plays in the realistic style of Sir Henry Irving but by 1900 had started to simplify his staging. He produced Shakespeare's plays with only a few stock sets, placing primary attention on the actors. William Poel, also producing Shakespeare, attempted to recreate an Elizabethan theatre. His attempt to reproduce the actual theatrical conditions of the original performance instead of historical accuracy was also being tried at the Royal Court Theatre in Munich, at the Odéon in Paris by Antoine, and elsewhere by Reinhardt and others.

English nonillusionistic staging



Between 1912 and 1914, the actor-manager Granville-Barker staged Shakespeare so that the action could be continuous, an approach influenced by his having worked with Poel. He remodelled the Savoy Theatre by adding an apron and doors in front of the proscenium. He divided the stage into three parts, the apron, a main acting area, and a raised inner stage with curtains. This permitted a continuous flow of action and eliminated the rearrangement of scripts that had previously been necessary for nonillusionistic staging. Norman Wilkinson and Albert Rutherston, artists with reputations outside the theatre, were his principal designers, and their usual settings were brightly painted, draped curtains.

Russian influences. There was, during this period of ferment, another movement that ran counter to many of the others. For the most part, the reaction against realism had taken the direction of simplifying or rendering symbolic the ordinary elements of the set. The other direction was that of the Russian impresario Sergey Diaghilev, the founder of the Ballets Russes, whose designers deliberately painted in two dimensions but emphasized the artificiality through false perspective and exaggeration. This was particularly evident in the work of Léon Bakst, Aleksandr Benois, and other members of the St. Petersburg school founded by Wronbel. In opposition was a Moscow group that included Mikhail Larionov and others who were in touch with such Parisian movements as Cubism. Diaghilev enlisted their services and later those of French painters of the stature of Pablo Picasso, Henri Matisse, Joan Miró, and André Derain.

In 1905 Stanislavsky established a studio to experiment with nonrealistic production styles, with Vsevolod Meyerhold in charge. They did not get along, for Meyerhold rejected the introspective drama of Anton Chekhov and the Moscow Art Theatre. He conceived a stage composed of machinery and abstract arrangements of scaffolding, with the actor as one who had to undergo rigorous training to climb around the scaffolding. This training, which became known as Meyerhold's system of "biomechanics," assumed that the actor is a large and wonderful engine composed of smaller engines, such as muscles and tendons. For him, the new problem of the theatre was how to get the engine in full motion—a machine-age equivalent of the commedia dell'arte principle of the actor as gymnast.

Meyerhold was succeeded at the theatre of the actress Vera Komissarzhevskaya, in Moscow, by Nikolay Yevreinov, a director who emphasized theatricality. His most important innovation was the "monodrama," in which he attempted to make the audience the alter ego of the protagonist. In his productions, Yevreinov treated the staging as though it were seen only through the mind of the protagonist. The scenery, lighting, and sound effects reflected the major character's moods and feelings.

To Alexandr Tairov, the actors under Meyerhold were puppets in his control, while the actors at the Moscow Art Theatre under Stanislavsky were dominated by the playwright. He attempted to train a company of actors who would be capable of improvising on an idea in the tradition of the commedia dell'arte and developing it in front of an audience. He believed that the future of the theatre

Early 20th century.

lay both in the synthesis of all the arts and in the development of complex machinery that would act as an extension to the performer. Influenced by Appia and Craig and assisted by lighting and the choreographed movements of actors, Tairov used space to create dynamic relationships. He saw the stage as the "keyboard" of actors and varied it with ramps, levels, stairways, and abstract shapes.

The appearance of the Ballets Russes in Paris in 1909 started a new wave of nonrealistic experiments in France. Among those who were particularly impressed was Jacques Rouché, the director of the Théâtre des Arts. His aim was not the extreme stylization of the Russians but a simplicity in which colour and line would subtly characterize a mood. He in turn inspired Jacques Copeau, who in 1913 published a manifesto for a new theatre. Copeau's philosophy was the reverse of Meyerhold's and Tairov's; he argued that the director's job is faithfully to translate a play into a "poetry of the theatre." Believing the actor to be the only important element in a production, he advocated return to the bare platform stage; he was bolstered in his stand by Appia's precepts. In the Théâtre du Vieux-Colombier, he removed the proscenium arch to create a raised open platform. At the rear of the stage he placed an alcove with a balcony, making the acting space similar to that of an Elizabethan theatre.

Copeau's formal stage

Late-19th-century technical developments. The theatre is a social institution as well as an art, and it responds more slowly than other arts to changes in form. The profound innovations of the 19th century in playwriting, directing, and acting were not immediately assimilated into the staging of plays. It was not until the late 1800s that significant technical innovations were made. Some of these innovations were motivated by the need to shift the heavy three-dimensional scenery that had replaced wings and drops. One such invention was the revolving stage, which was discovered in Japanese Kabuki theatre and adopted in Munich in 1896. Able to accommodate several settings, which were changed simply by revolving the stage, it became very popular after 1900. The rolling platform stage, introduced in Berlin in 1900, allowed sets to be mounted offstage on the platform, which then could be wheeled in on tracks. In Dresden a few years later, a complex variation was designed to use both rolling platforms and elevator stages.

Many German theatres also installed plaster domes, *Kuppel-horizants*, which curved over and around the stage, thus eliminating the need for overhead and side masking pieces (and ultimately rendering difficult any scene changing except those using a complete elevator stage). Under the influence of Wagner's theatre at Bayreuth, auditoriums were also modified during this period. Boxes were removed, the number of balconies was decreased, and centre aisles were eliminated. And as a result of the tendency to remove the separation between the actors and the audience, the apron stage returned and the proscenium arch disappeared. For the first time since the 1600s, the Italian-style theatre building had competition.

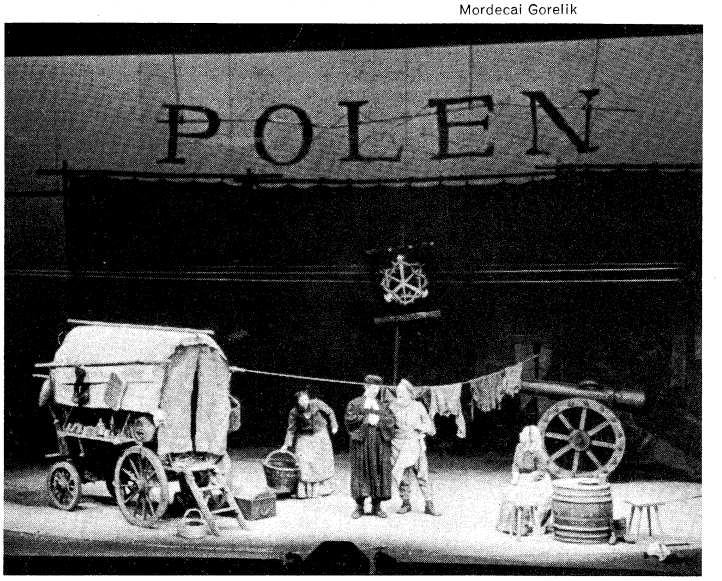
American stagecraft. The currents of innovative stagecraft eventually reached the United States. The first migration was represented by the Viennese Joseph Urban, who went to the Boston Opera before World War I, taking with him an entire atelier of draftsmen and scenic artists. They decorated the opera with the patterns of the Austrian Sezessionist movement combined with a lush, fairybook world. Urban moved into the musical comedy field and displaced the acreage of painted vistas and box sets that were manufactured by the stock scenic studios. The next change grew out of marginal experimental groups, such as the Provincetown Playhouse and the Neighborhood Playhouse, which fostered designers such as Robert Edmond Jones, Cleon Throckmorton, and Aline Bernstein. By the middle 1920s, their simple, tasteful romanticism had invaded Broadway as the groups had become commercial and as the more artistic theatre managers extended commissions to the free-lance designers. The industrial designer Norman Bel Geddes entered the growing ranks of theatre artists and devised grandiose projects and engineering marvels. With the impetus provided by ecstatic reports from Europe on the work of Reinhardt, Copeau, Meyerhold, and Tairov, American directors such as Arthur Hopkins and Phillip Moeller stressed the synthesis of all the elements of production into a persuasive whole. The imaginative poetry of Robert Edmond Jones was balanced by the sensible craftsmanship of Lee Simonson for the Theatre Guild. Simonson as the exponent of "selective realism" was more attuned to the practicalities of the earthbound psychological problems that provided the staple fare of Broadway's "serious" drama. By the 1930s, scenery consisted of solid carpentry and tasteful furnishings that were tailored to the mood, atmosphere, and mechanical requirements of the individual play. The Urban style in musical comedy design was replaced by that of Albert Johnson—a style of loose colour plus calligraphic line that was more appropriate to the sharp revues that prevailed until World War II. In staging musicals, a peculiar division persisted between the direction of the plot and comedy segments and that of the "production numbers" —the sumptuous song-and-dance displays under the overall supervision of a "stager" who was noted for his taste. Director-producer George Abbott surmounted this artificial departmentalization in an important step forward in the development of the rhythmic, lively musical show that became America's contribution to world theatre.

Staging musicals

During the 1940s many American dramatists began to break up the standard three-act format into linear strands of brief episodes. The designers devised scenery that provided a shorthand indication of locale, which could be wheeled onstage and off rapidly. The remnants of three-dimensional architecture were soon supplanted with more mobile and graceful skeletonized fragments. The convention of the toothpick framework combined with gauzes for smooth transitions was particularly helpful for the simultaneous scenes spread across the stage: indoors-outdoors, upstairs-downstairs, separated places. The skeleton-plus-gauze pattern was the characteristic scenery in the theatre of the 1940s, 1950s, and 1960s. Musicals also borrowed from the graphic arts such techniques as collage and transparencies.

In the 1950s the bitterly realistic plays of Britain's so-called Angry Young Men brought back naturalistic detail and a consciousness of environment to flesh out the abstract framework, though little attention was paid to scenery in these productions. In decided contrast were the lush revivals of Britain's Royal Shakespeare and Old Vic companies. The Absurdist dramatists, such as Eugène Ionesco in France, when they alluded to staging at all, tended to prefer "normal" surroundings as a counterpoint to the wild behaviour and nihilistic philosophy of their characters.

Recently, there has emerged a dissatisfaction with the skeleton tracery; particularly for certain classics, fragments of primitive masonry—Stonehenge fashion—were adopted. This type of scenery reflected not only an interest in myths and archetypes current in all the arts but also a romantic reaction to the chaos of the present and a search for artifacts of a time when life appeared to have had more meaning and grandeur.



The internationalism of theatre today has erased national and local styles in decor and staging. Two prime tendencies in modern production—one stemming from the work of the Germans Bertolt Brecht and Erwin Piscator and the other from the Pole Jerzy Grotowski—are global in influence.

MODERN STAGING AND DESIGN

Brecht and Piscator: epic theatre. Just as the modern theatre can be said to have come into being with Antoine and the Naturalists, the contemporary theatre of the "theatrical" was ushered in by the collaboration of two Germans—director Erwin Piscator and dramatist Bertolt Brecht. After World War I, during the Weimar Republic, Germany sheltered a wide variety of drama including Max Reinhardt's productions, the People's Theatre under Socialist Party sponsorship, the cabaret theatre of the artists of the Dada movement, and theatricals staged by the influential Bauhaus school of design, as well as standard boulevard theatre. Piscator's approach to production was personified in his production of *The Good Soldier Schweik* in 1928, which returned to the concept of the stage as a platform and added all the devices of modern technology. The result was strikingly different from traditional dramaturgy; Piscator utilized his assorted machinery to shake up his audiences, to force them to think, and, hopefully, to change the world as a result of the lessons learned in his theatre. Treadmills, revolving stages, slides, films, cartoons, vaudeville, music, and sound were used to drive home the content. This total bombardment of the audience, this use of the stage as tribunal, was called "epic theatre." The theoretician and codifier of epic theatre was Brecht, who maintained that in conventional theatre the uncritical synthesis of words, music, acting, and production were passively absorbed into the emotions of the audience in a manner that tended to perpetuate the ideology of the status quo. In place of that, he called for the conscious separation of the elements of theatre, a breakdown into logically analyzable quantities. This requires a certain objective distance from the material on the part of both the performer and the spectator, which Brecht called the "alienation effect." Conventions were borrowed from Meyerhold and the Oriental theatre to formalize the cool approach to staging. With a score by Kurt Weill, Brecht's *Three Penny Opera* (1928) established him as a dominant figure in Western theatre. That position was consolidated after World War II with the founding of Brecht's own company, the Berliner Ensemble, by the German Democratic Republic. The ensemble under Brecht presented exciting, concrete works that corrected many previous misinterpretations of Brecht that had been staged in London, Paris, New York, and elsewhere. The ensemble had a profound influence on Peter Brook and Peter Hall in England, Roger Planchon in France, and Giorgio Strehler in Italy. In the United States, Mordecai Gorelik's book *New Theatres for Old* (1940) was decades ahead of its time as a social history of theatre and as a polemic for epic theatre.

Staging of the "epic theatre"

Mordecai Gorelik

Setting for a scene in *Mutter Courage und ihre Kinder*, staged by Bertolt Brecht for the 1949 production by the Berliner Ensemble.

Brecht affected production concepts in a fundamental sense. Although there had been a revival of presentational, as opposed to representational, staging by Meyerhold and in the various attempts to reconstruct the Elizabethan stage, Brecht went far beyond these formal exercises. He used the bare platform as an arena, unmasked the full stage, and exposed the lighting equipment as tangible preconditions of an approach that negated all Romantic-Symbolic-Illusionist-Idealistic theatre. The present was treated as a historical period, and physical objects used onstage were chosen as artifacts to be handled by the performers in a manner that lifted the drama out of its customary context of an unchanging human nature set in front of different backgrounds. Brecht's designers Neher, Otto, and von Appen, evolved stage structures that were in themselves pertinent comments rather than stylistic entities. In keeping with Brecht's insistence on the radical separation of the production components, to avoid a synthesis of the kind that engendered passivity in the audience, the scenic element of his productions tended to be confined to side and back blackboards, on which the designer sketched his opinions. The danger inherent in this departmentalization is that the actor could fail to develop any organic interaction with the stage environment. Such an interaction is essential if the spectator is to put together the man and the world presented onstage.

In the 1930s Brecht's political ideas reached the United States principally through the agitational-propaganda troupes of the progressive labour movement. A full-scale expression of his ideas was a section of the U.S.-government-sponsored Federal Theatre called the Living Newspaper. Based on factual data, the Living Newspaper took social topics and developed them by any device—films, projections, loudspeaker commentary, burlesque bits, patter songs, ventriloquists, masks, puppets—to render graphic the dry statistics. The exuberant theatricality of the Living News project has never been rivalled.

Grotowski's Lab Theatre. The other major tendency in today's theatre arises from an investigation of the sources of the theatre's uniqueness and strength. The prophet of this search was Antonin Artaud, a French stage and film actor, who had a vision of a total, visceral theatre with the potency and terror of primitive myths. Like Craig and Appia, his actual performance was minimal but his writings inspired many directors, such as Peter Brook in England and Gerald Savory in France and Jerzy Grotowski, whose Polish Lab Theatre, a fiercely dedicated acting ensemble, sought to cut through the bonds of the polite literary tradition to rediscover basic human drives and conflicts. The actors undergo exhaustive exercises, designed to break down the layers of superficial technique and repressions. Each production is conceived as a unique entity, requiring its own playing space and actor–audience relationship; the rectangular hall-theatre is rearranged for each production to create a configuration consisting of onlookers, company, properties, dividers, and boundaries appropriate to the single dramatic piece. Grotowski relies on his own dramaturgical skills in freely molding the texts and on his architect-designer for the carving of the space in which the ritual takes place.

The influence of Artaud

By discarding pictorial backgrounds, disciples of both Brecht and Grotowski put more emphasis on objects, which appear, impinge on the performers in a meaningful fashion, and then disappear. Thus, the theatrical event in process supplants the story enfolded within a static environment. For the director and his designer, staging and design fuse into an indivisible organism.

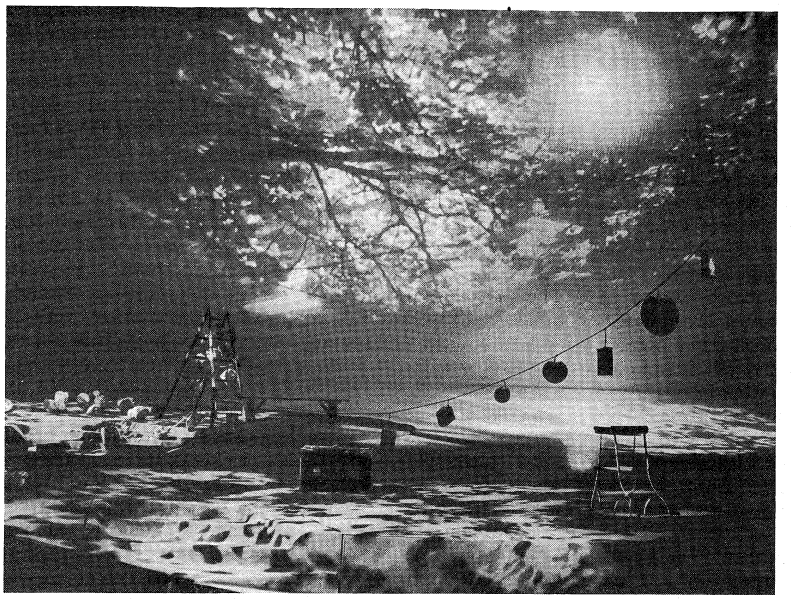
II. Scenic design

DEVELOPMENT OF SCENIC DESIGN

The execution of scenic effects passed from the guilds in the late Middle Ages to artists, with their apprentices and assistants, during the Rennaissance and the Baroque and to commercial scene painting studios from the mid-19th century until today. Each tiny Baroque state maintained a court painter and staff to embellish the court revels, masques, and operatic presentations. Large permanent companies such as the Paris Opéra, La Scala in Milan, Covent Garden in London, and the Vienna State Opera employed their own artists and shops. The independent actor-managers, stock companies, and travelling troupes and acts of the late 1800s ordered stock settings from firms that were prepared to turn out acres of mountain crags, sumptuous temples and palaces, picturesque hovels, and town squares. Historical research was crammed into every meticulously painted border, side wing, and backdrop, but no thought was given to the particular requirements of the individual scripts. The major firms printed illustrated catalogs so that single hangings or complete backgrounds could be ordered by number through the mails. Leading managers, such as Sir Henry Irving in England and Max Reinhardt on the Continent, and the French art theatres commissioned painters who either did the painting themselves or supervised its execution from their sketches. In the United States, even on Broadway, the standard procedure well into the 1920s was for the actor-producer-director to dispatch a ground plan to the scenic shop, which made up a coloured model based on research and, after approval of the design, made the finished setting. The scenic artists who made such settings were highly skilled artisans, with thorough art schooling; though they frequented art galleries and museums, they seldom attended the legitimate theatre. As a result, free-lance designers with a better understanding of theatre began to play a greater role on the New York stage, and studios arose that catered to their new, personal styles. Bergman Studios, for example, executed works by Robert Edmond Jones, Lee Simonson, Norman Bel Geddes, Donald Oenslager, and Jo Mielziner, and Triangle Studios, an outgrowth of the Urban migration from Vienna and Munich, concentrated on musical comedies. Generally, carpentry, painting, property, and drapery shops were separate businesses. Not until the 1950s would all branches of scenery making in New York be found under one roof. With the diminution of theatrical activity, the all-in-one studio is an economic necessity. In London, the shops are still separate. Most resident theatres, such as the Metropolitan Opera and the Los Angeles Civic Light Opera, maintain their own shops.

Early scenery shops

PROCEDURES



Design procedures are fairly similar throughout the world. First, the script is studied closely and notes are made of mandatory action and mechanical requirements. Next, there is a consultation with the director on a production scheme. Thumbnail sketches are expanded into colour renderings or a model, if the structure is complex or the setting is primarily plastic, usually on a scale of one-half inch to one foot. Extensive research is undertaken and incorporated into the designs. Upon approval, the sketches are translated into working drawings. The execution shops are sent a ground plan, a section to determine masking and light placement, elevations of all units, and all details that require larger scale. The designer does not break down the elements into construction pieces or into actual framing or building details; this is done by the layout man in the scenic firm. Usually there is a great deal of questioning and discussion between the artist and the technicians over the mechanics and the use of materials before the final drawings are consigned to the shops.

In spite of the marginal financial status of the legitimate theatre, the physical layout of a modern scenic shop is extensive; vast amounts of space and equipment are required for the wide variety of designs to be translated into solid items, especially in the rush of preparations for the theatre season. Templates for flats, which once occupied the major amount of floor space, have been supplanted by three-dimensional fabrication, with scene-shifting wagons and overall stage decks. More recently, a blacksmith shop has been a requirement, since metal has replaced lumber in the scaffolding and in delicate open-tracery sets. The power tools, both for lumber and for metal, and all the workbenches are mounted on castors for mobility; essentials such as traveller tracks, winch motors, and the material stock for immediate use are stored around the edges. The paint shop also has required a larger space since looser, wetter techniques were adopted and bulk objects replaced flats and drops, which could be painted on upright frames. The drapery department produces soft maskings, drapes, upholstery, and any other special scenery covering. Vacuum form machines turn out ornaments wholesale and also make sizable, lightweight plastic objects that could not be carved in Styrofoam or wood. The drafting layout room is where mechanical problems are solved, the work distributed, and models translated into working drawings. Working models have come back into use to represent the sculptured units on the open stages that have replaced traditional flat scenery of the peephole tradition. If there is room, an acting company may practice on an elaborate structure for a few days before it is moved to the theatre. Ideally, the electrical shop is incorporated into the scenic complex to service the units that onstage will come within the province of the production electrician.

Property making

Properties, once produced in quaint workshops, are now a part of the scenic firms' mundane output. Celastic casting has taken over from wood turning and whittling. The procurement of ready-made props, furniture, and dressing is handled by the property master, but the artistic choice resides with the designer. On today's open stages the primacy of properties demands the absolute rightness of every object in the visual ensemble. The theatre has sheltered the last remaining medieval craftsmen, the scenic painters and the blacksmiths; the production property master is the last all-around handyman, able to find or make any intricate contraption called for by the dramatist.

Despite the ingenuity and invention of the accredited shops, they remain deficient in two key sectors: engineering, beyond a simplistic mechanical level; and multimedia, as an organized production technique. Backstage-nurtured electricians and carpenters have not been able to

Stage design by Josef Svoboda for the 1958 production of *August Sunday* by the National Theatre, Prague, showing his use of patterned lighting to achieve special designs.
© Jaromir Svoboda

cope with complex electronic gear, and advanced film-slide devices have been left to gypsy groups. Only Josef Svoboda's laboratory at Prague's Czechoslovakian National Theatre succeeds in truly integrating science with the theatre.

Working relations in the theatre still reveal influences of their long historic development from their origins within the medieval church, through the guilds, the artists' ateliers under noble patronage, the permanent companies and their staffs, the itinerant scenic painters (the term "journeyman scenic artist" continues until this day), to the modern practice of using shops plus free-lance designers. In Britain there are now artists' and technicians' organizations primarily concerned with information exchange. In the United States there is a rigid union and guild structure geared to economic concerns. Nearly all the crafts in film, theatre, and television are under the jurisdiction of the International Alliance of Theatrical Stage Employees of the United States and Canada or of the United Scenic Artists. The production heads of departments—the master electrician and the property master—are personally selected for each attraction; under the designer's direction, they oversee first the execution of the designs by the shops, then the setup in the theatre, and finally the running of the production in the theatre. The commercial playhouses of America have no built-in equipment beyond the overhead gridiron system (*i.e.*, a series of girders from which scenery can be suspended) and the electrical power, so that incoming shows must travel with all the equipment they need, including portable switchboards and cable, as well as all lighting units.

The American system of specialization of crafts has resulted in a loss of creativity on the one hand, balanced by the maintenance of minimum craft standards, scales, and working conditions on the other. This closed system has made designing a profession and prevented the dilettantism found in other Western nations, where fine artists often accept theatre commissions and professional theatre designers are rare. This system accounts in part for both the conservatism and the technical brilliance of Broadway musical design.

The economy of New York and London theatre, which is based on one production at a time, has suffered under the competition from mass media. The relative inefficiency of the handicraft mode of operation versus automated industry has aggravated the economic problem.

Scenic design in the future

Designers have gravitated toward subsidized resident theatres in which they can work with good physical equipment and permanent creative staffs.

The future of design and staging is difficult to chart, since Western theatre is in a period of transition. The competitive nature of commercial entertainment has encouraged a pervasive exhibitionism, which in turn has prompted a rebellion against the pictorial and the bombastic and a search for the roots of what is unique in theatre—the actor-human and his immediate object world. The uncritical rejection of all technique, however, has made the concrete dramatic product tend to be arid. Ultimately, this new theatre may be fleshed out with a fresh type of colour and magic that will attract and excite more of the population than its initial primitive and puritanical experiments have done. The designers, with their command of visual tools, will then play a leading part in such a theatre. (Ho.B.)

III. Stage lighting

EARLY FORMS OF STAGE LIGHTING

The classic Greek *theatron* was built in the open air, usually on a hillside, and placed so that the afternoon sunlight came from behind the audience and flooded the performing area with light. The larger Roman theatres were also outdoors, but the added luxury of coloured awning stretched over the spectators softened the glare of the sun. Later, in the Middle Ages, the miracle and mystery plays were performed outdoors on the front steps of the church and the adjoining square. In England, the pageant wagon, complete with actors and properties, was drawn through the main street of a town. Until the 16th century, the theatre continued to be basically an outdoor institution.

Under the patronage of the aristocracy in Italy, private performances, pageants, and tableaux began to be given indoors. Serlio, the Italian architect, gave considerable attention to theatre design and in a treatise written in 1545 discussed theatre construction and the creation of lighting effects. He recommended placing candles and torches behind flasks filled with amber- and blue-coloured water. Palladio's indoor theatre, also in Italy, used the common everyday light sources: torches, pine knots, open wick lamps, and tallow candles. In England at the end of the 16th century, the Globe Theatre was used for summer performances of Shakespeare's plays, but in winter performances were given in the completely enclosed Blackfriars Theatre. Artificial light, mainly candles, was used in several indoor theatres to light the stage and the auditorium.

Beginnings of artificial lighting

In the early 17th century, Inigo Jones introduced several innovations in lighting and stagecraft, using reflectors to intensify the light sources and making use of colour on stage. The earliest known definite description of stage

lighting may be found in *Sciena d'Comoedia* (1628) by Joseph Furtenbach. He describes the use of oil lamps and candles set in a row along the front edge of the stage but out of sight of the audience, as well as vertical rows of lamps behind each wing at the sides of the stage. The common method of lighting the stage and auditorium was by means of tallow candles. As seen in old prints, these candles were mounted in crude hoops or chandeliers, which were hoisted aloft on pulleys to hang in dripping splendour. Gold decorations applied to the interior of the auditorium caught the many reflections. The inconvenience of the lighting system was that candles were expensive and hard to control. The twisted wicks had to be constantly trimmed during the performance, and this was the duty of the snuff boy. A transformation from light to darkness was effected by the agile skill of the candle snuffers.

When David Garrick used footlights at the Drury Lane Theatre in 1765, he masked the candles with metal screens. By 1784, when Richard Brinsley Sheridan managed the Drury Lane, all lights used to illuminate the stage were out of sight, hidden by the now familiar wings and borders.

A floating oil wick lamp was replaced after 1783 by the Argand oil lamp, in which the cylindrical wick was enclosed in a glass chimney to steady the flame and provide a brighter, whiter, and cleaner light source. And so the chimneyed oil lamp replaced the candle, but it was still hung in clusters above and bracketed to the walls. At the Haymarket Theatre in London, the oil lamps had chimneys of white and green glass that were controlled by levers, so that raising or lowering the chimneys could effect light changes. Actually, the result merely made the actors and scenery visible. Stage design and stagecraft had now advanced as far as was technically possible under the limitations of low-intensity stage lighting.

Introduction of gas lighting

The first major advance in several centuries was the introduction of gas lighting. A Scottish engineer, William Murdoch, developed a practical method to distill gas from coal for illumination. The first successful adaptation of gas lighting for the stage was demonstrated in the Lyceum Theatre, London, in 1803 by a German, Frederick Winsor. The Chestnut Street Opera House in Philadelphia installed a gas lighting system in 1816 and supplied its own gas by installing a gas generator on the premises. (Gas stations and city mains did not come into use before 1850.) The advantages of gas lighting were immediately realized and exploited, despite the initial cost. No new methods of lighting, however, were devised for stage lighting. The conventions remained the same: footlights (*i.e.*, a row of lights across the front of the stage floor); border lights (a long horizontal row of lights used for the general lighting of the stage from above); and striplights (a row of lights, usually mounted in a trough reflector and placed in the wings to illuminate specific portions of the stage or setting).

Even without a chimney, an open gas jet flame was brighter than oil lamps or candles. The additional advantage was control: by varying the control valves from a central point, a smooth increase or decrease of light could be effected, and at variable speeds. For the first time, to add to the realism of the play, the auditorium lights could be darkened. Elaborate central control systems were devised, with a main regulator, branch mains, more and more regulators, branch mains, and valves. This growing array of valves and pipes was organized into circuits and displayed on the "gas table"—the forerunner of the modern switchboard.

But there were also disadvantages to gas; namely, heat, offensive vapours, and the serious fire hazard of the open flame. A protective code was established to provide guards, screens, and glass chimneys and was made compulsory. In 1890, after the introduction of electric lighting, the incandescent gas mantle was developed. Although the mantle greatly improved the quality of light —brighter and whiter—the hazards of fire still remained.

Introduction of the limelight

Although Thomas Drummond, a British engineer, invented the limelight in 1816, it did not come into general use until some 30 years later. Limelight is produced by directing a sharp point of oxyhydrogen flame against a cylindrical block of lime. The tiny area of lime becomes incandescent and emits a brilliant white light that is soft and mellow. As the lime is slowly consumed by burning, the block of lime has to be slowly and constantly turned by an operator to supply the flame with a fresh surface. Since the brilliant area was very small, the addition of a mirrored reflector was necessary to give accurate control.

The intensity of the limelight permitted it to be directed onto the stage from the auditorium. Since it offered control as well as intensity, the limelight was quickly adapted to follow individual performers about the stage. The sharpness produced by the small point source made possible the creation of realistic effects, such as sunlight and moonlight, and moving effects, such as clouds, water, and fire.

ELECTRIFICATION

An advance of great importance was the introduction of the electric carbon arc, which was exhibited in experimental form in 1808 by Sir Humphry Davy. Davy used a large battery to provide current for his demonstration, since no means of mechanically generating electricity had as yet been developed. In principle, an "arc" of current across the gap between two rods of carbon heated the tip of the positive carbon to brilliant incandescence. As the carbons gradually vaporized, however, they had to be continually adjusted to maintain a constant gap. The use of the carbon arc was not practical until some 50 years later, when adequate generating sources were developed. The Paris Opéra developed the earliest electric arc effect —a beam of sunlight—as early as 1846. By 1860 the Paris Opéra had also developed a lightning machine, a rainbow projector, and a luminous fountain. Most important, the company made the earliest spotlight, a carbon arc and reflector housed in a hood, which included a lens and a shutter.

Development of incandescent light

The next great advance in lighting was the development of the incandescent electric lamp, in which light is produced by a filament electrically heated to incandescence. The invention of a practical electric lamp by Thomas Edison in 1879 marked the beginning of the modern era of stage lighting. Gas was quickly discarded; within one year the progressive Paris Opéra introduced the new system. Two years later, at the Electrotechnical Exposition in Munich, a small theatre was erected that used electric lighting exclusively for both stage and auditorium. The success of the experiment received worldwide acclaim. In London, the Savoy Theatre was the first to install the new lights; while in Boston, the Bijou Theatre followed the new trend in 1882. The following year, 1883, the Landestheatre in Stuttgart, the Residenztheatre in Munich, and the Staatsoper in Vienna were the first completely electrified theatres.

At the turn of the century, incandescent lamps were in almost universal use for stage lighting, but no new methods or techniques of lighting appeared. The conventional footlights, border lights, and striplights were merely electrified, and the arc light was used for concentrated light sources. Gradually, new improvements provided brighter lamps that were both more durable mechanically and available in larger wattages. Metallic filaments replaced carbon, and finally drawn tungsten filament lamps appeared in 1911. The use of inert gas in place of a vacuum produced lamps of even higher efficiency and larger sizes. The introduction of concentrated coil filaments made practical the development of the incandescent spotlight. And the refinement of the incandescent spotlight added an exciting new tool for the advance of stage lighting and the further development of stagecraft. Gradually the arc spotlight was replaced by the new incandescent spotlight, which provided all the advantages of flexibility and control.

In his music dramas, Wagner suggested new possibilities for the use of light and design in a unified production—a lyrical synthesis. Adolphe Appia and Gordon Craig gave tremendous impetus to the new plastic stagecraft. Their conception of the stage was a cubic volume of space bathed in a continuous play of functioning light. All the

vast optical effects of Baroque design previously obtained with paint were now possible by means of light.

About 1902, in Germany, Mariano Fortuny developed an elaborate system of soft reflected light using arc lights bounced off of coloured silk fabrics. The simulation of natural lighting was remarkable, but the entire mechanism was too bulky and intricate and required the construction of a special theatre. In the course of his experiments, Fortuny evolved a dome-shaped cyclorama, a rear wall surfaced in plaster. Flooded with light, it gave the illusion of infinite space and was the perfect means of simulating spectacular sky and background effects. Because it was dome-shaped, however, it occupied a large amount of stage space and tended to distort optical projections. In modified form, as a curved, hanging cyclorama, it became an indispensable tool of the new stagecraft. Earlier, Sir Henry Irving had used transparent coloured lacquers to coat lamps to produce colour effects, using separate circuits for each colour. Irving was also the first producer to introduce organized light rehearsals in his productions. David Belasco, with his electrician Louis Hartman, developed a standard of realism in stage lighting that anticipated the motion picture and that remains in effect in today's theatre. In their lighting laboratory, Belasco and Hartman developed and refined many new lighting instruments. Individual sources were developed and used to light the acting areas from above the proscenium as well as from the auditorium.

The first dimmer boards

The earliest types of electrical dimmer board—a centralized control of the intensity of all of the lights—followed the conventions of the gaslight era. Groups of resistance-type dimmers were permanently wired to particular circuits in the footlights or borderlights. The only open or flexible dimmer circuits were the floor pockets (*i.e.*, electrical outlet boxes set in the floor of the stage) used to accommodate a wide variety of floodlights and special effects. Like the pipes and rubber tubing of the gas mains, all electrical circuits were wired solid. The location of the large banks of resistance dimmers in permanent installations of this kind was backstage in the wings and in close communication with the stage manager, who could see what was happening on stage. Later, however, even in large Broadway musicals, the array of portable switchboards may be (and is sometimes) relegated to the cellar or some other place with a scant view of the action on stage.

With the inception of individual spotlights for controlled-area illumination, in contrast to the earlier banks of footlights and borderlights, there arose a need for a flexible patch panel, in which temporary connections of such lights could be easily made and controlled. A group of spotlights could now be placed for the most effective direction, colour, and overall intensity. It became possible, for example, to place several spotlights together to achieve the realistic effect of an actor lighting an oil lamp, upstage right, without flooding the entire set with light.

The first electricity that was commercially available was direct current. For arc lights and resistance dimmers, today or 50 years ago, direct current presents no problems, and many theatres still draw their main supply of electricity from direct current. Most up-to-date theatres have the benefit of alternating current, which allows the use of more advanced dimmers.

Use of colour in stage lighting

The use of colour in stage lighting adds immeasurably to the realistic and atmospheric mood of a setting. Through the use of contrasting colours, the power of light to reinforce plastic qualities may be enhanced, and accents of appropriate intensity may be obtained. Coloured glass is the oldest medium of coloured light still in use in the theatre. As glass does not fade and comes in a variety of pure colours as well as some tints, it may be used in permanent installations for footlights or borderlights. Glass is available in cast roundels or in sheets; in sheet form, it is cut into narrow strips and mounted in holders to protect it as it expands and contracts with changes in heat. On the negative side, glass is heavy, fragile, and expensive, and its colour range is limited.

Gelatin is an expendable colour medium made of purified animal matter that is dyed and dried in sheets. It comes in a wide range of colours, it is cheap, and its light-transmission properties are excellent. Gelatin, however, is affected by moisture, and it deteriorates rapidly under heat. Plastic colour mediums are now available in the same range of colours as gelatin and have the advantages of durability, resistance to water, and strength. Although plastic costs more than gelatin, it lasts about five times longer. Later plastic colour mediums have been made of Mylar, which is virtually indestructible and more resistant to heat than sheet glass, which is much more expensive.

LIGHT SOURCES

Illumination sources. The earliest incandescent spotlight used a rather heavy plano-convex lens. The socket assembly with attached reflector moved forward and backward in the housing in relation to the lens and widened or narrowed the spread of the beam of light. As higher wattage lamps appeared, larger-diameter lenses were required, and soon they grew too bulky. Larger and more practical spotlights were made possible by the adaptation of the Fresnel, or stepped, lens, a type of lens invented in the 1820s, consisting of thin concentric sections that allow much more efficient use of a light source and, therefore, much smaller lamps. A slightly pebbled effect on the rear of the lens helped give an even, soft light with soft edges. Fresnel spotlights became available in wattages as low as 50 or, with a 24-inch (61-centimetre) lens, as high as 10,000.

The ellipsoidal reflector spotlight

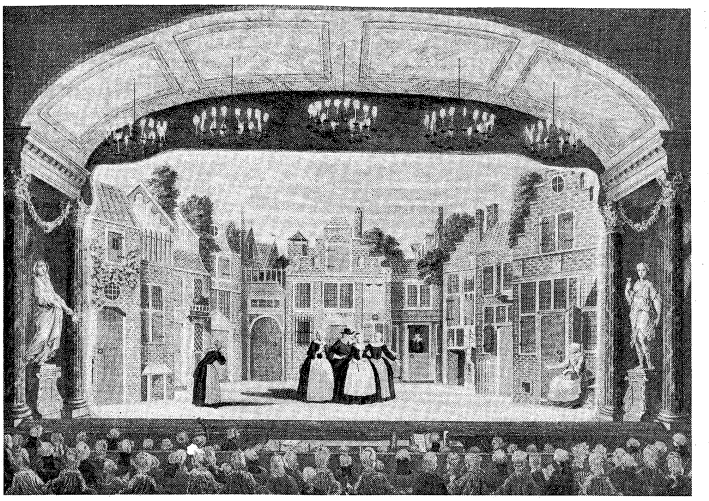
The refinement of the coiled filament made possible the development of the tubular lamp, which in turn made possible a second type of spotlight, the ellipsoidal reflector spotlight. This type of spotlight uses an ellipsoidal reflector to gather the light at the focal point of the reflector. In front of the reflector, the beam of light is shaped by means of adaptable shutters, an iris, or a predetermined pattern. One or two lenses are used as an objective to project the image. The field of the beam is of even intensity, and a hard or soft edge can be obtained by focus adjustment. The focal lengths of the lenses can be changed if necessary to compensate for the length of throw or to widen or narrow the field. Special wide-angled lenses are useful in projecting patterns, such as leaves, at close distance. Available in a range from 250 watts to 3,000 watts, the ellipsoidal spotlight is a highly efficient and versatile light source. The larger ellipsoidal spotlight can also be fitted with coloured quartz patterns of any design, from realistic clouds to abstract rotating patterns. Used in combinations at different intensities, a cyclorama can be flooded with light in either bold or subtle patterns.

Borderlights and striplights are available with wiring for control in three circuits. Older types had reflectors that produced a soft, even blend; later versions use a range of highly efficient sealed-beam lamps, such as the quartz halogen sealed-beam lamps, which are available in a variety of wattages and reflectors—from flood to narrow spot. Mounted in striplights, the sealed-beam lamps have become a versatile and effective source, either for lighting large surfaces or as a strong backlight wash. Television and motion-picture lighting has rapidly developed such sources, which were initiated in the theatre.

Use of floodlights

A floodlight is a refined version of the old bunchlight—a half dozen old filament lamps grouped into a square housing, usually painted white on the inside to serve as a reflector. Later, a single large-wattage lamp replaced such multiple lamps. Floodlights today are usually ellipsoidal reflectors in a wide or narrow beam. The reflectors are mat-finished, accommodate a variety of lamp sizes, and do not require a lens. The quality of light is soft and diffused; it is ideal for a wash of light over a drop or a cyclorama. Usually, more than one circuit is used to achieve a variety of colour changes. Large banks of fluorescent lamps with colour filters are effective in lighting a large and very high cyclorama, but the difficulty in dimming fluorescent sources has limited their use.

The parabolic "beam" projector was developed for outdoor lighting and slightly modified for stage lighting. The



familiar carbon arc searchlight, which throws an intense narrow beam of light several miles into the night sky, is a simple parabolic unit without a lens. Such a searchlight consists of a strong pinpoint source (the arc) and a large parabolic reflector of silvered glass. The same simple optical principles were adapted to incandescent lamps for floodlighting the exteriors of buildings. The output is highly efficient, but to reinforce it and control it a lens can be added in front of the source. Used in a phalanx as far offstage as possible, the beam projector can serve as a strong source to give the effect of long rays of sunlight streaking across the stage. A most significant advance was made by hanging beam projectors so that they provided backlighting; this resulted, for the first time, in the actors' being strongly separated from the background, creating an illusion of depth and a haze.

Projections and special effects. A significant amount of lighting equipment has been developed for "special effects." Standard effects include moving clouds, water ripple, fire effects, rain or snow, painted rainbows, and fireworks. For practicality, most special effects are built around a standard spotlight housing. The effect head, containing a painted or photographic transparent disk and the mechanism for revolving it, is placed in front of the spotlight housing. An additional objective lens is used to magnify and focus the image.

The oldest effect projector, dating from the World War I era, is the Linnebach lantern, often called a "scene" projector. It is simple both in principle and in construction. A concentrated light source is placed in a deep black box, and a painted slide is placed on the side of the box left open; since light travels in straight lines, the design painted on the glass is thus projected against a drop onstage, greatly enlarged, at a relatively short distance. Since no lens is used in a Linnebach lantern, the light source must be powerful and concentrated. The design must be simple and bold, for any line narrower than the point source itself will be lost. The overall effect is stylized and borders on the abstract. Rear projection with at least two projectors is required for any ambitious production. Large incandescent lights replaced the original carbon arcs in the Linnebach lantern.

About mid-20th century there was renewed interest in the use of projections. Fortunately, the development of new projection equipment provided a powerful instrument to produce effects not possible before. In the post-World War II years at the music festivals at Bayreuth, Germany, Richard Wagner's grandson Wieland reduced three-dimensional scenic elements to the barest essentials and then flooded the stage with multiple, overlapping projected patterns. In later years, more scenic elements were added to give variety of texture and depth to the flow of light and pattern. Still later at the Festspielhaus in Salzburg, Austria, the productions of Wagner's music dramas designed by Gunther Schneider-Siemssen elaborated this concept to achieve even more dramatic and sumptuous productions; he filled the vast, extra-wide stage with patterns of light in depth, softened with scrims (loosely woven meshes that diffuse the light) and translucent drops (backdrops with sections dyed to transmit some light). The Czechoslovakian designer Josef Svoboda did more than any other contemporary designer with "visions in space." For some productions, Svoboda used a direct, journalistic approach, massing three-dimensional screens to create a montage effect with slides and film. Polyvision, a production conceived and executed by Svoboda for the Czech pavilion at the 1967 international exhibition at Montreal, was a brilliant multimedia experience. In his other productions, which were equally stylized but more indirect and abstract, he used alternating surfaces of scrim and scenic elements to catch the patterned light, cast complex shadows, and float in depth before a seemingly infinite background. The concept is reinforced by a constant play of changing light upon the performers. No matter how flexible the technique of projection may be, however, it does not take the place of conventional scenery, such as a door or a flight of steps. In Svoboda's productions these diverse elements are blended together with light.

Svoboda's productions

"Street Setting, Schouwburg," hand-coloured etching, *c.* 1765, of the scenic design, showing an 18th-century theatre lit by candles.

Innovative contributions to lighting and the use of projections were also made in dance. The American Alwin Nikolais made very original use of dancers, costumes, light, and projections to form moving geometric and abstract designs. At times, the moving bodies of the dancers become the screen for the projections. The Robert Joffrey Ballet, which is also based in New York City, in its production *Astarte*, created a unique combination of film and slides on a moving, pulsating screen. The screen is a "living" element that repeats the images of the dancers as it changes contour with the development of the dance. The screen moves, strains, relaxes, contracts, and, in the end, slowly lifts to reveal the empty stage behind.

All such approaches to the theatre as a total concept combine the old and the new. The designer reaches out to try new materials, to create new textures and dimensions. The most versatile technique of blending the designer's concept into a "total environment" is the art of stage lighting.

LIGHTING CONTROLS

The dream of a practical system of remote control of lighting has always tantalized designers. Relays for remote switching have been commonplace for years. Motor-driven dimmers have proved practical for controlling auditorium lighting but for stage lighting are too cumbersome, expensive, and limited in speed control and are unpredictable in responding to changes. Banks of resistance and transformer switchboards were too bulky to be installed in a light booth at the rear of the auditorium with a clear view of the stage.

The first primitive but successful remote-controlled dimmer was used in 1890 but not perfected until later; it used a reactor coil operating on a relatively small amount of direct current to control a huge amount of alternating current.

Remote control became a reality largely as the result of the development by George Izenour of Yale University in 1948 of a dimmer using the thyratron, a type of electron tube. His concept brought continuous and instantaneous control to remote systems for the first time. In addition to its simplicity of operation, the development gave the lighting designer the facility for an "infinite" system of preset cues as an integral part of the system. It also became practical to install the control console at a vantage point in the auditorium so that the lighting designer (or operator) could see every nuance of lighting on stage.

Izenour's system of remote control

Meanwhile, transformer manufacturers developed a major breakthrough in design using new magnetic alloys. The result was a reactor with great efficiency and speed. This new reactor, combined with the silicon rectifier, another post-World War II development, resulted in a device called a magnetic amplifier—with no moving

parts or tubes, and capable of controlling large amounts of alternating current with no time lag.

Tube manufacturers, meanwhile, were furthering the development of the transistor, namely, the silicon-controlled rectifiers, or SCR, transistor-like devices which handle heavy currents and perform in the same manner as the thyratron tube, but with the advantage that they are compact in size, light in weight, low in cost, and provide instantaneous response, high efficiency, and long life. Control consoles using all three types of dimmers are in current use; future control boards will probably use dimmer units of the silicon-controlled rectifier type.

The design of lighting control boards is no longer a matter only of electrical engineering, in which the only concerns are engineering requirements or code specifications. Previously, the lighting designer had to make the most of whatever the engineers had given him. Now the remote lighting control console gives the lighting designer a flexible, artistic tool. Freed from the limitations of the mechanical controls and of the personnel who would operate them, the lighting artist can concentrate on the execution of his concept. No longer is there any reason for the mechanical limitations to interfere with the lighting.

One tool still remained to be developed—a memory bank to store all the cues of any number of productions. A console developed by George Izenour can hold ten mechanically preset cues and is practical and functional but nowhere near big enough. Various systems of punch cards, readout cards, tapes, and memory cores have been proposed to meet this problem, but the designs have been overcomplicated. Moreover, the cues were inaccessible, so that they could not be checked until they either were executed or failed to be executed. With the older ten-preset system, the operator could always turn to the particular dimmer of the preset in question and check the reading. He could see the actual value of the dimmer reading as well as every dimmer value in the entire preset. The great drawback of all subsequent systems was the lack of total visual readout of all circuits. A total visual display of the dimmer values in each cue (whether the cue is in actual operation or in a preview mode) is a practical necessity.

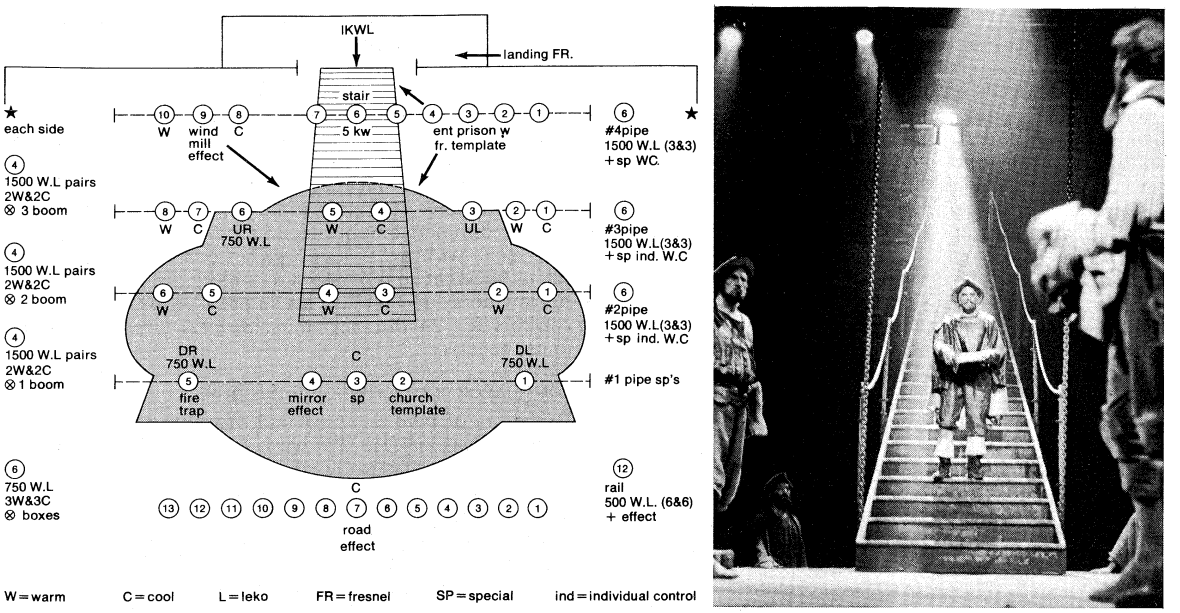
A television studio installation suggested one possibility for future stage lighting systems. Incorporated into an existing electronic switchboard, a small general-purpose computer functioned with remarkable success as the basic memory system. The console includes a large television monitor, and the cues are annotated with a "light pencil." Four fader handles (*i.e.*, devices controlling fade-ins and fade-outs) control any sequence of overlapping cues. These handles can be interfaced with any electronic dimming equipment, so that the need for an expansive array of control levers is eliminated. Any number of display monitors can be installed at strategic locations to monitor cues. Its unique value is in its constant display of cues. During a cross fade between two cues, every value change is indicated. Though cues normally follow in sequence, additional cues can be inserted or cues can be cancelled. The operator can jump forward or backward at his discretion. An agile operator can run through 70 cues in 15 seconds. A common application might be a sequence of cues timed to the beat of music.

A generous number of cues is available for storage and recall in this installation. Assuming that its lighting console has 100 dimmers, the memory bank of the computer is able to store from 400 to 2,400 cues on disk, or 5,000 cues on tape. For library storage purposes, an electric typewriter will provide printed copy of the cue sheets directly from the computer. Cartridge tape provides for storage on a season-to-season basis.

Since the heart of the system is a small, general-purpose computer about the size of a large suitcase, it can easily be moved with the rest of the production. The flexibility and adaptability of the computer system are not confined to lighting. It can be programmed for other theatre operations, including automated systems for moving suspended scenery, stage wagons or turntables, sound systems, and special effects. Since small, general-purpose computers are commercially available and need not be built to order, their price range is not forbidding.

Portable dimming equipment

There has been a long-standing need to develop portable dimming equipment for travelling. The practice of using banks of resistance dimmers (housed in a wooden crate that resembles an upright piano) came into use in the 1920s and is now considered an obsolete burden, bulky, extremely heavy, and mechanically primitive. Television has capitalized on small, lightweight silicon-controlled rectifier dimmers and produced a unitized system of dimmer racks with a five-scene preset console. A rack with six 12,000-watt dimmers is small enough to fit through a narrow door, and the five-scene preset console comprises controls for 24 dimmer units. Several consoles can be joined together.



CONTEMPORARY LIGHTING TECHNIQUES

In the era of painted wings and drops, the standard illumination was an even, flat wash from footlights and borderlights. Architecture and furniture, including tables and chairs, were painted into the background with heavy shadows and exaggerated perspective. The actors had to resort to grotesquely heavy makeup to convey any facial expression; while their very presence (and every movement) was visually in conflict with the forced perspective of the painted scenery. It is, thus, understandable that the impressive effects of modern lighting made it seem almost limitless in its possibilities. Borrowing effects from Rembrandt and other acknowledged masters, the theatre designer began to "paint with light"—putting light where he wanted it and taking it away from where he did not want it. Thus, romantic effects were born, such as that of the lone figure in a shaft of searing light, isolated by darkness. The first requisite of stage lighting, however, is visibility. Good illumination provides plasticity and modelling of the actors and of the inanimate objects. Superior lighting is orchestrated to underline the development of the drama.

Importance of visibility

Many plays permit no approach other than realism, which must be achieved by suggestive means. Nature provides the model: the time of day is suggested by the predominant directionality of sunlight or moonlight, the depth and length of shadow cast, and the intensity of light. On a cloudy day, the overcast sky diffuses the direct sunlight and produces a soft, shadowless light of low intensity, and colder in colour. Intense sunlight and the attendant light of the bright sky together produce reflected light that diffuses or fills in daytime shadows, while the ambient light of the moon reflected from sky, trees, and buildings is too weak to wash out the shadows. So by means of the direction, diffusion, and intensity of light, as well as its colour, it is possible to suggest time, place, and season.

The means of suggesting natural lighting indoors are more arbitrary. The simulated sky or sunlight seen through a door or window is essential to indicate the time of day or night; in which case, the dramatist and designer have provided the necessary scenic element. To render the feeling of bright daylight flooding a room, the strong motivating light (*i.e.*, light from a source apparent to the audience, in this instance the sunlight) must be supplemented with additional light from other directions for adequate illumination. If only a sliver of sunlight creeps through a parted curtain in a dark room as the scene begins, the mood may be retained as the scene progresses as the illumination of important areas is slowly increased with specials. Artificial light indoors is easier to suggest because it more closely approaches the normal quality of stage lighting. Actual light fixtures are used on stage to suggest the sources of the light, and opaque shades can be used on some of these fixtures so that they cast actual patches of light against walls and furniture. The exteriors seen through doors and windows are darkened and different in colour from their appearance in a brightly sunlit scene. The walls fall off in shadow even though the general illumination is more diffused and even than in daylight. Light serves as a unifying medium for the stage composition. It is a mobile and changing accent that reinforces the action, sustains the mood, and focus-

Modern lighting.

ses the attention of the audience. Light and shade, brightness and contrast, define the size and shape of objects; but it is colour that creates emotional response, mood, and atmosphere.

Use of backlighting

The dynamic potential of lighting is best realized when the changes of light underscore and propel the development of the drama. Current techniques of stage lighting use arbitrary means to create realistic effects. The first real attempt at creating space and a real haze on stage (in a depth of 30 feet) came into being with the use of backlighting—light emanating from the rear of the stage rather than the front—which made the actors appear to be pulled away from the background. At first, parabolic beam projectors were used to achieve this effect, then ellipsoidal spotlights, and later, in some instances, sealed-beam parabolic reflector lamps. The ellipsoidal reflector spotlights afford the best control and the least spill. The beam projector may be deployed in a battery offstage to create the illusion of paths of sunlight or moonlight or a strong sidelight or crosslight. For strong crosslight, clusters of low-wattage units were supplanted by powerful ellipsoidal spotlights, hung low. With the addition of lamps attached to the auditorium's boxes, or box booms, besides the lamps already on the balcony rail or ceiling coves, modern lighting began to take shape. The open stage of the musical and dance furthered the development of effective lighting.

The square pattern of modern lighting

In bold outline, modern lighting can be described in terms of a square consisting of a lucid pattern of strong backlight, paths of strong crosslight, and the necessary fill light from the front from the boxes and first pipe (*i.e.*, lights hanging from a horizontal pipe just inside the proscenium) on stage, plus special lights as needed. Richer colours are used in the backlighting and crosslighting. Lights creating warm and cool effects are wired to circuits that allow them to be controlled right, centre, and left stage. The crosslighting coming from offstage and from the box booms is usually less saturated in colour. The lights on the balcony rail give a pale wash—passive illumination to produce visibility without destroying the sharp modelling of the backlighting and sidelighting. Special lights, in colour or clear, cut through particular areas from the box booms and the pipes on stage.

When box sets began to go out of style, and suggestive sets, skeletal fragments without ceiling and walls, were introduced, the lighting technique was already at hand in the layouts for musicals. There was need for more special lights, different circuiting, softer colours, more pattern projections, and more intricate, overlapping changes of light. The pattern of back, sides, and front, however, still holds; it is a clear-cut, three-dimensional approach, with distinct functions meshing into a controlled pattern.

For the most part, ellipsoidal reflector spotlights are used to cover acting areas from all locations. Fresnel spotights are used for area washes or to accent plastic scenery elements. The appearance of scenery as it is illuminated by the lighting intended for the acting areas is totally unpredictable; it is necesary to provide separate blending or accent lighting for most plastic scenery. Patterned projections, such as leaves or abstract patterns, may be used in wide-angled, ellipsoidal spotlights to project on scenery that is solid or even made of gauze.

The three-dimensional approach to lighting, developed within the confines of the proscenium stage; it is also valid for the thrust stage or arena theatre. For theatre in the round, the predominant angles for lighting will tend to be sharper and also to be steeper, to avoid spill into the audience area that would disturb the spectators. The ellipsoidal reflector spotlight is used for all acting areas, and an added high hat (a hollow tube that extends out 6 to 12 inches) will confine unwanted spill as well as hide the lens and colour frame.

In simple language, lighting is a matter of hanging the right instrument in the right place and focussing on the right target. Stage lighting cannot be mastered except through the observation and experience that are necessary to learn the practical and aesthetic functions of light. It is essential to know the physical characteristics of different light sources and how and when to use them to best advantage. It is also mandatory to learn the complexities of control and how to build lighting changes. Stage lighting must be more than good illumination. Light must be used as a subtle flux, exerting a subconscious influence that unifies all the media of the theatre.

The creative concept formed for lighting a production requires that the essential qualities of the play be understood and absorbed. The theme or main line of the script may suggest an overriding motif: enervating heat, damp clamminess, dappled sunlight, cold penetrating north light, a feeling of being in limbo or underwater. The final choice must satisfy the particular qualities of the production and the concepts of the playwright, director, and actors, as well as the designer. Attending run-throughs in the final period of rehearsals will reinforce previous impressions and suggest refinements in the rhythmic changes of light required. The actors' performances will suggest lighting changes that can enhance the emotional range of the total performance. (Ra.Ho.)

IV. Stage machinery

In the modern theatre, a variety of mechanisms are used to erect, position, and manipulate scenery. These devices fall into three categories: hoists, lifts, and horizontal drives.

Use of hoists

Hoists are used for flying (*i.e.*, raising or lowering) scenery up to or down from the stage penthouse; lifts are used to bring up scenic elements from beneath the stage floor; and horizontal drives are used to slide platforms, flats, and large properties from the wings onto the visible part of the stage or from one area of the stage to another.

Hoists are the most common type of mechanism in the theatre, and there are three types: counterbalance, electrical, and fluid drive. The simplest method of hoisting is by counterbalancing, and there are two types, the "hemp system" and the "iron-counterweight system." In the hemp system, sandbags and iron ingots are used as a counterbalance. Four to six lines are attached to a batten; each line passes over its associated "loft block" and then goes to the master head-block sheave. There are sandbags of varying weight used to counterbalance the scenery. The iron-counterweight system is similar except that the lines are made of wire rope and the operating rope is not directly attached to the hoisting line. Instead, it is a fixed system, held between the master head-block sheave and a fixed-tension sheave. For counterweighting, there is an arbor or carriage, in which the iron weights are placed. Finally, there is a lock-rail combination to insure the safe use of the counterweights.

In an electrically powered stage hoist system, electricity may provide only the pulling power, while still requiring counterbalancing (electrical counterweight-assisted hoists), or it may provide the lifting ability and the force needed to counterbalance (pure-power hoists). There are two types of electrical counterweight-assisted hoists, traction drive and linkage drive. In the traction-drive system, the hoisting line-counterweight system is not directly coupled to the electric motor drive, and slippage develops during acceleration and deceleration of the payload. It varies according to the weight of the payload and the velocity developed. Consequently, traction-drive hoists are utilized only when a relatively constant weight is lifted at a constant velocity, such as the asbestos curtains, light bridges, and orchestra shells.

The linkage drive is similar to the traction-drive hoist, except that the hoisting lines are attached directly to the motor.

The second category of electric hoist is the pure-power type, in contrast to the counterweight-assisted type. It is composed of a motor (usually placed on a gridiron), a brake, a gear reducer, and a drum around which several hoisting lines wind. At the Metropolitan Opera House in New York, there are 110 motors linked into a single console that can be run by a single operator.

The third type of hoist is the fluid-drive system, in which an electric power unit is used to run a fluid piston, which in turn moves the hoisting lines. There are several advantages to this system: the electric generator does not have to be physically near the fluid drive, so the system is virtually noiseless; and the operator may divide the power between any number of pistons, a feat not possible with an electric motor alone.

Use of lifts

Lifts are used in the theatre to move platforms, actors, scenery, and other production elements above or below the stage floor. In contrast to the hoist, which is supported by the "over stage" structure, the lift is supported and guided by the stage floor or the cellar floor below the stage. The two general types of lifts are the architecturally integrated and the temporary production apparatus.

Architecturally integrated lifts must be designed in accordance with local building-safety codes: in New York, for instance, only two types can be built into a theatre. One of these, the direct-plunger lift, is hydraulically driven, using a piston attached to a portion of the stage floor. The piston operates under hydraulic pressure (like the pure-power hoist) and is expanded and collapsed to elevate the associated platform. The other type, the screw-actuated lift, is either electrically or hydraulically driven and coupled to a vertical screw through a nut in which the upper end of the screw is connected to a portion of the stage floor.

The layout and installation of permanent architecturally integrated lifts must be carefully determined; the frequency of use and the type of events to be accommodated must be envisioned, along with the attendant inflexibility of the permanent mechanization of the stage floor. In general, architecturally integrated lifts are successfully employed where they are designed to meet the specific production needs of a permanent resident company.

Use of horizontal drives

Horizontal drives are used to rotate, propel, and project scenery, actors, properties, etc., from the offstage areas on to the acting area. In an effort to meet the audience demand for rapidly changing scenery, designers often utilize a system of horizontally moving platforms. Although the articulation of horizontal motion on the stage is unlimited, there are several established configurations that are easily identifiable. These include the wagon, in which scenery is built on a low platform mounted on casters so that it can be quickly rolled onstage and offstage; the jacknife stage, which is similar to the wagon except that it is anchored at one corner from which it pivots onstage and offstage; and the revolve or turntable, in which several settings are built on a huge circular platform, or turntable, which is revolved so that only the appropriate setting may be seen through the proscenium. In each of these, the scenery may be changed when the unit is offstage and then rolled back on. Treadmills and revolving segments are also used. (W.Cr.)

V. Theatrical costume design

Theatrical costumes are neither historical nor contemporary; they elaborate a style and convention of their own. Their success in any production depends in large measure on the designer's ability to understand and interpret the director's production concept. The spirit of the production and the director's aims may call for special emphasis on certain characteristics in clothing. Designs may be copies of period costumes or may attempt only to evoke a period. Whether real or illusory or a subtle balance between the two, research is an important start to the designer's work. Museums and other repositories of the decorative and literary arts are rich sources of inspiration. Since the subject of theatrical costume design is so closely related to the art and history of dress, the reader's attention is called to the article DRESS DESIGN AND BODY DECORATION, in which these topics are treated comprehensively.

HISTORICAL DEVELOPMENT

Classical theatrical costume. Theatrical costumes were an innovation of Thespis, in Greece in the 6th century BC, and theatrical costumes are still called "the robes of Thespis." Athenians spent lavishly on the production and costumes at the annual drama contests since each poet was given a wealthy citizen, the *chorēgos*, who, encouraged by the honour of a separate state impresario's prize, tended to make the event a demonstration of his spending power.

The earliest tragedies were played in long, rich robes similar to those worn by the priests of Dionysus. To increase the height and importance of the principal actors, Aeschylus introduced the buskin, Asiatic elevated boots, called *kothornoi* in Greek, which became one of the chief characteristics of the Greek tragic actor. The soles increased in thickness according to the status of the wearer. To balance his height, padding often was used to add bulk to the actor's stature. The chorus did not wear these boots, so that they could dance with ease. The performers were clad in stage tunics, *chitōn*s, which were longsleeved, high-girdled, and elaborately embellished, as were their long and short cloaks (*himatia* and *chlamydes*). Aeschylus was renowned for the brilliant mounting and costuming of his tragedies, and by the time of his death, in 456 BC, a traditional tragic costume had evolved. Each costume was in a symbolic color.

Greek masks

The most important feature of the Greek costume was the mask, which indicated an actor's age, sex, station, and customary mood. The masks were made of linen, cork, or

wood and were skillfully carved and painted. Their funnel-shaped mouths acted as megaphones to amplify the voice. In his *Onomasticon*, Julius Pollux, a Greek writer of the 2nd century AD, gives a detailed account of the special features given to each character. He enumerates 30 masks used in tragedy and 17 female masks and lists the characteristics of the comedy series, which are particularly exaggerated and grotesque. Crowning the mask and adding more inches and importance to its wearer sat the *onkos*, a high ornate headdress.

Scene from a burlesque showing Heracles tempting Apollo. Actors wear short tunics and tubular pants of Greek Old Comedy. Detail from a phlyax vase in the Hermitage, Leningrad.

In the Doric mimes and Old Comedies, the upper class characters wore stage *chitōn*s and cloaks and the lower classes and slaves wore short tunics, revealing pendant phalli. These character tunics were often worn under light-fitting vests and over grotesque padding of torso and buttocks.

Mimic horses, satyrs, bird figures, and other animal imitations were much in evidence. Aristophanes, in *The Wasps*, *The Birds*, and *The Frogs*, calls for all manner of such figures and clothing. Actors performed in skins and wore horses' heads, birdlike visors, and mock wings.

In the later comedy of Menander, the phallus and mythological elements were abandoned, for his intention was to represent urban life, and the costumes worn reflected this intention. Masks became more stereotyped; they were used over and over again for character parts in different plays. The symbolic colour for characters still held great importance.

Roman drama had its indigenous roots in the Etruscan mimetic dances. Mime without masks, together with acrobatic dancing, became a favourite part of the day's entertainment at the games or circuses. Plays, too, were among the diversions; to satisfy the crowd's taste for realism and sensation, legions of spectacularly dressed soldiers were introduced to the tragedies. Costumes for tragedy were modelled on Greek styles; by Roman times the name *cothurnus* had come to designate the tragic genre itself. Kings and queens in tragedies wore appropriate padding, tall wigs, and sleeved *syrma* (the robe corresponding to the *chitōn*). Bands of bright hues decorated the costumes of happy characters, and gray, green, or blue those of fugitives. Gods and goddesses were distinguished by their insignia; seers were clad in woolen garments over a shorter, less full *syrma;* and huntsmen rolled a purple shawl around their left arms. Slaves wore leather jackets and light breeches or braids indicating their barbarian origin. In the *fabula palliata*, Roman comedies on Greek subjects and based on Greek models, actors wore *chitōn*s and the *pallium*, a cloak resembling the *himation*. In tales of Rome based on Greek models, and *fabula togata*, actors were costumed in the mantle and toga. The heroes of plays dealing with Roman history, called *fabulae praetextatae*, wore togas with the *praetexta* decoration indicating magistrates.

The *fabula Atellana*, rustic plays originating in southern Italy, were given both public and private performances. In the homes of patricians, young noblemen often took the parts of the standard characters—the bragging, greedy Maccus, the stupid Bucco, the foolish miser Pappus—wearing masks to disguise their identities. Their masks, known as *personae*, were decorated with hair; they were not worn by professional actors until introduced by the actor Quintus Roscius in the 1st century BC. Before their introduction, wigs (*galeri*) were worn. Also, Italian comedians wore a flat slipper called the *succus*.

Roman mime costume

The garment peculiar to mime productions was a gay coloured-patchwork jacket called *centunculus*, and this name became applied to mime actors in general. At Corneto, a tomb painting depicts Stupidus (the fool of the mimes) wearing another coat covered with coloured patches, a tall pointed cap decorated with a tassel, and a square, short cloak known as a *ricinium*. Because of this garment, the mime players were also known as *riciniati*. The producers of the mimes also provided their performers with gigantic phalli. "The mimes," it was said, "pulled down the gods and heroes from on high and provided them with phalli."

As drama in Rome declined, the mimes introduced plays on the theme of the oldish cuckold and the frail and plotting lover, which became most bawdy and obscene during the 6th century AD, as did the pantomimes featuring lavish licentious entertainments. Such entertainment continued to be presented until the fall of the Roman Empire later in that century. Through the Dark Ages, jugglers, fools, and small mime troupes roamed through Europe, but a record of organized drama has yet to be found.

Medieval costume. Originally, mystery plays were performed before the altar, with the actors, priests, and clerics wearing church vestments. The miracle plays, which retold incidents in the lives of saints, were also originally played by clerics and actors. Inventories were kept of garments made and bought, and these lists indicate that Adam and Eve were clad in close-fitting white leather, God in bishop's robes, and Jesus in a simple white robe. Cain, Abel, Joseph, Lazarus, and other biblical characters would appear in contemporary clothes, hoods, pourpoints or doublets, or loose gowns. A female character was indicated by the simple addition of a kerchief on the head. During the 12th century, when the performances moved outside the church, priestly vestments were still the main costumes.

When European craft guilds became responsible for the mounting and dressing of these productions, their scenic plans became ornate and ambitious and the early simplicity was lost. The exotic robes, angels with gilded limbs, halos, and ornate wings may be seen in the paintings of the 15th-century Flemish masters Lucas van Leyden, Memling, and Van Eyck. Satan and his devils enjoyed great popularity with the large audiences. Their grotesque masks, lashing tails, fangs, and snouts in lurid blacks, reds, and blues are well recorded by artists of the period. There is a large collection of devil masks preserved at the Tiroler Landesmuseum Ferdinandeum, Innsbruck, Austria.

In the morality plays, concerned with allegorical subjects, that became popular toward the end of the 14th century, costumes personified the virtues and vices, life and death, and similar abstractions. The Bible stories and morality dramas were also taken through the streets on two-story pageant carts; these processions of gorgeously dressed groups and tableaux can be seen in 15th-century paintings such as Piero di Cosimo's "Triumph of Theseus and Ariadne" and Botticelli's "Triumph of Chastity."

Renaissance costume. From the early 14th century, in addition to religious performances, secular theatre also developed in the form of popular celebrations, spectacles, royal and ambassadorial entrances, weddings, and other lavish entertainments that surround the royal courts. A monarch entering a town or dominion would do so with a large entourage in full pomp and heraldic dress. These entrances included a series of stops at stages placed at various intervals en route. *Tableaux vivant* and mimes

Costumes of royal celebrations

were performed in costumes similar to those worn in the mystery and morality plays. With the gradual decline of church power and the revival of classic ideas, Renaissance designers found their inspiration in the myths and legends of Greece and Rome.

Countries and designers competed in the sumptuousness of their displays. The progresses in England, *entrees* in France, *trionfi* in Italy were all based on the triumphal processions of the ancient world. The monarch or emperor was glorified as the hero, and his entourage and vassals appeared in semiclassical grandeur. There were floats of allegorical figures and legions of splendour such as Caesar had never dreamed.

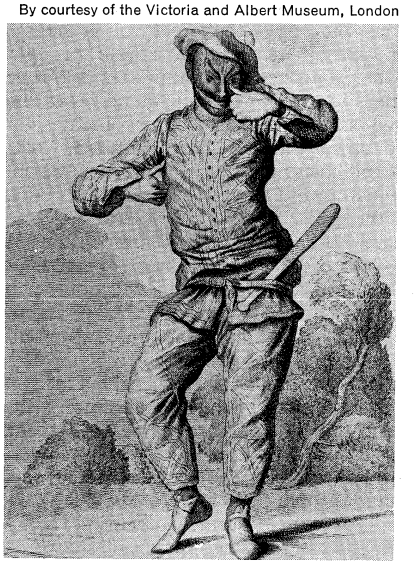
The Italian designers, who included artists as eminent as Leonardo da Vinci, led the field. Costume plates of specific festivals indicate the awe-inspiring splendour of these occasions.

At court, the tragic, comic, and satiric dramas of classical theatre were revived, with the addition of entertaining entr'actes. From these descended the intermezzi—pantomimes that included song and dance. Again, the designers wished to appeal to the eye of the Renaissance public. The designer in charge of theatrical productions for the court of Mantua in the mid-16th century explained in his treatise on stagecraft that the Italian object was to captivate and charm the audience:

> I tell you especially that I make efforts to dress the actors always in as noble a fashion as is possible for me, but in such a manner that there is a sense of proportion among them, in view of the fact that the rich costume . . . particularly in these times when pomp is at its highest peak, adds much reputation and beauty to comedies, and even more to tragedies. I would not hesitate to dress a servant in velvet or colored satin, as long as his master's costume were embroidered or decorated with gold, so rich that there would be maintained the proper proportion between them. . . . I do my utmost to dress the actors very differently from one another, and this is of great help, both in adding beauty and in facilitating the understanding of the plot.

In 1589 the sophisticated Florentine court produced an intermezzi called "Harmony of the Spheres," a spectacular type of masque, with music, that was the immediate forerunner of opera. Etchings of the Grand Ducal fetes in Florence of 1606, 1608, 1615, and 1616 show groups of dancers in towering plumed classical helmets, Roman costume, and cuirass (body armor) worn over doublets, with Roman labels hung from the cuirass, over breeches and hose, to cover the thighs. The Renaissance developed these labels into an exaggerated ornate skirt and named it the *tonneler*. Each item of costume was decorated with a profusion of curved ornaments, flowers, vines, and animal and human forms, suggestive of Baroque design.

Strongly influenced by these Florentine specialists during a visit to Italy, Inigo Jones transformed English court masques and entertainments in the early part of the 17th century. The Duke of Devonshire's archives at Chatsworth preserve his designs. Through him, English designs followed the Italian pattern: breastplates molded to the body, plumes, helmets, and various Roman kilts mixed with modified elements of contemporary dress. Ladies' costumes followed the dress of the period more closely but strove for a looseness and for the transparency of fabric typical of classical dress. Decolletage and low-cut bodices were much in evidence, with bosoms often veiled with gauze. The cost of these costumes was borne by the wearers, the lords and ladies of the court. There seemed at times no limit to their embroidered, bejewelled luxury and fine headpieces.



Besides court entertainments, literary noblemen maintained companies of professional actors to perform the new plays and classical revivals.

Early English costumes

Little pictorial evidence of the first public theatres in England survives. It is known, however, that the best part of the actors' wardrobes were gifts from wealthy patrons. One drawing of Shakespeare's *Titus Andronicus* dated 1595 shows contemporary costume mixed with *costume a la romaine* similar in design to the courtly work of Inigo Jones. Mixtures of styles and periods were accepted by the audiences. Certain famous characters such as Shakespeare's Sir John Falstaff became identified with a particular type of dress; a sketch that Inigo Jones made of Sir William Davenant in *The Temple of Love*, produced in 1635, was inscribed: "a roabe of russet Girt low w^{t} a great belley . . . the sleeues shorte . . . buskines to shew a great swolen legge . . . a great head and balde. Like a S^{r} Jon fall staff."

In Italy, the commedia dell'arte presented a multiplicity of character and types. Their fine costumes evolved from garments representing different Italian provinces and rustic personalities and gradually became stylized, subject to the dictates of changing taste. To make the costumes decorative or funny there were exaggerations in form and colour. The characters of the lovers appeared in contemporary street clothes, and comic personages in curious or grotesque garb with leather half-masks. They were ideal theatre clothes for they identified the characters, allowed complete freedom for movement and acrobatic dancing, and charmed the spectator with their amusing devices, patterns, and colour motifs. A typical character, Arlecchino, originally dressed in shreds and patches, emerged by the 17th century in a suit of red, blue, and green triangles arranged symmetrically and joined together with yellow braid. One hundred years later, the triangles became diamonds, and his soft cap was exchanged for a pointed one. Now as Harlequin he still appears as a central character in English pantomime, carrying his original wooden sword and wearing his black mask. A fine pictorial record of the commedia characters may be seen in the works of the 17th-century French artists Jacques Callot and Antoine Watteau.

Typical costume worn by players in commedia dell'arte. Anonymous German engraving of Arlecchino, early 18th century. In the Victoria and Albert Museum, London.

The commedia dell'arte toured and performed throughout Europe and was particularly popular at the French court. Molière's company also toured France in improvised farces based on the style of the commedia dell'arte. Actors in his comedies, such as *Le Tartuffe*, played in contemporary dress, but his company also performed with the King and court in brilliantly dressed spectaculars at Versailles. Texts were by Molière, music by Jean-Baptiste Lully, and costumes and decor by Jean Berain.

The introduction of actresses

The Restoration of the English monarchy in 1660 led to the opening of theatres again, and the great innovation was the introduction of actresses. Talented, confident, and flamboyant ladies replaced the Elizabethan boy actors. Records indicate that "splendidly clothed" persons lent costumes, and wardrobe keepers now aided players in selecting from available stock. The ladies chose the gown most becoming and elaborate. No attempt was made at character dressing or historical accuracy.

Costume in Baroque opera and ballet. A galaxy of specialists joined the courts of Louis XIII and Louis XIV.

with Giacomo Torelli, the chief originator of Baroque theatre, arriving from Venice. This monumental scenic style included magnificent colonnades, temples, palaces, and scenes so lavish that only the great ruling houses could afford them. Designers such as Torelli brought great prestige to their patrons. An outburst of Baroque opulence bore witness to the power and splendour of the Sun King. In France in the early 17th century, the designer Daniel Rabel worked inventively, producing many witty and droll effects and costumes of grotesque conception. Burlesque costume had found its way to amuse the court.

Henri Gissey and the great Jean Berain were attached to the Royal Cabinet of Louis XIV. Gissey is most famous for his celebrated Carrousel (1662), a horse spectacular never since surpassed in its magnificence—500 noblemen in plumed regalia escorted by a greater number of elaborately dressed attendants. Costumes represented different nations, each having a particular colour scheme: the Romans were in red and gold led by the King; the Turks in black and yellow; the Indians in white and gold; the Americans in green and gold. The marvellous scene played in front of the Louvre was indeed the grandest fantasy in costuming, with both horses and riders decorated in full Baroque trappings.

Chroniclers record gorgeous costumes appearing in ballet, opera, and dramatic offerings: gold brocades covered with lace, diamonds, emeralds, ribbons, and immense trains graced the stages of France. The French surpassed the Italians in their opera costumes, which were richer than any elsewhere. In the designs of Jean Berain there is a homogeneity of style that is the mark of a great master. In 1680 women first appeared on the operatic stage. Berain's costumes for them were serious and noble in style, based on contemporary court dress. Their tight bodices and flared basque shirts had decorative overskirts with trains; they followed an almost uniform silhouette. The headdress, also carefully designed, was a formal arrangement of feathers or lace. Male garments were in the Roman style, the tunic fitting tightly to the chest, worn with *tonneler* (short skirt), high boots, and cape. To avoid monotony, Berain devised an amazing variety of ingenious trimmings—embroideries, fringes, slashings, puffs and paddings, inlaid ornamental motives, pastes, and semiprecious stones to punctuate every small decorative panel and part. Scaly bodies, bejewelled ones, serrated leaves —every elegant or fantastic theatrical device was used to create a sophisticated ensemble. Berain coordinated all aspects of scenic decor in an equally industrious way and as a decorative artist dominated French and European taste and costume design.

Berain's costumes

After Berain died in 1711, the sumptuous Baroquerie of the early years of Louis XIV declined. Berain's son Jean succeeded his father as court designer and carefully documented his father's drawings, which are now kept at Musée de L'Opéra and at the Victoria and Albert Museum in London.

By 1721 Claude Gillot's designs for the ballet *Les Elements* showed a great change in taste. Heavy fabrics and embroideries used by Berain were replaced by lighter, more delicate weights and appliques. Ladies' costume, following the caprices of the contemporary modes, included a panier. Peasant and rustic characters began to appear and were most popular with the court, in be-ribboned garments of pastel satins and silks. Extensive records of these costumes exist in the form of engravings.

Costume of the 18th and 19th centuries. Jean-Baptiste Martin, who was appointed designer for the Paris Opera in 1748, devised decorative and amusing Rococo variations for the male dancer's traditional costume. Incas, Africans, Chinese, and Mexicans graced his ballets and under his direction the *tonneler* took on an elliptical shape.

All the elegance and sophistication seen in Rococo court circles of Louis XV were brought to the stage by Martin's successor, Louis-René Boquet. His designs were theatricalized versions of the new fashionable silhouette. Boquet clothes were delicate, artificial, and pale in tone, trimmed with garlands and Rococo finery. All Europe imitated the French ideas, the English and German facsimiles without Boquet's innate good taste.

Denis Diderot wrote in 1758 of the current fashions in the French theatre:

> Ostentation spoils everything. . . . Wealth has too many caprices: it can dazzle the eye, but not touch the heart. Beneath the garment that is overloaded with gilding, I never see more than a rich man, and it is a *man* I look for. . . .
>
> Comedy ought to be played in informal dress. On the stage it is not necessary to be either more or less dressed up than one is at home. . . .
>
> The more serious the play, the more austerity there must be in costume. . . .
>
> What expense were not our actors put to for the production of *l'Orphelin de la Chine*? How much has it not cost them to rob this work of part of its effect?

Historical authenticity of 18th-century French costumes

In 1755 the great French actors Henri-Louis Lekain and Mlle Clairon, who were also bent on more simplicity and historical accuracy, dressed Voltaire's play *L'Orphelin de la Chine* without the hoops or overskirts of currently fashionable dress, while the men appeared dressed as Tartars and Chinamen. In 1789 the French tragedian François-Joseph Talma provoked a scandal by appearing in Voltaire's *Brutus* in a severely simple toga appropriate to the ancient Roman setting of the play.

In England David Garrick abandoned heroic Roman garments in favour of realistic, contemporary dress, which he designed himself to insure the simplicity he desired. The Irish actor Charles Macklin was first to play Shakespeare in authentic "ancient dress" when he appeared on the stage in 1773 as Macbeth in a highland military habit.

Public knowledge of historical costume was increasing, though some critics disapproved of it, believing it weakened the plot. The thirst for historical accuracy won the day, in part because of the efforts of its major champion, the 19th-century playwright and antiquary James Robinson Planché. A playbill of a Planché production of 1824 read:

> Shakespeare's Tragedy of King John with an attention to Costume never equalled on the English Stage. Every Character will appear in the precise HABIT OF THE PERIOD, the whole of the Dresses and Decorations being executed from indisputable Authorities. . . . King John's Effigy in Worcester Cathedral . . . Queen Elinor's Effigy in the Abbey of Fontevraud. . . . Illuminated Mss in the British Museum, Bodleian and Bennet College Libraries . . . &c.

Planché's success amply reimbursed the management for the enormous expenditures required to make even the meanest extra's garments authentic. Correct costumes became the order of the day. The actor-manager Charles Kean splendidly mounted a series of Shakespearean productions in London in the 1850s. In Germany, August Wilhelm Iffland's productions closely followed the same reforms, and costume designers were urged to emulate the past.

Dance costume

Dancers, too, wished to be liberated from the pannier and *tonneler*. In *Pygmalion*, a ballet of her own composition, Marie Sallé danced in London in 1734 dressed only in a muslin robe like that of a Greek statue; she wore no panniers, petticoat, or bodice, and her hair was loose and without ornament. The French ballet master Jean-Georges Noverre had advocated drastic reform in dance dress as early as 1760. He proposed to put his dancers in simple draperies of contrasting colours, worn in such a manner to reveal the figure in movement. Both male and female dancers became increasingly impatient with the hampering Rococo conventions; and as dancing technique grew even more intricate, designers prepared innovations that anticipated the general development in fashion. By the end of the 18th century, every woman had abandoned her panniers and was "dressed only in a single muslin robe."

Civil codes at the start of the 19th century greatly aided those who would reform theatrical costume. The fashion for classic robes and tunics modelled on Greek and Roman patterns took to the streets; the high-heeled shoe was replaced by a flat slipper.

Leading French ballet designers of the period were Auguste Garneray and Hippolyte Lecomte. The former's work shows ingenuity in adapting contemporary dress to suggest different lands and periods. The latter was originally a painter of historical episodes; accuracy rather than imagination is the distinguishing quality of his designs. In 1832 the influence of the Romantic period was first seen in ballet with a production of *La Sylphide*. Eugène Lami designed for Marie Taglioni, the greatest dancer of her day, a muslin dress, an ethereal costume that became the new uniform of the classical dancer and is still worn today.

Opera and dramatic productions followed Planché's regard for period and regional detail. Unfortunately, the elaborate stage settings and the costumes were seldom coordinated successfully. This led the Duke of Saxe-Meiningen to design his own productions, as he wished to achieve an integrated style. He was the first of the directors who controlled all aspects of production. His example has been followed by the most prominent directors of the 20th century.

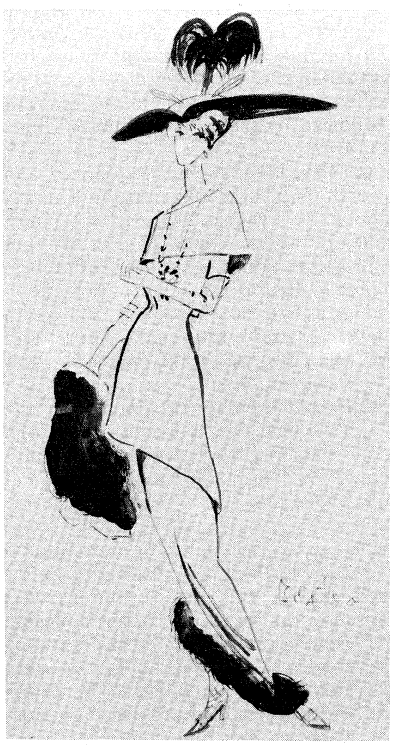
Amid spectacular scenery, large ensembles danced and mimed in fanciful versions of contemporary and historical dress in the ballet-extravaganzas of the 1880s (forerunners of the Folies-Bergères revues of Paris), that played at La Scala in Milan and the London Alhambra. The ingenious designer Wilhelm translated insects, flowers, birds, and reptiles into dance costumes. The main interest, however, lay in framing the female figure, and most of the costumes were designed to reveal as much as the law permitted.

20th-century costume. At the turn of the century the theories of Appia and Craig called for symbolism and voiced a strong reaction against the naturalism of Meiningen and the Moscow Art Theatre. Appia advocated that stage costume should evoke and suggest, but never copy historical lines.

A painters' theatre arose after Diaghilev's presentation of the Ballet Russe in 1909 in Paris. The brilliant palettes and well-coordinated decors (of Bakst, Benois, and Roerich) were praised. Natalya Goncharova's design for *Le Coq d'or* in 1914 was unprecedented in its use of vivid colours, chiefly shades of red, yellow, and orange, with other colours for discordant emphasis. The forms of the costumes and their decorations were based on Russian folk dress (of fairly recent times, though transformed and made uniquely of their epoch by the jaggered influence of Cubism). Avant-garde artists of many of the flourishing movements of modern art—cubists, constructionists, surrealists—brought about an acceleration of innovation in design concepts, which in previous centuries had evolved gradually throughout Europe.

Expressionist theatre costumes

Appia, Craig, and Diaghilev led others to experiment. Meyerhold's 1907 production of Leonid Andreyev's play *The Life of Man*, with expressionistic costumes designed by Theodore Komisarjevsky, was purely mechanical in its design. The German advocates reasoned that since the actor man is enclosed in the space of the stage, either the stage must be arranged according to the illusion of reality so as to fit the natural man or the natural man must be transformed to match the cubist and abstract space of the stage.



The most daring stage work of the 1920s was created in Dessau, Germany, by Oskar Schlemmer, of the faculty of the Bauhaus school of design He devised a costume of coils of wire projecting from black tights; his masklike designs reduced the human head to a sphere, and by means of vertical white tapes he sought to transform the human body into a spinning top. Many of his ballet designs anticipated the space suits of the astronauts.

As modern dance evolved, its rapid rhythms and pace offered the costume designer new challenges and scope for original work. The creative presentations of Merce Cunningham and Alwin Nikolais in New York presented unique shapes that attempted to express the exploration of time and space. Nikolais made his costumes part of a total stage design, a theatrical abstraction of the way he saw man—as part of a socio-economic mechanism, an agreeable but not a central part. Accused of dehumanizing the dancers, he maintained they are rather an expression of a greater state of being for man, of the experience of living in a world of motion, sound, colour, and action, which strongly affects them and is affected by them.

The rise of the American musical owes much to the close collaboration of the composers, writers, and choreographers with the designers. In a musical, the costume

designer's task is manifold. The designs must capture the spirit of the music and lyrics, interpret the period, heighten the characterization of the actors, and help the dancers in their varied, often athletic routines. The costumes for *West Side Story* (1957) and *My Fair Lady* (1956) were especially successful in these respects.

Sir Cecil Beaton

Sir Cecil Beaton's design for Liza Doolittle in the "Ascot scene" of *My Fair Lady*.

New concepts in 20th-century costume

The radical creative talents of Bertolt Brecht created new production concepts and styles: the clothes worn conveyed to the audience in a satirical fashion not only a characterization of the wearer but also his social status. Another compelling force in contemporary experimental theatre, Jerzy Grotowski, conceived his production *Akropolis* at the Polish Laboratory Theatre as a poetic paraphrase of an extermination camp. There is no hero and no individuality among the characters. The costumes are bags full of holes covering naked bodies, and the holes are lined with material suggesting torn flesh; wooden shoes cover the feet, and anonymous berets the heads.

A form of 20th-century pageantry can be seen in the designs of Tanya Moiseyevich for the simple thrust stage of the Tyrone Guthrie Theatre, Minneapolis, Minnesota, and the Festival Theatre, Ontario, Canada. For the brilliant productions of these theatres, with their deft handling of large crowd scenes, highly skilled costumiers are engaged each season. The costumes and props that they make enhance the productions' limited scenic elements, recalling the style of the Greek classic theatre and that of Japan. The growth of such regional theatres in Europe and the United States has afforded many opportunities for costume designers. Most of the opera and repertory companies that operate in larger cities have their own well-established costume workshops.

CONTEMPORARY COSTUME-DESIGN PROCEDURES

Coordination of costume sketches with the scenic and lighting designers' schemes is essential from the start. The line, shape, and colour of the entire company's costumes must be viewed in relation to the set and the production's lighting plot. Rough preliminary sketches are made and discussed, revised, and redrawn. A thorough and creative meeting of minds at this stage is invaluable. It may be necessary to call many production meetings before the final rough sketches are approved by the director.

The costume designer

The costume designer can now search for the appropriate fabrics. Fabric buying is a time-consuming and arduous task, conditioned by the size of the production budget. Costumes can be made from an enormous variety of materials; often what is needed can be located only with ingenuity and imagination in some unusual place. The correct weight and weave must be selected if the cutter and draper are to translate the sketches into fact. The fabrics must be suitable for shaping and molding the silhouettes and styles as indicated by the designer, and they must hold up for as long as the production runs. Heavy-textured wools, fine cottons, upholstery fabrics, industrial felts and rubbers, natural fibres, and man-made stiffeners all help to create costumes for varied stage characters. When they are finally selected small samples of the fabrics are stapled to the rough sketches.

Once the cast list is made known, final costume renderings can be completed. Many designers sketch details of all millinery, wig work, and accessories. Hand props, such as snuff boxes, are also often considered the costume designer's responsibility. Spectacles, parasols, and walking sticks also fall in this category.

The costume maker

The management submits approved final designs to costume makers and invites bids. The costumers estimate prices according to the number of man-hours required for manufacture and the price of the fabrics to be used. The designer often confers with the producer regarding the figures submitted by the costume makers. The designer may recommend a particular firm because it has the craftsmanship and skills required for a particular style of work. Contracts are finally drawn up and construction begins.

A costume house is staffed with experienced and creative crafts people, who translate all items of the costume sketch into shapes fashioned in the chosen fabrics. Millinery, jewellery, armour making, and dyeing can often be supervised by the designer under one roof. The construction of costumes starts with the appropriate underwear and necessary padding. Corsets, hooped skirts, panniers, bustles, and petticoats form the base on which period silhouettes are fashioned; they are fitted on the actors before the basic muslin pattern of the overgarments. On the skills of the cutter, draper, and fitting hands rests the ultimate success of the finished garment. All fittings are crucial, and the designer normally is present to supervise.

At the second fitting, shoes, wigs, and headwear must be tried on; and at the third and final fittings, the complete outfit is presented for approval of the designer and cutter. The dress parade follows, usually held onstage before the appropriate setting. This parade, ideally, is held at least ten days before the dress rehearsal to allow for revisions by the director. Despite the long continuing collaboration, the designer still may find himself spraying, re-dyeing, and artificially aging garments to make the stage picture perfect in every detail. Last-minute adjustments can be most satisfying. When the costumes are completed, the production's own wardrobe staff takes over responsibility from the costume house. Supplied with inventories and wardrobe plots, the staff takes care of all items during the run of the production. (M.H.)

VI. Theatrical makeup

Theatrical makeup is the practice of painting, enhancing, or altering the face and body of the actor with cosmetics, plastic materials, and hair; it is also the collective term for the materials used in making-up. Actors have used makeup in the theatre for a long time, not only to look their best and to transform their appearance but also to ensure that they will be seen and recognized by the entire audience. How well an actor is seen depends upon the distance between him and the farthest spectator and the amount of available light. Distances blur the features and make recognition of the actors extremely difficult for the spectators.

EARLY DEVELOPMENT

It is impossible to say when the first actor daubed paint on his face in an attempt to make his performance more effective. Some maintain that Thespis, the first actor to

step out of the chorus in Greek theatre in the 6th century BC, smeared his face with white lead and red cinnabar. He may have done so, but the very large size of some of the Greek theatres (containing up to 15,000 spectators) made the use of the masks a more practical solution. Not only did masks enable the actor to play more than one role but their larger-than-life size and exaggerated features enabled the audience to identify the actor's role from a distance.

Use of masks

The Roman theatre borrowed and continued the use of the mask. Evidently some actors thought that their own faces would be more effective, however, since there are contemporary descriptions of certain mimic actors with painted faces. Like the Roman mimes, the travelling actor-comedians of the commedia dell'arte in the 16th century developed a set of stock characters using masks. There may have been some continuity of tradition, for there are resemblances betweeen the comedians' leather masks and those of the Roman farces.

As actors in the 17th century began to perform in permanent theatres, in which they were separated from the audience by the proscenium arch, they had to deal with the problem of making the face look distinctive in illumination from candles and oil lamps. It is probable that the actors adapted the cosmetics of fashionable ladies to their own use.

The use of cosmetics increased greatly during the 18th century. Women, and men to a lesser extent, painted their faces with lead oxide for a pale complexion and cinnabar (mercuric sulfide) for rouge. Both were poisonous compounds. With the widespread use of cosmetics it was noticed that the paler faces were easier to see in dim light. By the 1770s the use of white paint was general upon the stage even though it tended to conceal the expressive motion of the muscles.

The impact of artificial light

The introduction of limelight in 1816, of gaslight in 1817, and arc lights in 1846 created the necessity for a more subtle use of cosmetics on the stage. The actor's palette consisted at this time of white chalk, carpenters' blue chalk, papers impregnated with red colouring, and India ink. Some actors were known to make up their faces with whitewash rubbed off the walls, dust scraped from red bricks, and black from a burned match, paper, or cork. Credit for the invention of greasepaint belongs to Carl Baudin of the Leipziger Stadt Theatre. Wishing to conceal the join between the front edge of his wig and the forehead, he mixed a flesh-coloured paste of zinc white, yellow ochre, vermillion, and lard. By 1890 theatrical greasepaints were available commercially in many colours, and other items of makeup also began to be manufactured for use in the theatre.

CONTEMPORARY PRACTICES

The practice of makeup in the theatre has changed greatly with the wave of vitality that swept over the theatre after World War II. As the stage was thrust into the auditorium and the audience was arranged experimentally on all sides of the acting area, the actor was brought closer to the spectator, making close scrutiny possible. Poorly executed and heavy makeup looked obvious, and several time-honoured practices had to be abandoned. Red dots in the corners of the eyes and the use of bright eyeshadow (which had first been used to counteract the effects of footlights) appeared ridiculous. Actors began to reject greasepaint in favour of a makeup that had been developed for the motion picture industry, a water-soluble cake makeup capable of being spread in a thin wash of colour, making a completely natural look possible. The desire for naturalism in appearance became very important.

Many improvements in makeup techniques were developed primarily for films and television and rapidly adopted by the theatre. There has been a great change in theatrical wigs, for example, which once had a band of silk that was blended with colour into the forehead This type of wig was not successful for film work since the join was obvious to the camera. A new type of wig was developed, and now most wigs for films and theatre are made with an edge of plastic lace into which hairs are knotted. When the lace is glued to the forehead the hairs seem to grow from the skin, resulting in a natural-looking hairline.

Film and television makeup artists have perfected the use of foam rubber and plastic facial appliances to the point that a young actor can be transformed into a very old man and yet withstand the scrutiny of a camera close-up. This process frequently takes a makeup artist and an assistant four hours to complete. Audiences accustomed to these miracles of transformation are beginning to expect the same verisimilitude in the theatre. But this kind of makeup requires more time than is generally practical in the theatre, and the cost could be prohibitive. Theatres cannot hope to compete with the motion picture industry: one film budgeted $1,500,000 to transform a large cast of actors into realistic-looking apes.

There is a growing trend in the theatre to include makeup in the total production design. What was once considered the prerogative and responsibility of the individual actor is now being influenced by designers, directors, and, in some instances, by makeup artists. In most German opera houses, for example, singers are not allowed to do their own makeup. A staff of makeup artists assures that each makeup is executed as designed and that the style is consistent. This expert supervision has hitherto been considered possible only in the motion picture industry or in commercial television because of costs, but government subsidy of theatres and television in England and other European countries has enabled the hiring of such specialists. Rubber latex makeup can be used on the stage to give the skin the textured look of extreme old age, to make bald caps, and to make realistic-looking false noses, jowls, and other forms of sagging flesh.

The emphasis upon design and production techniques in recent years has, in the opinion of some, tended to minimize the importance of the actor and, therefore, of makeup. Jerzy Grotowski, director of the Polish Laboratory Theatre, said that his experiments indicated that theatre could exist without makeup, though he did not wish to eliminate it entirely. Rather, he advised the actor to try to form himself without its help; then, if it is used after all the changes possible without makeup have been studied, it will be much more expressive and will surpass all technical tricks.

Others have sought a return to primitive origins, to a ritual theatre of magic and fantasy, unencumbered by the constraints of objective reality. Experiments in ritual theatre tend to result in the use of masks or a decorative style of makeup, as is found in Chinese opera and Kabuki theatre. (S.D.)

Stahl, Georg Ernst

Georg Ernst Stahl, German physician and chemist, developed the phlogiston theory, the first comprehensive explanation of the phenomenon of combustion and of such related biological processes as respiration, fermentation, and decay. While Stahl's theory was eventually replaced by that of Antoine Laurent Lavoisier (1743–94), it dominated chemical thought for almost a century and provided a rational basis for much useful experimental work. It led Stahl himself to define the relationships between acids, bases, and salts; to determine the relative strength of acids; and to distinguish between the bases of sodium and potassium.

By courtesy of the Bildersammlung des Universitatsarchivs, Martin-Luther-Universitat Halle, Wittenberg, East Germany

Stahl, copper engraving attributed to a member of the Bernigeroth family, 18th century.

Early training

Stahl was born on October 21, 1660, in Ansbach, Franconia, Germany. He grew up under the influence of Pietism, a vigorous movement for moral reform in the Lutheran Church that had begun to spread across Germany. German Pietism stressed the inward, practical, devotional, and tolerant aspects of Christianity in a manner not unlike that of the Friends (Quakers) in England. Stahl studied medicine at Jena, Thüringen. His teacher, Georg Wolfgang Wedel (1645–1721), was a proponent of the chemiatric school, which sought to explain life processes in terms of chemical composition. Even when Stahl later broke new ground in chemistry as well as in medicine, his early training remained apparent in his firm belief in the essential unity of these two sciences. At Jena, Stahl formed a close friendship with his fellow student Friedrich Hoffmann (1660–1742). Stahl graduated in 1684, having begun to teach the year before. In 1687 he was appointed court physician by Johann Ernst, duke of Sachsen-Weimar.

In 1694, Frederick III, elector of Brandenburg, founded the University of Halle. When Hoffmann was asked to organize the medical school of the new university, he asked Stahl to join him. For the next twenty years the two worked side by side; Stahl taught theoretical medicine, physiology, pathology, dietetics, pharmacology, and botany, while Hoffmann lectured on practical medicine, anatomy, physics, and chemistry. But gradually deep temperamental differences and increasingly divergent views on theoretical questions divided them. Hoffmann became an ardent convert to the school of iatromechanics, which saw living organisms as machines to be explained by the laws of classical mechanics. Stahl could not accept such an oversimplification. He remained faithful to his iatrochemical training in seeing physiological processes as chemical changes, but he insisted that neither mechanical nor chemical laws alone were sufficient to account for the phenomenon of life. To live, an organism required direction by a force for which Stahl used the Latin word *anima*. That word, the full meaning of which is not well caught in the usual translations of "soul" or "spirit," gave rise to the name animism for this theory. Vitalism and antimaterialism are later words for very similar views.

Their opposition in scientific matters eventually destroyed the friendship between Stahl and Hoffmann. The friends became rivals and, at last, enemies. Stahl must have welcomed his call in 1716 to Berlin, where he served as personal physician to Frederick William I, king of Prussia. He died there on May 14, 1734.

Assessment

Stahl's contributions to science are to an extraordinary degree reflections of his personality. By character he was contemplative, melancholy, and deeply inclined toward the inner-directed religious Pietism of the late 17th century. His intellect, on the other hand, was analytical and sweeping and compelled him toward large abstractions in the manner of the 18th century. Stahl bridged two ages, as did his phlogiston theory. It was the first systematic account of chemical transformation, but without the concepts of atom or element. The roots of his ideas lie not in the prior use of the word phlogiston by Jan Baptist van Helmont (1577–1644) or in the vaguer theories of Johann Joachim Becher (1635–82) but in Aristotelian thought: phlogiston is the property of being combustible that is lost in the process of combustion but that may be regained by contact with materials especially rich in phlogiston, such as coal. On an ancient philosophical foundation, Stahl built a practical theory that clarified fundamental chemical concepts.

Stained Glass

All coloured glass is, strictly speaking, "stained," or coloured by the addition of various metallic oxides while it is in a molten state; nevertheless, the term stained glass has come to refer primarily to the glass employed in making ornamental or pictorial windows. However, the singular colour harmonies of the stained-glass window are due less to any special glass-colouring technique per se than to the exploitation of certain properties of transmitted light and the light-adaptive behaviour of human vision. Rarely equalled and never surpassed, the great stained-glass windows of the 12th and early 13th cen-

turies actually predate significant technical advances in the glassmaker's craft by more than half a century. And much as these advances undoubtedly contributed to the delicacy and refinement of the stained glass of the later Middle Ages, not only were they unable to arrest the decline of the art, they may rather have hastened it to the extent that they tempted the stained-glass artist to vie with the fresco and easel painter in the naturalistic rendition of his subjects. Neither painting on stained glass nor its assembly with grooved strips of leading is an indispensable feature of the art. Indeed, the leaded window may well have been preceded by windows employing wooden or other forms of assembly such as the cement tracery that has long been traditional in Islāmic architecture; and the single most important technical innovation in 20th-century stained glass, slab glass and concrete, is a variation on the earlier masonry technique.

ELEMENTS AND PRINCIPLES OF DESIGN

Of all the painter's arts, stained glass is probably the most intractable. It is bound not only by the many light-modulating factors that affect its appearance but also by comparatively cumbersome, purely structural demands. And yet no other art seems so little earthbound, so alive, so intrinsically beguiling in its effect. This is because stained glass, far more directly and intensively than other media, exploits the interaction between two highly dynamic phenomena, the one physical and the other organic. The physical factor is light and all of the myriad changes in the general light level and the location and intensity of particular light sources that occur as a matter of course not only from moment to moment but from place to place—a prairie to a forest, a greenhouse to a dungeon. The other phenomenon is the spontaneous light-adaptive process of vision, which seeks to maintain orientation in all luminous environments.

Architecture, by determining the apparent brightness value of the light seen through its window openings, always establishes a definite scale of brightness values with which the stained-glass artist must work. Because the light that penetrated the interior of the 12th- and early-13th-century church took on a brilliance, even harshness, in contrast to the surrounding darkness, the artisans of the period very logically composed their windows with a palette of deep, rich colours. When for doctrinal or economic reasons only clear glass could be used, it was decorated with a fine opaque mesh of grisaille, or monochromatically painted ornament, that effectively broke up and softened the light. Later, as the walls of the churches were opened up to admit more and more light, the difference between the interior and exterior light levels was no longer great enough to illuminate the dense, saturated rubies and blues of the earlier period. In the 14th and 15th centuries, generally higher keyed, drier, and more muted colour harmonies were developed. This reflected a growing preference for lighter, less awesome effects and an actual limitation that the architecture of the time imposed upon the medium of stained glass.

Role of light

The static elements of the glass and its architectural setting are modified by the element of change inherent in natural light. A seemingly endless spectrum of changes in the appearance of stained glass is a result of the changes in the intensity, disposition, atmospheric diffusion, and colour of natural daylight. The luminous life of stained glass, therefore, can best be observed by watching the organic effect of light on the window through the course of a day. If one were to enter the Cathedral of Chartres just after sunrise on the morning of a clear day, it would be to the east windows, especially those in the clerestory, that his eyes would first be drawn. They alone will have come fully to life and all of the others will still seem to half-exist in a kind of hushed twilight. Gradually, as the sun rises in the sky, these windows will become more luminous. Then the east windows will begin to lose their earlier brilliance to those all along the south flank of the cathedral, which by midday will be fairly aglow from the direct rays of the sun. The light streaming through the south windows, however, will have raised the light level inside the north windows opposite them sufficiently to create a distinct, though by no means unpleasant, muting of the radiance of the latter. If the sun at this point disappears behind a cloud and the sky becomes generally overcast, the appearance of all of the windows is immediately and dramatically altered. Because the light, now diffused, comes more or less equally from all directions, the south windows will lose some of their earlier brilliance and vivacity and the north windows will recover theirs. The overall atmosphere of the cathedral is distinctly cooler and graver in its effect, and more than ever before one begins to become aware of absolute differences in the tonality of the various windows themselves. The grisaille windows in the east end of the cathedral, the highly keyed 15th-century window in the Vendôme Chapel in the south aisle of the nave, and the three 12th-century windows over the great west portal all stand out as being substantially more luminous than the rest. If, late in the afternoon, the sun reappears, the viewer is treated to an extraordinary spectacle as the blues in the west windows, by far the most intense in the cathedral, are further emblazoned by the direct rays of the sun. Should the main doors of the cathedral be opened, the direct rays of the late afternoon sun, streaming halfway down the nave of the cathedral, will cast a blinding pall over all the windows within their vicinity until the doors are closed once more. Then as the sky begins to redden with the setting sun, the intense 12th-century blues in the west windows lose their former intensity, and the warmer colours, especially the rubies, become so fiery and assertive that they seem almost to have displaced the blues as the predominant colour in the windows. Finally, when the sun is gone the whole cathedral is plunged once more into a deep twilight, which gradually diminishes until there is no light at all.

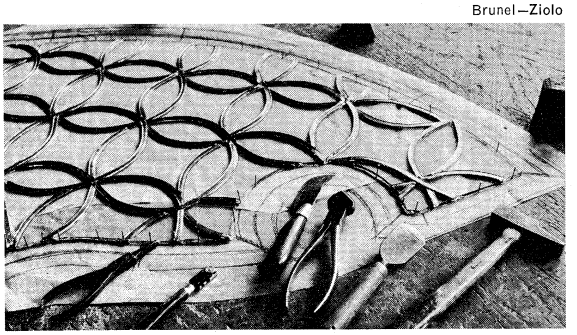
Insofar as stained glass may be considered an art of painting, it must be considered an art of painting with light. Whatever techniques or materials it may employ, its own most unique and indispensable effects are always the product of colouring, refracting, obscuring, and fragmenting light.

MATERIALS AND TECHNIQUES

Contrary to popular belief, the glassmaker and the stained-glass artist could seldom have been the same person even in the earliest times; in fact, the two arts were rarely practiced at the same location. The glassmaking works was most readily set up at the edge of a forest, where the tremendous quantities of firewood, ash, and sand that were necessary for the making of glass could be found, whereas the stained-glass-window-making studios were normally set up near the major building sites. The stained-glass artist, thus, has always been dependent upon the glassmaker for his primary material. Coloured with metallic oxides while in a molten state—copper for ruby, cobalt for blue, manganese for purple, antimony for yellow, iron for green—sheets of medieval glass were produced by blowing a bubble of glass, manipulating it into a tubular shape, cutting away the ends to form a cylinder, slitting the cylinder lengthwise down one side, and flattening it into a sheet while the glass was still red hot and in a pliable state. It was then allowed to cool very slowly in a kiln so that it would be properly annealed and not too difficult to cut up into whatever shapes might be required. Since these sheets of glass, with the exception of a type known as flashed glass, were intrinsically coloured with one basic colour throughout, changes from one colour to another in the design of a window could be effected only by introducing separate pieces of glass in each of the requisite colours.

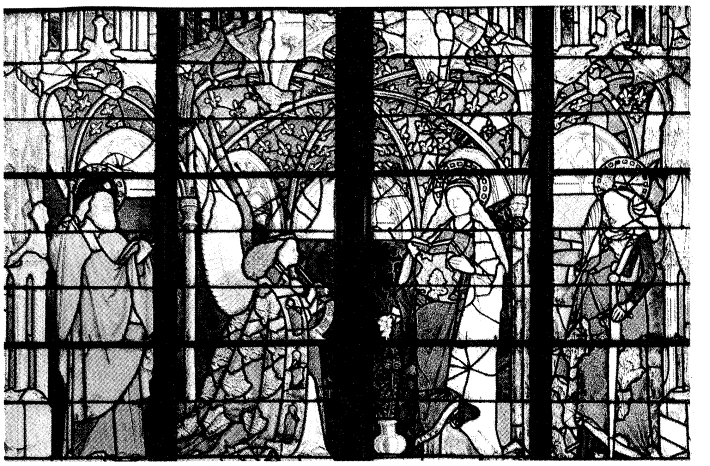
Role of the glassmaker

Whether by accident or by deliberate intent, the glass made in the 12th and 13th centuries had almost the ideal combination of crudity and refinement for stained glass. The sheets, 10 by 12 inches (25 by 30 centimetres) in size, were both flat enough and thin enough to be cut very accurately into the necessary shapes, yet still variable enough in thickness (from less than ⅛ inch [0.317 centimetre] to as much as 5/16 inch [0.793 centimetre]) to have rich transitions in the depth of its colour. With the progress of glass technology in the Middle Ages and Renais-



sance came the ability to produce larger, thinner, and flatter sheets of glass in a considerably larger range of colours than had been possible in the 13th century. At each distinguishable stage in this development, however, the glass became less visually interesting as an aesthetic element in its own right. The Gothic Revivalists later realized this, and in the mid-19th century they initiated a return to the earlier methods of producing glass. They developed the so-called "antique" glass, which is remarkably similar in colour, texture, and shading to that used in the 12th- and 13th-century windows. "Antique" glass remains the basic material used in stained-glass windows to this day.

Traditional techniques. The art of stained glass is the translucent offspring of such earlier art forms as mosaic and enamelling. From the mosaicist came the conception of composing monumental images out of many separate pieces of coloured glass. Cloisonné enamelling probably inspired not only the technique of binding these pieces together with metal strips but that for treating the strips themselves as a positive design element. From the enamellers must also have come the near-black vitreous enamel made from rust powder and ground glass that was mixed with a mild water-based glue to form a paint. This could be used to render more or less opaquely onto glass the details of figures, ornaments, and inscriptions.



The technique of making stained-glass windows is first described in the *Schedula diversarum artium*, a compendium of craft information probably written between 1110 and 1140 by the monk Theophilus (tentatively identified as the 12th-century goldsmith Rugerus of Helmarshausen). First, a full-sized cartoon, or line drawing, of the window was painted directly onto the top of a whitewashed table, showing the division of the various colour areas into individual pieces of glass. Next, sheets of glass of the appropriate colours were selected and from these pieces were cut, or, more accurately, cracked away with a red hot iron. By applying the hot iron to the edge of the sheet it was possible to start a crack that could then be guided more or less in the direction in which the iron was moved, thus enabling the glazier to break away from the sheet of glass a piece of approximately the right shape and size. This he would then further shape by "grozing," or crumbling away bits of glass from its edges with a notched tool known as a grozing iron. When all of the pieces were thus accurately cut to shape, with due allowance between pieces for the leads that would join them together, the details of the design were painted onto the glass wherever necessary with vitreous enamel. The pieces were then placed in a kiln and fired at a temperature just hot enough to fuse the enamel to the glass. This done, the windows were ready for assembly with grooved strips of lead that look in cross section like the letter H. The glazier would begin by butting together on his workbench two long strips of lead, to form a corner of the panel. He would then set the corner piece of glass in place between these two leads and cut another strip of lead just long enough to surround the rest of the piece. Against this lead he would then be able to set the next piece of glass, and so on across the panel, until it was completely assembled on the glazing bench. The joints between the leads were then soldered, the panel was waterproofed by rubbing a putty compound under the leads, and it was ready for installation.

Cutting and leading techniques

Brunel—Ziolo

Construction of a stained-glass window.

Promophot—Ziolo

Because of the flexibility of the leading it was found necessary to divide all but the very smallest windows into a series of separate leaded panels and to insert iron framing members, or armatures, between the panels. In the earliest single-figure lancet windows, such as the "Prophets" in Augsburg Cathedral, the divisions tend to be purely functional. Very soon, however, more ambitious windows became much too large to be handled in this manner. Whereas the Augsburg "Prophets" measure only about 12 square feet (1.1 square metres) in area, the Poitiers Cathedral "Crucifixion" window contains approximately 175 square feet (16.3 square metres) of stained glass, and the "Life of Christ" in Chartres contains more than 250 square feet (23.2 square metres). A much more elaborate system of subdivisions in the window opening, consisting of vertical as well as horizontal members, was developed. These systems of supports often formed a geometric pattern that was incorporated in the overall design of the window. In fact, it was the ingenious conversion of this structural necessity into a positive design element that set the stage for the creation of the medallion windows of the great Gothic cathedrals. By utilizing these armatures to delineate the principal ornamental subdivisions of the windows, as in the Chartres "Good Samaritan," the glass painters were able to fuse a complex didactic imagery and an austere architecture into one of the most compelling artistic unities of Western art. At the same time, particularly in the upper levels of a church, stone mullions began to be employed for the same purpose. The most spectacular examples are the great rose windows, in which masonry is so literally dissolved into fenestration, and the individual window opening so completely absorbed into the overall pattern, as to defy any meaningful distinction between window and wall. This perfect fusion of image, ornament, and structure, with each deriving strengths from the others that none would ever have alone, was one of the most significant turning points in the history of stained glass. From this point on the relation between stained glass and architecture begins to decline. The aims, techniques, and achievements of the stained-glass artist begin to resemble those of the fresco and easel painters, and it is by the standards applicable to the latter that the stained glass of the 14th, 15th, and 16th centuries must be judged.

Developments in the 14th century. The first significant developments in the glass painter's craft appear to have been made more or less simultaneously in the early years of the 14th century. Glass in a range of previously unavailable secondary colours—smoky ambers, moss greens, and violet—become generally available for the first time. The technique of staining glass yellow by painting it with silver salts is discovered. The glass painters also begin to develop a number of techniques for shading or modelling

Painting and grinding techniques

model forms with vitreous enamel by applying translucent matts of halftone to the whole surface of the window and delicately brushing it away where highlights are desired. Darker shading is sometimes reinforced by painting on the outer as well as the inner surface of the glass. The uses of line also become increasingly refined and versatile, especially in the 15th century.

To these refinements of the craft was added one wholly new technique, the abrasion of flashed glass. Ruby glass, whose unique composition made this technique possible, was a laminated glass, although it appears to be coloured intrinsically throughout like all of the other glass in the early windows. Because the metallic agent used to produce its colour was so dense, all but the thinnest films of ruby were opaque. To obtain sufficient translucency, either the glassmaker had to suspend striations of ruby in a clear glass, thereby creating the "streaky rubies" of the early 13th century, or the glass was "flashed"; that is, clear glass while still pliant was dipped into molten coloured glass, thus coating its surface with a thin film of colour. Detailed effects, unhindered by intricate leading, could then be achieved by grinding away portions of this coloured film, first on ruby glass and then on other colours deliberately "flashed" for this purpose. To these colours could now also be added the silver stain in tones of yellow ranging from the palest canary tint to a deep fiery amber, depending on how heavily the stain was applied and how thoroughly it was fired. The whole gamut of more or less translucent tonalities that could be created with vitreous enamel were also used. Taken altogether, these techniques when used in combination represented a considerable liberation of stained glass from what was increasingly considered to be the "tyranny" of the lead line.

The technique of grinding flashed glass was first practiced in the late 13th and early 14th centuries; one of the earliest extant examples is in the church at Mussy-sur-Seine in France, where the windows have a blue groundwork covered all over, or diapered, with ruby roses with white centres, each rose being a single piece of glass. This type of work, however, was not common until the 15th and 16th centuries.

Later developments. At the end of the 15th century a whole new range of vitreous enamels was developed, and by the middle of the 16th century the technique of painting in enamel colours on glass began to be of major importance. In this method, granulated coloured glass of the desired colour is mixed with a flux of clear ground glass and fired onto the surface of the glass. Enamel painting was not altogether successful either technically or

aesthetically, since the colours thus created were translucent rather than transparent, generally pallid, and of uncertain durability. Political disturbances in the mid-17th century created a scarcity of coloured glass throughout Europe, and gradually the traditional use of coloured glass was replaced by the new technique of painting in enamel colours on clear glass.

Modern techniques

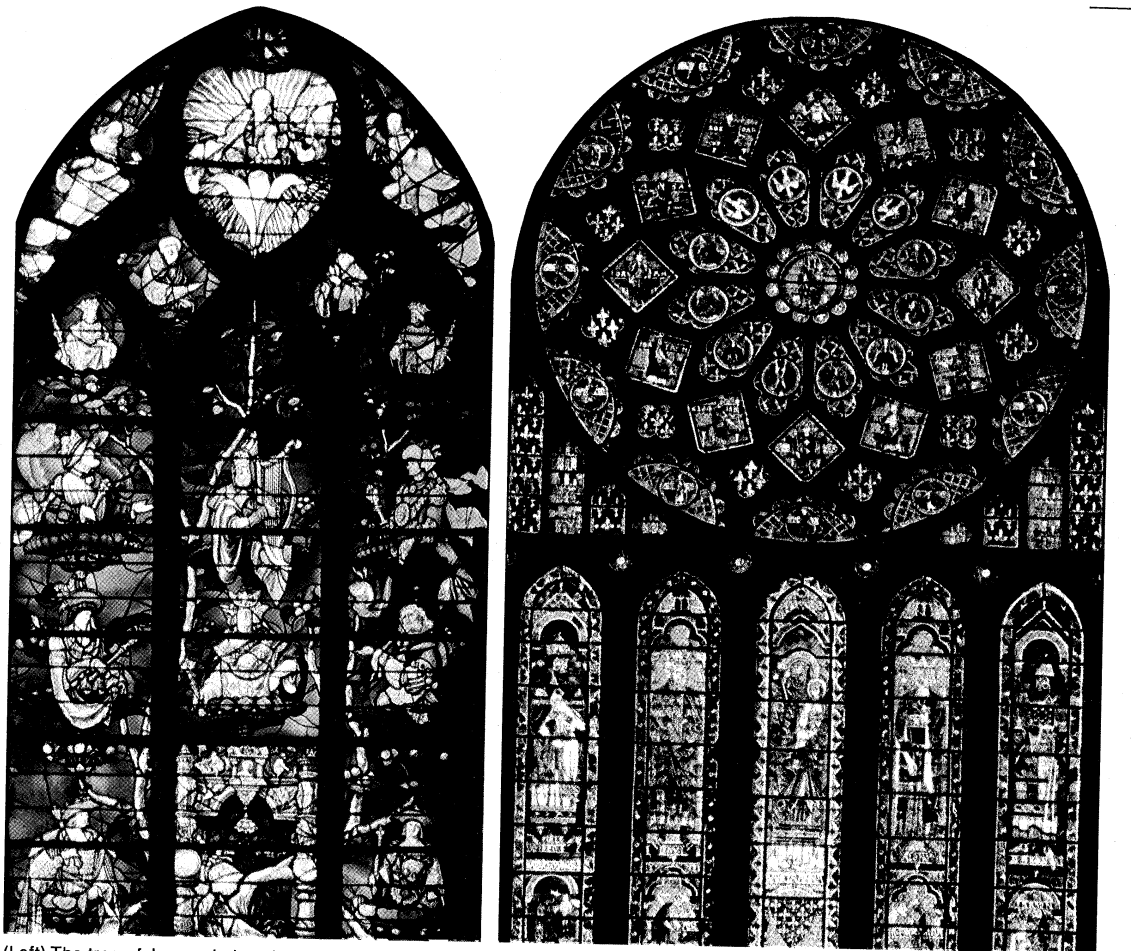
Between the 16th and 20th centuries the developments in the craft of making stained-glass windows were purely utilitarian. In the 16th century the diamond glass cutter was invented, and in the 18th century hydrofluoric acid was introduced as a means of etching flashed glass. In the 19th and 20th centuries, gas and electric kilns and soldering irons were used, as were plate-glass easels upon which stained-glass panels could be temporarily mounted for painting before they were leaded. The largest palette of glass—the widest range of colours, textures, and thicknesses that the art has ever known—was also developed in the 20th century. Contemporary technical innovations include the slab glass and concrete windows developed in France around 1930, where glass set in concrete provides an alternative to leading. In the mid-20th century such experimental techniques as bonding glass to glass with transparent resin glues were developed. Measured purely by technical standards, contemporary stained glass has never been rivalled in its versatility as an instrument of artistic expression.

SUBJECT MATTER

In the Middle Ages ecclesiastical art was primarily didactic. The subjects painted in the windows played an important part in the expounding of the Scriptures and the glorification of the church and its saints.

Iconographic programs

The iconographic program of medieval stained-glass windows for ecclesiastical buildings is a product of several factors. To begin with, the cruciform plan of the churches themselves created four focal areas. Each area, by its architectural form and orientation to the sun, tended to elicit the development of certain subjects or types of subject. In Chartres, for example, the five central windows of the choir clerestory and the north rose window are consecrated to the Virgin, the south rose window to the glorification of Christ, and the west rose window to the Last Judgment. In Bourges Cathedral the huge figures of the Apostles in the south clerestory are paired off against the prophets in the north clerestory, the representatives of the New Testament thereby receiving the full light of the sun and their Old Testament counterparts the more crepuscular light of the north sky. The great rose windows, whose circular form is itself cosmological in its implications, are invariably devoted to cosmological themes: the Last Judgment, the Apocalypse, the cycle of the year as expressed in the signs of the zodiac, the glorification of Christ and of the Virgin as the rulers of heaven. On the other hand, one of the reasons that the theme of the Jesse tree remained popular throughout the Middle Ages was that it lent itself to such a rich variety of ornamental treatments. And finally there was the will of the donors of the windows, whose personal preferences determined the subjects of many excellent works that clearly cannot be related to any comprehensive iconographic program. Some idea of the scope of these medieval enterprises can be indicated by the fact that Chartres, by no means the largest of the cathedrals, contains more than 27,000 square feet (2,518.14 square metres) of stained glass, in 176 windows. Of the 64 windows on the lower level, all but a few are medallion windows, which contain anywhere from 20 to 30 or more separate pictorial compositions; and the three rose windows, each more than 40 feet (12 metres) in diameter, are vast composite creations. The work of at least nine separate master designers has been distinguished in the windows of the cathedral, which was completely glazed in less than 40 years, between about 1203 and 1240.



It must be assumed that clerics supplied the master glazier with a program to which he had to conform. A 12th-century manuscript in the British Museum contains a series of circular drawings illustrating the life of St. Guthlac. These drawings might have been intended as a model for a glazier, but the scenes could equally well have been expressed in wall paintings, sculpture, or metalwork. There is more complete knowledge for the later Middle Ages. The glazier was given written instructions from which to prepare provisional sketches that were submitted for the patron's approval before being redrawn in actual size to form the final cartoon. The provisional sketch was known as a *vidimus* (literally, "we have seen"). One example of such written instructions is the program for a window given by Henry VII to the Grey Friars Church at Greenwich, England.

There is ample evidence to show that by the 14th century it was the practice of glaziers to have a stock of finished cartoons, executed on parchment or paper, which could be adapted for different glazing schemes. That these cartoons were used and reused over a long period can be deduced from the will of a York glazier, who died in 1450, in which he bequeathed to his son all his cartoons.

It is evident that in the later Middle Ages the master glazier's workshop was a highly organized enterprise, capable of producing various classes of designs, according to the expense his patrons were prepared to incur. Although the donor, cleric or layman, exercised considerable influence over the choice of subject and its manner of representation, the finished design was essentially the creation of the master glazier. The latter was often an artist in his own right, expressing in the formal language of his own technique the artistic aspirations of his time. (R.So.)

PERIODS AND CENTRES OF ACTIVITY

Early developments. The evolution of the stained-glass window was a slow process. Both texts and excavation testify to the existence of stained-glass windows before the 12th century, but the textual references are too brief and nontechnical to give any clear picture of how the art evolved. The writings of the Fathers of the Latin Church, Lactantius (*c.* AD 240–*c.* 320), Prudentius (AD 348–after 405), and St. Jerome (before 420), mention coloured glass windows in the early Christian basilicas. The 5th-century poet Sidonius Apollinaris described glazed windows in Lyon, France. Pope Leo III (795–816) is recorded to have provided windows of different coloured glass for St. Paul's basilica at Rome. Glazed church windows were widespread in pre-Carolingian Europe in the wealthiest establishments: the Cathedral of York in England was glazed as early as 669. On the site of the Abbey of Monkwearmouth in Sunderland, England, a number of pieces of window glass dating from the late 7th century were found. Coloured green, blue, amber, and red, the edges of several pieces were grozed, or cut for fitting into a window.

In form these early medieval windows varied considerably: the actual window openings were at first filled with thin sheets of marble, alabaster, gypsum, or even wooden boards, which were pierced with holes, coloured glass being inserted into these holes. In addition to glass, other materials were used for the same purpose, thin strips of alabaster set in bronze frame being not uncommon. This form of design, called a "mosaic" window, persisted even in western Europe into the Romanesque period, and 11th-century examples are to be found in Italy in the Cathedral of Torcello near Venice and in the Church of S. Miniato at Florence.

Early leaded windows

Leading was possibly used to hold together the pieces of glass in a window opening contemporaneously with the above early methods. Leading that may have been used in window glazing dating from the 4th century has been uncovered in excavations. The earliest example of a leaded window design was a small panel (destroyed in 1918) in the church at Séry-les-Mézières, northwest of Reims in France, probably of the 9th century. It appears certain that, as at Séry-les-Mézières, many of these early windows contained coloured glass arranged in comparatively simple decorative designs, with little use of the painted design.

There is no documentary evidence even to suggest the existence of pictorial windows until the 9th century, when several rather vague references testify to the appearance of figures in German and French glass. In the 10th-century history of the Church of Saint-Remi at Reims, it is stated that the windows contained various stories.

The fragments of what may be the earliest pictorial window extant were excavated at Lorsch in Germany. It was possible to reconstruct a head of Christ, which shows some stylistic affinity with Carolingian manuscript paintings and probably dates from the 9th, 10th, or 11th century. The earliest complete pictorial windows extant are those containing five figures of prophets in the Cathedral of Augsburg in Germany, belonging to the beginning of the 12th century.

In Carolingian and early Romanesque architecture the window openings, partly for structural reasons, were small and few in number. Polychrome decoration was naturally concentrated on the large mural areas and the vaults rather than on the windows. The development of late Romanesque and Gothic architecture brought a new emphasis on fenestration and openness. It was then that pictorial windows of stained glass became a major art form and in northern Europe the most important single element in church decoration.

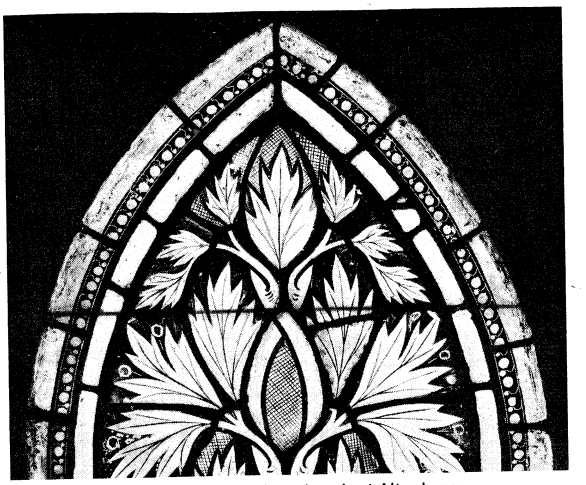
Although the pictorial stained-glass window is normally regarded as the invention of and indigenous to western Europe, where its development can be followed with reasonable coherency from the beginning of the 12th century onward, there is still much that is obscure about its earlier evolution. The discovery in Istanbul of stained-glass windows, apparently deriving from a tradition independent of that in the West and datable before 1136, adds to the complexity of the fragmentary evidence already cited.

12th century. It is probable that many of the early stained-glass windows of the 12th century were of the single figure, monumental in character like those examples in the cathedrals of Augsburg and Canterbury or the well-known Virgin and Child known as "La Belle Verrière" at Chartres. The most important feature of the 12th century, however, was the development of the narrative window, consisting of a series of medallions painted with pictorial subjects. This type of window was, so far as is known, first used extensively between 1140 and 1144 at the Abbey of Saint-Denis near Paris. A secondary but

significant development of the second half of the century was the use of allover decorative patterns, or diapers, on the groundwork adjacent to the figures. This design device was probably more common at first in Germany than elsewhere, and an early example is in the Jesse window (*c.* 1170–80) at Frankfurt am Main, now in the city's Städelsches Kunstinstitut.

France. By the 12th century the production of stained-glass windows in northern Europe was considerable, and regional schools begin to be discernible, especially in France, Germany, and England. In France, a number of important regional schools of glass painting emerged, one of the earliest of which was in the west. The most important works of this group include the Ascension window (*c.* 1145) in Le Mans Cathedral and the Crucifixion window (*c.* 1165) in Poitiers Cathedral. In the northeastern region of Champagne appeared another quite distinct group, whose best work is found in the Redemption and St. Stephen windows (*c.* 1150–60) in the cathedral at Châlons-sur-Marne, together with the very important later windows (*c.* 1190) at Saint-Remi in nearby Reims, whose stately figures indicate that Romanesque monumentality has already begun to be tempered by the less austere, less rigorously formal mode of the Gothic.

Regional schools of glass painting in France



The most important workshop in the Île-de-France region around Paris was connected with the rebuilding of the choir of the Abbey of Saint-Denis. Only fragments of these windows are left, but the three windows (*c.* 1150–55) of the west facade at Chartres are later products of the Saint-Denis workshop and are a summation of all that is most uniquely Romanesque in stained glass.

The stylistic antecedents of these schools are difficult to pinpoint. The Saint-Denis–Chartres group has certain similarities to north French manuscript paintings that are not precisely dated, and the problem is further complicated by Abbot Suger's recording that the glaziers employed at Saint-Denis came from many different regions. The strongly Romanesque character of the Le Mans Ascension window, its general composition, and the particular stylization of drapery forms is similar to earlier manuscript paintings from western France. The Crucifixion window at Châlons-sur-Marne, on the other hand, has precedents in general arrangement in Ottonian manuscript painting and is also closely related in style and composition to the contemporary Mosan school of metalwork centred in the valley of the Meuse River. The similarities between the two are so marked that it is not impossible that the artist worked in both mediums.

Germany. There is less 12th-century glass extant in Germany than in France. The outstanding example of German stained glass of the first half of the century is the series of five prophets (*c.* 1125) in the Cathedral of Augsburg. These hieratic figures have the monumentality of design, rigidly frontal and schematic, characteristic of Romanesque art. The bold use of ruby, green, yellow, and violet glass is completely alien to contemporary French developments. In the second half of the century, art in northern Europe generally, and perhaps more so in Germany, was influenced by Byzantine models. An example is the "Moses and the Burning Bush" window now in the Städelsches Kunstinstitut at Frankfurt am Main or the Magdalen (*c.* 1170) from the church at Weitensfeld, near Klagenfurt, in Austria.

England. England has only fragmentary remains of 12th-century glass. The nave clerestory windows in York Minster contain some reused panels from a series of narrative windows, one of which depicted the life of St. Benedict (*c.* 1140–60). Another panel, a single figure of a king from a tree of Jesse, shows some affinity in style with the glass at Saint-Denis and Chartres but is probably later in date (*c.* 1190). The outstanding survival from the end of the century is the splendid series of figures representing the descent of Christ from Adam, made for the choir clerestory windows (*c.* 1178–1200) of Canterbury Cathedral, which resemble the "Prophet" windows in Saint-Remi at Reims. Their features show a new humanism, and there is a sense of movement, even tension, in their bodies and draperies, comparable to contemporary English manuscript painting.

12th-century English glass

13th century. A significant feature of the 13th century was the development of the grisaille window, composed largely of white glass, generally painted with foliage designs, and leaded into a more or less complicated geometric pattern. This type of design was employed partly as a means of introducing a larger amount of light and partly because it was considerably cheaper than coloured glass. The combination of grisaille glass and coloured subject medallions, or figures, however, disrupted the monumental overall unity, which is a feature of a window composed entirely of coloured glass, by allowing the penetration of pure light. This change had an important effect on style; the painted design became more linear and refined, the scale more broken and delicate. Although the combination of grisaille and medallions, or figures, is not unknown in the early part of the century, it is more common in the second half, particularly in France and England.

The movement toward humanism, partly inspired by St. Francis of Assisi and his teaching, was accompanied by a related tendency toward naturalism discernible in the visual arts in the later 13th century. The conventional formalized foliage designs of the 12th and earlier 13th centuries gave place to more natural plant motives of oak, vine, and maple, and these break out of the formal patterns and coil with a more organic natural movement.

France. In France, where surviving material is most extensive, the various regional schools are mostly a natural development of their immediate predecessors. There is no radical change in style or technique during the first quarter of the century. In western France the severe Romanesque style was softened and refined, as seen in the Saint-Vital window (*c.* 1200) at Le Mans Cathedral, the Saint-Martin window (*c.* 1210) at the Cathedral of Angers, and the slightly later windows of Abraham, Lot, and Joseph at Poitiers Cathedral. Another distinct workshop, centred at Lyon and responsible (*c.* 1215–20) for the apse windows of Lyon Cathedral, is characterized by a strong Byzantine influence, particularly in iconography. An important workshop in Champagne had already produced in the late 12th century the clerestory windows of Saint-Remi at Reims that foreshadowed the mature Gothic style, while later works of this atelier can be found in the clerestory windows (*c.* 1235) of Reims Cathedral and the choir clerestory windows in the Cathedral of Troyes. In the Île-de-France and eastern France the situation is complicated by the almost complete loss of the later 12th-century works. The north rose window (*c.* 1200–05) of Laon Cathedral is stylistically related to the contemporary sculptures of the facade and to manuscript painting such as the Ingeborg Psalter (Musée Condé, Chantilly). The work of this atelier is extremely distinguished, with an elegance and purity of style and a knowledge of classical art that transcend most of its contemporaries. The rose window (1231–35) of Lausanne Cathedral in Switzerland

Styles in 13th-century French glass

was made by a wandering artist from Picardy, Peter of Arras, and is related in style and iconography to the Laon workshop.

The most extensive glazing program of the first half of the century was at Chartres Cathedral, a tremendous enterprise that brought together various workshops from different regions. The stylistic interactions between the different workshops resulted, particularly in the second quarter of the century, in a more general similarity of style between the various regional workshops. Contemporary with Chartres are the windows (*c.* 1214–35) of the east end of Bourges Cathedral, while four windows (before 1225) at Sens Cathedral are related in composition and ornament to Chartres and Bourges and also have certain stylistic affinities with the contemporary windows at Canterbury Cathedral.

Considerable activity was also centred in the Paris area during the second quarter of the century. The major monument of the period is the Sainte-Chapelle, which was built in Paris between 1243 and 1248. Forming what amounts to a continuous wall of 50-foot- (15-metre-) high stained glass around three sides of the chapel, it contains the most extensive narrative cycle ever produced in this medium, numbering 1,134 scenes in 15 windows. Stylistically, these windows are closely related to Parisian court art of the same date, and their influence can be seen in the later windows at Le Mans Cathedral (about 1254–60) and in the Cathedral of Tours (1245/55–76).

England. The only extensive remains of 13th-century glass in England are found at Canterbury Cathedral, where the 12 Theological windows were produced in about 1200 and the windows relating to St. Thomas Becket about 1200–30. Lincoln Cathedral retains impressive fragments of a series of windows made between 1200 and 1220, but it is impossible fully to appreciate either of these series without making comparison with French work. There are important similarities between Canterbury and Sens, on the one hand, and probably between Lincoln and Paris, on the other. The glaziers, however, were probably English with a close acquaintance with French models.

Germanic countries. Thirteenth-century stained glass in Germanic countries, however, was comparatively uninfluenced by French models. It is more turbulent in design, with agitated draperies, expressive faces, and a complicated ornamented character, particularly in the backgrounds. There were many distinct regional schools, among which Cologne was an important centre. The full-length figures of saints and the Legend of St. Kunibert window (*c.* 1220–30) in the Church of St. Kunibert at Cologne have elaborate geometrical frames around the figures and scenes that are without parallel in French art. These frames are a typical feature of German work; they occur again in later work of this school in the St. Nicholas window (*c.* 1240–50) at Büchen, west of Hamburg, and elsewhere. Another workshop, which produced the Jesse window (*c.* 1225) in the Cathedral of Freiburg im Breisgau, shows a marked affinity with the slightly earlier enamel and metalwork produced by Nicholas of Verdun and his circle (active 12th–13th century), while the remains of a group of windows (*c.* 1230) made for the Franciscan church at Erfurt constitute a particular group strongly indebted to Byzantine models. It appears that after the completion of the Erfurt windows, this workshop, or at least some of its members, went to Assisi in Italy and also to Gotland in Sweden. The most outstanding glass of the mid-century is a related series of windows in the cathedrals of Naumburg, Strasbourg, and Frankfurt. The Naumburg window of Holy Knights and Virgins can be contrasted with the delicate mannered style of Parisian court art.

Features of 13th-century German glass

The earliest Italian examples of stained glass were the three windows executed by German craftsmen of the Erfurt school in the apse of the Upper Church at Assisi between 1230 and 1240. At the end of the 13th century, native designers and craftsmen produced windows. The oculus window (*c.* 1288) in the apse of Siena Cathedral has been attributed to Duccio di Buoninsegna (died 1318 or 1319), and the style of the painter Guido da Siena (active *c.* 1250–75) seems evident in the Madonna and Child panel of the Sanctuary of the Madonna della Grotta near Siena.

Early examples of stained glass in Italy

Early 14th century. Stained glass of the first half of the 14th century is everywhere distinguished by an insouciant fairy tale quality and a langorous charm sometimes tinged with pathos. Regional differences, however, persisted—the gentle reserve and earthy lyricism of the English; the virtuoso painting and exquisite drolleries of the Norman-French; and the full green-, gold-, and russet-dominated palettes of the German windows. The full flowering of the Gothic style side by side with the beginnings of stylistic developments that were to culminate in the Renaissance characterized the aesthetic nature of the early 14th century. The new movement toward the representation of volume and spatial depth, by means of modelling and perspective, had its origins in Flemish and Italian painting. That the glass painter was quickly influenced by this new style is seen, for example, in the St. Anthony window in the Lower Church at Assisi. North of the Alps the earliest extant manifestation of this new interest in perspective and modelling, based on Italian models, occurs in the chancel windows (1325–30) of the Habsburg expiatory church at Königsfelden, near Brugg, Switzerland. The knowledge of Italian models spread quickly and extensively and can be seen in France in the windows (1325–39) at Saint-Ouen in Rouen and those made about 1330 at Évreux Cathedral. In the Germanic lands proto-Renaissance spatial illusionism influenced the transept windows at Augsburg Cathedral and the east window (*c.* 1340) of Vienna Cathedral, while the earliest remaining example in English glass painting is probably the nave windows (*c.* 1330–35) of Stanford-on-Avon in Northamptonshire.

In the early 14th century, the third dimension in canopies was still highly untheoretical and largely governed by considerations of pure design. The practice of representing a figure beneath an architectural canopy was an established convention of the 13th century, particularly used in clerestory windows. In earlier examples the canopy plays a comparatively unimportant part in the total design, but by the end of the 13th century, although still two-dimensional, it had become more elaborate and is an important ornamental feature of the windows of Merton College, Oxford. In German and Austrian windows, the canopy work is often very elaborate and complex in its spatial organization; examples are found at Vienna Cathedral (*c.* 1340) and Erfurt Cathedral (*c.* 1360–70).

Currents in France and England

The art of glass painting, however, did not respond equally to these new influences emanating from Italy. It subdivides itself into two groups, of which France and England together make up one, characterized by its resistance to Italian influences. The use of perspective was purposefully restrained, so that the essential overall surface unity of the design was not violently upset, for the use of flat, patterned diaper grounds effectively counterbalanced the suggestion of spatial effect. In the first half of the century the most important work in France is found in the region of Normandy, especially in the choir windows (*c.* 1330) of Évreux Cathedral and those dating around 1325 to 1339 at Saint-Ouen in Rouen. The English glaziers of this period were extremely prolific, with Oxford, Coventry, and York as important regional centres. The nave windows of York Minster were made during the period 1300 to 1338 and are the largest single enterprise of this period in England. It appears probable that some of the later glass at York (*c.* 1350–70), now distributed over the windows of the choir clerestory, was the work of an imported French glazier, probably from Rouen. A flourishing school in western England, whose best work is found at Wells Cathedral and Eaton Bishop in Herefordshire, shows some affinity with German work. The best French and English work, however, has a lightness of colour and graphic refinement that is enhanced by an extensive use of yellow stain. After about 1300 the geometric grisaille glass gave way to simpler diamond-shaped pieces, painted with delicate trails of foliage and leaded together to give the effect of trellis work.

The second group, which might be termed "Germanic," as it embraces Germany, Bohemia, and Austria, displays

Three-dimensional style of the Germanic countries

a much more three-dimensional style; the colours are deeper and more saturated, the compositions are more complex, both on the surface and in depth, and the canopy designs particularly are often very complicated essays in perspective; the figures are shorter in proportion and their volume more accentuated. It is brusque, almost harsh, contrasting strongly with the elegance of French and English work. All of these traits can be seen, for example, in the panels (*c.* 1350) from Strassengel, near Graz, Austria, now in the Victoria and Albert Museum, London; the earlier windows (*c.* 1350–60) at St. Maria-am-Gestade in Vienna; and at Erfurt Cathedral (*c.* 1360–70). A particular trait of this Germanic group, of which Erfurt is a good example, is a tendency to extend a single composition across the main lights of a window, ignoring the natural divisions of the stonework. The reason for this is partly architectural: the window lights are comparatively much narrower and taller than those in French or English windows.

The International Style

Late 14th and early 15th centuries. The arts from about 1380 to about 1430, which are conveniently grouped together under the title of the International Style, belong essentially to an era of court art inspired by the patronage of kings, the nobility, and the higher orders of ecclesiastics. Surviving windows are extensive, and interactions between the various centres of patronage, complicated by family alliances and the exchange of works of art and artists, are particularly complex. The various national and regional styles can still be distinguished in glass painting, but there is a general tendency toward a mannered, extremely sophisticated elegance of style, sometimes verging on the precious, combined with an interest in portrait realism.

If the genius of the 13th-century stained glass lay in its epic sense of monumentality and that of the early 14th century in its warmth of human feeling, that of the late 14th and early 15th centuries is far more difficult to characterize in a phrase. The style of glass painting became at once more corporeal and more introspective. Figures are rendered with far more attention to individual human traits yet are akin in their majesty to the great prophets in the 13th-century windows. The figures painted between 1384 and 1392 by Hermann von Münster, for the west window of Metz Cathedral in France, and those painted around 1400 by Thomas of Oxford for the chapel of William of Wykeham's College at Winchester, England, seem both newer and older than their immediate predecessors—newer in that they are beginning to bear the signature of a personal style, older in that they recall the grandeur of an earlier, essentially collective expression that now seemed everywhere to be giving way to arid cameo-like refinements on the one side and an earnest rusticity on the other.

The glass painting of this period is of high quality. The most significant examples in France are the "Royal" windows (*c.* 1395) at Évreux Cathedral. One of the most ambitious works of the period is the great east window of York Minster, made between 1405 and 1408 by John Thornton of Coventry.

In Germany and Austria the International Style brought about a softening and refining of the "plastic style" of the earlier part of the century. In Austria an important atelier associated with the court produced the window (*c.* 1386–95) in the church of St. Erhard in der Breitenau and later the series of windows (*c.* 1400) at Viktring, and for the Freisingerkapella at Klosterneuburg (*c.* 1410). Germany contains a large amount of work of this period. At Erfurt Cathedral the window given by Johann von Tiefengruben (*c.* 1400) is lighter in tone and has a more refined pictorial style than the earlier windows there. The series of windows at Rothenburg, which were probably made about 1400, should be noted, together with the cycle of windows (*c.* 1420–30), for the Bessererkapelle at Ulm Cathedral, which show an admirably refined technique.

15th and 16th centuries. The period 1430–1550 saw not only the decline of the Gothic style and the establishment of the new Renaissance style but also the beginning of the transformation of the art of glass painting from a significant means of artistic expression into a hybrid art form: the translucent emulation of fresco and easel painting.

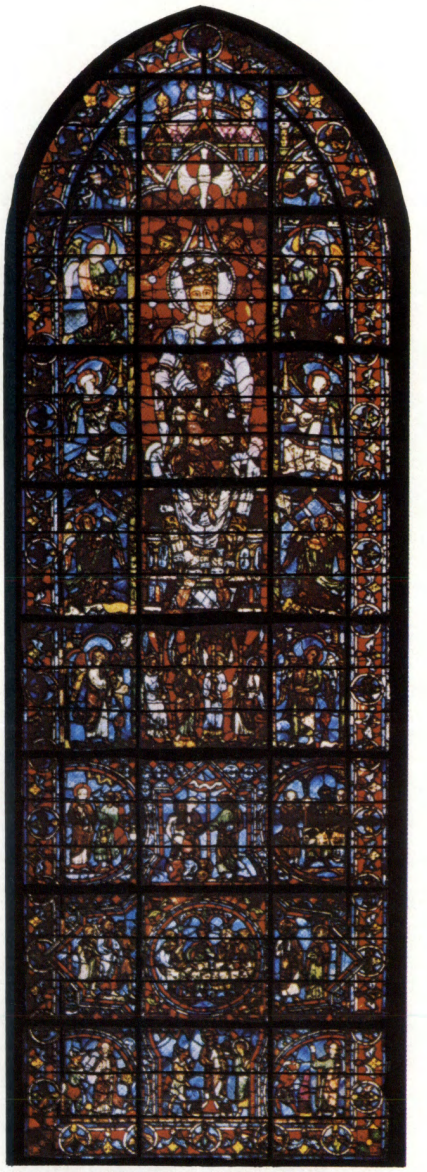
The International Style continued to influence glass painting during the first half of the 15th century but to a lesser degree. Its mannered elegance and extravagant costumes can still be seen in France in the two rose windows (*c.* 1440) at Le Mans Cathedral and also the rose windows (1441–42) at Angers Cathedral. In England this aesthetic is continued in the east window (*c.* 1423–39) of the priory in Great Malvern (Worcestershire), the chapel windows (1441–47) of All Souls College at Oxford, and in the windows made by John Prudde, the king's glazier, for the Beauchamp Chapel of St. Mary's in Warwick, which were commissioned in 1447. The work of Germanic glass painters provides outstanding examples, particularly the window (after 1424) from St. Lambrecht, now in the museum at Graz, Austria, and the charming Alsatian window of St. Katherine (*c.* 1425–50) at Sélestat, France.

The Flemish style

There were, however, important new influences affecting the styles of glass painting. In northern Europe during the first half of the 15th century a flourishing school of painting emerged in Flanders. Although the origin of the Flemish style is partly to be found in the International Style, a more realistic manner of representation and a detailed awareness of actuality developed that is almost the antithesis of the mannered sophistication and the essentially unrealistic world of the International Gothic.

It was impossible for the glass painter to participate fully in the new realism. Glass is a translucent material; the passage of light through it is alone sufficient to create a feeling of unreality. Furthermore, although the panel or mural painter could use the new discoveries of linear perspective to heighten the sense of reality, the glass painter had to contend with the presence of the leading line, which emphasizes the surface plane. This creates a tension and a sense of ambiguity between the actual surface and the illusion of depth. Attempts were made to resolve the problems, but with little success; one result was that the lead line became increasingly divorced from the design instead of being an integral part of it. The increasing use, from the mid-16th century onward, of vitreous enamel pigments had the effect of accelerating this process.

The full flowering of the Renaissance style in Italy and the intense interest in classical art that it stimulated resulted, around 1500, in a profusion of ornamental details, borrowed from the formal language of classical art, in contemporary window designs. In addition, the glaziers at this time often drew inspiration from contemporary engravings, particularly those of Albrecht Dürer.



The period 1450–1550 saw no decline in demand for stained glass. One of the most productive and influential areas at this time was Flanders. The six windows (*c.* 1475–1500) of the church of St. Gommaire at Lier and the Virgin window (*c.* 1482) at Anderlecht, although restored, have original portions of excellent quality and close affinity with contemporary Flemish painting.

English stained glass in the 15th century becomes more intimate, more anecdotal. It is less a cathedral art than an art of parish churches and is addressed less to an assembled ecclesia than to the individual believer. At its best it achieves a quiet intensity in the woodcut-like figures in East Harling church (Norfolk), a pathos in the Long Melford church (Suffolk) "Pieta," and a sheer power of expression in the Clavering church (Essex) "Martyrdom of St. Catherine."

The trading and political links between Flanders and England in the second half of the 15th century encouraged the influx of Flemish works of art and artists into England. A number of Flemish glaziers established themselves in Southwark, London, and some even assumed English names. The early 16th century was marked by a series of disputes between the London Guild of Glaziers and the foreigners. The latter were particularly patronized by the court and the more wealthy merchants. The two outstanding monuments of this imported style are the windows (*c.* 1480) of Fairford church (Gloucestershire) and the windows (1515–31) at King's College Chapel,

Sainte-Chapelle, the Upper Church, 1243–48, Paris.

Cambridge, many of which were probably designed by the Antwerp painter and engraver Dirk Vellert.

New realism in French glass painting

The spread of the new realism can be traced in French glass painting. The interactions with Flemish glaziers can be seen, for example, in the realism of the windows (*c.* 1430–40) from the Duke of Burgundy's chapel at Dijon, now in the Victoria and Albert Museum, London, which are the work of Flemish glaziers, and also the Jacques Coeur window (*c.* 1450) at Bourges Cathedral, which is markedly Flemish in style. Native French glaziers were extremely prolific at this time, and Normandy and particularly the city of Rouen contain an incomparable display of windows produced by a large number of distinctive workshops. The leading figures of the first part of the 16th century were Arnoult of Nijmegen (*c.* 1470–1540) and the Le Prince family at Beauvais. Arnoult of Nijmegen worked in both Flanders and France. His most important works are the windows he executed between 1490 and 1500 in Flanders for Tournai Cathedral and the Jesse window (1506) in Saint-Godard at Rouen, which is one of the most impressive examples of glass painting of the period. The works by the Le Prince family are equally impressive, particularly the tree of Jesse window (*c.* 1522–25) in Saint-Étienne at Beauvais.

In Germany the later 15th century is dominated by the prolific activity of Peter Hemmel von Andlau (active 1430–1500) and his workshop. Examples of his work were done for St. Wilhelm's Church in Strasbourg.

In Italy a remarkable ensemble of stained-glass windows was created in the first half of the 15th century for the cupola of Sta. Maria del Fiore in Florence by some of the greatest masters of early Renaissance art: Ghiberti, Donatello, Castagno, and Uccello. Domenico Ghirlandajo created in the second half of the century windows for the Florentine church of Sta. Maria Novella. The late 15th and early 16th centuries are mainly associated in Italy with the name of Guglielmo de Marcillat (1467–1529), a Frenchman whose works display a thorough mastery of technique. His finest windows are at Arezzo Cathedral. The building of Milan Cathedral caused an important school of glass painting to develop there, and the work of Conrad Munch, a German from Cologne, and Nicolo da Varallo, carried out during the second half of the 15th century, is noteworthy. The Milan school continued in full activity during the 16th and 17th centuries.

In Spain, especially at Seville, Leon, and Avila, there are some good 16th-century windows; they are in all cases the work of imported Flemish glass painters.

17th and 18th centuries. The spatial illusions of Baroque paintings were beyond the limitations imposed by the stained-glass medium. The glass painter of the 17th and 18th centuries found himself reduced to completing the cycles of stained-glass windows in medieval churches or to creating contemporary art for an architecture with no artistic affinity with traditional stained glass. The most interesting development in the late 16th and early 17th centuries was the intimate and portable heraldic panel, which became fashionable to hang in domestic windows, particularly in Switzerland, the Low Countries, and Germany. These panels, seldom more than two feet high, are the glass painter's showpieces; they complete the divorce between stained glass and architecture.

The fashionable heraldic panel

Painting glass with vitreous enamels in the 17th and 18th centuries led to the final decline of the art of stained glass. In the St. Janskerk windows at Gouda, Holland, painted by the brothers Wouter and Dirk Crabeth at the end of the 16th century, and in the works of Abraham and Bernard van Linge, made between 1620 and 1640, the realization of the window as a translucent canvas painting is complete. Abraham van Linge's windows painted in 1630 to 1640 for Christ Church Cathedral at Oxford are an excellent example of the destruction of the lead line as an integral part of the design. The leading simply holds together the square sheets of glass: the effect is the same as looking at a picture set behind a rectangular grid. This type of design was continued by English glass painters such as Henry Gyles and the Price and Peckitt families, all of York, and by such as Francis Eginton and Sir Joshua Reynolds, who designed in 1778 the west window for New College Chapel, Oxford.

19th century. The Gothic revival that came as an offspring of the Romantic movement of the late 18th and early 19th centuries represents the beginning of a revitalization of the art of stained glass. The revival of interest in Gothic art stimulated an interest in both the technique and history of medieval glass painting. The pioneer figures in this field were E. Viollet-Le-Duc in France and Charles Winston in England. Winston was a lawyer and antiquarian who associated with various London glaziers and, with the technical help of James Powell and Sons, brought about a considerable improvement in the technical quality of coloured glass; and in 1847 he wrote the first comprehensive study of the medium. The experiments were continued by W.E. Chance, who first successfully produced "antique" glass in 1863.

Revival of medieval glass painting

In the first half of the 19th century the styles and methods of the early Gothic period were reconstructed, but without much aesthetic appreciation of medieval art. Much of the work was stereotyped and mass-produced, particularly in Germany, and varied considerably in technical quality. The latter part of the century is dominated in England by Edward Burne-Jones and William Morris. Burne-Jones provided the designs and Morris adapted them to the medium of stained glass. In windows by them the lead line is once again treated as an integral part of the design, as seen, for example, in the windows for Christ Church at Oxford (1874–75 and 1878), Salisbury Cathedral (1879), and Birmingham Cathedral (1897). In the U.S. the works of John La Farge and Louis Comfort Tiffany were influential in creating an American interest in stained glass. Although the style and sentiment of 19th-century work has not been much in favour in the 20th century, the period had great historical significance in the revival of the basic technique of making stained glass.

Art Nouveau designers used stained glass decoratively for making such objects as lampshades and light fixtures, and turn-of-the-century architects increasingly employed stained glass as an integral element in wholly modern architectural settings: Victor Horta in his Hotel Solvay (1895–1910), Brussels; Antonio Gaudí in his Chapel of Santa Coloma de Cervelló (1898–1914) in the Güell Colony (1898–1914) near Barcelona; Charles Rennie Mackintosh in the Willow Tea Rooms (1904), Glasgow; and Frank Lloyd Wright in the Coonley House (1908), Riverside, Illinois, and the Unity Church (1906), Oak Park, Illinois. These windows and panels clearly mark the beginnings of an authentically modern stained glass, despite their strictly ornamental intent.

20th century. Three interrelated creative currents can be discerned in the development of 20th-century stained glass. First, a significant number of architects, following the lead of their turn-of-the-century predecessors and taking advantage of the new systems of fenestration made possible by modern structural engineering, have continued to discover many new ways of using stained glass. Second, especially in post-World War II France, several major easel painters turned their attention to stained glass, infusing it with many new and powerful images. Third, during the 1950s and 1960s Germany produced the first authentic school of stained glass since the Middle Ages, dedicated to exploiting the unique technical and expressive resources of the medium.

Although the bulk of significant 20th-century stained glass belongs to the period after World War II, earlier experiments, especially in France and Germany, suggested the range of possibilities that could be creatively explored. In Auguste Perret's church of Norte-Dame (1922–23) in Le Raincy, near Paris, the entire wall surface of the church becomes a geometric grillwork of coloured glass designed by the Symbolist painter Maurice Denis. In 1930, the Dutch-born artist Johan Thorn Prikker completed a cycle of windows for the Romanesque Church of St. George in Cologne in which lead lines are used with a graphic eloquence and deep smoldering colours with a monumental gravity that have no parallel even in the greatest medieval windows.

Work after World War II

After 1946 there was an unusual burst of activity. In Le Corbusier's Notre-Dame-du-Haut (1952–55) at Ronchamp, northwest of Dijon in France, the massive south wall, 12 feet (2.72 metres) thick at the base and five feet at the top, is dramatically punctuated with a series of crude, yet remarkably effective, stained-glass windows through which shafts of light fairly explode into the church. Simultaneously, in Dominikus Böhm's Church of Maria Königin (1953–54) in Cologne-Marienburg an entire sidewall of the church is conceived as a diaphanous veil of silvery gray stained glass that half reveals and half conceals the parklike grounds outside with equally dazzling effect. In Wallace K. Harrison's First Presbyterian Church (1958) in Stamford, Connecticut, the whole central section of the church is very nearly engirdled with slab glass and concrete. In all of these structures, different as they are in nearly every other respect, stained glass is seen boldly exploited once again not merely for its local ornamental quality but as a major, integral atmosphere-creating element.

The most seminal contributions of the School of Paris painters to the art of stained glass were Henri Matisse's Chapel of the Rosary (1948–52) in Vence and Fernand Léger's windows for the Church of the Sacred Heart (1950–52) in Audincourt. Both are the creation of artists whose manner of working was rather directly translatable into stained glass. It was but a comparatively short step from Matisse's large coloured-paper collages to the disarmingly simple decorative windows in Vence, but the way Matisse used them to create an enchanting play of colour in the chaste white space of the chapel is masterful. And it took the boldly emblematic style of Léger to reveal the true expressive potentialities of slab glass and concrete. A third important work of this period is the long friezelike window created by the sculptor Léon Zack for the Church of Notre-Dame-des-Pauvres (1955) in Issy-les-Moulineaux, remarkable for its daring sequence of colour harmonies and delicate lead line motifs reminiscent of the art of Paul Klee. The stained-glass windows of Braque, Villon, Rouault, Chagall, and Manessier are also noteworthy if less authoritative in their handling of the medium.

In Germany such distinguished prewar church architects as Dominikus Böhm and Rudolf Schwarz and the stained-glass artist Anton Wendling were able to resume careers that had been interrupted by the Hitler era and to set the course for a whole new generation of stained-glass artists, especially in the Rhineland. Inspired by the example of Thorn Prikker, these artists have continued to explore the unique qualities of stained glass—the special refractory properties of opal-flashed antique glass, the graphic potentialities of the lead line, the bold effects of texture and relief that had become possible with slab glass and concrete—and to create a whole gamut of strange brooding colour harmonies the like of which had not been seen in stained glass since the Augsburg prophets. Among the more important works of this Rhenish school of stained glass are Georg Meistermann's windows for the Dom Sepulchur (1957) in Würzburg and his complete ensemble of windows for the 15th-century church of St. Matthew (1964) in Sobernheim; Ludwig Schaffrath's cycle of modern grisaille windows for the cloister (1962–65) in Aachen, his high triple-gabled window walls for the transepts of St. Peter's Church (1964) in Birkesdorf, near Düren, and his powerfully iconic and technically innovative slab- and rod-glass sanctuary window in St. Matthew's Church (1966–67) in Leverkusen; Wilhelm Buschulte's unusually rich colour harmonies in his cycle of nave windows for the Cathedral of Essen (1964) and the choir of the Church of SS. Peter and Paul (1967) in Wegsburg, near Mönchengladbach; and Johannes Schreiter's almost monochromatic Abstract Expressionist windows for the Church of St. Margaret (1961) in Bürgstadt. Trained once again to work of the scale of the cathedral windows and to develop their art in accordance with its own intrinsic potentialities, such artists have been collaborating with some of the best architects in Germany to create the most impressive body of stained-glass windows since the Middle Ages.

BIBLIOGRAPHY. Illustrated monographs include: COMITE INTERNATIONAL D'HISTOIRE DE L'ART, *Corpus Vitrearum Medii Aevi* (1956–), a series intended when complete to document all medieval stained glass extant; J. BAKER and A. LAMMER, *English Stained Glass* (1960), probably the best collection of high-quality detail photographs of medieval stained glass ever published; H.E. READ, *English Stained Glass* (1926); A.C. SEWTER, *The Stained Glass of William Morris and His Circle* (1972); M. AUBERT *et al.*, *Le Vitrail française* (1958), the standard work on French stained glass, although marred by many poor reproductions. This fault is remedied in part by the following works: M. AUBERT, *Stained Glass of the XIIth and XIIIth Centuries from French Cathedrals* (1947); and E. VON WITZLEBEN, *French Stained Glass* (1966). H. WENTZEL, *Meisterwerke der Glasmalerei*, 2nd ed. (1954), is the standard work on German medieval stained glass; E. VON WITZLEBEN, *Farbwunder Deutscher Glasmalerei aus dem Mittelalter* (1965) is the most copiously illustrated recent monograph on German medieval stained glass. S. BEEH-LUSTENBERGER, *Glasmalerei um 800–1900 im Hessischen Landesmuseum in Darmstadt* (1967), an excellent guide to one of the largest museum collections of medieval stained glass; P. WEMBER, *Johan Thorn Prikker: Glasfenster, Wandbilder, Ornamente 1891–1932* (1966); G. MARCHINI, *Italian Stained Glass Windows* (1957); M. STETTLER, *Swiss Stained Glass of the Fourteenth Century from the Church of Koenigsfelden* (1949); and F. ZSCHOKKE, *Medieval Stained Glass in Switzerland* (Eng. trans., 1947).

Books on aesthetic analysis include J.R. JOHNSON, *The Radiance of Chartres: Studies in the Early Stained Glass of the Cathedral* (1965), valuable not only for its somewhat too sweeping criticisms of Viollet-le-Duc but for its original analysis of the effect of the twilight atmosphere of the cathedral upon our perception of its stained-glass windows; and R. SOWERS, *Stained Glass: An Architectural Art* (1965), a thoroughly illustrated analysis of the relation between stained glass and architecture, with numerous photographs of contemporary stained glass.

Stained-glass techniques are discussed in THEOPHILUS (RUGERUS), *Diversarum Artium Schedula* (1847; Eng. trans., 1963), the earliest account of stained-glass window-making techniques, now believed to have been written in the early 12th century; C. WINSTON, *Hints on Glass Painting* (1847), and his *Memoirs* (1865), two books containing some of the most thorough and perceptive analyses of medieval glass-painting techniques ever written; E. VIOLET-LE-DUC, "Vitrail," in *Dictionnaire Raisonné de l'architecture française*, vol. 9 (1868; Eng. trans., "Mediaeval Stained Glass," 1946), still valuable for its many acute observations; and C.W. WHALL, *Stained Glass Work* (1905), a thorough craft manual by one of the leading turn-of-the-century stained-glass artists in England. Recent manuals include E.L. ARMITAGE, *Stained Glass* (1959); P. REYNTIENS, *The Technique of Stained Glass* (1967); and R. and G. MECALF, *Techniques of Stained Glass* (1971).

(R.So./Ed.)

Stalin, Joseph

During the quarter of a century preceding his death in 1953, the Soviet dictator Joseph Stalin probably exercised greater political power than any other figure in history. Stalin industrialized the Union of Soviet Socialist Republics, forcibly collectivized its agriculture, consolidated his position by intensive police terror, helped to defeat Germany in 1941–45, and extended Soviet controls to include a belt of eastern European states. Chief architect of Soviet totalitarianism and a skilled but phenomenally ruthless organizer, he destroyed the remnants of individual freedom and failed to promote individual prosperity, yet he created a mighty military–industrial complex and led the Soviet Union into the nuclear age.

Stalin's biography was long obscured by a mendacious Soviet-propagated "legend" exaggerating his prowess as a heroic Bolshevik boy-conspirator and faithful follower of Lenin, the founder of the Soviet Union. In his prime, Stalin was hailed as a universal genius, as a "shining sun," or "the staff of life," and also as a "great teacher and friend" (especially of those communities he most savagely persecuted); once he was even publicly invoked as "Our Father" by a metropolitan of the Russian Orthodox Church. Achieving wide visual promotion through busts, statues, and icons of himself, the dictator became the object of a fanatical cult that, in private, he probably regarded with cynicism.

Stalin, 1950.
Sovfoto

The young revolutionary. Of Georgian—not Russian—origin, Stalin was born on December 21 (December 9, old style), 1879, as Joseph Vissarionovich Dzhugashvili, son of a poor cobbler in the provincial Georgian town of Gori in the Caucasus, then an imperial Russian colony. The drunken father savagely beat his son. Speaking only Georgian at home, Joseph learned Russian—which he always spoke with a guttural Georgian accent—while attending the church school at Gori (1888–94). He then moved to the Tiflis Theological Seminary, where he secretly read Karl Marx, the chief theoretician of international Communism, and other forbidden texts, being expelled in 1899 for revolutionary activity, according to the "legend"—or leaving through ill health, according to his doting mother. The mother, a devout washerwoman, had dreamed of her son becoming a priest, but Joseph Dzhugashvili was more ruffianly than clerical in appearance and outlook. He was short, stocky, black haired, fierce eyed, with one arm longer than the other, his swarthy face being scarred by smallpox contracted in infancy. Physically strong and endowed with prodigious willpower, he early learned to disguise his true feelings and to bide his time; in accordance with the Caucasian blood-feud tradition, he was implacable in plotting long-term revenge against those who offended him.

In December 1899, Dzhugashvili became, briefly, a clerk in the Tiflis Observatory, the only paid employment that he is recorded as having taken outside politics; there is no record of his ever having done manual labour. In 1900 he joined the political underground, fomenting labour demonstrations and strikes in the main industrial centres of the Caucasus; but his excessive zeal in pushing duped workers into bloody clashes with the police antagonized his fellow conspirators. After the Social Democrats (Marxist revolutionaries) of the Russian Empire had split into their two competing wings—Menshevik and Bolshevik—in 1903, Dzhugashvili joined the second, more militant, of these factions and became a disciple of its leader, Lenin. Between April 1902 and March 1913, Dzhugashvili was seven times arrested for revolutionary activity, undergoing repeated imprisonment and exile. The mildness of the sentences and the ease with which the young conspirator effected his frequent escapes lend colour to the unproved speculation that Dzhugashvili was for a time an *agent provocateur* in the pay of the imperial political police.

Work with Lenin

Rise to power. Dzhugashvili made slow progress in the party hierarchy. He attended three policy-making conclaves of the Russian Social Democrats—in Tammerfors (now Tampere, Finland; 1905), Stockholm (1906), and London (1907)—without making much impression. But he was active behind the scenes, helping to plot a spectacular holdup in Tiflis (now Tbilisi) on June 25 (June 12, O.S.), 1907, in order to "expropriate" funds for the party. His first big political promotion came in February (January, O.S.) 1912, when Lenin—now in emigration—co-opted him to serve on the first Central Committee of the Bolshevik Party, which had finally broken with the other Social Democrats. In the following year, Dzhugashvili published, at Lenin's behest, an important article on Marxism and the national question. By now he had adopted the name Stalin, deriving from Russian *stal* ("steel"); he also briefly edited the newly founded Bolshevik newspaper *Pravda* before undergoing his longest period of exile: in Siberia from July 1913 to March 1917.

In about 1904 Stalin had married a pious Georgian girl, Ekaterina Svanidze. She died some three years later and left a son, Jacob, whom his father treated with contempt, calling him a weakling after an unsuccessful suicide attempt in the late 1920s; when Jacob was taken prisoner by the Germans during World War II, Stalin refused a German offer to exchange his son.

Reaching Petrograd from Siberia on March 25 (March 12, O.S.), 1917, Stalin resumed editorship of *Pravda*. He briefly advocated Bolshevik cooperation with the provisional government of middle class liberals that had succeeded to uneasy power on the last tsar's abdication during the February Revolution. But under Lenin's influence, Stalin soon switched to the more militant policy of armed seizure of power by the Bolsheviks. When their coup d'etat occurred in November (October, old style) 1917, he played an important role, but one less prominent than that of his chief rival, Leon Trotsky.

Active as a politico-military leader on various fronts during the Civil War of 1918–20, Stalin also held two ministerial posts in the new Bolshevik government, being commissar for nationalities (1917–23) and for state control (or workers' and peasants' inspection; 1919–23). But it was his position as secretary general of the party's Central Committee, from 1922 until his death, that provided the power base for his dictatorship. Besides heading the secretariat, he was also member of the powerful Politburo and of many other interlocking and overlapping committees—an arch-bureaucrat engaged in quietly outmanoeuvring brilliant rivals, including Trotsky and Grigory Zinoviev, who despised such mundane organizational work. Because the pockmarked Georgian was so obviously unintellectual, they thought him unintelligent: a gross error, and one literally fatal in their case.

Ministerial posts

From 1921 onward Stalin flouted the ailing Lenin's wishes, until, a year before his death, Lenin wrote a political "testament," since widely publicized, calling for Stalin's removal from the secretary generalship; coming from Lenin, this document was potentially ruinous to Stalin's career, but his usual luck and skill enabled him to have it discounted during his lifetime.

Lenin's successor. After Lenin's death, in January 1924, Stalin promoted an extravagant, quasi-Byzantine cult of the deceased leader. Arch-priest of Leninism, Stalin also promoted his own cult in the following year by having the city of Tsaritsyn renamed Stalingrad (now Volgograd). His main rival, Trotsky (once Lenin's heir apparent), was now in eclipse, ousted by the ruling triumvirate of Zinoviev, Lev Kamenev, and Stalin. Soon afterward Stalin joined with the rightist leaders Nikolay Bukharin and Aleksey Rykov in an alliance directed against his former co-triumvirs. Pinning his faith in the ability of the Soviet Union to establish a viable political system without waiting for the support hitherto expected from worldwide revolution, the Secretary General advocated a policy of "Socialism in one country"; this was popular with the hardheaded party managers whom he was promoting to influential positions in the middle hierarchy. His most powerful rivals were all dismissed, Bukharin and Rykov soon following Zinoviev and Kamenev into disgrace and political limbo pending execution. Stalin expelled Trotsky from the Soviet Union in 1929 and had him assassinated in Mexico in 1940.

The policy of "Socialism in one country"

Collectivization of agriculture and industrialization

In 1928 Stalin abandoned Lenin's quasi-capitalist New Economic Policy in favour of headlong state-organized industrialization under a succession of five-year plans. This was, in effect, a new Russian revolution more devastating in its effects than those of 1917. The dictator's blows fell most heavily on the peasantry, some 25,000,000 rustic households being compelled to amalgamate in collective or state farms within a few years. Resisting desperately, the reluctant muzhiks were attacked by troops and OGPU (political police) units. Uncooperative peasants, termed kulaks, were arrested en masse, being shot, exiled, or absorbed into the rapidly expanding network of Stalinist concentration camps and worked to death under atrocious conditions. Collectivization also caused a great famine in the Ukraine. Yet Stalin continued to export the grain stocks that a less cruel leader would have rushed to the famine-stricken areas. Some 10,000,000 peasants may have perished through his policies during these years.

Crash industrialization was less disastrous in its effects, but it, too, numbered its grandiose failures, to which Stalin responded by arraigning industrial managers in a succession of show trials. Intimidated into confessing imaginary crimes, the accused served as self-denounced scapegoats for catastrophes arising from the Secretary General's policies. Yet Stalin was successful in rapidly industrializing a backward country—as was widely acknowledged by enthusiastic contemporary foreign witnesses, including Adolf Hitler and such well-known writers as H.G. Wells and George Bernard Shaw.

Among those who vainly sought to moderate Stalin's policies was his young second wife, Nadezhda Alliluyeva, whom he had married in 1919 and who committed suicide in 1932. They had two children. The son, Vasily, perished as an alcoholic after rising to unmerited high rank in the Soviet Air Force. The daughter, Svetlana, became the object for her father's alternating affection and bad temper; emigrating after his death, she wrote memoirs that illuminate Stalin's well-camouflaged private life.

The great purges. In late 1934—just when the worst excesses of Stalinism seemed to have spent themselves—the Secretary General launched a new campaign of political terror against the very Communist Party members who had brought him to power; his pretext was the assassination, in Leningrad on December 1, of his leading colleague and potential rival, Sergey Kirov. That Stalin himself had arranged Kirov's murder—as an excuse for the promotion of mass bloodshed—was strongly hinted by Nikita Khrushchev, first secretary of the party, in a speech denouncing Stalin at the 20th Party Congress in 1956.

Stalin used the show trial of leading Communists as a means for expanding the new terror. In August 1936, Zinoviev and Kamenev were paraded in court to repeat fabricated confessions, sentenced to death, and shot; two more major trials followed, in January 1937 and March 1938. In June 1937, Marshal Mikhail Tukhachevsky, at the time the most influential military personality, and other leading generals were reported as court-martialled on charges of treason and executed.

Such were the main publicly acknowledged persecutions that empowered Stalin to tame the Soviet Communist Party and the Soviet elite as a whole. He not only "liquidated" veteran semi-independent Bolsheviks but also many party bosses, military leaders, industrial managers, and high government officials totally subservient to himself. Other victims included foreign Communists on Soviet territory and members of the very political police organization, now called the NKVD. All other sections of the Soviet elite—the arts, the academic world, the legal and diplomatic professions—also lost a high proportion of victims, as did the population at large, to a semi-haphazard, galloping persecution that fed on extorted denunciations and confessions. These implicated even more victims until Stalin himself reduced the terror, though he never abandoned it. Stalin's political victims were numbered in tens of millions. His main motive was, presumably, to maximize his personal power.

Role in World War II. During World War II Stalin emerged, after an unpromising start, as the most successful of the supreme leaders thrown up by the belligerent nations. In August 1939, after first attempting to form an anti-Hitler alliance with the Western powers, he concluded a pact with Hitler, which encouraged the German dictator to attack Poland and begin World War II. Anxious to strengthen his western frontiers while his new but palpably treacherous German ally was still engaged in the West, Stalin annexed eastern Poland, Estonia, Latvia, Lithuania, and parts of Romania; he also attacked Finland and extorted territorial concessions. In May 1941 Stalin recognized the growing danger of German attack on the Soviet Union by appointing himself chairman of the Council of People's Commissars (head of the government): his first governmental office since 1923.

Stalin's prewar defensive measures were exposed as incompetent by the German blitzkrieg that surged deep into Soviet territory after Hitler's unprovoked attack on the Soviet Union of June 22, 1941. Khrushchev claimed that Stalin was shocked into temporary inactivity by the onslaught, but, if so, he soon rallied and appointed himself supreme commander in chief. When the Germans menaced Moscow in the winter of 1941, he remained in the threatened capital, helping to organize a great counter-offensive. The battle of Stalingrad (in the following winter) and the Battle of Kursk (in the summer of 1943) were also won by the Soviet Army under Stalin's supreme direction, turning the tide of invasion against the retreating Germans, who capitulated in May 1945. As war leader, Stalin maintained close personal control over the Soviet battlefronts, military reserves, and war economy. At first overinclined to intervene with inept telephoned instructions a la Hitler, the Soviet generalissimo gradually learned to delegate military decisions.

Role as supreme commander in chief

Stalin participated in high-level allied meetings, including those of the "Big Three" with Churchill and Roosevelt at Teheran (1943) and Yalta (1945). A formidable negotiator, he outwitted these foreign statesmen; his superior skill has been acclaimed by Anthony Eden, then British foreign secretary.

Last years. After the war Stalin imposed on eastern Europe a new kind of colonial control based on native Communist regimes nominally independent but in fact subservient to himself. He thus increased the number of his subjects by about a hundred million. But in 1948 the defection of Titoist Yugoslavia from the Soviet camp struck a severe blow to world Communism as a Stalin-dominated monolith. To prevent other client states from following Tito's example, Stalin instigated local show trials, manipulated like those of the Great Purge of the 1930s in Russia, in which satellite Communist leaders confessed to Titoism, many being executed.

Postwar foreign policy

Far from continuing his wartime alliance with the United States and Britain, Stalin now regarded these countries —and especially the United States—as the archenemies that he needed after Hitler's death. At home, the primacy of Marxist ideology was harshly reasserted, Stalin's chief ideological hatchet man, Andrey Zhdanov, the secretary of the Central Committee, mounting a reign of terror in the Soviet artistic and intellectual world; foreign achievements were derided, and the primacy of Russians as inventors and pioneers in practically every field was asserted. Hopes for domestic relaxation, widely aroused in the Soviet Union during the war, were thus sadly disappointed.

Increasingly suspicious and paranoid in his later years, Stalin ordered the arrest, announced in January 1953, of certain—mostly Jewish—Kremlin doctors on charges of medically murdering various Soviet leaders, including Zhdanov. The dictator was evidently preparing to make this "Doctors' Plot" the pretext for yet another great terror menacing all his senior associates, but he died suddenly on March 5, 1953, according to the official report; so convenient was this death to his entourage that suspicions of foul play were voiced.

Assessment. A politician to the marrow of his bones, Stalin had little private or family life, finding his main relaxation in impromptu buffet suppers, to which he

Personal life

would invite high party officials, generals, visiting foreign potentates, and the like. Drinking little himself on these occasions, the dictator would encourage excessive indulgence in others, thus revealing weak points that he could exploit. He would also tease his guests, jocularity and malice being nicely balanced in his manner; for such bluff banter Stalin's main henchman, Vyacheslav Molotov, the stuttering foreign minister, was often a target. Stalin had a keen, ironical sense of humour, usually devoted to deflating his guests rather than to amusing them.

Achievements

Foremost among Stalin's accomplishments was the industrialization of a country which, when he assumed complete control in 1928, was still notably backward by comparison with the leading industrial nations of the world. By 1937, after less than a decade's rule as totalitarian dictator, he had increased the Soviet Union's total industrial output to the point where it was surpassed only by that of the United States. The extent of this achievement may best be appreciated if one remembers that Russia had held only fifth place for overall industrial output in 1913, and that it thereafter suffered many years of even greater devastation—through world war, civil war, famine, and pestilence—than afflicted any of the world's other chief industrial countries during the same period. Yet more appallingly ravaged during World War II, the Soviet Union was nevertheless able, under Stalin's leadership, to play a major part in defeating Hitler while maintaining its position as the world's second most powerful industrial—and now military—complex after the United States. In 1949 Stalinist Russia signalized its arrival as the world's second nuclear power by exploding an atomic bomb.

Against these formidable achievements must be set one major disadvantage. Though a high industrial output was indeed achieved under Stalin, very little of it ever became available to the ordinary Soviet citizen in the form of consumer goods or amenities of life. A considerable proportion of the national wealth—a proportion wholly unparalleled in the history of any peacetime capitalist country—was appropriated by the state to cover military expenditure, the police apparatus, and further industrialization. It is also arguable that a comparable degree of industrialization would have come about in any case—and surely by means less savage—under almost any conceivable regime that might have evolved as an alternative to Stalinism.

Stalin's collectivization of agriculture did not produce—either during his lifetime or during the decades immediately following his death—positive economic results remotely comparable to those attained by Soviet industry. Considered as a means of asserting control over the politically recalcitrant peasantry, however, collectivization triumphantly justified itself and continues to do so, remaining one of the dictator's most durable achievements. Moreover, the process of intensive urbanization, as instituted by Stalin, continued after his death in what still remained a population more predominantly rural than that of any other major industrial country. In 1937, 56 percent of the population was recorded as engaged in agriculture or forestry; by 1958 that proportion had dropped to 42 percent, very largely as a result of Stalin's policies.

The most lasting of all the dictator's achievements may prove to be his elaborately bureaucratized administrative machinery based on the interlinking of the Communist Party, ministries, legislative bodies, trade unions, political police, and armed forces, as also on a host of other meshing control devices. During the two decades following the dictator's death, these continued to supply the essential management levers of Soviet society, often remaining under the control of individuals who had risen to prominence during the years of the Stalinist terror. But the element of total personal dictatorship did not survive Stalin in its most extreme form. One result of his death was the resurgence of the Communist Party as the primary centre of power, after years during which that organization, along with all other Soviet institutions, had been subordinated to a single man's whim. Yet, despite the great power wielded by Stalin's successors as party leaders, they became no more than dominant figures within the framework of a ruling oligarchy. They did not develop into potentates responsible to themselves alone, such as Stalin was during his quarter of a century's virtually unchallenged rule.

That Stalin's system persists, in all its major essentials, after the death of its creator is partly due to the very excess of severity practiced by the great tyrant. Not only did his methods crush initiative among Soviet administrators, physically destroying many, but they also left a legacy of remembered fear so extreme as to render continuing post-Stalin restrictions tolerable to the population; the people would have more bitterly resented—might even, perhaps, have rejected—such rigours, had it not been for their vivid recollection of repressions immeasurably harsher. Just as Hitler's wartime cruelty toward the Soviet population turned Stalin into a genuine national hero—making him the Soviet Union's champion against an alien terror even worse than his own—so too Stalin's successors owed the stability of their system in part to the comparison, still fresh in many minds, with the far worse conditions that obtained during the despot's sway.

Stalin has arguably made a greater impact on the lives of more individuals than any other figure in history. But the evaluation of his overall achievement still remains, nearly two decades after his death, a highly controversial matter. Historians have not yet reached any definitive consensus of opinion on the worth of his accomplishments, and it is unlikely that they ever will. To the United States scholar George F. Kennan, Stalin is a great man, but one great in his "incredible criminality . . . a criminality effectively without limits," while Robert C. Tucker, a United States specialist on Soviet affairs, has described Stalin as a 20th-century Ivan the Terrible. To the British historian E.H. Carr, the Georgian dictator appears as a ruthless, vigorous figure, but one lacking in originality—a comparative nonentity thrust into greatness by the inexorable march of the great revolution that he found himself leading. To the late Isaac Deutscher, the author of biographies of Trotsky and Stalin—who, like Carr, broadly accepts Trotsky's version of Stalin as a somewhat mediocre personage—Stalin represents a lamentably deviant element in the evolution of Marxism. Neither Deutscher nor Carr has found Stalin's truly appalling record sufficiently impressive to raise doubts about the ultimate value of the Russian October Revolution's historic achievements.

Reputation

To such views, each illuminating a facet of Stalin's personality, may be added the suggestion that Stalin was anything but a plodding mediocrity, being rather a man of superlative, all-transcending talent. His special brilliance was, however, narrowly specialized and confined within the single crucial area of creative political manipulation. Outside the realm of pioneering political manoeuvre, in which Stalin's flair remains unsurpassed, his qualities appear in no way superhuman, apart perhaps from the dogged persistence with which he was accustomed to pursue to the death both his manifold goals and his innumerable enemies.

MAJOR WORKS

BOOKS: *Anarkhizm ili sotsializm?* (1949, Russian version of articles published serially in Georgian periodicals, 1906–07; *Anarchism or Socialism?*, 1950); *Natsionalny vopros i marksizm* (1914, based on article "Natsionalny vopros i sotsial-demokratiya" in periodical *Prosveshchenie*, 1913, and reissued as *Marksizm i natsionalnokolonialny vopros*, 1934; *Marxism and the National and Colonial Question*, 1935); *Na putyakh k Oktyabryu* (1925; selections translated as *The Road to Power*, 1937); *Voprosy leninizma* (1926, 11th ed., much enlarged, 1939; *Leninism*, 1940, or *Problems of Leninism*, 1940 and 1953), a monumental collection of treatises, articles, reports, and speeches including "Ob osnovakh leninizma" (1924; *Theory and Practice of Leninism*, 1925, and *Foundations of Leninism*, 1932); "K voprosam agrarnoy politiki v SSSR" (1929); "O proyekte konstitutsii Soyuza SSR" (1936; *On the Draft Constitution of the U.S.S.R.*, 1936, and *The New Democracy*, 1937); and "O dialekticheskom i istoricheskom materializme" (1938; *Dialectical and Historical Materialism*, 1941); *Ob oppozitsii* (1928), a massive collection of writings of the period 1921–27; *O pravom*

uklone v VKP(b) (speech of 1929 published integrally as a separate book in 1954); *O nedostatkakh partiynoy raboty i merakh likvidatsy Trotskistskikh i inykh dvurushnikov* (1937); *Istoriya Vsesoyuznoy Kommunisticheskoy Partii (Bolshevikov): Kratky kurs* (1938, ostensibly the work of a party committee, but wholly Stalinian in inspiration; *Short History of the Communist Party of the Soviet Union*, 1939); *Iosif Vissarionovich Stalin: Kratkaya biografiya* (1940, 2nd ed. 1947, likewise ostensibly a collective production; *Stalin*, 1943); *O Velikoy Otechestvennoy Voyne Sovetskogo Soyuza* (1942, 5th ed., much enlarged, 1946–52; *The Great Patriotic War of the Soviet Union*, 1945, or *War Speeches, Orders of the Day, and Answers to Foreign Press Correspondents during the Great Patriotic War, July 3, 1941–June 22nd, 1945*, 1946); *Marksizm i voprosy yazykoznaniya* (1950; *Marxism and Linguistics*, 1951); *Ekonomicheskie problemy sotsializma v SSSR* (1952; *Economic Problems of Socialism in the U.S.S.R.*, 1952); *Perepiska Predsedatelya Sovieta Ministrov SSSR s prezidentami SShA i premier-ministrami Velikobritanii vo vremya Velikoy Otechestvennoy Voyny* (1957; *Correspondence with Churchill, Attlee, Roosevelt and Truman, 1941–45*, 2 pt., 1958).

BIBLIOGRAPHY. The standard Soviet edition of Stalin's works in Russian is his *Сочинения*, 13 vol. (1946–51), covering publications up to January 1934; an American-published continuation of this edition and containing later works (vol. 14–16) in Russian has been issued in similar format by the Hoover Institution (1967), ed. by ROBERT H. MCNEAL.

An annotated bibliography by ROBERT H. MCNEAL, *Stalin's Works* (1967), considers the authenticity of material in Russian attributed to Stalin. Bibliographies more useful to the general reader will be found in the works of Deutscher, Payne, Souvarine, and Smith cited below.

There is no definitive biography of Stalin. The most useful among scores of published studies include: ROBERT PAYNE, *Rise and Fall of Stalin* (1965), readable, but verbose; ISAAC DEUTSCHER, *Stalin: A Political Biography*, 2nd ed. (1966), one-sidedly Marxist in its approach; LEON TROTSKY, *Stalin: An Appraisal of the Man and His Influence*, 2nd ed. (1946), an eloquent and witty but biassed and uncompleted study; also denunciatory, BORIS SOUVARINE, *Stalin: A Critical Survey of Bolshevism* (1939), still commands some respect, as does BERTRAM D. WOLFE, *Three Who Made a Revolution* (1956). *Stalin*, ed. by T.H. RIGBY (1966), is an excellent short anthology of biographical and critical material.

Reliable, detailed firsthand accounts of Stalin's domestic background are few, the only family memoirs not subject to Stalinist censorship being those published by the dictator's daughter, SVETLANA ALLILUYEVA, in emigration: *Twenty Letters to a Friend* (Eng. trans. 1967) and *Only One Year* (Eng. trans. 1969); for Soviet-censored memoirs by Svetlana Alliluyeva's grandfather and aunt, see *The Alliluyev Memoirs*, trans. and ed. by DAVID TUTAEV (1968); the most valuable full account of Stalin in his role as dinner-party host is that of MILOVAN DJILAS, *Conversations with Stalin* (Eng. trans. 1962); on this subject the memoirs of Winston Churchill, Anthony Eden, Charles de Gaulle, and many others may be consulted (see also the bibliographies in works by Payne and Deutscher cited above).

On Stalin's pre-revolutionary career, EDWARD ELLIS SMITH, *The Young Stalin* (1967), unsuccessfully but informatively attempts to prove that the subject was an agent of the Tsarist political police; erring far more in the opposite direction, LAVRENTY BERIA, *On the History of the Bolshevik Organizations in Transcaucasia* (1949), mendaciously glorifies Stalin's role as an anti-Tsarist political conspirator and is the chief classic of Stalinist legend-building.

For the political background of Stalin's mature career, LEONARD SCHAPIRO, *The Communist Party of the Soviet Union*, 2nd ed. (1970), is especially valuable, as is JOHN A. ARMSTRONG, *The Politics of Totalitarianism* (1961); a more subjective version of the same events by a former participant is ABDURAKHMAN AVTORKHANOV, *Stalin and the Soviet Communist Party* (1959). BORIS I. NICOLAYEVSKY, *Power and the Soviet Elite* (1965), is an illuminating collection of essays bearing on Stalin's activities from 1934 onward by the leading Russian émigré authority on Soviet conspiratorial politics. ROBERT CONQUEST, *The Great Terror* (1968), is the fullest and liveliest account of the persecutions of 1937–38, on which ZBIGNIEW K. BRZEZINSKI, *Permanent Purge* (1956), is also helpful; see further *The Great Purge Trial*, ed. by ROBERT C. TUCKER and STEPHEN F. COHEN (1965). F. BECK and W. GODIN, *Russian Purge and the Extraction of Confession* (1951), remains a classic account of Stalin's terror; on this see also W.G. KRIVITSKY, *I Was Stalin's Agent* (1939); and ALEXANDER ORLOV, *Secret History of Stalin's Crimes* (1953), informative primary sources, but they cannot always be checked against other material.

On Stalin's role as wartime leader, SEWERYN BIALER'S anthology of Soviet memoir material, *Stalin and His Generals* (1969), is outstandingly useful; so too is HERBERT FEIS, *Churchill, Roosevelt, Stalin* (1957); see further, ALEXANDER WERTH, *Russia at War, 1941–1945* (1964), and *The Memoirs of Marshal Zhukov* (1971).

On post-war and posthumous Stalin, ROBERT CONQUEST, *Power and Policy in the U.S.S.R.* (1961), plausibly unravels many mysteries. On the controversy surrounding Stalin's image after his death, see *The Anti-Stalin Campaign and International Communism: A Selection of Documents*, ed. by the RUSSIAN INSTITUTE, COLUMBIA UNIVERSITY (1956); BERTRAM D. WOLFE, *Khrushchev and Stalin's Ghost* (1957); and *The Stalin Dictatorship: Khrushchev's "Secret Speech" and Other Documents*, ed. by T.H. RIGBY (1968).

(R.F.Hi.)

Stanislavsky, Konstantin

With legitimate claims to historic significance as an actor, as a director, and as a founder of the Moscow Art Theatre, Konstantin Stanislavsky (also spelled Stanislavski) is best known as the innovator of what may have been the most influential theory of acting of the 20th century—his celebrated system, the basis of what became widely known as the "method." Beginning as a Realist opposed to the highly stylized theatrical conventions of the late 19th century, he remained preoccupied throughout his career with the complex relationships between inner truths felt by the performer and the outer truths his performance conveys to the audience, that is, between the actor's subjective psychological states and the external physical expression of those states. Seeking a means of commanding the resources that are evident in a performer's moments of "inspiration," Stanislavsky came close to creating a science of theatre.

Stanislavsky as Vershinin in Chekhov's *Three Sisters*, 1901.

Early influences. Stanislavsky was born Konstantin Sergeyevich Alekseyev in Moscow on January 17 (new style; 5, old style), 1863. His father, a manufacturer, and mother, the daughter of a French actress, were intimate with the outstanding art and literary personalities of Moscow. As a child Stanislavsky attended the circus, opera, and ballet, and his early years were influenced by an atmosphere of family affection and a fascination with the theatre. When he first appeared on his parents' amateur stage, at the age of 14, he believed his performance was inspired and was distressed that it was not praised. In the dramatic group that subsequently was organized by his family and called the Alekseyev Circle, he was teased for his clumsiness while performing comedy and vaudeville. At first hiding his desire to become an actor with characteristic self-doubts and self-criticism, Stanislavsky obsessively worked on his shortcomings of voice and diction

The Alekseyev Circle

and on the awkwardness of his body. His thoroughness and his preoccupation with all aspects of a production came to distinguish him from other members of the Alexeyev Circle, and he gradually became its central figure. Stanislavsky also performed in other groups as theatre came to absorb his life. He adopted the pseudonym Stanislavsky in 1885, and in 1888 he married Maria Perevoshchikova, a schoolteacher, who became his devoted disciple and lifelong companion, as well as an outstanding actress under the name Lilina.

Stanislavsky's love for theatre developed into an allegiance to what he saw as an art of social significance. Theatre, a powerful influence on people, he believed, must be on the highest level, and the actor must be the people's educator. Evaluating his own and his colleagues' acting from this viewpoint, he found it unsatisfactory. Moreover, he found that it could not be improved through sporadic productions but required instead a permanent company.

Building a people's theatre. In 1888 Stanislavsky and others established the Society of Art and Literature with a permanent amateur company. Endowed with great talent, musicality, a striking appearance, a vivid imagination, and a subtle intuition, Stanislavsky began to develop the plasticity of his body and a greater range of voice. Praise came from famous foreign actors, and great Russian actresses invited him to perform with them. Thus encouraged, Stanislavsky staged his first independent production, Tolstoy's *Fruits of Enlightenment*, in 1891, a major Moscow theatrical event. Most significantly, it impressed a promising writer and director, Vladimir Nemirovich-Danchenko (1858–1943), whose later association with Stanislavsky was to have a paramount influence on the theatre.

Collaboration with Nemirovich-Danchenko

Nemirovich-Danchenko followed Stanislavsky's activities until their historic meeting in 1897, when they outlined a plan for a people's theatre. It was to consist of the most talented amateurs of Stanislavsky's society and of the students of the Philharmonic Music and Drama School, which Nemirovich-Danchenko directed. As the Moscow Art Theatre, it became the arena for Stanislavsky's reforms. Despite differences in personality, the two men, both of whom were vital to the artistic development of the theatre, worked closely until Stanislavsky's death. Nemirovich-Danchenko was a man of the world, who enjoyed gaiety: Stanislavsky's tastes were puritanical. When Nemirovich-Danchenko reprimanded an actor, he did so privately in his office; Stanislavsky, demanding respect toward theatre, admonished actors in a voice that echoed through the building. A major artistic disagreement occurred in 1905, when Stanislavsky suggested rehearsing a play by having the actors first improvise their parts. Nemirovich-Danchenko and the director Vsevolod Meyerhold (1874–1942) vehemently objected to the proposal. Stanislavsky thus abandoned the idea, but 30 years later he formulated it as a law for the analysis of a play and a role.

Although Stanislavsky was a compassionate man, he was uncompromising in educating actors. He might occasionally ban actors from rehearsal for days as punishment for a few minutes' tardiness. He insisted on integrity of performance on stage, repeating for hours his dreaded "I do not believe you." His dedication was total: when an actor asked Stanislavsky to demonstrate and then interrupted his demonstration with "I do not believe you," the concentrating master replied "Really? Then I shall have to work on this at home." Throughout his career, Stanislavsky went to the theatre hours before curtain time to put on what he called his physical and spiritual makeup. Addressing the cast for Aleksey Tolstoy's *Tsar Fyodor Ioannovich* before the opening of the Moscow Art Theatre on October 14 (26, O.S.), 1898, Stanislavsky said: "We strive to brighten the dark life of poor people, to give them happy aesthetic moments. We are striving for the first sensible, moral, popular theatre, and to this high goal we dedicate our lives."

Developing the system. Stanislavsky was disappointed in the acting that night. He found it to be merely imitative of the gestures, intonations, and conceptions of the director. To affect the spectators, he reflected, there must be alive people on stage, and the mere external behaviour of the actors is insufficient to create a man's unique inner world. To learn about inner behaviour, Stanislavsky turned to psychologists and at the same time sharply changed his approach—from the purely external to the purely psychological. He began developing the first elements of his "grammar of dramatic art." A play was studied around a table for months; the actors were required to achieve the experience they were to portray before entering on stage.

Relations with Chekhov

Stanislavsky's experience with Anton Chekhov's *Sea Gull* confirmed his convictions about the need for what he called "the life of the human spirit" on stage. With difficulty, Stanislavsky obtained Chekhov's permission to restage *The Sea Gull* after its original production in St. Petersburg in 1896 had been a failure. Directed by Stanislavsky and Nemirovich-Danchenko in 1898, *The Sea Gull* became a triumph, heralding the birth of the Moscow Art Theatre as a new force in world theatre. Chekhov, who had resolved never to write another play after his initial failure, was acclaimed a great playwright. His writings significantly influenced the development of the system that was to evolve over decades in Stanislavsky's search for the best means to be used by actors and directors.

Staging Chekhov's play, Stanislavsky and Nemirovich-Danchenko discovered a new manner of performing, of revealing a man's inner world: they emphasized ensemble and the subordination of each individual actor to the whole. All technical means were directed toward creating one image. Seeking a theatrical language through which the play's life would be relived by the audience, Stanislavsky subordinated the director's and actors' interpretation to the dramatist's "superobjective," that is, to his intent. Actors, he felt, had to have a common training and be capable of "reincarnation." That reincarnation, however, did not imply the complete identification of an actor with the character; rather, some part of the actor's personality must remain independent of the role in order to subordinate it to the needs of the play as a whole. This point was clarified by Stanislavsky's teachings of conscious control and of the actor's "I" and "not I." Total "melting"—that is, the total identification of an actor with a particular role—he said, occurred only in pathological cases.

Stanislavsky was haunted by the actor's need for a means to stir his inner life, to awaken his own initiative. Endowed with an analytical mind, Stanislavsky generalized and systematized his own experience and that of his colleagues and students. He combined all this with his knowledge of the performances and statements of major artists. Fighting against the artificiality of stage, dilettantism, and acting "by instinct," he sought a natural state based on the laws of man's organic nature. Stanislavsky was building a theatre of "living experience" that demanded not an external demonstration of emotions, as was found in what he called the "theatre of representation," but the reproduction of authentic emotions at every performance: "Here, today, now." Actors, he said, must learn to use the natural laws through which geniuses sometimes spontaneously channel their creativity. This is the essence of the system: to enable the capable actor to achieve the creative state that was hitherto the privilege of genius alone.

The "super-super-objective"

The basis of Stanislavsky's educational program is expressed in his "Love art in you, not you in art." He stressed friendship in the group and ensemble on stage, and he cited as the actors' "super-superobjective" the striving to contribute to society. His dedication and powerful personality had great influence. Emphasizing dignity in the theatre, Stanislavsky demanded harmony between the actor's life and professional behaviour. He warned that the artist's spiritual formation would be sensed in his creations. Stanislavsky's ethical principles, which were the foundation of his aesthetics, were always indivisible from his methodology; he believed them to be essential to an atmosphere in which collective creativity was possible.

In 1902 Stanislavsky successfully staged both Gorky's *Petty Bourgeois* and *The Lower Depths*, codirecting the latter with Nemirovich-Danchenko. Among the numerous powerful roles performed by Stanislavsky were Astrov in *Uncle Vanya* in 1899 and Gayev in *The Cherry Orchard* in 1904, by Chekhov; Doctor Stockman in Ibsen's *Enemy of the People* in 1900; and Satin in *The Lower Depths*. Both as an actor and as a director, Stanislavsky demonstrated a remarkable subtlety in rendering psychological patterns and an exceptional talent for satirical characterization.

Commanding respect from followers and adversaries alike, Stanislavsky became a dominant influence on the Russian intellectuals of the time. He formed the First Studio in 1912, where his innovations were verified through the work of young actors, avoiding the older, more conservative actors' resistance. In 1918 he undertook the guidance of the Bolshoi Opera Studio, which was later named for him. There he staged Tchaikovsky's *Eugene Onegin* in 1922, which was acclaimed as a major reform in opera.

Revising the system. In 1922-24 the Moscow Art Theatre toured Europe and the United States with Stanislavsky as its administrator, director, and leading actor. A great interest was stirred in his system. During this period he wrote his famous autobiography, *My Life in Art*. Ever preoccupied in it with content and form, Stanislavsky acknowledged that the "theatre of representation," which he had disparaged, nonetheless produced brilliant actors. In the best of them he perceived true emotions; the great opera singer Fyodor Chaliapin combined depth and grand theatrical form, and other celebrated Realist actors would not have been so impressive, Stanislavsky recognized, if they had not attached importance to external expression.

Return to theatricality

Recognizing that theatre was at its best when deep content harmonized with vivid theatrical form, Stanislavsky supervised the First Studio's production of Shakespeare's *Twelfth Night* in 1917 and Gogol's *Government Inspector* in 1921, encouraging the actor Michael Chekhov in a brilliantly grotesque characterization. His staging of Aleksandr Ostrovsky's *Ardent Heart* (1926) and of Beaumarchais's *Marriage of Figaro* (1927) demonstrated increasingly bold attempts at theatricality. His monumental *Armored Train 14–69*, a play about the Russian Revolution, was a milestone in Soviet theatre in 1927, and his *Dead Souls* was a brilliant incarnation of Gogol's masterpiece.

Stanislavsky continued to establish, to destroy, and to establish again. Although his techniques changed, his method for many years remained purely psychological. Always critical of his own means, however, Stanislavsky noted that after prolonged mental work, actors went on stage with "swollen heads" and that they could not act as characters but were simply dwelling in their own experience. He witnessed the transformation of his own precepts into a new theatrical cliché: actors presented a demonstration of an experience that only had the look of truth. He concluded that mental analysis alone harboured the danger of a calculated rather than a creative approach, paralyzing the actor's subconscious. Stanislavsky's efforts to create an alive man on stage seemed to be threatened. With increased zeal, he pursued the means to "organized" emotions; that is, a means by which the emotions implicit in a role could be aroused at will.

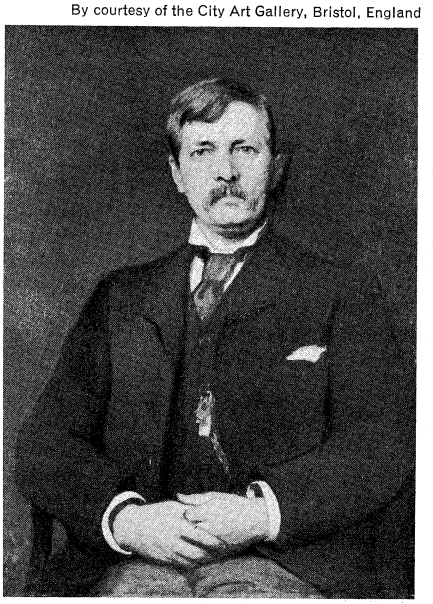
Last years. While acting in *The Three Sisters* during the Moscow Art Theatre's 30th anniversary presentation on October 29, 1928, Stanislavsky suffered a heart attack. Abandoning acting, he concentrated on directing and educating actors and directors. In 1935 he founded the Opera Drama Studio.

Pavlov's influence

In the early 1930s Stanislavsky studied the writings of physiologist Ivan Pavlov and attempted to analyze the actor's creativity on the basis of the brain's higher nervous activity. Pavlov, too, was interested in Stanislavsky's system, an association interrupted by Pavlov's death in 1936.

Stanislavsky now followed Pavlov's road in the science of the brain. Seeking a means of synthesizing content and form, Stanislavsky in 1935 fulfilled a 40-year quest with the discovery of what he regarded as the unbreakable psychophysical unity of the human experience and its external expression. Using this discovery, Stanislavsky developed his "method of physical actions," an analysis leading to the synthesis of content (or experience) and form (or expression) and the means to "organized" emotions. He immediately began an experimental production of Molière's *Tartuffe*.

Although his teachings influenced theatre throughout the world, Stanislavsky was reluctant to publish his discoveries until his theses had been verified in practice. Thus, many of his writings were prepared for publication only after his death in Moscow on August 7, 1938, by the scholars who compiled and edited the eight volumes of his *Complete Works*.



BIBLIOGRAPHY. DAVID MAGARSHACK, *Stanislavsky: A Life* (1950); K.S. STANISLAVSKY, *My Life in Art*, trans. from the Russian by J.J. ROBBINS (1924, reprinted 1956), an outstanding autobiography; *An Actor Prepares*, trans. from the Russian by E.R. HAPGOOD (1936, reprinted 1956), Stanislavsky's first book on his technique and the only one published during his lifetime; and *Building a Character*, trans. from the Russian by E.R. HAPGOOD (1949), a text prepared for publication by Stanislavsky's disciples; SONIA MOORE, *The Stanislavski System*, rev. ed., preface by SIR JOHN GIELGUD, foreword by JOSHUA LOGAN (1965), an updated discussion of the Stanislavsky acting technique, *Training an Actor: The Stanislavski System in Class* (1968), a work based on class tape recordings demonstrating the Stanislavsky technique in practice.

(S.M.)

Stanley, Sir Henry Morton

Though Sir Henry Morton Stanley first achieved fame for his rescue of David Livingstone, in 1871, his true importance lies in his discovery and development of the Congo. To him belongs the credit of having assembled the geographical discoveries and guesses of an earlier generation into a coherent whole which approximates the present map of central Africa.

Stanley, portrait by Sir Hubert von Herkomer (1849–1914). In the City Art Gallery, Bristol, England.

Early life in Wales

He was born on January 28, 1841, at Denbigh, North Wales, the illegitimate son of John Rowlands and Elizabeth Parry, and was registered as John Rowlands. His mother left him to the care of her father, Moses Parry, and he grew up partly in the charge of reluctant relatives and partly in the St. Asaph workhouse, where he suffered from the severity of the workhouse master. He acquired a reasonable education at St. Asaph, developed a strong religious faith, and learned to value order and cleanliness; but the humiliations of institutional life left deep marks

The expeditions of Sir Henry Morton Stanley.

on his character, as did his mother's continued neglect. At the age of 15 he ran away from the workhouse, and his escape was followed by an unhappy interlude of dependence on his mother's relatives which ended only when he sailed from Liverpool as a cabin boy to New Orleans, Louisiana, where he landed in 1859.

There Rowlands met Henry Morton Stanley, a kind-hearted merchant who took charge of him, gave him his own name, and declared his intention of providing for him. Although the merchant died abroad soon afterward, leaving his protégé once more alone in the world, his kindness gave a new direction to the boy's life, and henceforth young Stanley felt that at least one person had loved him and believed in him. In his own prosperous middle age he, too, adopted a son.

For some years Stanley led a roving life: a soldier in the American Civil War, a seaman on merchant ships and in the Federal navy, a journalist in the early days of frontier expansion—he even managed a trip to Turkey, recorded in *My Early Travels and Adventures in America and Asia* (1895). Twice he visited his mother in Wales, only to encounter the same indifference she had shown since his birth.

In 1867 Stanley offered his services to James Gordon Bennett of the *New York Herald* as a special correspondent with the British expeditionary force sent against Theodore II of Ethiopia, and he was first to report the news of the fall of Magdala in 1868. He was in Madrid covering the Spanish Civil War for the *New York Herald* in 1869, when James Gordon Bennett, Jr., summoned him to Paris and commissioned him to "find Livingstone."

Relief of Livingstone. Little had been heard of Livingstone after he left for the interior of Africa in 1866 to explore the central African lakes and to ascertain the source of the Nile, but he was thought to be in the neighbourhood of Ujiji on Lake Tanganyika. Bennett instructed Stanley to travel to Africa by way of Egypt (for the opening of the Suez Canal), Syria, and Palestine, and it was not until January 6, 1871, that he reached Zanzibar.

Intent on a "scoop," Stanley was secretive with the Zanzibar authorities, including Sir John Kirk the British consul, who was responsible for Livingstone's supplies. Stanley set out for the interior on March 21, and with a well-equipped caravan forced his way through a countryside disturbed by fighting and stricken with sickness. He reached Ujiji in November, where he found Livingstone ailing and short of food and medicine, greeting him with the famous words "Dr. Livingstone, I presume?" Together they explored Lake Tanganyika and proved that since the Rusizi River flowed into and not out of the northern end of the lake, it could not be the source of the Nile as had been suggested by some geographers who doubted that Lake Victoria was the main source. Stanley arrived back in Zanzibar in May 1872, leaving Livingstone to pursue his search for the Nile further west in the region of what, as Stanley himself was later to prove, was the Congo. Stanley was not well received in England. In the same year (1872) he published his story in *How I Found Livingstone*.

Expedition with Livingstone

The Royal Geographical Society (Livingstone's chief sponsor) awarded him its Patron's Medal for 1873. He addressed the British association at Brighton in October 1872 and was received by Queen Victoria who gave him a gold snuffbox and her thanks for his services. In 1873 Stanley went to Ashanti (in modern Ghana) as war correspondent for the *New York Herald*, and in 1874 he published *Coomassie and Magdala: the Story of Two British Campaigns in Africa*, describing his experiences there and in Ethiopia.

Discovery and development of the Congo. When Livingstone died in 1873, Stanley resolved to take up the exploration of Africa where he had left off. The problem of the Nile sources and of the position and size of the central African lakes had been only partly solved by Livingstone, Sir Richard Burton, John H. Speke, and Sir Samuel Baker. Stanley secured financial backing from the *Daily Telegraph* and the *New York Herald* for an expedition to Africa. Well manned and provisioned and with three companions, Stanley left Zanzibar on November 12, 1874, and headed for Lake Victoria. His visit to King Mtesa of Buganda during 1875 led to the admission of Christian missionaries in 1876 and for the eventual establishment of a British protectorate. Circumnavigating Lake Victoria in his boat, the "Lady Alice," Stanley confirmed Speke's estimate of its size and importance. Skirmishes with suspicious natives on the lake shore and, especially, a fight at Bumbireh that resulted in a number of casualties gave rise in England to much criticism of this new kind of traveller with his journalistic outlook and forceful methods. On this voyage were sown many of the seeds of Stanley's later unpopularity among the English and of the rough parliamentary campaigns in which he was heckled as a "man of blood." His claim that he had been acting in self-defense was itself put forward in aggressive terms that did not reassure public opinion.

Stanley was prevented by tribal unrest from investigating Lake Albert, and he turned south to Lake Tanganyika, which he also circumnavigated, finding no outlet to connect it with Lake Albert and the Nile system.

By the end of 1876 Stanley was ready for what he called "the grandest task of all"—the identification of the Lualaba River, which Livingstone had hoped might be the Nile

but thought more likely to be the Congo. In 1876 the expedition arrived at Nyangwe, the northernmost point reached by Livingstone on the Lualaba, and set off down the river with Tippu Tib, the leading Arab trader of the region.

Because of the extreme difficulties and danger of the journey, the Arabs turned back at the limit of their trading area. Undaunted, Stanley launched the "Lady Alice" and sailed down the unexplored river to the lake he called Stanley Pool; further on, he encountered a 280-foot drop in the river and 32 cataracts, which he named Livingstone Falls. Unable to navigate further, he was forced to proceed overland on foot to the Atlantic Ocean, which he reached on August 12, 1877. His three companions and half his Africans were dead, but he had traced the Congo. Stanley described this tremendous journey in *Through the Dark Continent* (1878).

Founding of Congo Free State

Failing to enlist British interests in the development of the Congo, Stanley accepted the invitation of King Leopold II of the Belgians to lead an expedition there under the auspices of the Comité d'Études du Haut Congo. This offshoot of Leopold's International African Association (founded 1876) was transformed later into the Association Internationale du Congo, out of which grew the Congo Free State. From August 1879 to June 1884 Stanley was in the Congo basin, where he made a road from the lower Congo up to Stanley Pool, launched steamers on the upper river, and built a chain of stations. His perserverance in the face of difficulties earned him, from his men, the nickname of Bula Matari—"the rock breaker." The Berlin West Africa Conference of 1884–85, which Stanley attended, recognized the Congo Free State under the sovereignty of King Leopold.

Relief of Emin Paşa. Stanley's last expedition in Africa was for the relief of Mehmed Emin Paşa, governor of the Equatorial Province of Egypt. Emin had been cut off by the Mahdist revolt of 1882 in the neighbourhood of Lake Albert. Sir William Mackinnon, chairman of the British India Steam Navigation Company, launched a rescue fund and invited Stanley to lead the rescue expedition. Stanley chose to travel by way of the Congo; he knew the route and relied on Tippu Tib to supply porters. He left England in January 1887 and, stopping to recruit men in Zanzibar, arrived at the mouth of the Congo in March. The expedition reached the navigable head of the river in June, and there, at Yambuya, Stanley left a rear column with orders to await Tippu Tib's porters and to follow him later if these failed to arrive.

Stanley and four associates led the advance guard out of the camp on June 28, reaching Lake Albert five months later after a gruelling march through dense forest. They did not contact Emin until April 1888 when Stanley found, to his astonishment, that Emin was unwilling to evacuate his province. Leaving him to assemble his troops, Stanley then returned to look for the missing rear column. He reached Banalia, just short of Yambuya, on August 17, where he found the remains of the column, depleted and demoralized. Tippu Tib had not sent the porters, and Stanley's officers were dead—one had been murdered, and the other died of fever soon after.

Stanley blamed the dead officers for the disaster, and on his return to England a controversy arose about the fate of the rear guard. This was the most bitter of the many quarrels that heavily damaged Stanley's reputation.

Back at Lake Albert in January 1889, Stanley heard that Emin had been detained by disaffected troops, but eventually the party was reunited, and on April 10, 1889, some 1,500 persons set out, arriving at Bagamoyo on the east coast on December 4. Stanley cleared up some other geographical points on this expedition. The mist-covered Ruwenzori Range, which had been concealed when Lake Albert had been discovered in 1864, and which Stanley himself had passed unnoticed in 1876, was identified as Ptolemy's Mountains of the Moon; the size of Lake Albert was correctly estimated, and its tributary, the Semliki River, traced south to the lake that Stanley named Albert Edward (now Lake Edward). *In Darkest Africa* (1890) is Stanley's account of this arduous and unlucky expedition.

Parliament. Stanley married Dorothy Tennant on July 12, 1890, and they adopted a son, Denzil. Stanley was renaturalized a British subject in 1892 (he had become a United States citizen on May 15, 1885) and sat in Parliament as Liberal Unionist member for North Lambeth from 1895 to 1900.

In 1897 he visited South Africa and wrote *Through South Africa* (1898). He was awarded a Grand Cross of the Bath in 1899, becoming Sir Henry Morton Stanley. His last years were spent mainly at Furze Hill near Pirbright, Surrey, a small estate bought in 1898.

Stanley died in London on May 10, 1904, and was buried at Pirbright after a service in Westminster Abbey.

Significance. From a modern viewpoint, much contemporary criticism of Stanley appears unjust. To the select band of travellers whose centre was the Royal Geographical Society, dedicated to the pursuit of knowledge, Stanley appeared as an outsider, an American journalist with huge funds at his disposal. His motives in exploring were suspect, and his methods were considered to be rough. His humble origin probably mattered less than he supposed to men who came, in fact, from a variety of social backgrounds, but his uncouth and uncooperative manners and his tendencies toward self-righteousness and boastfulness ensured him an unpopularity that long coloured his reputation. Harsh and humourless, touchy and intolerant, Stanley antagonized many who should have been his friends, and the controversies that arose around him have tended to obscure his considerable achievements. He was the bridge between the old and the new; at first the intrepid explorer, the friend of Livingstone, and the discoverer of the Congo; then the pioneer who made possible the Congo Free State; finally, the British elder statesman who lived into the age of the great colonialist Cecil Rhodes and observed the opening up of modern Africa.

BIBLIOGRAPHY. *The Autobiography of Henry Morton Stanley*, ed. by DOROTHY STANLEY (1909), was completed by his wife after Stanley's death; it contains the only firsthand account of his early years, otherwise scantily documented. F. HIRD, *H.M. Stanley: The Authorized Life* (1935), is a reliable account of his career; usefully supplemented by IAN ANSTRUTHER, *I Presume* (1956); and BYRON FARWELL, *The Man Who Presumed* (1957). *Stanley's Despatches to the New York Herald, 1871–72, 1874–77*, ed. with an illuminating introduction by NORMAN R. BENNETT (1970), is a reassessment of Stanley and his place in the history of 19th-century exploration. The books in which Stanley described his adventures can be compared usefully with complementary sources. A partial check on *Through the Dark Continent* (1878) is provided by *The Exploration Diaries of H.M. Stanley*, ed. by RICHARD STANLEY and ALAN NEAME (1961), containing a hitherto unpublished record of part of the transcontinental expedition of 1874–77. *The Congo and the Founding of Its Free State*, 2 vol. (1885), should be read with reference to *Stanley: lettres inédites*, ed. by ALBERT MAURICE (1955; Eng. trans., *H.M. Stanley: Unpublished Letters*, 1957), covering the years 1881–84. Stanley's *In Darkest Africa*, 2 vol. (1890), should be supplemented by the following: W.G. BARTTELOT (ed.), *The Life of Edmund Musgrave Barttelot* (1890); DOROTHY MIDDLETON (ed.), *The Diary of A.J. Mounteney Jephson* (1969); and T.H. PARKE, *My Personal Experiences in Equatorial Africa* (1891). A good general account is A.J. WAUTERS, *Stanley au secours d'Émin-Pacha* (1890; Eng. trans., *Stanley's Emin Pasha Expedition*, 1890), by the Belgian geographer who was much concerned in the preparations for the venture. A modern reassessment based on exhaustive research into published and unpublished sources is IAIN R. SMITH, *The Emin Pasha Relief Expedition, 1886–90* (1971). MARCEL LUWEL, *Stanley* (1959, in French), includes a good general bibliography.

(D.Mi.)

Star

Stars are massive, self-luminous objects, shining by radiation derived from internal energy sources. With respect to mass, radius, and luminosity, the Sun is a typical star. Its mass is 1.99×10^{30} kilograms (more than 300,000 times that of Earth); its radius is 696,000 kilometres; its power output is 3.8×10^{23} kilowatts. The masses, radii, and luminosities (total intrinsic brightness) of other stars are often expressed in terms of those of the Sun.

Table 1: The Twenty Brightest Stars

name	visual magnitude* and spectrum		distance in light-years†	visual luminosity ⊙	
	A‡	B‡		A‡	B‡
Sirius	−1.50 A1 V	+7.20 dA5	8.6	23.0	0.0080
Canopus	−0.73 F0 Ib		98.0	1,450.0

Beta Crucis	+1.24 B0.5 V		500.0	5,700.0	

*Negative magnitudes are brightest, and one magnitude difference corresponds to a difference in brightness of 2.5 times; *e.g.*, a star of magnitude −1 is ten times brighter than one of magnitude +1.5. †One light-year equals about 5.88×10^{12} miles (9.46×10^{12} kilometres). ‡A and B are brighter and fainter components, respectively, of star.
Source: From H.C. van de Kamp; C.W. Allen; R. Hanbury Brown; J. Davis, L.R. Allen and J. Rome; G. Abell.

Table 1 gives approximate data pertaining to the 20 brightest stars, or, more precisely, stellar systems, since some of them are double (binary) or even triple stars. Successive columns give the name of the star, its brightness expressed in units called visual magnitudes and in the quality of the light radiated (that is, the spectral class or classes to which the star [or its components] belongs), the distance in light-years, and the visual luminosity in terms of the Sun, symbol ⊙ in Table 1 and the rest of the article. All of the primary stars in Table 1 are intrinsically as bright as or brighter than the Sun; some of the companion stars are fainter. Many stars vary in the amount of light they radiate. Stars such as Altair, Alpha Centauri, and Procyon are called dwarf stars; their dimensions are roughly comparable to those of the Sun. Sirius and Vega, though much brighter, are also dwarf stars; their higher temperatures yield a large rate of emission per unit area. Aldebaran, Arcturus, and Capella are examples of giant stars, whose dimensions are much larger than those of the Sun. Thus, measurements with an interferometer (an instrument that measures the star's angular diameter; *i.e.*, the angle subtended by the diameter at the observer's position) combined with parallax measurements, which give the star's distance, give diameters of 24 and 45 solar diameters for Arcturus and Aldebaran, respectively. Betelgeuse and Antares are examples of supergiant stars; the latter has a diameter 560 times that of the Sun, whereas the diameter of the variable star Betelgeuse (at a distance of 600 light-years) varies between 600 and 900 solar diameters. Other supergiants are Alpha Herculis and the variable star Mira Ceti, whose diameters are 480 and 420 times that of the Sun. Several of the stellar class of white dwarf stars, which have low luminosities and high densities, are also listed.

Range of stellar sizes

The 20 nearest stars. Table 2 gives information about the 20 nearest known stars. Only Alpha Centauri, Procyon, and Sirius appear in both lists. All other nearby stars are intrinsically fainter than the Sun, and most of them can be seen only with the telescope. The very luminous stars can be seen at great distances; intrinsically faint stars can be seen only if they are very near the Sun. Several of the nearby stars have planet-like companions.

Tables 1 and 2, which pertain to only a small number of stars, illustrate some important points. The stars listed fall roughly into three groups: (1) dwarfs, with radii that range between one-tenth solar radius and five solar radii and masses from 0.07 to about 20 solar masses; (2) giant and supergiant stars, with radii tens or even hundreds of solar radii and extremely low average densities; and, finally, (3) white dwarf stars, which may have masses comparable to that of the Sun but dimensions appropriate to planets. Hence, they have average densities hundreds of thousands of times greater than that of water.

Table 2: The Twenty Nearest Stars

*A and B are brighter and fainter components, respectively, of star. †The two components of Alpha Centauri have masses of $M_1 = 1.0$ and $M_2 = 0.9$ solar masses, respectively. They are separated by 23.1 astronomical units and revolve around one another with a period $P = 79.9$ years. A third component of the system is an 11th magnitude M5 dwarf with a luminosity $L = 0.00006\ L_{Sun}$. ‡These stars have unseen, planet-like companions whose presence is revealed by gravitational attraction on the visible star. §The two components of Sirius are separated by 19.9 astronomical units, $P = 50.1$ years. The bright component has 2.2 solar masses; the faint component is a white dwarf of 0.9 solar masses. ‖The mean separation of these stars is 15.3 astronomical units, $P = 200$ years, but the masses are 0.05 and 0.04 Suns; they probably do not shine by nuclear energy generation but are radiating away gravitational energy. ¶Binary with mean separation $\alpha = 83.2$ astronomical units, $P = 653$ years, $M_1 = 0.7$, $M_2 = 0.7$ solar masses. The brighter component has a planet-like companion circling it with a period $P = 4.8$ years and a mass of about $0.008\ M_{Sun}$. ♀1–87 = fainter. ♁Binary separation = 15.8 astronomical units, $P = 40.6$ years, $M_1 = 1.8 M\odot$, $M_2 = 0.6\ M\odot$. The fainter component is a white dwarf star.
Source: From H.C. van de Kamp.

These rough groupings of the stars correspond to stages in their life histories (see below *Stellar evolution*). The first category, which will be identified with what is called the main sequence (see below), contains stars that obtain their energy mainly by converting hydrogen into helium in their cores. The second category comprises stars that have exhausted the hydrogen in their cores and are burning hydrogen in small shells surrounding the core. The white dwarfs represent the final stage in the life of a typical star, at a point when most available sources of energy are used up and the star becomes relatively dim.

The large number of binary and even multiple systems is notable. These systems are built on scales comparable with that of the solar system. Some of the nearby single stars have invisible companions, which can be detected only by their gravitational effects upon the primary star, which cause it to move through space not along a straight line but following a sinusoidal (wavelike) curve. These invisible companions are not self-luminous; they have masses of the order of 0.01 solar mass or even less and, properly, may be considered as planets. The implication that may reasonably be drawn from these data is that double stars and solar systems are formed by similar evolutionary processes.

Invisible companion stars

Before there can be any adequate discussion of the masses, dimensions, and luminosities of various types of stars, it is necessary to know their distances. For making this determination, there are several methods, some of them of a statistical nature, permitting only the average distances of various types of objects to be ascertained. The quantity and character of the electromagnetic radiation the stars emit must also be measured.

Distances of the stars. This subject is treated in detail in the article PARALLAX, ASTRONOMICAL. Summarized here are a few highlights and essential definitions.

The basic method is determination of trigonometric parallax. If the position of a nearby star is measured from two points on opposite sides of the Earth's orbit, a small angular displacement will be observed. Using the Earth's orbit as the base line, the distance of the star can be found from the angular size of the parallax p (see Figure 3; PARALLAX, ASTRONOMICAL). If $p = 1''$ (one second) of arc, the distance of the star would be 206,265 times the Earth's distance from the Sun, that is, 3.26 light years. This unit of distance is called the parsec, derived from *par*allax of one *sec*ond of arc. One light-year, the distance through which light waves travel in one year, is a popularly used unit; 3.26 light-years are equivalent to one parsec.

Parallax

Parallax is inversely proportional to distance. Thus, a star at ten parsecs has a parallax of 0.1″ of arc. Stars at greater distances have smaller parallaxes, and these are more difficult to measure directly. Hence, indirect methods depending on the absolute brightness of different classes and other classifications are used for the majority of stars. The nearest star, the triple system of Alpha Centauri, has a parallax of 0.760″ of arc. Hence, its distance is 1/0.760, or 1.31 parsecs, or 4.3 light-years. Probable errors of such parallaxes are typically 0.005″ of arc, which means that there is a 50:50 chance that a star whose parallax is 0.01″ of arc lies between 67 and 200 parsecs (corresponding to parallaxes of 0.015 and 0.005, respectively) and an equal chance that it lies outside that range. Thus, measurement of trigonometric parallaxes are of little value beyond the nearby stars.

Identification of individual stars: nomenclature. The earliest designations of the stars still in common use are their Arabic names. These follow no particular system, are often fanciful in character, and are rarely used except by navigators and amateurs. The brighter stars in each constellation are now denoted by a system introduced in 1603 by the German astronomer Johann Bayer. The star appearing brightest in a constellation is denoted as α (alpha), the next brightest as β (beta), etc. When stars are of comparable brightness, as in the Big Dipper, they are lettered according to their position in the constellation. Later, the first British Astronomer Royal, John Flamsteed, introduced a system of numbers assigned in order of the stars' position coordinate, right ascension.

Star catalogs

Stars too faint to be given a Bayer letter or Flamsteed number are listed in other ways, often by number, in star catalogs, one of the most extensive of which is the *Bonner Durchmusterung* (BD). It has been extended to cover the Southern Hemisphere by the *Córdoba Durchmusterung* (CD) and the *Cape Photographic Durchmusterung* (CPD). Star charts are provided for each of these catalogs, so that the identification of a given star is not difficult. Many stars are known only by the number listed for them in one or more of the major catalogs. Perhaps the most important is the *Henry Draper Catalogue* (HD), which with its extensions contains data for 225,000 stars (see also ASTRONOMICAL MAPS).

Variable stars

Variable stars—*i.e.*, stars variable in brightness—may be listed in one or more of such lists and, if bright enough, may have been assigned a name, a Flamsteed number or a Bayer letter, or all three. When known to be variable, however, they are also assigned a capital letter or letters, written with the possessive or genitive case of the constellation. RR Lyrae, R Coronae Borealis, and U Cephei, for example, are such variables and are important as prototypes, being the first discovered with the particular characteristics of a whole class of variables now known by their name. RR Lyrae stars, for example, are periodic variables and a subclass of the larger group called Cepheids (after the prototype, Delta Cephei).

After single letters and combinations of double letters have been exhausted in a given constellation, the next discovered variable star in that constellation is assigned a number, and after that consecutively increasing numbers are assigned to subsequent discoveries as they occur.

This article is divided into the following sections:

I. Observable data for stars
  Stellar positions
    Fundamental measurements
    Stellar motions
  Brightness of the stars
    Stellar colours
    Magnitude systems
  Stellar spectra
    Spectral classes
    Effects of stellar density and luminosity
II. Derived, or calculated, stellar characteristics
  Intrinsic stellar brightness
    Absolute magnitudes
    Total luminosities; bolometric magnitudes
  Stellar masses
  Stellar diameters
  Stellar temperatures
  Average values of temperatures, radii, masses, and luminosities for dwarf stars
III. Stellar variability
  Geometric variables
  Intrinsic variables
    Pulsating stars
    Explosive variables
IV. Statistics of stars
  Correlations among luminosity, spectrum, mass, and radius
    Relation between the number of stars and their luminosities
    Mass–luminosity correlation
  Statistics of binary systems
  Statistics of special types of stars
V. Stellar structure
  Stellar atmospheres
  Internal structure of stars
    Relations obtained from physical laws
    Energy generation in stars
VI. Stellar evolution
  The life history of a typical star
    Protostars
    The star reaches the main sequence
    Evolution away from the main sequence
    Estimates of stellar ages
  Formation of chemical elements in stars
  Probable fate of a star: white dwarfs, pulsars, and black holes
    White dwarfs and novae
    Neutron stars
    Black holes

I. Observable data for stars

STELLAR POSITIONS

Fundamental measurements. Accurate measurements of stellar positions are essential to many problems of stellar astronomy. Positions of the brighter stars can be measured very accurately in the equatorial coordinate system (the coordinates are called right ascension [α, or RA] and declination [δ] and are given for some epoch). Fainter stars are measured upon photographic plates with respect to these brighter stars, and finally the entire group is referred to the positions of known external galaxies. These external galaxies are far enough away to define an essentially fixed, or immovable, system, whereas

positions of both the bright and faint stars are affected over quite short periods of time by galactic rotation and by their own motions through the Galaxy.

The *General Catalogue* gives precise positions for about 30,000 stars. Even more accurate data are found in the *Dritter Fundamental-Katalog des Berliner astronomischen Jahrbuchs* (FK 3) or its revision (the FK 4).

Stellar motions. Accurate measurements of position (for example α, δ) make it possible to determine the motion of a star across the line of sight (proper motion). The amount of the proper motion denoted by μ (in seconds of arc per year) divided by the parallax of the star and multiplied by 4.74 equals the tangential velocity, T, in kilometres per second in the plane of the celestial sphere. Thus, tangential velocity = (annual proper motion/parallax) $\times$ 4.74 km per sec, or $T = 4.74$ (μsec/parallax).

Tangential and radial velocity

The motion in the line of sight (called radial velocity) is obtained directly from spectroscopic observations (Figure 1). If λ is the wavelength of a characteristic spectrum

Figure 1: Components of stellar motion. V represents radial velocity; T is tangential velocity of the star S with respect to the Sun; ν is the total velocity (see text).

line of some atom or ion present in the star, and λ_L is the wavelength of the same line on the Earth, then the difference $\Delta\lambda$, or $\lambda - \lambda_L$, divided by λ_L is equal to the radial velocity V divided by the velocity of light, c: $\Delta\lambda/\lambda_L = V/c$. Shifts of the spectral line toward red (positive V) indicate recession. If the parallax is known, measurements of μ and V make it possible to determine the space motion of the star. Radial velocities are corrected for the Earth's rotation and for its motion around the Sun so that they will refer to the line-of-sight motion of the star with respect to the Sun.

The observed motion of a given star is made up of two parts: the motion of the star with respect to the average of the nearby stars (the local standard of rest) and the motion of the Sun with respect to this same standard of rest. The first problem to be solved is the determination of the Sun's motion, both in velocity and in direction, with respect to the nearby stars. This directional, or vector, quantity is established most reliably from radial velocity data. Stars in the region of the sky toward which the Sun is moving (called the apex of the Sun's way) show a predominantly negative velocity (approach), whereas those in the opposite region of the sky (the antapex) show a positive velocity (recession). Stars at a position 90° away from the apex or antapex show a random mixture of positive and negative radial velocities. A statistical analysis of the observed radial velocities permits the determination of the apex and the velocity of the Sun, $V_\odot$, with respect to the average of the nearby stars. For the naked-eye stars, the apex is not far from the star Mu Herculis. With respect to fainter stars or special types, such as RR Lyrae variables, the position of the apex will be different, since these objects have their own systematic motion.

Components of proper motion

Once the direction of the solar motion is known, the proper motion of any star can be divided into two components, one along the great circle passing through the apex, the star, and the antapex, and the other perpendicular thereto. The first, or upsilon, component contains the effects of both the star's own peculiar motion and the reflection of the Sun's motion. A backward drift caused by the Sun's motion will be a maximum for stars 90° from the apex and zero at both the apex and antapex. The second, or tau, component is unaffected by the solar motion.

Special efforts have been made to detect stars of large proper motion, since these tend to be nearby, often being intrinsically very faint stars. Searches for stars of large parallax are often based on lists of stars of large proper motion. Although proper motions can be measured for very faint stars, radial velocities can be determined only for stars whose spectra can be photographed with sufficient dispersion.

BRIGHTNESS OF THE STARS

Brightness and magnitude scales

Stellar brightnesses are usually expressed by means of their magnitudes, a usage inherited from classical antiquity. A star of the first magnitude is about 2.5 times as bright as one of the second magnitude, which in turn is about 2.5 times as bright as one of the third magnitude, and so on, so that a star of the first magnitude is 100 times as bright as one of the sixth magnitude. The magnitude of Sirius, apparently the brightest star in the sky, is −1.5. Canopus, the second-brightest, has a magnitude of −0.73, while the faintest star that can normally be seen without telescopic aid is of the sixth magnitude. Stars as faint as the 23rd magnitude have been measured with the 200-inch telescope on Palomar Mountain in California.

The scale of magnitudes constitutes a geometrical progression of brightness. Magnitudes may be converted to light ratios by letting l_n and l_m be the brightnesses of stars of magnitudes n and m, respectively; the logarithm of the ratio of the two brightnesses is then equal to 0.4 times the difference between them—*i.e.*, $\log (l_m/l_n) = 0.4\ (n - m)$. Magnitudes are actually defined in terms of observed brightness, a quantity that depends on the light-detecting device employed. Visual magnitudes are measured with the eye, photographic magnitudes from images on a photographic plate; and there are various types of photoelectric magnitudes. A magnitude system must have a reference, or zero, point. In practice this is fixed arbitrarily and is essentially based on the star catalogs of Ptolemy and Hipparchus.

Absolute magnitude

The actually measured brightnesses give apparent magnitudes. These cannot be converted to intrinsic brightnesses until the distances of the objects concerned are known. The absolute magnitude of a star is defined as the magnitude it would have if it were viewed at the standard distance of ten parsecs (32.6 light-years, or 2,062,650 astronomical units; an astronomical unit is the average Earth–Sun distance). The apparent visual magnitude of the Sun is −26.9, that of the Full Moon is −12.7, and that of the brightest star is −1.5. The visual absolute magnitude of the Sun corresponds to a diminution in brightness by a factor $(2{,}062{,}650)^2$ and is, using logarithms, $-26.9 + 2.5 \times \log (2{,}062{,}650)^2$, or $-26.9 + 31.6$; that is, 4.7. The absolute magnitude of the Full Moon is about +32, and to see it at ten parsecs would require a telescope with an aperture about a quarter-mile wide. The very brightest stars, such as Rigel (Beta Orionis), have absolute magnitudes of −7 to −9 (see Table 1). The faintest known star, the companion to BD+4°4048, which was discovered by the U.S. astronomer G. Van Biesbroeck and is therefore often called Van Biesbroeck's star, has an absolute visual magnitude of 19—1,000,000 times fainter than the Sun. A large number of such faint stars may exist, but they are extremely difficult to detect.

Stellar colours. Stars differ in colour. Most of the naked-eye stars in the constellation Orion are blue-white, but Betelgeuse (Alpha Orionis) is a deep red. In the telescope, Albireo (Beta Cygni) is seen as two stars, one blue, the other orange. One quantitative means of measuring stellar colours is to compare the visual magnitude of the star with a magnitude measured on a photographic plate. Yellow, the colour to which the eye is most sensitive, contributes most to visual magnitude. The ordinary photographic plate is insensitive to yellow and red light but is sensitive to blue and violet, so that hot blue stars appear bright, and yellow and red stars are recorded as relatively faint. In all magnitude scales, one magnitude step corresponds to a brightness ratio of about 2.5. The zero point is chosen so that white stars with surface temperatures of about 10,000° K (about 17,500° F) have the same visual and photographic magnitudes. The conventional colour index is defined as the photographic magnitude minus the visual magnitude; the colour index of the Sun is $+5.46 - 4.84 = 0.62$.

Colour index

Visual magnitudes have been determined photographically with the aid of orthochromatic or yellow-sensitive

plates and yellow filters. Such photovisual magnitudes differ from visual magnitudes less than naked-eye estimates of visual magnitudes by different observers differ among themselves.

Fundamental measurements of stellar magnitudes and colours are now made photoelectrically, although the photographic plate continues to play a vital role as an interpolation device when very large numbers of stars are to be measured (see PHOTOMETRY, ASTRONOMICAL).

Magnitude systems. The older system of stellar magnitudes, normally employed only for photographic and photovisual (or visual) magnitudes, encountered a number of severe difficulties. Furthermore, when only one colour is observed, if, for instance, the star's colour is found to be red, without further information it is impossible to decide whether the star is red because it is cool or whether it is really a hot star whose colour has been reddened by the passage of the light through material in space. By measuring the magnitudes of the same stars in three or more colours, it is possible to overcome these difficulties.

Modern magnitude systems are based on measures, usually made photoelectrically, of a few standard stars, the measurement accuracy being limited chiefly by the quality of the atmosphere through which the light has to pass. Magnitudes that measure light from only parts of the wavelength range are usually named for the colour of the light. Thus, there are blue magnitudes, M_B, or B, whose range roughly corresponds to that of the (blue) photographic magnitudes; visual magnitudes, M_v, or V, whose range is centred in the yellow-green part of the spectrum, red magnitudes; and so on.

In the 1960s, measurements in infrared light assumed considerable importance (see below). Also, photometric observations of individual stars from space vehicles and rockets made possible the measurement of stellar colours over a large range in wavelength. These data are important for hot stars and for assessing the effects of interstellar extinction.

The measured total of all radiation at all wavelengths from a star is called a bolometric magnitude and is described below.

STELLAR SPECTRA

A star's spectrum contains information about its temperature, chemical composition, and intrinsic luminosity. Spectrograms secured with a slit spectrograph consist of a sequence of images of the slit in the light of the star at successive wavelengths; adequate dispersion may show the star to be a member of a close binary system, in rapid rotation, or to have an extended atmosphere. Quantitative determination of its chemical composition then becomes possible. Inspection of a high-dispersion spectrum of the star may reveal evidence of a strong magnetic field.

Spectral classes. Most stars are grouped into a small number of spectral classes. The *Henry Draper Catalogue* lists spectral classes from the hottest to the coolest stars, designated by the letters O, B, A, F, G, K, M. This group is supplemented by R and N stars (now more frequently referred to as the carbon C stars) and S stars. The R, N, and S stars differ from the others in chemical composition; also, they are invariably giant or supergiant stars (see ASTRONOMICAL SPECTROSCOPY, PRINCIPLES OF).

Conditions in stellar atmospheres

The spectral sequence O–M represents stars of essentially the same chemical composition but of different temperatures and atmospheric pressures. This simple interpretation, put forward in the early 1920s by an Indian physicist, Meghnad Saha, has provided the physical basis for all subsequent interpretations of stellar spectra. The spectral sequence is also a colour sequence; the O and B stars are intrinsically the bluest and hottest; the M, R, N, and S stars are the reddest and coolest. When the effects of space reddening are eliminated, and stars of a given kind, such as dwarf stars, are considered, there is a one-to-one correspondence between colour and spectral class or between spectral class and temperature. These dwarf stars form what is known as the main sequence in the so-called Hertzsprung–Russell diagram (see below).

In the case of the cool stars of class M, the spectra indicate the presence of familiar metals, such as iron, calcium, magnesium, and so on, and also (particularly in the red and green parts of the spectrum) titanium oxide molecules. In the somewhat hotter K stars the titanium oxide bands disappear, and the spectrum exhibits a wealth of metallic lines. A few especially stable fragments of molecules such as cyanogen and the hydroxyl radical persist in these stars and even in G stars, such as the Sun. The spectra of G stars are dominated by the characteristic lines of metals, particularly of iron, calcium, sodium, magnesium, and titanium.

The behaviour of calcium illustrates the phenomenon of thermal ionization. At low temperatures a calcium atom retains all its electrons and radiates a spectrum characteristic of the neutral, or normal, atom; at higher temperatures, collisions between atoms and electrons and the absorption of radiation both tend to detach electrons and to produce singly ionized calcium atoms. At the same time these ions may recombine with electrons to produce neutral calcium atoms. At high temperatures or low electron pressures, or both, most of the atoms are ionized. At low temperatures and high densities the equilibrium favours the neutral state. The concentrations of ions and neutral atoms can be computed from the temperature, the density, and the ionization potential (the energy required to detach an electron from the atom, usually expressed in electron volts).

The line of neutral calcium at 4227 angstroms thus is strong in cool M dwarf stars, in which the pressure is high and the temperature is low; but in the hotter G stars the lines of ionized calcium at 3968 angstroms and 3933 angstroms (called the H and K lines) become much stronger than any other feature in the spectrum.

In stars of spectral class F, lines of neutral atoms become weak relative to those of ionized atoms. The hydrogen lines become stronger, attaining their maximum intensities in A stars, in which the temperature is around 9,000° K. Thereafter they gradually fade as the hydrogen becomes ionized.

Production of spectral lines

Spectral lines are produced by transitions of atoms or ions between energy levels, when energy in the form of light is absorbed or emitted. The yellow D lines of sodium or the H and K lines of ionized calcium are produced by jumps from the lowest energy levels (ground levels) of these atoms. The observable hydrogen lines, however, are produced by jumps from atoms in the so-called second energy level, which lies far above the ground level. Only at high temperatures are sufficient numbers of atoms maintained in this level by collisions, radiations, etc., to permit an appreciable number of absorptions to occur. At the low temperatures of the M or even of the K stars there are few atoms in the second level. On the other hand, at the very high temperatures of the B and O stars, the hydrogen atoms are nearly all ionized and therefore cannot absorb or emit any line radiation whatsoever, so that, at best, only faint hydrogen lines are seen. The lines of ionized metals such as iron in the F stars never attain the strength that the neutral lines do in the K stars. These lines often involve higher energy levels, which are more sparsely populated than the lower levels. Another factor is that the general fogginess or opacity of the atmospheres of these hotter stars becomes greatly increased so that there are fewer and fewer atoms in the visible layers that can produce the observed lines.

Opacity of the star's outer layers

The continuous (as distinct from the line) spectrum of the Sun is produced primarily by the photo-dissociation of negative hydrogen ions; that is, atoms of hydrogen to which an extra electron is loosely attached. In the solar atmosphere, when these negative hydrogen ions are subsequently destroyed by photodissociation, they absorb energy at any of a whole range of wavelengths in the process and thus produce a continuous range of absorption of radiation. The principal source of absorption of light in the hotter stars is the photo-ionization of hydrogen atoms, both from ground level and from higher levels.

Photoelectric absorption by normal hydrogen atoms in a cool environment is confined to the very short wavelength ultraviolet; but if the hydrogen atoms become

excited to higher energy levels, the photo-ionization energies then required are much lower, and the continuous absorptions fall in the visual range. Other usually less important sources of absorption leading to opacity in the stars' atmospheres exist (see below).

The hot B stars, such as Epsilon Orionis, are characterized by lines of helium, singly ionized oxygen, nitrogen, and neon. In the very hot O stars, lines of ionized helium appear. Other prominent lines include those of doubly ionized nitrogen, oxygen, and carbon and trebly ionized silicon, all of which require more energy to produce.

Effects of stellar density and luminosity. The physical processes behind the formation of stellar spectra are well enough understood to permit determinations of temperatures, densities, and quantitative chemical compositions of stellar atmospheres. The star studied in greatest detail is, of course, the Sun, but other stars also have been investigated in detail.

Although the general characteristics of the spectral sequence can be understood in terms of a variation of temperature, many spectral features depend on the densities of the stars' atmospheric gases. These densities depend in turn on surface gravities. Dwarfs, with great surface gravities, tend to have high atmospheric (surface) densities; giants and supergiants, with low surface gravities, have relatively low surface densities.

The hydrogen lines provide an illustration in point. Normally, an undisturbed atom radiates a very narrow line. If its energy levels are disturbed by charged particles passing nearby, it will radiate at a wavelength near its characteristic wavelength. In a hot gas the range of disturbance of the hydrogen lines is very high, so that the spectrum line radiated by the whole mass of gas will be much spread out; the amount of the blurring depends on the density of the gas in a known fashion. Dwarf A stars, such as Sirius, show broad hydrogen lines with extensive "wings" where the line fades slowly out into the background, whereas supergiant A stars, with less dense atmospheres, show relatively narrow hydrogen lines. The relationship between the spectrum of a star and its intrinsic luminosity, called the luminosity effect, has to be established empirically.

M–K spectral classification system

In the modern system of spectral classification called the M–K system, for the American astronomers W.W. Morgan and P.C. Keenan who introduced it, luminosity class is assigned to the star along with the Draper spectral class. Thus, Alpha Persei is classed as F5 Ia, which means that it falls about halfway between the beginning of class F(F0) and of class G(G0). The Ia means that it is a particularly luminous supergiant. The star Pi Cephei, classed as G2 III, is a giant falling between G0 and K0 but much closer to G0. The Sun, a dwarf star of class G2, is classified as G2 V. A star of luminosity class II falls between supergiants and giants; one of class IV is called a subgiant.

Some stars are binaries or multiple stars, and their colours and spectral classes often provide important information relevant to stellar evolution. Other stars are variable in magnitude, colour, and spectrum (see below).

II. Derived, or calculated, stellar characteristics

INTRINSIC STELLAR BRIGHTNESS

Absolute magnitudes. Positions, apparent magnitudes, and colours can all be measured for vast numbers of stars. If the star is close enough, its parallax can be measured directly; for more remote stars the moving-cluster method, which depends on similarity of proper motions, extends the range further. The intrinsic luminosities of many types of bright stars and average luminosities for certain variables have been established from their membership in open clusters. Such clusters contain stars of intrinsic brightnesses and colours similar to those of the Sun and its neighbours. As has been pointed out, stellar brightnesses are expressed in terms of their absolute magnitudes; *i.e.*, the brightness the star would have at a distance of ten parsecs. If the distance is known, the absolute magnitude, *M*, and corresponding luminosity can be found by simple arithmetic from the apparent brightness of the cluster stars.

Total luminosities; bolometric magnitudes. The corrections required to reduce visual magnitudes to bolometric magnitudes (see above) are large for very cool and for very hot stars but are relatively small for stars such as the Sun (see Figure 2). The determination of the true total luminosity of a star affords a measure of its actual energy output. When the energy radiated by a star is observed at the Earth, only that portion to which the energy detector is sensitive and that can be transmitted through the atmosphere is recorded. Most of the energy of stars like the Sun is emitted in spectral regions that can be observed from the Earth's surface; but an M star with a surface temperature of 3,000° K has an energy maximum on a wavelength scale at 10,000 angstroms, far in the infrared, and most of its energy cannot therefore be measured as light. Bright cool stars can be observed at infrared wavelengths, however, with special instruments that measure the amount of heat radiated by the star. Corrections for the heavy absorption of the heat by water molecules and others in the Earth's atmosphere must be made. Such magnitudes are referred to as radiometric magnitudes (see also INFRARED SOURCES, ASTRONOMICAL).

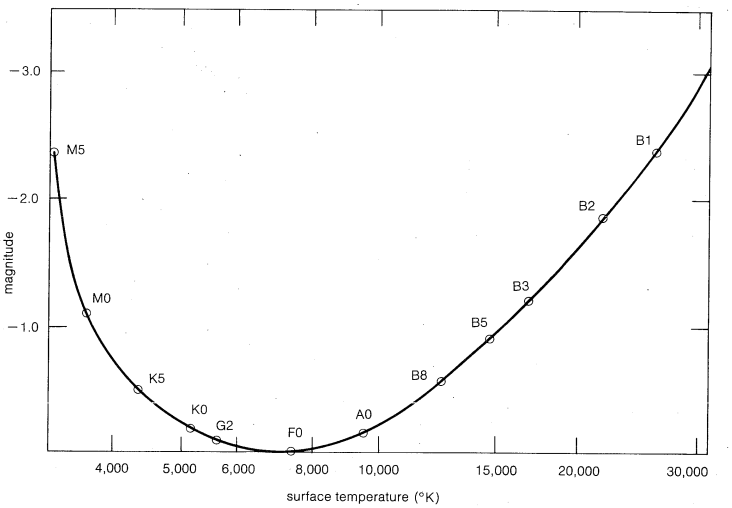

Figure 2: Bolometric correction. Dwarf and main sequence stars of twelve spectral classes are shown on the curve. Cool and hot stars have large corrections. The corrections always increase the stellar luminosity (see text).

Spectra of hot stars

The hotter stars pose more difficult problems, since the Earth's atmosphere extinguishes all radiation at wavelengths shorter than 2900 angstroms. A star whose surface temperature is 20,000° K or above will radiate most of its energy in the inaccessible ultraviolet. Measurements made with detectors flown in rockets or satellites extend the observable wavelength region down to 1000 angstroms or less, although all radiation of distant stars is cut out below 912 angstroms, a region in which absorption by neutral hydrogen atoms in intervening space becomes effective.

To compare the true luminosities of two stars, the appropriate bolometric corrections must first be added to each of their absolute magnitudes; then the ratio of the luminosities can be calculated.

STELLAR MASSES

The masses of stars can be found only from binary systems, if the scale of the orbits of the stars around each other is known. Binary stars are divided into three categories, depending on the mode of observation employed. Visual binaries can be seen as double stars in the telescope. True doubles, as distinguished from optical (line-of-sight) doubles, move through space together and display a common space motion; sometimes a common orbital motion can be measured as well. Spectroscopic binaries are found from radial-velocity observations. A component of such a binary has a continuously changing periodic velocity that alters the wavelengths of its spectral lines in a rhythmic way; the velocity curve repeats itself exactly from one cycle to the next, and the motion

can be interpreted as orbital motion. In a few cases rhythmic changes in both components' lines can be measured. Eclipsing binaries are detected from the light variations they show when one star passes between the observer and the other. The best known example is Algol (Beta Persei); good data are known for many such systems (see ECLIPSE, OCCULTATION, AND TRANSIT).

Masses of visual binaries. Visual-binary systems permit a determination of stellar masses when the parallax, p, and from it the distance are known. The period, P, of the binary system is expressed in years, and the angular radius, a'', of the orbit (more accurately, its semimajor axis), can be measured directly; the distance measure provides a scale, so that the true dimensions of the semimajor axis, a, can be found. If, in astronomical units, $a = a''/p''$, the sum of the masses $m_1 + m_2$ is, by Kepler's law, proportional to the cube of the mean distance, a, between them and inversely proportional to the square of the period, P, in years. In symbols, $m_1 + m_2 = a^3/P^2 = a''^3/(p''^3P^2)$, in units of the Sun's mass. For example, for the binary 70 Ophiuchi, $P = 87.85$ years, $p'' = 0.199''$ of arc, $a'' = 4.55''$ of arc, so that $a = 22.8$ astronomical units, and $m_1 + m_2 = 1.56$ solar masses. From a measurement of the motions of the two components with respect to the background stars, the orbit of each star has been determined with respect to the common centre of gravity. The mass ratio $m_2/(m_1 + m_2)$ is 0.422; the individual masses are 0.90 and 0.66 solar masses.

The star known as 61 Cygni was the first whose distance was measured and the first stellar system found to contain a planet. Visually, it is a double star separated by 83.2 astronomical units. Its components move about one another with a period of 653 years. The brighter component has an invisible companion, with a mass 0.008 of that of the Sun, which moves about it at a distance of 4,200,000 kilometres with a period of about 4.8 years. According to all accepted criteria, this companion must be regarded as a bona fide planet. Careful examination of the motions of other stars in the neighbourhood of the Sun has suggested that other planetary companions may exist.

Planetary companions to stars

Masses of spectroscopic binaries. By 1967, orbital elements for 737 systems had been listed. The semimajor axes or the masses cannot be found for most spectroscopic binaries, since the angle between the orbit plane and the plane of the sky cannot be determined; the possible foreshortening introduces uncertainty. If two spectra can be observed, mass ratios can be found. If one spectrum alone can be observed, only a quantity called the mass function can be found, from which is calculated a lower limit to the stellar masses. If the spectroscopic binary is also observed to be an eclipsing system, the inclination of the orbit and often the masses of the individual stars can be found.

STELLAR DIAMETERS

Eclipsing binary systems provide extensive data on stellar dimensions. These systems include dwarf stars and also supergiant stars such as 31 Cygni and VV Cephei. Components of close binary systems are sometimes subject to evolutionary effects, mass exchange, and other disturbances that change the details of the spectra (see below).

Angular diameters of bright red giant and supergiant stars were first measured directly in the 1920s, using the principle of interference of light. Only bright stars with large angular diameters can be measured by this method.

Interferometer measurements

A more recently developed photon-correlation interferometric method is usable for bright stars of smaller apparent size; in this way the angular diameters of 15 stars ranging in brightness from Sirius (−1.46) to Alpha Pavonis (+1.74) have been measured.

A very recent method, called speckle interferometry, has been developed to reproduce the true disks of red supergiant stars and resolve spectroscopic binaries such as Capella. The speckle phenomenon is a rapidly changing interference diffraction effect seen in a highly magnified diffraction image of a star observed with a large telescope.

If the absolute magnitude of a star and its temperature are known, its size can be computed. The temperature determines the rate at which energy is emitted by each unit of area, and the total luminosity gives the total power output. Thus, the surface area of the star and, from it, its diameter may be estimated. This is the only way available for estimating the dimensions of white dwarf stars. The chief uncertainty here lies in choosing the temperature that represents the rate of energy emission.

STELLAR TEMPERATURES

Stellar temperatures may be defined in a number of ways. From the character of the spectrum and the various degrees of ionization and excitation found from its analysis, an ionization or excitation temperature can be derived.

Meaning of a star's temperature

A comparison of the V and B magnitudes yields a colour index, $m_B - m_V$, related to the colour temperature of the star. The colour temperature is therefore a measure of the relative amounts of radiation in two more or less broad-wavelength regions, while the ionization and excitation temperatures pertain to the temperatures of strata wherein spectral lines are formed.

If the angular diameter of a star can be measured (see above) and if the total energy flux received at the Earth (corrected for atmospheric extinction) is known, the so-called brightness temperature can be found.

The effective temperature, T_{eff}, of a star is defined in terms of its total energy output and radius. Thus, since σT^4_{eff} is the rate of radiation per unit area for a perfectly radiating sphere and if L is the total radiation of a star considered to be a sphere of radius R, such a sphere (called a blackbody) would emit a total amount of energy that is the surface area, $4\pi R^2$, times the energy per unit area just given. In symbols, $L = 4\pi R^2\sigma T^4_{eff}$. This relation defines the star's equivalent black-sphere or effective temperature.

Since the total energy radiated by a star cannot be directly observed (except for the Sun), the effective temperature is a derived quantity, not an observed one. Yet, theoretically, it is the fundamental temperature. If the bolometric corrections (see above) are known, the effective temperature can be found for any star whose absolute visual magnitude and radius are known.

AVERAGE VALUES OF TEMPERATURES, RADII, MASSES, AND LUMINOSITIES FOR DWARF STARS

Table 3 gives surface temperatures, bolometric or total luminosities, masses, and radii in terms of corresponding solar values for main-sequence stars ranging from very luminous objects to faint M dwarf stars. There is a considerable range for each of these quantities. For a given mass (M, the fundamental factor), a fair spread in radius (R), luminosity (L), surface temperature, and spectral class may exist. This spread is produced by stellar evolution effects and causes a broadening of the dwarf or main sequence. Masses are obtained from visual and eclipsing binary systems observed spectroscopically. Radii are found from eclipsing binary systems, from direct measurements in a few favourable cases, by calculations, and from absolute visual magnitudes and temperatures.

Meaningful average values of R, L, and M can be given only for dwarf stars. Giant and subgiant stars all show large ranges in R for a given mass. Conversely, giant stars of very nearly the same radius, surface temperature, and luminosity may have appreciably different masses.

Stars more massive and luminous than Y Cygni (see above) exist, but their diameters and true luminosities are not accurately known. Stars also exist with masses less than 0.2 of the Sun's mass, although, if M is less than 0.07 of the Sun's mass, the object cannot shine by nuclear energy at all and will simply cool down directly as a black dwarf or even a planet.

Minimum stellar mass

III. Stellar variability

Many of the stars in the sky are variable. Some are geometric variables, as in eclipsing binary systems; others are intrinsic variables.

GEOMETRIC VARIABLES

These are stars from which the amount of light reaching the observer alters because of changes in the stars' posi-

Table 3: Temperatures, Luminosities, Masses, and Radii for Main-Sequence Stars

spectral class	temperature (°K)	luminosity	mass	radius
O9.5	33,000	30,000.000	18.00	5.90
B0	32,000	16,000.000	16.00	5.70
B2	22,000	8,300.000	10.50	5.10
B3	17,000	2,500.000	8.30	4.80
B5	15,000	750.000	5.40	3.70
B8	12,500	130.000	3.50	2.70
B9	10,800	100.000	2.90	2.50
A0	9,500	63.000	2.60	2.30
A2	9,000	40.000	2.20	2.00
A5	8,700	24.000	1.90	1.80
A7	8,100	11.000	1.80	1.70
F0	7,400	9.000	1.60	1.50
F2	7,100	6.300	1.50	1.30
F5	6,400	4.000	1.35	1.20
F8	6,100	2.500	1.20	1.10
G0	5,900	1.450	1.08	1.05
G2	5,800	1.100	1.00	1.00
G5	5,600	0.700	0.95	0.91
G8	5,300	0.440	0.85	0.87
K0	5,100	0.360	0.83	0.83
K2	4,830	0.280	0.78	0.79
K5	4,370	0.180	0.68	0.74
K8	3,900	0.120	0.58	0.67
M0	3,670	0.075	0.47	0.63
M1	3,500	0.050	0.40	0.56
M2	3,400	0.030	0.33	0.36
M3	3,300	0.014	0.26	0.29
M4	3,200	0.005	0.20	0.21

Source: Compiled from data given by D.M. Popper, D.L. Harris, K. Strand, and C.E. Worley. The temperature scale is based on work of Hanbury Brown and his associates, G.J. Peters and E.K.L. Upton, S. Wolff, L.V. Kuhi, and D. Hayes, of D.C. Morton and T.A. Adams, of D.M. Popper, J.E. Stebbins and A.E. Whitford, A. Code, and J.B. Oke.

tions. Most geometric variables are eclipsing binaries (see also ECLIPSE, OCCULTATION, AND TRANSIT). An eclipsing binary consists of two close stars moving in an orbit so placed in space that the light of one may at times be hidden behind the other. Depending on the orientation of the orbit and the sizes of the stars, the eclipses may be total or annular (a ring of one star shows behind the other at the climax of the eclipse), or both eclipses may be partial. The best known example of an eclipsing binary is the famous star Beta Persei, or Algol, which has a period (interval between eclipses) of 2.87 days. The brighter (B8) star contributes about 92 percent of the light of the system and the eclipsed star much less than 8 percent; the system contains a third star, which is not eclipsed. About 17 eclipsing binary systems are visible to the naked eye.

Light curves of binaries

The light curve for an eclipsing binary displays magnitude measurements for the system over a complete light cycle. The light of the variable star is usually compared with that of a nearby (comparison) star believed to be fixed in brightness. In Figure 3A, the deep, or primary, minimum is produced when the star of higher surface brightness is eclipsed. It represents the total eclipse and is characterized by a flat bottom. The shallower secondary eclipse occurs when the star of higher surface brightness passes in front of the other; it corresponds to an annular eclipse (or transit). In a partial eclipse (Figure 3B) neither star is ever completely hidden, and the light changes continuously during an eclipse.

The shape of the light-curve during an eclipse gives the ratio of the radii of the two stars, and also one radius in terms of the size of the orbit, the ratio of the luminosities, and the inclination of the orbital plane to the plane of the sky.

If radial-velocity curves are available—*i.e.*, if the binary is spectroscopic as well as eclipsing—additional information is found. When both velocity curves are observable, the size of the orbit and the sizes, masses, and densities of the stars can be found. If the parallax of the system can be found, the brightness temperatures of the individual stars may be estimated from their luminosities and diameters. All of these procedures have been carried out for the faint binary Castor C and for the bright B star Mu Scorpii.

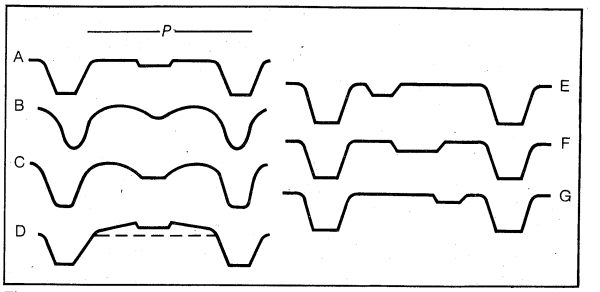

Figure 3: Schematic light curves of eclipsing binaries. *P* is the period (see text).

Light curves of the types shown in Figures 3A and 3B usually occur in systems in which the companions are moderately distant from one another. In a close system, tidal distortion caused by the strong mutual gravitation may cause the stars to become elongated along the line joining their centres so that the light curve is of the type shown in Figure 3C.

Close stars may reflect each others' light noticeably. If a small, high-temperature star is paired with a larger object of low surface brightness and if the distance between the stars is small, the part of the cool star facing the hotter one will be substantially brightened by it. Just before (and just after) secondary eclipse, this illuminated hemisphere is pointed toward the observer, and the total light of the system is a maximum (see Figure 3D).

Light curves need to be corrected for these effects before they can be further analyzed. Another complication is that stars such as the Sun show a darkening to the limb, or edge, of their disk.

One other effect on the light curves must be mentioned. Some stars move around each other in strongly elliptical orbits. If the major axis of the orbit is at right angles to the direction toward the observer, the stars will take different lengths of time to go from primary minimum to secondary minimum and from secondary minimum to primary minimum, because they move faster when close together than when far apart. Hence, the secondary minimum will not fall precisely at the midpoint between primary eclipses (Figure 3E). If the orbit precesses and the system is observed at a later date, the secondary minimum may then be symetrically placed, but now the two eclipses are of unequal duration (Figure 3F); at this time the major axis is pointed toward the observer. One eclipse now occurs when the occulting star is moving most rapidly, the other when it is moving most slowly. At a still later date the secondary minimum is displaced to the opposite side from the midpoint (Figure 3G). Observation of these effects in an eclipsing system shows the rate of rotation of the orbit. A third body might cause this rotation and possibly sometimes does but would produce other effects that could be seen but are not observed; in most instances it must be concluded that only two stars are present. The orbit rotation can then be explained as follows.

Tidal effects

If the stars are distorted by their mutual tidal attractions, the elliptical orbit will slowly rotate; the speed of rotation will depend in a precisely known fashion on their separation, masses, radii, and degree of density increase toward the centre. The orbit would turn at a maximum possible speed for stars that were homogeneous; *i.e.*, of equal density throughout. It would not rotate at all for stars whose masses were essentially all concentrated to the centre (approximately, very small stars with very deep but tenuous atmospheres). All theories of stellar structure predict large mass concentrations toward the centre; for the Sun the central density is about 100 times the mean density. These predictions can be tested by the behaviour of eclipsing binaries; in all instances the central condensations are large, providing a useful check on the theory.

The data from eclipsing binary systems are not necessarily applicable to isolated single stars. Systems in which a smaller, hotter star is accompanied by a larger, cooler object are easier to detect than are systems that contain, for example, two main-sequence stars. In such an unequal

system, at least the cooler star has certainly been affected by evolutionary changes and probably also the brighter one. The evolutionary development of two stars near one another does not exactly parallel that of two well-separated or isolated stars.

Eclipsing binaries include combinations of a variety of stars ranging from white dwarfs to huge supergiants (such as VV Cephei), which would engulf Jupiter and all the inner planets if placed at the position of the Sun.

Some members of eclipsing binary systems are intrinsic variables. In many such systems large clouds of ionized gas swirl between the components. In others, such as Castor C, the faint M dwarf component may be a flare star, one in which the brightness may unpredictably and suddenly increase to many times its normal value (see below).

INTRINSIC VARIABLES

A fair number of stars are intrinsically variable; that is, their total energy output fluctuates with time. Some of these stars were found by accident, but many were detected as a result of carefully planned searches. Variable stars are important in astronomy for a number of reasons. They usually appear to be stars at critical or short-lived phases of their evolution; detailed studies of their light and spectral characteristics, spatial distribution, and association with other types of stars may provide important clues to the life histories of various classes of stars. Certain kinds of variable stars, such as Cepheids (periodic variables) and novae (explosive variables), are extremely important in that they make it possible to establish the distances of remote systems beyond the Galaxy, such as the Magellanic Clouds and some of the nearer external galaxies (see GALAXIES, EXTERNAL). If the intrinsic luminosity of a recognizable variable is known and this kind of variable star can be found in a distant stellar system, the distance of the latter can be estimated from a measurement of the apparent magnitude, m, and the absolute magnitude, M, if the space absorption is known (see above and INTERSTELLAR MEDIUM). Historically, the absolute magnitude turned out to be difficult to establish for the Cepheid variable stars, a very important class of objects named after the prototype, Delta Cephei.

Kinds of intrinsic variables

Variable stars are often classified as behaving like a prototype star, and the class is then named for this star; *e.g.*, RR Lyrae stars are those whose variability follows the pattern of the star RR Lyrae. The most important classes of intrinsically variable stars are the following:

1. Pulsational variables; *i.e.*, stars whose variations in light and colour are believed to arise primarily from stellar pulsations. These include Cepheids, RR Lyrae stars, and Delta Scuti stars, all with short regular periods up to a few days; long-period variables; semiregular variables; irregular red variables; and Beta Canis Majoris stars.
2. Explosive, or catastrophic, variables, in which the variations are produced by the wrenching away of part of the star, usually the outer layers, in some explosive process. They include SS Cygni or U Geminorum stars; novae; and supernovae (which are usually regarded as representing an enormous explosion involving most of the material in a star).
3. Miscellaneous and special types of variables: R Coronae Borealis stars; T Tauri stars; flare stars; pulsars (neutron stars); spectrum and magnetic variables; X-ray variable stars; radio variable stars.

T Tauri and flare stars, spectrum and magnetic variables, X-ray stars, radio stars, and pulsars are considered in a later section.

R Coronae Borealis variables are giant stars of about the Sun's temperature whose atmospheres are characterized by excessive quantities of carbon. Their brightness remains constant until suddenly the star dims by several magnitudes and then slowly recovers its original brightness; the star's colour remains the same during the changes in brightness. The dimmings occur in a random fashion and seem to be due to the huge concentrations of carbon. At times the carbon vapour literally condenses into soot, and the star is hidden until the smog blanket is evaporated. Similar veiling may sometimes occur in other types of low-temperature star, particularly the long-period variables.

Pulsating stars. An impressive body of evidence indicates that stellar pulsations can account for the variability of Cepheids, long-period variables, semiregular variables, Beta Canis Majoris stars (pulsating stars with periods of only a few hours; see below), and even the irregular red variables. Of this group the Cepheids have been studied in greatest detail, both theoretically and by observation. These stars are regular in their behaviour; some repeat their light curves with great faithfulness from one cycle to the next over periods of many years.

Cepheid variables. Much confusion existed in the study of Cepheids until it was recognized that different types of Cepheids were associated with different groups, or population types, of stars. Stars fall into distinct groups as defined by motions, age, and position in the Galaxy. Population I is the name given to the stars associated with the spiral arms of this and other galaxies. This group contains stars of all ages, from those in the process of formation to defunct white dwarfs. They are always associated with the dust and gas of the interstellar medium. The best examples of type I populations are the stars of the galactic, or open, clusters such as the Pleiades or the beautiful double cluster in Perseus (h and χ Persei). Population I is sometimes divided into an "old" Population I (which includes the Sun) and a "young" Population I (stars a few tens of millions of years old or less).

Population types I and II

Population II is often divided into two categories. The oldest stars (extreme type II) are those associated with the central bulge of the Galaxy, globular clusters, the galactic halo, and certain external elliptical galaxies. A second group, called the disk population, comprises stars found between the spiral arms of the Galaxy and at some distance above and below the galactic plane. These stars are also very old, perhaps 10^{10} years, although not quite as old as the extreme Population II. In this article the populations are called simply types I and II.

Separate species of variable stars with different characteristics correspond to these population types. Cepheids belonging to the spiral-arm population (type I) are characterized by regularity in their behaviour. They show continuous velocity curves indicative of a regular pulsation. They exhibit a relation between period and luminosity in the sense that the longer the period of the star, the greater its intrinsic brightness; this period–luminosity relationship has been used to establish the distance of remote stellar systems. Cepheids with different properties are found in the type II population, away from the Milky Way, in globular clusters. They are bluer than classical type I Cepheids of the same period, and their light curves have different shapes. Studies of the light and velocity curves indicate that shells of gas are ejected from the stars as discontinuous layers that later fall back toward the surface. These stars exhibit no well-defined relation between period and luminosity; consequently, they are worthless as distance indicators. The distance of a Cepheid in a distant stellar system can be determined only if it is known to be a classical Cepheid.

Type II Cepheids

RR Lyrae variables. Closely associated with type II Cepheids are the cluster-type, or RR Lyrae, variables. Many of these stars are found in clusters, but some, such as the prototype RR Lyrae, are found far from any cluster or the central galactic bulge. The periods are less than a day, and there is no correlation between period and luminosity. Their absolute magnitudes are about 0.6; that is, they are about 50 times as bright as the Sun. They are useful for determining the distance of star clusters and some of the nearer external galaxies, since their short periods permit them to be detected readily.

Pulsation theory. An impressive amount of evidence supports the pulsation theory, first proposed as a possibility for stellar variation in 1879, applied to Cepheids in 1914, and further developed by the English astronomer Sir Arthur Eddington. He found that if stars have roughly the same kind of internal structure, then the period, P, multiplied by the square root of the density, ρ, is equal to a constant that depends on the internal structure.

The Eddington theory, although a good approximation, encountered some severe difficulties that have been met through modifications made in the 1960s. If the entire star pulsated in synchronism, it should be brightest when compressed and smallest and faintest when expanded and largest. The velocity curve should pass through zero at both maximum and minimum light. Observations contradict these predictions. When the star pulsates, all parts of the main body move in synchronism, but the outer observable strata get out of step or lag behind the pulsation of the inner regions. Running waves are set up within the outer regions (envelope) of the star. Pulsations involve only the outer part of a star; the core, where energy is generated by thermonuclear reactions, is unaffected.

Many years ago, careful measurements of the average magnitudes and colours of RR Lyrae stars in the globular cluster M3 showed that all these stars fell within a narrow range of luminosity and colour (or surface temperature; see Figure 4) or, what amounts to the same thing, luminosity and radius. Also, every star falling in this narrow range of brightness and size was an RR Lyrae variable. Later work has indicated that similar considerations apply to classical Cepheids. Variability is thus a characteristic of any star whose evolution carries it to a certain size and luminosity.

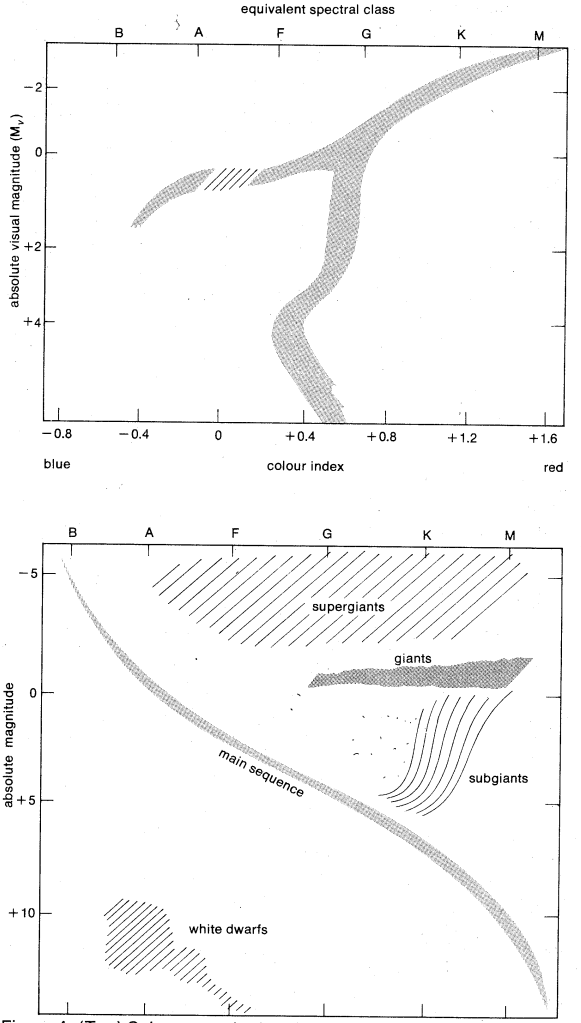

Figure 4: (Top) Colour–magnitude array for a typical type II population in a globular cluster. Absolute magnitude is plotted against the colour index (visual magnitude minus photographic magnitude). It is assumed that RR Lyrae stars (crosshatched area) have an absolute magnitude of 0.6. (Bottom) Schematic spectrum–luminosity correlation (Hertzsprung–Russell diagram) of spiral-arm stars (neighbourhood of the Sun).

In the pulsation theory as now developed, the light and velocity curves of Cepheids can be interpreted not only qualitatively but also quantitatively. For example, the complicated light curves of Population II Cepheids have been precisely predicted by the theory. Stellar pulsation, like other rhythmical actions, may give rise to harmonic phenomena wherein beats reinforce or interfere with one another. Beat and interference phenomena then complicate the light and velocity curves. The RR Lyrae stars supply some of the best examples; but semiregular variables such as the RV Tauri stars, "dwarf" Cepheids such as Delta Scuti, or SX Phoenicis evidently vibrate simultaneously with two or more periods.

Beta Canis Majoris variables. The Beta Canis Majoris variables are high-temperature stars (spectral class B) that often show complicated variations in spectral line shapes and intensities, velocity curves, and light. They often have two periods of variation so similar in duration that complicated interference or beat phenomena are observed, both in radial velocities and in the shapes of spectral lines.

Long-period variables. Long-period variables also probably owe their variations to pulsations. Here the situation is complicated by the vast extent of their atmospheres, so that radiations originating at very different depths in the star are observed at the same time. At certain phases of the variations, bright hydrogen lines are observed, overlain with titanium oxide absorption. The explanation is an outward-moving layer of hot, recombining gas, whose radiation is absorbed by strata of cool gases. These stars are all cool red giant and supergiant stars of spectral classes M (normal composition), R and N (carbon-rich), or S (heavy-metal rich). The range in visual brightness during a pulsation may be a hundredfold, but the range in total energy output is much less, because at very low stellar temperatures (1,500°–3,000° K) most of the energy is radiated in the infrared as heat rather than as light.

Unlike the light curves of classical Cepheids, the light curves of these red variables show considerable variations from one cycle to another. The visual magnitude, M_v, of Mira Ceti (Omicron Ceti) is normally around 9 to 9.5 at minimum light, but at maximum it may lie between 5 and 2. Time intervals between maxima often vary considerably. In such cool objects a very small change in temperature can produce a huge change in the output of visible radiation. At the low temperatures of the red variables, compounds and probably solid particles are formed copiously, so that the visible light may be profoundly affected by a slight change in physical conditions. Random fluctuations from cycle to cycle, which would produce negligible effects in a hotter star, will produce marked light changes in a long-period variable.

Types of long-period variables

Long-period variables appear to fall into two groups: (1) those with periods around 200 days tend to be associated with the type II population; (2) those of periods around a year belong to the type I population.

Red semiregular variables such as the RV Tauri stars show complicated light and spectrum changes. They do not repeat themselves from one cycle to the next; their behaviour suggests a simultaneous operation of two or more modes of oscillation. Betelgeuse is an example of an irregular red variable. In these stars the free period of oscillation does not coincide with the periodicity of the driving mechanism.

Explosive variables. *Novae.* Novae, or temporary stars, are explosive stars. In ordinary novae the explosion seems to involve only the outer layers, as the star later returns to its former brightness; in supernovae the explosion is catastrophic. Normally, novae are small blue stars much fainter than the Sun, although very much hotter. When an outburst occurs, the star may brighten very suddenly, ten magnitudes or even more in a few hours. Thereafter it fades; the rate of fading is connected with the brightness of the nova. The brightest novae, which reach absolute magnitudes of about −8, fade most rapidly, whereas a typical slow nova, which reaches an absolute magnitude of −5, may take ten times as long to decline in brightness. The changes in light are accompanied by pronounced spectroscopic changes that can be interpreted as arising from changes in an ejected shell that dissipates slowly in space. In its earliest phases the

Probable ejection of a shell of gas

expanding shell is opaque; as its area rapidly grows, with a surface temperature near 7,000° K, the nova brightens rapidly. Then, near maximum light, the shell becomes transparent, and its total brightness plummets rapidly, causing the nova to dim.

The mass of the shell is believed to be rather small, comparable with the mass of the Earth. Only the outer layers of the star seem to be affected; the main mass settles down after the outburst into a state much as before until a new outburst appears. The existence of repeating novae such as the star T Coronae Borealis suggests that perhaps all novae repeat at intervals ranging up to thousands or perhaps millions of years; and probably, the larger the explosion, the longer the interval. There is strong evidence that novae are components of close double stars and, in particular, that they have evolved from the most common kind of eclipsing binaries, those of the W Ursae Majoris type, which are pairs of stars apparently similar to the Sun in size but revolving about one another while almost touching.

Nova-like variables. Stars of the SS Cygni type show nova-like outbursts but with a much smaller amplitude. The intervals between outbursts are a few months to about a year. These variables are close binaries. The development of this particular type may be possible only in close binary systems.

Also associated with novae are stars such as Z Andromedae, which show remarkable spectra combining the characteristics of cool M-type stars, gaseous nebulae, and hot stars with bright emissions of hydrogen and helium. They occasionally show nova-like outbursts.

Eta Carinae

A peculiar object with no known counterpart is Eta Carinae, which appears in the telescope as a fuzzy red "star" slightly less than 2″ of arc in diameter. Surrounding it is a roughly elliptical nonuniform shell or halo about 10″ of arc in diameter. First observed as a star of about the fourth magnitude in 1677, it brightened irregularly, undergoing an outburst in 1843. Unlike a proper nova or supernova, it remained bright for several years, fading out of sight to the naked eye about 100 years ago. Since then it has shown irregular variations around the seventh magnitude. The first spectrum obtained of the object resembled that of a somewhat abnormal supergiant, but it now shows very complex emission-line structures dominated by the radiations of ionized iron. If a star was present, it may have been blown to bits. Eta Carinae was brighter than normal novae, yet it resembles no known supernova; it does not appear to be a source of X-rays or nonthermal radio-frequency emission.

Supernovae. Supernovae represent a distinct type of phenomenon: a star suddenly becomes up to several hundred million times as bright as the Sun, then fades away. Three have been observed optically in the Galaxy —Tycho's star of 1572, Kepler's "nova" of 1604, and the outburst in 1054 that produced the Crab Nebula. Hundreds have been found in other galaxies. Several remnants have been found by radio-astronomy methods.

The Crab Nebula itself is an emitter of nonthermal radiation. The residue of the supernova, now identified as a pulsar, believed to be a rotating neutron star, is a remarkable variable in optical, X-ray, and radio-frequency ranges (see below). Supernovae are believed to be stars that actually explode as a consequence of runaway thermonuclear reactions in their interiors (see below).

Probably all variable stars represent more or less ephemeral phases in the evolution of a star. Aside from such catastrophic events as those that produce a supernova, some phases of stellar variability may be of such brief duration as to permit recognizable changes during an interval of 50 or 100 years. Other stages may require many thousands of years; the period of Delta Cephei, for example, has not changed by a detectable amount since its variability was discovered.

IV. Statistics of stars

CORRELATIONS AMONG LUMINOSITY, SPECTRUM, MASS, AND RADIUS

Some of the most important generalizations concerning the nature and evolution of stars can be made from correlations between observable properties and from certain statistical results. One of the most important of these correlations concerns the spectrum and luminosity.

When the absolute magnitudes of the stars (or their intrinsic luminosities on a logarithmic scale) are plotted in a diagram against the temperature or, what is equivalent, the spectral types, the stars do not fall at random on the diagram but tend to congregate in certain restricted domains (see Figure 4, bottom). Such a diagram is usually called a Hertzsprung–Russell diagram, for a Danish astronomer, Ejnar Hertzsprung, and an American astronomer, Henry Norris Russell, who independently discovered the relations shown in it. Most of the congregated stars are dwarfs lying closely around a diagonal line called the main sequence. These stars range from hot blue objects 10,000 times (or more) brighter than the Sun, down through white A stars such as Sirius, yellow-white F stars such as Procyon, through the Sun, to orange K stars such as Epsilon Eridani, and finally to faint red dwarfs thousands of times fainter than the Sun. The sequence is continuous, the luminosities fall off smoothly with decreasing surface temperature, the masses and radii decrease but at a much slower rate, and the densities gradually increase (see Table 3).

Hertzsprung–Russell diagram

The second group of stars to be recognized was a group of giants, objects such as Capella, Arcturus, and Aldebaran, yellow, orange, or red stars about 100 times as bright as the Sun and with diameters of the order of 10,000,000 or 20,000,000 miles (20,000,000 or 30,000,000 kilometres). The class of supergiants includes stars of all spectral classes; they show a big spread in intrinsic brightness; some even approach absolute magnitudes —7 or —8. Some red supergiants, such as the variable VV Cephei, exceed in size the orbit of Jupiter or even that of Saturn, although most of them are smaller. Supergiants are short-lived and rare in space, though their great luminosity enables them to be seen at great distances.

Giant stars

Subgiants are stars that are redder and larger than main-sequence stars of the same luminosity. Many of the best known examples are found in close binary systems, particularly in eclipsing systems where conditions favour their detection.

The white-dwarf sequence lies about ten magnitudes below the main sequence. These stars are in the last stages of their evolution (see below *Stellar evolution*).

The spectrum–luminosity diagram has numerous gaps. There are very few stars above the white dwarfs and to the left of the main sequence. The main sequence and the giants are separated by a gap named after Hertzsprung, who in 1911 was the first to recognize the difference between main-sequence and giant stars. The actual concentration of stars differs considerably in different parts of the diagram. Highly luminous stars are rare; those of low luminosity are very numerous.

Figure 4 (bottom) applies to the spiral arm in the neighbourhood of the Sun and represents what would be obtained if a composite Hertzsprung–Russell diagram were constructed combining data for a large number of the star groups called open clusters, such as the double cluster h and χ Persei, the Pleiades, the Coma cluster, and the Hyades. It includes very young stars, a few million years old, as well as very ancient stars, 8,000,000,000 or 9,000,000,000 years old.

Figure 4 (top) exhibits the type of spectrum–luminosity relation characteristic of globular clusters, the central bulge of the Galaxy, and elliptical external galaxies; that is, of stellar Population II. Since these systems are very remote from the observer, the stars are faint, and their spectra can be observed only with difficulty. Hence, it is necessary to measure their colours rather than the spectra. Since the colours are closely related to surface temperatures and therefore to spectral classes, equivalent spectral classes may be used; but it is to be emphasized that stellar colours, not spectral classes, are observed in this instance.

The difference between the two diagrams of Figure 4 is striking. In the top diagram there are no supergiants, and, instead of falling at $M_v = 0.0$, the giant branch starts around —3.5 for very red stars and forms a continuous sequence until an absolute magnitude of about 0 is

reached. Then there is a band of stars, all about the same colour, proceeding downward (*i.e.*, to fainter stars) to about $M_v = +3$. The giant branch is connected to the main sequence at about +4 by a narrow band. The main sequence extends to fainter redder stars in much the same way as in the spiral-arm population. It ends just above the Sun, however, and does not extend up through the A, B, and O spectral classes, though occasionally a few such stars are found in the region normally occupied by the main sequence.

The horizontal branch falls near magnitude +0.6 and fills the Hertzsprung gap, extending to increasingly blue stars beyond the RR Lyrae stars, which are indicated by the crosshatched area. Among these hot blue stars are found novae and the nuclei of planetary nebulae, so called because their photographic image is disk-shaped and resembles that of a distant planet. Not all globular clusters show identical colour–magnitude arrays, and the differences may be due to differences in the cluster ages. Some clusters have many RR Lyrae stars; others have very few. Some have numerous giants; others have numerous blue stars on the horizontal branch. In the cluster M92 the whole giant branch is bluer than that in the cluster M13.

Globular-cluster stars

Spectroscopic observations indicate that stars in globular clusters do not all have the same chemical compositions; in particular, the same metal–hydrogen ratios differ from cluster to cluster. In some globular clusters, such as 47 Tucanae, the metal–hydrogen ratio seems to be about the same as in the Sun. In Omega Centauri it is substantially less, whereas in M92 the ratio may be of the order of 1 percent of the solar value. Globular clusters may look very similar to one another and yet have substantially different metal–hydrogen ratios.

Not all metal-deficient stars are confined to globular clusters. Some so-called subdwarfs with metal–hydrogen ratios of less than 1 to 10 percent of the solar value are found in the neighbourhood of the Sun, as are also less extreme examples of Population II. High-velocity stars are of type II, but not all type II stars display a high velocity. Numerically, the ancient type II population and the so-called disk population probably greatly exceed the type I population in the Galaxy.

Relation between the number of stars and their luminosities. Of great statistical interest is the relationship between the luminosities of the stars and their frequency of occurrence. The naked-eye stars are nearly all intrinsically brighter than the Sun, but, for the known stars within 20 light-years of the Sun, the opposite is true. The bright stars are easily seen at great distances; the faint ones can be detected only if they are close. Only if stars of magnitude +11 were 1,000,000,000 times more abundant than stars of magnitude −4 could they be seen in equal numbers, provided all stars could be observed to some fixed limit of apparent brightness. Table 4 gives the relation between the numbers of stars and their luminosities for stars in the neighbourhood of the Sun. For a sphere of radius ten parsecs, about seven stars between the fourth and fifth magnitudes, 30 stars between the tenth and 11th, and 67 stars between the 14th and 15th magnitude could be expected in such a volume. There would be less than one chance in a thousand of finding a star brighter than magnitude −5. The luminosity function has a maximum near magnitude 15.5.

Table 4: Relation Between Numbers of Stars and Their Luminosities

absolute magnitude	numbers of stars	absolute magnitude	numbers of stars	absolute magnitude	numbers of stars
−0.5	0.05	+6.5	12.9	13.5	54
+0.5	0.52	7.5	16.1	14.5	67
+1.5	1.30	8.5	20.0	15.5	80
+2.5	3.20	9.5	24.5	16.5	60
+3.5	4.80	10.5	30.0	17.5	37
+4.5	7.00	11.5	35.0	18.5	23
+5.5	9.50	12.5	42.0	19.5	13

Source: After W.J. Luyten, *Monthly Notices*, Royal Astronomical Society, vol. 139 (1968).

The luminosity function depends on population type. For a pure type II population, the luminosity function will differ substantially from that of a pure type I population. There will be a small peak near absolute magnitude +0.6 corresponding to the horizontal branch for type II, and no stars as bright as absolute magnitude −5. The luminosity function for pure type I is evaluated best from galactic star clusters, the stars in such a cluster being at about the same distance. The neighbourhood of the Sun includes examples of both Populations I and II.

Mass–luminosity correlation. A plot of mass against bolometric luminosity for visual binaries for which good parallaxes and masses are available show that, for stars with masses comparable to that of the Sun, the luminosity, L, varies as a power, $3 + \beta$, of the mass M. This relation can be expressed as $L = (M)^{3+\beta}$. The power differs for substantially fainter or for much brighter stars (see Table 3).

The mass–luminosity correlation applies only to unevolved main-sequence stars. It fails for giants and supergiants and for the subgiant (dimmer) components of eclipsing binaries, all of which have changed considerably during their lifetime. It does not apply to any of the stars in a globular cluster that do not lie on the main sequence, nor to the white dwarfs, which are abnormally faint for their masses.

The mass–luminosity correlation, predicted theoretically by Eddington, is a general relationship that holds for all stars having essentially the same internal density and temperature distributions; that is, for what are termed the same stellar models.

STATISTICS OF BINARY SYSTEMS

Near the Sun, most stars are members of binary systems, and some of the nearest single stars are suspected of having companions.

Although some binary components are separated by hundreds of astronomical units while others are contact binaries, binary systems are most frequently built on the same scale as the solar system. The average separation between components is of the order of ten astronomical units. The division in mass between two components of a binary seems to be nearly random. A mass ratio of about 1:20 could occur about 5 percent of the time, and under these circumstances a solar system might form.

The formation of double and multiple stars on the one hand and that of solar systems on the other seem to be different facets of the same process. Planets may be produced by a process like that depicted in the nebular hypothesis, except that most of the mass and angular momentum is swept out of the system. Only a small fraction of the original material is retained in the planets. Solar systems may be frequent in the Earth's Galaxy; perhaps 100,000,000 stars have bona fide planets (see SOLAR SYSTEM).

STATISTICS OF SPECIAL TYPES OF STARS

White dwarfs. White dwarfs comprise a group of stars falling about ten magnitudes below the main sequence. They are more numerous than stars of any group except those of the main sequence. The masses of white dwarfs are comparable to that of the Sun; their densities far exceed anything on Earth. The first to be recognized was the companion to Sirius, originally detected by its gravitational attraction upon the larger, brighter star and only later discovered visually as a faint object, about 10,000 times fainter than Sirius, or 500 times fainter than the Sun. Its mass is slightly less than that of the Sun. Its colour and spectrum correspond roughly to spectral class A, with a surface temperature of 8,000° to 10,000° K. Hence, the energy emission per unit area from the surface must be much greater than that of the Sun. Since it is so faint, the surface area and therefore the volume must be very small, and the average density is of the order of 100,000 times that of water. Under these conditions the electrons are nearly all stripped off the atoms; the resulting material, called a degenerate gas, has remarkable properties. It does not obey the ordinary gas laws and is an almost perfect conductor of heat.

The companion to Sirius

One white dwarf, known as BD+16°516, is paired to a much cooler K0V dwarf star in an eclipsing system. The two stars, whose centres are separated by 1,300,000 miles, revolve about each other in a period of 12.5 hours. The white-dwarf star produces pronounced excitation and heating effects in the K star's atmosphere. The white dwarf's mass is about 0.6 that of the Sun, but its diameter is only 10,000 miles; hence, the density is about 650,000 times that of water.

In the faint object BD+70°8247, a measured value of 1 to 3 percent circular polarization implies the existence of a magnetic field of about 10,000,000 gauss. For comparison, the Earth's field is of the order of one gauss.

A white dwarf represents the terminal stage of the life of an average star; more massive stars may evolve into neutron stars (see PULSARS). Just before the white-dwarf phase, the star may be like the central stars of planetary nebulae. On the other hand, evidence suggests that T Tauri stars are objects either recently formed or in the process of formation from the interstellar medium.

T Tauri stars. T Tauri variables are dwarf stars of spectral classes G and K. They invariably lie in dense clouds of absorbing material. Their changes in brightness are erratic; some, such as R Monocerotis, are associated with small, fan-shaped nebulae. Their spectra show bright lines and washed-out absorption lines, suggesting that they are rapidly spinning objects in clouds of diffuse material. On an H–R diagram they always fall above the normal main sequence.

Flare stars. Flare stars are cool dwarfs (spectral class M) that display flares apparently very much like, but much more intense than, those of the Sun, in fact sometimes so bright as to overwhelm the normal light of the star. Solar flares are associated with copious radio emission, and simultaneous opitical and radio events appear to have been found in UV Ceti, YZ Canis Minoris, and V371 Orionis.

Spectrum and magnetic variables. Spectrum and magnetic variables, mostly of spectral class A, show only small amplitudes of light variation but often pronounced spectroscopic changes. Their spectra typically show strong lines of metals such as manganese, titanium, iron, chromium, and rare earths or lanthanides, which vary periodically in intensity. These stars have strong magnetic fields, typically from a few hundred to a few thousand gauss; one star, HD 215441, has a field that can reach 30,000 gauss. Not all magnetic stars are known to be variable in light; the variables seem also to possess variable magnetic fields. The best interpretation is that these stars are rotating about an inclined axis. As with the Earth, the magnetic and rotation axes do not coincide. Different ions are concentrated in different areas; for example, chromium in one area and the lanthanides in another.

Metallic-line A stars. The so-called metallic line stars in class A, called Am stars, appear to be deficient in calcium, sometimes in other metals. They are all binaries and appear to form a distinct group.

The Sun as a radio emitter

Radio stars. The Sun is an emitter of radio waves, but, with present techniques, even in its most active phases the Sun could not be detected at a distance greater than that of the nearest star, about four light-years. Most discrete radio-frequency sources have turned out to be old supernovae, radio galaxies, quasars, etc.; but in recent years well-recognized radio stars also have been recorded.

These probably include flare stars, possibly red supergiants such as Alpha Orionis, the high-temperature dwarf companion to the red supergiant Antares, and the shells ejected from Nova Serpentis 1970 and Nova Delphini. The radio emission from the last-named objects is consistent with that expected from an expanding shell of ionized gas and fades away as the gas becomes attenuated. The central star of the Crab Nebula has been detected as a (radio) pulsar.

X-ray stars. Measurements from rockets, balloons, and satellites reveal distinct X-ray sources outside the solar system. The strongest galactic source, named Scorpius X-1, appears to be associated with a hot variable star resembling an old nova. Three radio sources have been observed near the X-ray star. One coincides with the X-ray star, which shows rapid irregular time variations, as do the optical and radio sources. The other two radio sources lie on opposite sides of the X-ray source and are constant in brightness. X-ray stars may be massive objects near the end of their evolution and may be closely related to pulsars. Other objects similar to Sco X-1 have been detected.

V. Stellar structure

STELLAR ATMOSPHERES

To interpret a star's spectrum quantitatively, some idea of the progression of temperature and pressure with depth in the star is necessary. Some general theoretical principles are outlined below.

First, the variation of temperature with depth in the atmosphere will depend on whether energy is transported to the surface of the star by convection currents or by radiation. For the Sun, at least, a discriminant is possible.

Darkening at the limb, or edge, of a star's disk

High-speed photographs of the Sun's disk show that the centre of the disk is brighter than the limb. The difference in brightness depends on the wavelength of the light used. It is large in the violet, is small in the red, and almost vanishes in the infrared. This limb darkening arises because the Sun gets hotter toward its core. At the centre of the disk, radiation is received from deeper and hotter layers (on the average) than from the limb, and the dependence of temperature on depth can be shown to correspond to the transport of energy by radiation, not by convection, at least in the outer layers of the Sun's atmosphere.

The degree of limb darkening in any star will depend on the effective temperature of the star and on the variation of temperature with depth. Limb darkening must be taken into account in the analysis of light curves of eclipsing binaries. Here, again, the results suggest transport of energy by radiation.

The layers of a normal star are assumed to be in mechanical or "hydrostatic" equilibrium. At each point the pressure is such as to support the weight of the overlying layers. This gives a relation between pressure and density at any given depth.

The chemical composition of the layers and the absorptivity, or opacity, of the material must be known. In the Sun the principal source of opacity is the negative hydrogen ion; such an ion is a hydrogen atom with one extra electron loosely bound to it. In the atmospheres of many stars the extra electrons break loose and recombine with absorption or reemission of energy in the form of light. At visible wavelengths the main contribution to the opacity comes from the photo-dissociation of this ion. In hotter stars, such as Sirius ($T = 10{,}000°$ K), atomic hydrogen is the main source of opacity, while in cool stars much of the outgoing energy may be absorbed by molecular bands of titanium oxide, water vapour, carbon monoxide, etc. Additional sources of opacity are absorption by helium atoms and electron scattering in hotter stars, absorption by hydrogen molecules and molecule ions, by certain abundant metals such as magnesium, and Rayleigh scattering (a type of scattering of radiation by particles, named for the British physicist Lord Rayleigh) in cool supergiant stars.

Dependence of temperature on depth

For stars other than the Sun, the dependence of temperature on depth cannot be directly found; and calculations must proceed by a process of successive approximations, during which the flux of energy is taken to be constant with depth. At large depths in the Sun and similar stars, convection sets in. In broad outline, this scheme or model seems to be correct, but there are certain limitations. The outer layers are assumed to be plane-parallel stratified layers. Photographs of the solar granulation (see SUN) belie this simple picture, and realistic models must allow for rising columns of heated gases in some areas and descent of cooler gases in others. Particularly when the model is to be used for calculating the anticipated line spectrum of the star, the motions of the radiating gases are important. Typical velocities are of the order of two kilometres per second in the Sun; in other stars they may be much larger.

The temperature, density, and pressure all increase steadily inward in the Sun's atmosphere. The Sun has no distinct solid surface, so the point from which the depth or height is measured is arbitrary. The temperature of the visible layers ranges from 4,700° to 6,200° K, the density from about 0.0000001 to 0.0000004 gram per cubic centimetre, and the gas pressure from 0.002 to 0.14 atmosphere. The visible layers of stars such as the Sun have very low densities and pressures compared with the Earth's atmosphere, although the temperature is much higher. The strata of the solar atmosphere are very opaque compared with the terrestrial atmosphere.

Calculations have been carried out for atmospheres of a variety of stars ranging from dwarfs to supergiants, from cool K stars to hot O stars. Their validity can be evaluated only one way, by examining how well they predict the observed features of a star's continuous and line spectrum, including the detailed shapes of spectral lines and so on. In view of the known complexities of stellar atmospheres, the results fit the observations remarkably well.

Expanding atmospheres

Severe deviations exist for stars with extended and expanding atmospheres. Material flowing outward from a star produces a stellar wind analogous to the solar wind —but often much more extensive and violent. In the spectrum of certain very hot Of stars, such as Zeta Puppis, strong, relatively narrow emission lines can be seen, but in the ultraviolet, observations from rockets show strong emission lines with strong absorption components on the shorter wavelength side. These absorption features are produced by rapidly outflowing atoms that absorb the radiation from the underlying stellar surface. The observed shifts in frequency correspond to ejection velocities of about 100 kilometres per second. Much gentler stellar winds are found in cool M-type supergiants.

Such line profiles are commonly referred to as the P Cygni type and are shown schematically in Figure 5. The strong emission line is produced mostly by material moving across the line of sight. Broad profiles, presumably produced by expanding shells of gas, are also produced in the atmospheres of Wolf–Rayet stars. These objects are of much higher temperature than P Cygni—typically 30,000° to 50,000° K. Their spectra consist of wide emission lines superposed on a strong blue underlying continuous spectrum. Usually they are found in binary systems of which one component is often a conventional hot O-type star.

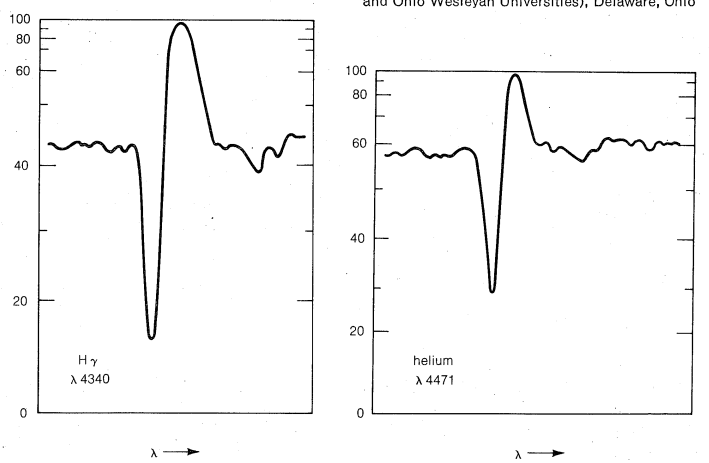

Figure 5: Line profiles in P Cygni. Figures indicate percentage intensities in terms of maximum of emission-line profile (August 24, 1941).

Effects of rapid rotation

Rapid stellar rotation may also modify the structure of a star's atmosphere. Since effective gravity is much reduced near the equator, the appropriate description of the atmosphere will vary with latitude. If the star is spinning at speeds near the breakup point, rings or shells may be shed from the equator.

Some of the most extreme and interesting examples are provided by close binary systems. When attempts are made to interpret the light and velocity curves of these objects, it is found that the spectroscopic observations cannot be reconciled with simple, orderly rotating stars. Instead, emission and absorption lines sometimes appear, jumbled together in such a way as to suggest streams of gas moving between the stars. Beta Lyrae is an eclipsing system with a period of 12.9 days but shows very large orbital-velocity shifts. The brighter component at visible wavelengths is a B9 star. The other component appears to be a hot, abnormal object; its spectral lines have not been observed. The spectrum of the B9 component shows the regular velocity changes expected of a binary star but with an absorption (and associated emission) spectrum corresponding to a higher temperature (near spectral class B5) and a blue continuum corresponding to a very high temperature star. The anomalous B5-type spectrum is evidently excited principally by the hotter source; it envelopes the entire system and shows few changes in velocity with time. Figure 6 shows Beta Lyrae schematically.

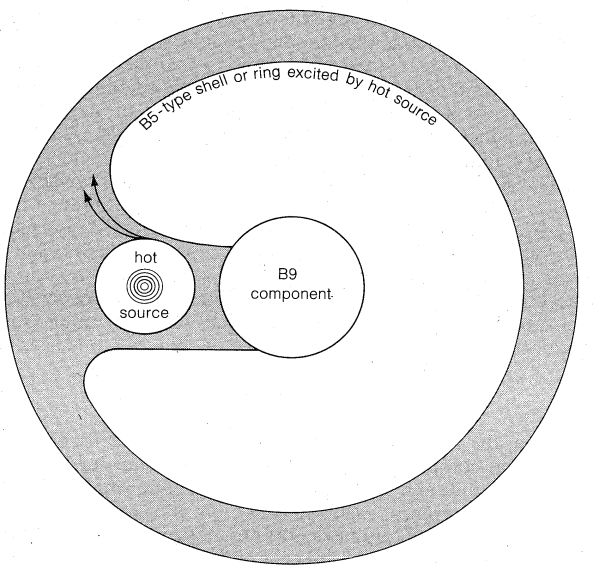

Figure 6: Probable behaviour of gases around "peculiar" double star Beta Lyrae. The nature of the "hot" component is not well understood.

Supergiant stars have very extended atmospheres, which are probably not even approximately in mechanical equilibrium. The atmospheres of M supergiant stars appear to be slowly expanding outward. Observations of the eclipsing binary 31 Cygni show that the K supergiant component has an extremely inhomogeneous, extended atmosphere composed of numerous blobs and filaments. As the B component of this system slowly moves behind the larger star, its light shines through larger masses of the K star's atmosphere. If the atmosphere were in orderly layers, the lines of ionized calcium, for example, produced by absorption of the light of the B star by the K-star atmosphere, would grow stronger uniformly as the eclipse proceeds—but they do not.

Flare-type and nova-type activity are other forms of instability that have been discussed above.

INTERNAL STRUCTURE OF STARS

Calculation of the internal structure of stars—that is, the dependence of pressure, temperature, and density on depth below the surface—depends on basic principles that are explained below. The calculations have to take into account the change of the star's structure with time as its hydrogen supply is gradually converted into helium.

Simplicity of relationships

Because of the basic simplicity of the relationship among temperature, density, and pressure, the internal pressures, temperatures, and densities of main-sequence stars and particularly of white dwarfs can be calculated with greater confidence than can the internal temperature and density of the Earth.

Relations obtained from physical laws. The star is assumed to be in mechanical equilibrium; that is, the pres-

sure at each point exactly balances the weight of the overlying layers. This balance can be expressed as a simple relation between the pressure gradient and the density. A second relation expresses the continuity of mass; that is, if M_r is the mass of material within a sphere of radius r, the mass, ΔM, added when one goes outward a distance Δr through a shell of volume $4\pi r^2\Delta r$, is equal to the volume of the shell multiplied by the density, ρ. In symbols, this is expressed as $\Delta M = 4\pi r^2\rho\Delta r$.

The third relation is an equation of state; it expresses the relation among the pressure, density, and temperature of the material. Throughout the star the material is entirely gaseous, and, except in certain highly evolved objects, it obeys closely the perfect-gas law. The molecular weight is 2 for molecular hydrogen, 4 for helium, and 56 for iron vapour. In the interior of a typical star, however, almost all of the material is completely ionized. Under these circumstances the hydrogen molecules are not only broken down into individual atoms, but the atoms themselves are broken down (ionized) into protons and electrons. Hence, the molecular weight of ionized hydrogen is the average mass of a proton and an electron, ½ on the atom-mass scale. On the other hand, a completely ionized helium atom contributes a mass of 4 with a helium nucleus (an alpha particle) plus two electrons of negligible mass; hence, the average molecular weight is ⅘. A completely ionized nickel atom contributes one nucleus of mass 58.7 plus 28 electrons; hence, its molecular weight is $58.7/29 = 2.02$. Since stars contain a preponderance of hydrogen and helium, which are completely ionized throughout the interior, the average particle mass, μ, is the (unit) mass of a proton, divided by a factor taking account of the concentrations by weight of hydrogen, X, and helium, Y, and α, which is nearly ½. In symbols the equation is as follows:

$$\mu = \frac{1}{2X + (\frac{3}{4})Y + \alpha(1 - X - Y)}$$

Hence, the molecular weight will depend critically on the chemical composition, particularly on the ratio of hydrogen to helium and the total content of heavier material.

If the temperature is sufficiently high, the radiation pressure, P_r, which is numerically equal to one-third of the energy density, must be taken into account as well as the perfect-gas pressure. Hence, the total equation of state is $P = P_g + P_r$. P_g depends on density, temperature, and the molecular weight, μ; P_r on the temperature T and a quantity a equal to 7.56×10^{-15} ergs cm^{-3} deg^{-4}; a is called the radiation density constant. Let $\mu = 2$ (upper limit), and $\rho = 1.4$ grams per cubic centimetre (mean density of the Sun), and the temperature at which the radiation pressure would equal the gas pressure can be calculated. This temperature is 28,000,000°, much hotter than the centre of the Sun, where the density is about 100 times that of water. Hence, radiation pressure in the Sun may be neglected, but it cannot be neglected in hotter, more massive stars. Radiation pressure may then set an upper limit to stellar luminosity.

Radiation density constant

Certain stars, notably the white dwarfs, do not obey the perfect-gas law. Instead, the pressure is almost entirely contributed by the electrons, which obey a law called the degenerate-gas law. If μ' is the average mass per free electron of the totally ionized gas, the pressure, P, and density, ρ, are such that P is proportional to a five-thirds power of the density divided by the average mass per free electron; that is, $P = 9.9 \times 10^{12}(\rho/\mu')^{5/3}$. The temperature does not enter at all. At yet higher densities the equation of state becomes more intricate, but it has been shown that even this complicated equation of state could be employed in the calculation of the internal structure of these white dwarf stars. The white dwarfs are probably better understood than most other objects.

For normal stars such as the Sun, the energy-transport method for the interior must be known. Except in white dwarfs or dense cores of evolved stars, thermal conduction is not significant, as the heat conductivity of gases is very low. One important mode of transport is an actual flow of radiation outward through the star. Starting as X-rays near the centre, the radiation is gradually "softened" as it works its way to the surface to emerge as ordinary light and heat. The rate of flow of radiation is proportional to the temperature gradient, the rate of change of temperature with distance. This relation uses the following important quantities: a, the radiation density constant mentioned above; the velocity of light, c; the density, ρ; and k, a measure of the opacity of the material. The larger the value of k, the smaller the transparency of the material and the steeper the temperature fall required to push the energy outward at the required rate. The opacity, k, can be calculated for any temperature, density, and chemical composition and is found to depend in a complicated way on the density and temperature.

In the Sun's outer layers and particularly in certain giant stars, transport of energy takes place by quite another mechanism—large-scale mass motions of gases, or convection. Large volumes of gas deep within the star become heated, rise to higher layers, and mix with their surroundings, thus releasing great quantities of energy. The extremely complicated flow patterns cannot be followed in detail, but when convection occurs a relatively simple relation exists between pressure and density. Wherever convection can occur, it is much more efficient than radiative energy transport.

Energy generation in stars. The most fundamental property of stars is that they radiate energy and must derive this energy from sources within themselves. For normal main-sequence stars such as the Sun, the source of the energy lies in the conversion of hydrogen into helium. The reaction believed to occur in the Sun is the proton–proton reaction. Two protons collide to form a deuteron (heavy hydrogen nucleus), with the liberation of a beta ray (positive electron, or positron). Also emitted is a neutral particle of negligible mass, called a neutrino; it escapes forthwith from the solar interior. The positive electron meets a negative electron, and the two annihilate one another with the liberation of much energy. The annihilation energy amounts to 1.02 megaelectron volts (MeV). This process is one of low probability, and many proton–proton collisions occur before a positive electron is created.

The proton–proton reaction

Next, a proton collides with the deuteron, ^{2}H, to form the nucleus of a light helium atom of atomic weight 3, ^{3}He. A "hard" X-ray or gamma ray is also emitted. The most likely event to follow in the chain is a collision of this ^{3}He nucleus with a normal ^{4}He nucleus or α-particle to form a nucleus of a beryllium atom of atom weight 7, ^{7}Be, with the emission of another gamma (γ) ray. The ^{7}Be nucleus in its turn captures a proton to form a boron nucleus of atomic weight 8, ^{8}B, with the emission of another gamma ray.

Boron-8, however, is very unstable. It decays to beryllium of atomic weight 8, ^{8}Be, with the emission of another positron, e^+, and a neutrino, ν; and then the nucleus itself decays into two α-particles (the helium nucleus, ^{4}He). These interactions can be represented by the following equations:

$$^3\text{He} + {}^4\text{He} \rightarrow {}^7\text{Be} + \gamma \qquad \text{(rather slow reaction)}$$
$$^7\text{Be} + {}^1\text{H} \rightarrow {}^8\text{B} + \gamma \qquad \text{(rapid reaction)}$$
$$\left.\begin{array}{l} {}^8\text{B} \rightarrow {}^8\text{Be} + (e^+) + \nu \\ {}^8\text{Be} \rightarrow 2\,{}^4\text{He} \end{array}\right\} \qquad \text{(instantaneous reactions)}$$

In the course of these reactions four protons have been consumed to form one helium nucleus, and two negative electrons have perished.

The mass of four hydrogen atoms is $4 \times 1.00797 = 4.03188$; that of a helium atom is 4.0026. Hence, 0.02928 atomic mass units, or 0.7 percent of the original mass, have disappeared. Some of this has disappeared in the form of the elusive neutrinos, but most of it has been converted into radiant energy. To keep shining at its present rate, a typical star like the Sun has to convert 674,000,000 tons of hydrogen into 670,000,000 tons of helium every second. More than 4,000,000 tons of matter literally disappear into radiation every second. The rate of energy generation according to the proton–proton reaction varies as about the fourth power of the temperature.

The theory gives a good picture of solar-energy generation except for one thing. Attempts have been made to observe the neutrino flux from the Sun by means of a very intricate and difficult experimental setup. To date, none have been found. No explanation for this discordance is known. Possibly the neutrino is an unstable particle.

The carbon cycle

The principal source of energy in hotter stars is the carbon cycle, in which hydrogen is converted into helium with carbon serving as a catalyst. The reactions are as follows: first, a carbon nucleus, ^{12}C, captures a hydrogen nucleus or proton, ^{1}H, to form a nucleus of nitrogen, ^{13}N; thus, $^{12}C + {}^{1}H \rightarrow {}^{13}N +$ gamma ray. A gamma ray is emitted in the process. The light ^{13}N nucleus is unstable, however. It emits a positive electron, e^+, which encounters a negative electron e^-, and the two annihilate one another. A neutrino is also emitted; the resulting ^{13}C nucleus is stable. Eventually the ^{13}C nucleus captures another proton, forms ^{14}N, and emits another gamma ray. In symbols the reaction is represented by the equations: $^{13}N \rightarrow {}^{13}C + e^+ + \nu$; $^{13}C + {}^{1}H \rightarrow {}^{14}N + \gamma$. The ^{14}N, ordinary nitrogen, is stable. When it captures a proton to form a nucleus of light oxygen-15, ^{15}O, the resulting nucleus is unstable against beta (β) decay; that is, it emits a positive electron, e^+, and a neutrino, ν. In symbols this is expressed as $^{14}N + {}^{1}H \rightarrow {}^{15}O + \gamma$; $^{15}O \rightarrow {}^{15}N + e^+ + \nu$. Again, the positive electron meets a negative electron and is annihilated while the neutrino escapes from the Sun. Eventually the ^{15}N nucleus encounters a fast-moving proton, ^{1}H, and captures it. It might be supposed that at this point a nucleus of ordinary ^{15}O would be formed. Actually, this process occurs rarely, the most likely reaction being $^{15}N + {}^{1}H \rightarrow {}^{12}C + {}^{4}He + \gamma$. The capture of the proton causes the resultant nucleus to break down into the original ^{12}C nucleus and an alpha particle, or helium nucleus, of mass 4. Thus, the original carbon nucleus reappears, and the four protons that have been added permit the formation of an alpha particle, or helium nucleus. The same amount of mass has disappeared, although a different fraction of it may have been carried off by the neutrinos.

In the interior of a star the particles are moving rapidly in every direction as a consequence of high temperatures. Once in a while a proton is sufficiently close to a nucleus for it to be captured and a nuclear reaction to occur. Only protons of very highest energy (many times the average energy in a star such as the Sun) are capable of producing such nuclear reactions. Since the energies of the protons are proportional to the temperature, the rate of energy production rises steeply as temperature increases. The temperature dependence is much steeper at the higher temperatures at which the carbon–nitrogen cycle takes place than it is for the proton–proton reaction.

The hottest stars of the main sequence shine with energy produced by the carbon cycle. The faint red dwarf stars use the proton–proton reaction exclusively, whereas stars such as the Sun shine mostly by the proton–proton reaction but have some contribution from the carbon cycle.

The aforementioned mathematical relationships, including the law of energy generation, permit the problem of stellar structure to be tackled. An early assumption that stars have a uniform chemical composition throughout their interiors simplified the calculations greatly; but it had to be abandoned when the importance of stellar evolution effects were taken into account, since evolution changes the composition. Calculations have to be carried out by a step-by-step process known as numerical integration and must take into account that at the surface the pressure and density vanish; at the centre of the star the pressure, density, and temperature must remain finite. A frequent procedure is to carry the computations from the surface inward and from the centre outward; then the two solutions must fit together, giving the same pressure, density, temperature, etc., when they meet. One of the most important generalizations that arise from such calculations is the mass–luminosity relation, discovered by Eddington. The mass–luminosity relation, which is, in its theoretical form, really a mass–radius–luminosity relation, expresses the fact that the luminosity, L, is proportional to a power of the mass and inversely proportional to a constant power of the radius, R. The molecular weight, μ, also appears in the formula, but this factor is almost constant. The luminosity depends on the mass but even more on the molecular weight and therefore on chemical composition. Thus: $L = C\frac{M^a\mu^b}{R^c}$, where a is of the order of 5, b about 7 or 8, and c near 1.5.

Theoretical derivation of a mass–luminosity relation

The mass–luminosity law does not explicitly contain the law of energy generation. The equations governing stellar structure require such a relation without invoking the detailed law of energy generation, which was not known in Eddington's time. Given the precise law of energy generation, an additional expression involving the chemical composition, luminosity, and radius may be derived. For a chemically homogeneous star shining on the carbon cycle, taking X and Y as the proportions by weight of hydrogen and helium, respectively, and with the powers d somewhere near 20, e about 22, and f about 23, since the carbon cycle depends on a high power of the temperature, the energy output relation can be written:

$$L = B(1 - X - Y)\mu^d \frac{M^e}{P^f}$$

It and the mass–luminosity relation are actually valid only for young stars.

Energy transport

The star model and the relation among mass, luminosity, and radius are determined by the mode of energy transport. In the Sun and the fainter main-sequence stars, energy is transported throughout the outer layers by convection currents, whereas, in the deep interior, energy is transported by radiation. Among the hotter stars of the main sequence, the reverse appears to be true. The deep interiors of stars that derive their energy primarily from the carbon cycle are in convective equilibrium, whereas in the outer parts the energy is carried by radiation. The observed masses, luminosities, and radii of most main-sequence stars can be reproduced with reasonable and uniform chemical compositions.

Chemically homogeneous possible models of giant and supergiant stars cannot be constructed. If a yellow giant star such as Capella is assumed to be built like main-sequence stars, the central temperature will turn out to be so low that no known nuclear process can possibly supply the observed energy output. Progress has been made only by assuming that these stars were once main-sequence objects that, in the course of their development, exhausted the hydrogen in their deep interiors. As a consequence, inert cores formed, composed mostly of helium, which is the ash of the hydrogen-burning processes. Since no nuclear helium reactions occur at the few tens of millions of degrees temperature and the densities likely to prevail in these interiors, no thermonuclear energy could be obtained from these depleted cores. Energy is assumed to be generated in a thin shell surrounding the inert core where some fuel remains and is presumably produced by the carbon–nitrogen cycle. Such models are called shell-source models. As the star uses up more and more of its hydrogen supply, the core increases in mass; but the outer envelope of the star continues to expand. These shell-source models can explain the observed luminosities, masses, and radii of giant and supergiant stars (see below).

Depletion of hydrogen in older stars

The depletion of hydrogen fuel is appreciable even for a dwarf star as old as the Sun (about 5,000,000,000 years); the Sun seems to have been shining at its present rate for about 1,000,000,000 years. For its observed luminosity to be maintained, the Sun's central temperature must have increased noticeably since the solar system was formed, largely as a consequence of the depletion of the hydrogen in the interior with an accompanying increase in molecular weight and temperature. Over the past 5,000,000,000 years the Sun may have brightened by about half a magnitude; and in the early Precambrian era (about 2,000,000,000 years ago) the solar luminosity was about 20 percent less than now.

Table 5 gives results of one calculation of the internal structure of the Sun. The carbon cycle and the proton–proton reaction and evolutionary effects are all taken into account. Density, temperature, and the fraction of

the total mass within a radius r (shown in Table 5 as a fraction of the Sun's radius R) are given. Nearly all the matter within the Sun is hotter than 1,000,000°. The central temperature attains about 15,000,000° K.

Table 5: Internal Structure of the Sun

r/R	mass within r/R fractional	density (water = 1)	temperature (°K)
0.0000	0.0000	149.8000	14,920,000

VI. Stellar evolution

Evolutionary effects have not been negligible even for the Sun. A more massive star must show more spectacular effects, since the rate of conversion of mass into energy is higher. The Sun produces energy at the rate of about two ergs per gram per second; a more luminous main-sequence star may produce energy at the rate of 2,000 ergs per gram per second. Consequently, effects that require billions of years to be easily recognized in the Sun may occur within a few millions of years in highly luminous stars. A supergiant star such as Antares, a bright main-sequence star such as one of the belt stars of Orion, or even a more modest star such as Sirius cannot have endured as long as the Sun.

Rates of energy production

THE LIFE HISTORY OF A TYPICAL STAR

These stars must have been formed relatively recently. Stars might be found within the Galaxy (and even near the Sun itself) that are well evolved or even approaching extinction or both, as well as occasional stars that must be very young or even in the process of formation. Stars are presumably formed from the grains and gas in the interstellar medium. The material between the stars is not uniformly distributed in space but is spread in a patchy fashion. Occasionally, a sufficiently massive cloud will form so that gravitational attractions can draw it still further together. The details of this process are not at all well understood.

Protostars. As the cloud or protostar begins to pull itself together, the internal temperature and density start to rise until it reaches incandescence with a faint red glow. At this stage the star is still shining by the energy released by its gravitational contraction. As the internal temperatures rise to a few million degrees, deuterium (heavy hydrogen) is first destroyed. Then lithium, beryllium, and boron are broken down into helium as their nuclei are bombarded by protons moving at high speeds.

Detailed calculations show that a star originally falls above the main sequence in the Hertzsprung–Russell diagram because it is too bright for its colour. As it contracts, it moves downward and to the left toward the main sequence.

The star reaches the main sequence. As the central temperature and density continue to rise, the proton–proton or carbon-cycle reactions become active, and the development of the star is stabilized. The star then reaches the main sequence, where it remains for most of its active life. The time required for the contraction phase depends on the mass of the star. A star of the Sun's mass may require millions of years to reach the main sequence, whereas one of much greater mass may reach the main sequence in a few hundred thousand years.

By the time the star reaches the main sequence, it is still chemically homogeneous. As time goes on and the hydrogen fuel in the core is converted into helium, the temperature slowly rises. If the star is sufficiently massive to have a convective core, the material in this region has a chance to be thoroughly mixed; but the outer region does not mix with the core. In the Sun, on the other hand, there is no convective core; and the helium–hydrogen ratio is maximum at the centre and decreases outward. During the lifetime of the Sun there has been a steady depletion of hydrogen, so that at the centre the concentration of hydrogen is probably only about one-third of the original amount. The rest has all been converted to helium. The rate of evolution becomes the more rapid the greater the mass of the star. A star of twice the Sun's mass burns its fuel at such a rate that it lasts about 3,000,000,000 years, whereas a star of ten times the Sun's mass has a lifetime measured in tens of millions of years.

Effects of composition changes

As the composition of the interior changes, the star begins to move away from the main sequence, slowly at first and then more rapidly. When about 10 percent of the star's mass has been converted into helium, the structure of the star changes drastically. All the hydrogen of the core has been burned out, and this central region is composed almost entirely of inert helium, with small admixtures of heavier elements. The energy production now takes place in a thin shell where hydrogen is consumed and added to the inert core. The outer portion of the star expands outward, and as the star swells up it may gradually rise in luminosity. The details of the evolution depend on the hydrogen–metal ratio, and the course of evolution will differ for stars of different population types (see above).

The main sequence for a globular cluster (Figure 4) is discussed above. The colour–magnitude diagram exhibits the effects of stellar evolution; all main-sequence stars more massive than 1.5 solar masses have evolved off the main sequence, and most of them have died. The colour–magnitude array then represents an evolutionary picture of the cluster. The giant branch is not the path of evolution but rather the envelope of evolutionary paths. It represents a snapshot of stars of different masses but of the same age. Presumably, the stars leave the main sequence and evolve into stars of steadily increasing luminosity until they reach the peak of the diagram. Later stages of evolution are presumably connected with the horizontal branch at absolute magnitude 0, where the RR Lyrae stars and other blue objects are found. The last stages of evolution are represented by the white dwarfs, which are too faint to be detected in globular clusters, although they must be present there in great numbers.

Evolution away from the main sequence. Theoretical calculations suggest that, as the star evolves from the main sequence, the hydrogen–helium core gradually increases in mass but shrinks in size as more and more "ash" is fed in through the hydrogen-burning shell. Energy is carried outward from the shell by rapid convection currents. The temperature in the shell rises; the star becomes more and more luminous and finally approaches the top of the giant sequence. The core shrinks by gravitational contraction and becomes denser and hotter until it reaches a temperature of about 120,000,000° K. At that temperature the previously inert helium is consumed in the production of heavier elements.

Helium burning

If two helium (He) nuclei each of mass 4 are jammed together, it might be expected that they would form a nucleus of beryllium, Be, of mass 8; in symbols, the reaction would be: $^4He + {}^4He \rightarrow {}^8Be$. Actually, however, ^8Be is unstable and breaks down again into two helium nuclei. If the density and temperature are high enough, however, the short-lived beryllium nucleus may capture another helium nucleus in what is essentially a three-body collision to form a nucleus of carbon-12; thus $^8Be + {}^4He \rightarrow {}^{12}C$. Further reactions producing oxygen, ^{16}O, neon, ^{20}Ne, magnesium, ^{24}Mg, and so on, may occur. In symbols, $^{12}C + {}^4He \rightarrow {}^{16}O$; $^{16}O + {}^4He \rightarrow {}^{20}Ne$; and $^{20}Ne + {}^4He \rightarrow {}^{24}Mg$. Energy is released, and the star again has a central energy source; but the details of its evolution are uncertain. Since the energy output of helium burning (per ton of material) is much less than for hydrogen burning, the star's lifetime in the helium-burning phase cannot be long. The star eventually evolves on the horizontal branch to bluer colours and lower luminosities but certainly ends as a white dwarf. The energy

output of the white dwarfs is so low that they may go on shining mainly by radiating away their store of energy until none is left to emit. The final stage of a star is typically a ball not much larger than the Earth but with a density perhaps 50,000 times that of water, covered possibly with a thin layer of ice and surrounded by an atmosphere a few feet thick.

Estimates of stellar ages. The shapes of the colour–magnitude diagrams permit an estimate of globular-cluster ages. Stars more massive than about 1.3 solar masses have evolved away from the main sequence at a point just above the position occupied by the Sun. The time required for such a star to exhaust the hydrogen in its core is about 5,000,000,000 or 6,000,000,000 years; and the cluster must be at least as old. More ancient clusters have been identified. In the Galaxy, globular clusters are all very ancient objects, with ages measured in billions of years. In the Magellanic Clouds, globular clusters exist, such as NGC 1866, that contain numerous blue stars and therefore must be relatively young. Exact ages, however, cannot yet be assigned to globular clusters. The details of the evolutionary tracks depend on the hydrogen–metal ratios, helium–hydrogen ratios, and the precise theory of stellar evolution.

Ages of cluster stars

Open (galactic) clusters in the spiral arms of the Galaxy, of extreme Population I, tell a somewhat different story. Figure 7 shows colour–magnitude diagrams for several

From *Astrophysical Journal*, reproduced by permission of the University of Chicago Press

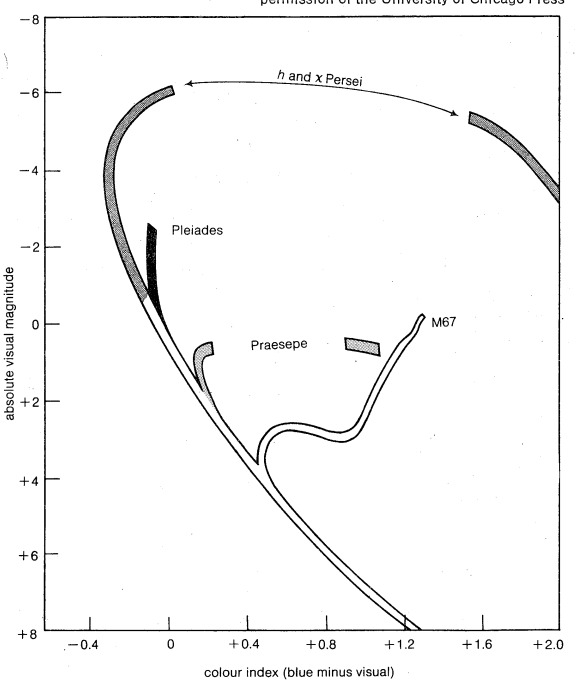

Figure 7: Colour–magnitude arrays for four galactic clusters of different ages.

different open clusters. The feature distinguishing these clusters is the difference in their ages. The youngest cluster, the pair h and χ Persei, a few million years old, contains stars of a great range in luminosity. Some stars have already evolved into the supergiant stage so that the top end of the main sequence is bent over. The stars of luminosity greater than 10,000 times that of the Sun have already largely depleted the hydrogen in their cores and are leaving the main sequence.

The brightest stars of the Pleiades have started to leave the main sequence and are approaching the critical phase when they will have exhausted all the hydrogen in their cores. There are no giants in the Pleiades. Presumably, the cluster contained no stars as massive as some of those found in h and χ Persei.

The Beehive, or Praesepe, cluster is older than the Pleiades. All stars much more luminous than first magnitude have started to leave the main sequence; there are some giants. The Hyades, about 1,000,000,000 years old, display a similar colour–magnitude array. These clusters contain a number of white dwarfs, indicating that the initially most luminous stars have already run the full gamut of evolution. Finally, M67 must be the oldest cluster of all; the best data of stellar structure indicate that it is several thousand million years old. All the bright main-sequence stars have disappeared.

The colour–magnitude diagrams for globular and open clusters differ quantitatively because the latter show a wider range of ages and because of differing chemical compositions. Most globular clusters have smaller metal–hydrogen ratios than have open clusters or the Sun. The gaps between the giants and main-sequence stars of the open clusters (Population I) often contain unstable stars such as variables; the Cepheids fall in these gaps.

The giant stars of the Praesepe cluster are comparable with the brightest stars in M67. The M67 giants have evolved from the main sequence near absolute magnitude +3.5, whereas the Praesepe giants must have evolved from main-sequence stars of absolute magnitude about +0.5. Consequently, the Praesepe giants must have masses about twice as great as those of the M67 giants. Giant stars of the same luminosity may therefore have appreciably different masses. The failure of the mass–luminosity law for giant stars is easily understood.

The components of the giant star Capella have masses three times that of the Sun, whereas each component of the giant binary TW Cancri has a mass 1.3 times that of the Sun. Capella is presumably a relatively young star, TW Cancri an ancient one.

The great spread in the luminosities and colours of giant, supergiant, and subgiant stars is also easily understood. When a star leaves the main sequence, its future evolution is precisely determined by its mass, rate of rotation (or angular momentum), chemical composition, and whether or not it is a member of a close binary system. Giant or supergiant stars of nearly the same radius and surface temperatures may have evolved from main-sequence stars of different ages and masses.

The spread in the main sequence

The spread in the main sequence can also be understood as a consequence of evolution. At the beginning of their lives as hydrogen-burning objects, stars define a nearly unique line in the Hertzsprung–Russell diagram called the zero-age main sequence. Without differences in initial chemical composition or in rotational velocity, all the stars would start exactly from this unique line. As the stars evolve, they burn hydrogen in their cores; the stars adjust to the change in the helium-to-hydrogen ratio in their cores and gradually move away from the zero-age main sequence. When the core is exhausted and a shell source develops, the internal structure of the star changes rapidly; and it quickly leaves the region of the main sequence, as it moves toward the giant or supergiant region. Hence the gap between the main sequence and the domains of these types of stars. Less massive stars leave the main sequence more slowly, as illustrated by the colour–magnitude diagram for M67. Table 3 refers to an average of main-sequence stars, not to the zero-age main sequence.

Possible observations of forming stars

In the clouds of dark obscuring matter in Taurus and other regions of the Milky Way are found variables of the T Tauri type, discussed above. These objects may represent stars in the actual process of formation. Several observations in which stars were actually "turned on" may have been identified. Other evidence is provided by color–magnitude diagrams such as that obtained for the cluster NGC 2264, associated with the star S Monocerotis. In this the brighter main sequence is well defined by stars somewhat more luminous than the Sun. The fainter redder stars, whose colours correspond to spectral classes G, K, and M, all fall above the main sequence defined by normal dwarf stars. Presumably, they are contracting toward the main sequence, shining mostly by liberation of gravitational energy; but they may be burning the light helium isotope helium-3 before they reach the main sequence and the proton–proton reaction is turned on.

Many sites of possible star formation have been identified in the Milky Way, and these are being investigated carefully for possible changes.

Table 6: The Most Abundant Chemical Elements
(by numbers)*

element	symbol	abundance	element	symbol	abundance	element	symbol	abundance
Helium	He	6.3×10^7	Magnesium	Mg	45,000	Potassium	K	76
Carbon	C	500,000	Aluminum	Al	2,140	Calcium	Ca	2,300
Nitrogen	N	100,000	Silicon	Si	32,000	Titanium	Ti	35
Oxygen	O	800,000	Phosphorus	P	320	Chromium	Cr	166
Fluorine	F	80	Sulfur	S	16,200	Manganese	Mn	75
Neon	Ne	93,000	Chlorine	Cl	420	Iron	Fe	22,000
Sodium	Na	1,900	Argon	Ar	1,200	Nickel	Ni	500

*Hydrogen = 10^9.

FORMATION OF CHEMICAL ELEMENTS IN STARS

The relative abundances of the chemical elements provide significant clues to their modes of origin. The Earth's crust has been affected severely by fractionation, so that its present varied composition offers few clues regarding the early stages. The composition of the material from which the solar system was formed is taken from that of stony meteorites, called chondrites, and from the composition of the solar atmosphere supplemented by data from hot stars and gaseous nebulae. Table 6, compiled from the efforts of many workers, lists the most abundant chemical elements.

The most obvious feature is that the abundances of light elements tend to be greater than those of heavier elements. That is, a plot of abundance against atomic mass, A, shows a decline with increasing A to about $A = 100$. Thereafter the abundance is more nearly constant. The abundance plot is not smooth. Among the lighter elements, those of even atomic number tend to be more abundant; and those with atomic numbers divisible by 4 are especially favoured. In particular, lithium, beryllium, and boron are very rare compared with carbon, nitrogen, or oxygen. There is a pronounced abundance peak at iron and less conspicuous peaks at other elements, often connected with the so-called magic-number nuclei. There is also a maximum at lead, the most stable of the heavy elements.

Preponderance of hydrogen

The preponderance of hydrogen suggests that all nuclei were built up from hydrogen, a hypothesis first proposed many years ago. This subject is considered in the article CHEMICAL ELEMENTS, ORIGIN OF. It has been suggested that the elements were created as the consequence of the initial expansion of the universe. At one stage, in this hypothesis, all matter was compressed into a huge neutron ball. As the density decreased, the neutrons decayed into protons and electrons. The protons then captured neutrons, one after another, underwent beta decay (ejection of electrons), and built up heavy elements. The major difficulty with this hypothesis is that atomic masses 5 and 8 are unstable, and there is no way to build many nuclei beyond helium.

A large body of evidence supports the idea that heavy elements are built in stars, although perhaps occasionally in stars of rather unusual types, particularly supernovae, and maybe even in certain supermassive objects not yet identified.

The splitting in the spectral sequence among the cooler stars can be understood in terms of composition differences. The M stars appear to have a "normal" (*i.e.*, solar) composition, with oxygen more abundant than carbon and the zirconium group of elements much less abundant than the titanium group. The R and N, or carbon, stars contain more carbon than oxygen, whereas the S stars appear to have an enhanced content of zirconium as compared with titanium. Other abundance anomalies are found in the high temperature Wolf–Rayet stars, in which objects containing predominantly helium, carbon, and oxygen are distinguished from objects containing helium and nitrogen, some carbon, and little observable oxygen. Significantly, all these abundance anomalies are found in stars believed to be well advanced in their evolutionary development. No main-sequence dwarf stars show such effects.

The most critical observation, however, was the detection of the unstable element technetium, Tc, in the S stars. The element has been produced on the Earth synthetically. The longest-lived isotope, ^{99}Tc, which has a half-life of 200,000 years, is produced from molybdenum, Mo, by reactions in which molybdenum of mass 98 captures a neutron to form molybdenum of mass 99, which decays in about 67 hours to form technetium of mass 99 with the ejection of a negative electron. In symbols this is expressed as $^{98}\text{Mo} + n \rightarrow {}^{99}\text{Mo}$, $^{99}\text{Mo} \rightarrow {}^{99}\text{Tc} + \beta^-$. Furthermore, the technetium in the S stars appears to be about as abundant as the neighbouring elements, ruthenium and molybdenum. The implication is that all these elements were built in the S stars and that these objects have lifetimes of about 200,000 years. How the star gets the heavy elements from the core to the surface without exploding provides an impressive challenge to theoreticians.

Theoretical workers have demonstrated how elements may be built in stars by nuclear processes occurring at very high temperatures and densities. No one mechanism can account for all the elements; hence, several distinct processes, occurring at different epochs during the late evolution of a star, have been proposed.

After hydrogen, helium is the most abundant element. Much of it may have been produced in the initial "big bang," in which the universe was created. Furthermore, it is the normal ash of hydrogen consumption. In the dense cores of highly evolved stars, the helium itself may be consumed to form, successively, carbon-12, oxygen-16, neon-20, and magnesium-24. When the core density and temperature attain values of the order of 20,000 grams per cubic centimetre and 200,000,000° K, respectively, three helium nuclei can become jammed together to form a carbon-12 nucleus. Then, by successive capture of alpha particles, nuclei of oxygen-16, neon-20, and magnesium-24 are built up. Finally, the helium becomes exhausted in the core, which contracts until the temperature reaches about 700,000,000° K, when the carbon nuclei interact with one another. Then fragments such as protons, neutrons, and alpha particles may be produced. These can interact with the oxygen and neon nuclei and others to produce a variety of other elements, such as fluorine, sodium, and others. At 10^9° K, also, oxygen-16 nuclei interact with other oxygen-16 nuclei, producing a wide range of elements from oxygen to silicon. As the core continues to contract and the temperatures and densities are forced even higher, a semi-equilibrium situation is set up wherein nuclides of the "iron peak" are produced.

Special conditions leading to supernova formation

If the temperature and density continue to rise, the iron-group nuclei can break down into alpha particles, but a large amount of energy is suddenly consumed in the process. The star suffers a violent implosion or collapse and then explodes as a supernova. In the supernova explosion, a great variety of nuclear reactions can occur.

When a nucleus captures a neutron, its mass is increased by one unit, and its charge remains the same. Such a nucleus may be too heavy for its charge and may emit an electron or beta ray to reach a more stable state. It then becomes a nucleus of the next element in the periodic table.

Slow and rapid processes

Two extreme situations have been envisaged. In one, called the slow, or *s*, process, the flux of neutrons is low. A nucleus captures a neutron and leisurely emits a beta ray; the nuclear charge increases by one.

Beta decay is often very slow, and, if the flux of neutrons is high, the nucleus may capture another neutron before there is time for it to undergo decay. In this rapid, or *r*, process, the evolution of a nuclide may be very different

from that in a slow process. In supernovae explosions vast quantities of neutrons may be produced, and these could result in the rapid buildup of massive elements. One interesting feature of the building up of heavy elements by neutron capture at a high rate in a supernova explosion is that nuclei much heavier than lead or uranium can be built. These may decay by fission, releasing further amounts of energy.

The superabundant elements in the S stars come from the slow neutron process. A variety of mechanisms of how the neutrons are produced have been proposed. One example, in which the symbols are the same as before, is: $^{13}C + {}^{4}He \rightarrow {}^{16}O + n + (2.6\ MeV)$ energy. Another is between neon-21 and helium-4 to give magnesium-24 and a neutron: $^{21}Ne + {}^{4}He \rightarrow {}^{24}Mg + n$. These neutrons are available for capture by heavier nuclei, particularly those with large target areas, to form yet heavier elements. Thus, the elements of the zirconium group, for example, could be built from lighter elements by successive neutron capture. Other nuclear processes could result in the production of neutrons and the subsequent formation of heavy elements. About 40 percent of the iron in a mixture would be transformed into heavier elements if about 20 neutrons could be produced for every iron atom in the mixture.

Some low-abundance atomic nuclei are proton-rich—*i.e.*, neutron deficient—and cannot be produced by the *s* or *r* process. Presumably, they have been created in relatively rare events—*e.g.*, one in which a quantum of hard radiation, a γ-ray, causes a neutron to be ejected.

No known nuclear process is capable of producing deuterium (heavy hydrogen), lithium, beryllium, and boron in stellar interiors. They are probably produced by the breaking down or spallation of heavier elements, such as iron and magnesium, by high-energy particles in stellar atmospheres or in the early stages of stellar formation. Presumably, these high-energy particles originate as a consequence of electromagnetic disturbances in the neighbourhood of sunspots and are probably connected with phenomena such as flares, which may be more active in early stages of a star's gravitational contraction or early in its life. Some light-element nuclei may be produced by cosmic rays shattering atoms of carbon, nitrogen, oxygen, and other elements in the interstellar medium.

The peculiar A stars comprise a class of objects with strange abundance anomalies, which may arise from mechanical effects—selective radiation pressure, photospheric diffusion and element separation, and so on—rather than from nuclear effects. Some stars show enhanced silicon, others enhanced lanthanides. The so-called manganese stars show great overabundances of manganese and gallium, usually accompanied by an excess of the element mercury. The latter stars show weak helium lines, low rotational velocities, excess amounts of gallium, strontium, yttrium, mercury, and platinum, and absences of elements such as aluminum and nickel. When these stars appear in binaries, the two components often show differing chemical compositions. It is very hard to envisage plausible nuclear processes that would account for the peculiarities of the abundances—particularly the strange isotope ratios of mercury.

Peculiarities of the galactic cosmic-ray abundances are consistent with the suggestion that they originate in supernovae, being particles accelerated in the strong, rapidly varying magnetic fields involved in these objects (see below). On the way to the Earth they suffer shattering encounters with light atoms.

PROBABLE FATE OF A STAR: WHITE DWARFS, PULSARS, AND BLACK HOLES

The final stages of the evolution of a star will depend on its mass, its angular momentum, and whether it is a component of a close binary.

White dwarfs and novae. The evolution of a member of a close double-star system can be markedly affected by the presence of its companion. As the stars age, the more massive one swells up more quickly as it moves away from the main sequence. It becomes so large that its outer envelope falls under the gravitational influence of the smaller star. Material is continuously fed from the more rapidly evolving star to the less massive one, which still remains on the main sequence. U Cephei is a classical example of such a system for which spectroscopic evidence shows streams of gas flowing from the more highly evolved star to the hotter companion, which is now the more massive of the two. Eventually, the latter will also leave the main sequence and become a giant star, only to lose its outer envelope to the companion, which by then may have reached a white-dwarf stage.

Possible causes of novae

Novae appear to be binary stars that have evolved from contact binaries of the W Ursae Majoris type. One component may have reached the white-dwarf stage. Material fed to it from its distended companion appears to produce instabilities that result in violent explosions or nova outbursts. The time interval between outbursts may range from a few score years to hundreds of thousands of years.

Single stars appear to evolve through the red-giant phase to their ultimate state along more straightforward paths. Perhaps in most instances the distended outer envelope of the star simply drifts off into space, while the core settles down as a white dwarf. In other instances the star may explode as a supernova. If the residual mass is less than 1.3 solar masses, the stellar remnant will become a white dwarf (see above). The material becomes a degenerate gas, wherein the electrons are all stripped from individual atoms. In a sense, they resemble conduction electrons in a metal. With sufficient momenta supplied to the electrons, this gas can be compressed to very high densities. The star has no longer any source of energy and simply cools down, although very slowly.

Neutron stars. When the mass of the core lies between 1.3 and 2 solar masses, it can settle down as a neutron star with a density about 10^{14} times that of the Sun and a diameter of the order of 30 miles (50 kilometres). Such a star would have a crystalline solid crust, wherein bare atomic nuclei would be held in a lattice of rigidity and strength some 18 orders of magnitude greater than that of steel. Below the crust the density is similar to that of an atomic nucleus, so the residual atomic cores lose their individuality as their nuclei are jammed together to form a nuclear fluid. The whole star resembles a single atomic nucleus.

Although neutron stars were predicted in the 1930s, their existence was recognized only very recently. In 1967 a radio source (a pulsar) emitting weak pulses, each lasting about 0.3 second with a remarkably constant period of approximately 1.337 seconds, was discovered. Other examples were soon found, including many detected in the Southern Hemisphere, where a pulsar was first identified with a supernova remnant (see PULSARS).

Pulsars as rotating neutron stars

A large body of evidence identifies pulsars as rotating neutron stars. All energy emitted in the pulses comes from a slowing down of this rotation, but only a small fraction appears in radio-frequency pulses. The rest goes into cosmic rays, maybe some into the emission of gravitational energy.

The pulsar at the centre of the Crab Nebula is observed not only in radio frequencies but also in optical and X-ray frequencies, where it emits 100 and 10,000 times, respectively, as much radiation as in the radio-frequency region. The slowing down of the pulsar rotation supplies the energy to account for the synchrotron emission from the Crab Nebula, which ranges from X-ray to radio frequencies.

Pulsar radiation is polarized—both linearly and circularly—and can be understood in terms of a rotating star with a magnetic field of 10^{12} gauss. Various mechanisms have been proposed whereby charged particles can be accelerated to cosmic-ray energies. Possibly most, if not all, galactic cosmic rays originate from pulsars.

Sudden changes have been observed in the rotation rates of pulsars. Early in 1969, the period of the Vela pulsar suddenly decreased and then began to increase again at its normal rate. This period change could be explained by a change of radius of one centimetre, possibly a sudden shrinkage of the crust. The pulsar phenomenon lasts much longer than the observable supernova remnant, but

pulsars cannot be detected at great distances in the Galaxy because the signals become distorted and wiped out by the ionized interstellar medium.

An object similar to a pulsar is probably the X-ray source in Scorpius, whose energy distribution was recently measured by workers who find that it cannot be interpreted by synchrotron radiation nor by interaction of fast electrons with protons; *i.e.*, bremsstrahlung. The emission is that of a hot body with a surface temperature in the millions of degrees and with a diameter of about ten miles (16 kilometres).

Black holes. If the remnant mass exceeds about two solar masses, it will just continue to contract. The gravitational field of the collapsing star will become so powerful that neither matter nor light can escape any more. It is said then that the star has collapsed to a Schwarzschild singularity—or, in popular terms, a black hole. Its powerful gravitational effects on other objects will still be felt. Bodies trapped in its gravitational field, or a laser beam directed at such an object, would just disappear—pulled into a "bottomless pit." To date, such objects remain theoretical, as none have been discovered.

Schwarzschild singularity

Eventually, the Sun will die as a white dwarf, but before that happens it will evolve as a giant star. The Earth will become uninhabitable and probably will be swallowed up in the vastly extended envelope of the red-giant-stage Sun. These events will not come to pass for thousands of millions of years.

(L.H.A.)

Star Clusters and Stellar Associations

The Sun is a single star. A high proportion of stars in the Earth's Galaxy, however, exists in physically related groups, pairs, multiple stars with a few members, or clusters with many, held together by mutual gravitation. The line of demarcation between such groups is not always strong. Star clusters fall into two main types. Open (formerly called galactic) clusters contain from a dozen to many hundreds of stars, usually in an unsymmetrical arrangement. Globular clusters are old systems containing thousands to hundreds of thousands of stars closely packed in a symmetrical, roughly spherical form. In addition, groups called associations, formed of a few dozen to hundreds of stars of similar type and common origin, whose density in space is less than that of the surrounding field, have now been recognized.

Four open clusters have been known from earliest times: the Pleiades and Hyades in the constellation Taurus, Praesepe (the Beehive) in the constellation Cancer, and Coma Berenices. The Pleiades was so important to some early peoples that its rising at sunset determined the start of their year. The appearance to the naked eye of the Coma Berenices cluster led to the naming of its constellation after the hair of Berenice, wife of Ptolemy Euergetes of Egypt, 3rd century BC, the only constellation named after a historical figure.

Though several globular clusters, such as Omega Centauri and Messier 13 in Hercules, are visible to the unaided eye as hazy patches of light, attention was paid to them only after the invention of the telescope. The first record of a globular cluster, in Sagittarius, was in 1665; it was later named Messier 22; the next, Omega Centauri (see Figure 1), was recorded by the English astronomer and mathematician Edmund Halley in 1677.

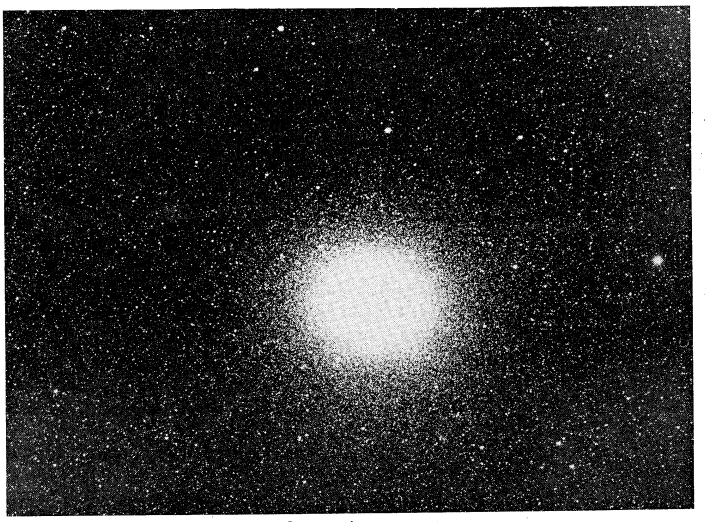

Figure 1: Globular cluster Omega Centauri.

In the late 18th century, a French astronomer, Charles Messier, made a catalogue of 107 "misty objects" so that he would not mistake them for the comets for which he was searching. Objects in this catalogue have a number preceded by M. At the same time, William Herschel began his catalogues of thousands of objects, which were expanded in the first half of the 19th century from observations of the southern sky. In 1888 Johann Ludwig Emil Dreyer, then director of Armagh Observatory, combined all the earlier lists and catalogues into his New General Catalogue (NGC), followed by its supplements, the Index Catalogues (IC), whose numbers are still in use. Of the 125 known globular clusters, 104 have these numbers.

Names and nomenclature

Investigations of globular and open clusters greatly assisted the understanding of the Galaxy. In 1917, from a study of the distances and distributions of globular clusters, Harlow Shapley of Mount Wilson Observatory determined that the galactic centre lies in the Sagittarius region. In 1930, from measures of angular sizes and distribution of open clusters, Robert Trumpler of Lick Observatory showed that light is absorbed as it travels through many parts of space.

The discovery of stellar associations depended on knowledge of the characteristics and motions of individual stars scattered over a substantial area. In the 1920s, it was noticed that young hot blue stars (spectral types O and B) apparently congregated together. In 1949 a Soviet astronomer, Victor Amazaspovich Ambartsumian, suggested that these stars were members of physical groupings of stars with a common origin and named them O associations. (The name OB association is also now sometimes used.) He also applied the term T associations (see below) to groups of dwarf irregular T Tauri type variable stars first noted at Mount Wilson Observatory by Alfred Joy.

The study of clusters in external galaxies began in 1847, when Sir John Herschel at the Cape Observatory published lists of such objects in the nearest external galaxies, the Magellanic Clouds. In this century, the identification of clusters has been extended first to more remote galaxies by the use of large reflectors and later by Schmidt telescopes (see TELESCOPE).

A recent catalogue lists 1,039 open clusters, 5 moving clusters, 11 stellar groups, 70 OB associations, 125 globular clusters, and 28 extragalactic objects. In the present century the number of globular clusters known in the Galaxy has increased by only one third. The number of open clusters known has more than trebled, and the total number is estimated to be 40,000 with 1,000 associations.

GLOBULAR CLUSTERS

Although globular clusters are widely scattered in galactic latitude (see Figure 2), about a third of them are concentrated around the galactic centre, as satellite systems,

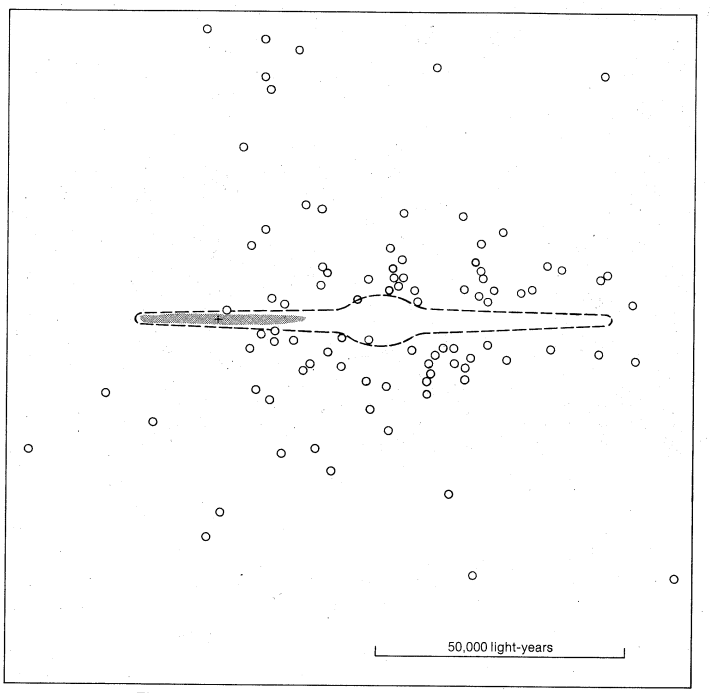

Figure 2: *Distribution of open and globular star clusters in the Galaxy.*
Dotted line indicates probable outline of the Galaxy, a flattened lens-shaped system formed by the stars, as seen edgewise from outside. Eccentric position of the Sun is shown by a cross. Some of the known open star clusters are scattered among the stars in shaded region. Small circles represent globular clusters.

in the rich Sagittarius–Scorpius star fields. Individual cluster masses include up to a million suns, and their linear diameters may be several hundred light-years (one-light-year equals 9.5×10^{12} kilometres); their apparent diameters range from one degree for Omega Centauri down to knots of a minute of arc. In a cluster like M 3, 90 percent of the light is contained within a diameter of 100 light-years, but star counts and the study of RR Lyrae member stars (whose intrinsic brightness varies regularly within well-known limits) indicate a larger one of 325 light-years. The clusters differ markedly in the degree to which stars are concentrated at their centres. Most appear circular and are probably spherical, but a few, such as Omega Centauri, are noticeably elliptic. The most elliptical cluster is M 19, the major axis being about double the minor.

Contents. Globular clusters are composed of what are called Population II objects; that is, old stars. The brightest stars are known as red giants, bright red stars with absolute magnitude (a measure of the true brightness on a logarithmic scale) −2, about 600 times the Sun's brightness or luminosity. In only six clusters have stars as intrinsically faint as the Sun been photographed, and in no globular clusters have the faintest stars yet been recorded. The luminosity function for M 3 shows that 90 percent of the visual light comes from stars at least twice as bright as the Sun, but more than 90 percent of the cluster mass is made up of fainter stars. The density near the centres of globular clusters is two stars per cubic light-year, compared with one star per 300 cubic light-years in the solar neighbourhood. Studies of 50 clusters showed a difference in spectral properties from stars in the solar neighbourhood. (The spectroscopic study of light from a star reveals the structural elements, and compounds, that emitted the light.) This difference proved to be due to a deficiency of metals in the clusters, which have been classified on the basis of increasing metal abundance. Globular cluster stars are 2 to 300 times poorer in metals than stars of the solar neighbourhood. The ratio of metals is higher for clusters near the galactic centre than for those in the halo. The amounts of other elements, such as helium, also differ from cluster to cluster. Radio astronomical studies have set a low upper limit on the amount of neutral hydrogen in globulars. Puzzling features in some globular clusters are dark lanes of nebulous material; though it is difficult to explain the presence of distinct, separate masses of unformed material in old systems, the nebulosity cannot be foreground material between the cluster and observer.

Nearly 2,000 variable stars are known in the 100 globular clusters that have been examined. Of these perhaps 90 percent are members of the class called RR Lyrae variables after the prototype RR Lyrae (formerly called cluster type variables). Other variables in clusters are W Virginis, RV Tauri, and U Geminorum stars, Cepheids, Mira stars, eclipsing binaries (pairs of stars that periodically eclipse each other as seen from Earth), and novae (exploding stars). Most of these variables are named after their prototype star. They are valuable in studies of distance and stellar evolution.

Colour-magnitude and spectrum-magnitude diagrams. The colour of a star has been found generally to correspond to its surface temperature and in a somewhat similar way the type of spectrum shown by a star depends on the degree of excitation of the light-radiating atoms in it, and therefore also on the temperature. All stars in a globular cluster are, within a very small percentage of the total distance, at equal distances from Earth so that the effect of distance on brightness is common to all. Colour-magnitude and spectrum-magnitude diagrams can thus be plotted for the stars of a cluster and the position of the stars in the array, except for a factor that is the same for all stars, will be independent of distance.

All such arrays show a major grouping of stars along a diagonal line called the Main Sequence, and the categories range from hot, bright bluer stars to cool and redder. In many cases a Giant Branch containing very luminous stars is also present (see Figure 3), as well as some other

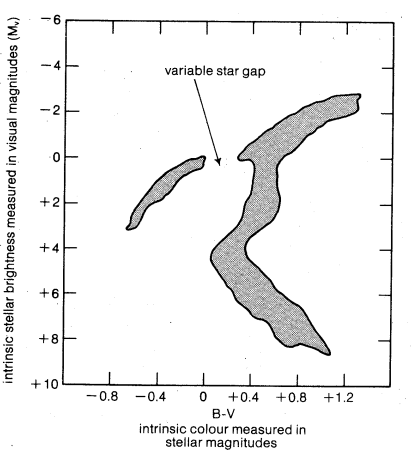

Figure 3: *Colour–magnitude diagram of globular star cluster.*
B and V are magnitudes in blue and visual light. Shaded areas indicate regions occupied by globular stars. Variable-star gap indicates region in which cluster variables occur.

minor groupings, but the extent and concentration of the stars in the various parts of the diagram can be quite different from cluster to cluster.

In 1917 a more distinct difference in colour–magnitude diagrams between open and globular clusters was noticed. This was later explained as a result of differences in the courses of evolutionary change that stars with similar compositions but different masses would follow after long intervals of time. The magnitude at which the brighter stars leave the Main Sequence (called the turnoff point or knee) is a measure of the age of the cluster, assuming that most of the stars formed at the same time. RR Lyrae

By courtesy of Lick Observatory, California

variables, when present, lie in a special region, called the variable gap, near the mean visual magnitude and the blue end of the horizontal (giant) branch of the colour-magnitude diagram. The hydrogen in cluster stars is thought to amount to 70 to 75 percent by mass, helium 30 to 25 percent, and the heavier elements .1 to .01 percent. Globular clusters prove to be as old as the universe, perhaps 12 to 13,000,000,000 years.

Distances and motions. Integrated magnitudes (measures of the total brightness of the clusters), their diameters, and the mean magnitude of the 25 brightest stars made possible the first distance determinations on the basis of the assumption that the apparent differences were due entirely to distance. The colour-magnitude diagram, or the apparent magnitudes of the variables, if their absolute magnitude (the magnitude reduced to a standard distance) is known, however, leads to the best distance estimates. The correction factor for interstellar reddening, due to intervening material that absorbs and reddens their light, is substantial for many but small for those in high galactic latitudes away from the Milky Way. Distances range from about 8,000 light-years for M 71 and NGC 6397 to intergalactic distances of 270,000 light-years for the highly luminous NGC 2419 and 325,000 for the clusters called Palomar 3 and 4.

Velocities and orbits of clusters

The radial velocities (the speed at which objects approach the observer or recede from him, taken as positive when the distance is increasing) measured by Doppler effect have been determined from integrated spectra for a total of 70 clusters. The largest negative velocity is −360 kilometres per second (km/sec) for NGC 6934, the largest positive is +493 km/sec for NGC 3201. These velocities suggest that the globular clusters are moving around the galactic centre in highly elliptical orbits. The globular cluster system as a whole has a rotational velocity of about 140 km/sec relative to the Sun, or 110 km/sec on an absolute basis. For one cluster, Omega Centauri, motions of the individual stars about the massive centre have actually been observed and measured. Though proper motions (the movement across the sky relative to the distant background) of the clusters are very small, those for individual stars provide a useful criterion for cluster membership.

Noteworthy individual clusters. The two clusters of highest absolute luminosity are in the Southern Hemisphere, in the constellations Centaurus and Tucana. Omega Centauri, also called NGC 5139, with (integrated) absolute blue magnitude −9.4, is the second richest cluster in variables, with 171. From this large group, the three types of RR Lyrae stars were first distinguished in 1902. Omega Centauri is relatively near, at a distance of 17,000 light-years, and it lacks a sharp nucleus (Figure 1). The cluster designated 47 Tucanae, or NGC 104, with absolute magnitude −9.5 at a similar distance of 16,000 light-years is of different appearance with strong central concentration. It is near the Small Magellanic Cloud in the sky but is not connected with it. For an observer placed at the centre of this great cluster, the sky would have the brightness of twilight on Earth due to the light of the thousands of stars nearby. In the Northern Hemisphere, M 13 in the constellation Hercules is the easiest to see and is the best known. At a distance of 20,000 light-years, it has been thoroughly investigated, is relatively poor in variables, and has conspicuous lanes of dark nebulosity. M 3 in Canes Venatici, 35,000 light-years distant, is the cluster richest in variables, with 189 known. Their study led to putting the RR Lyrae stars in a special region of the colour–magnitude diagram.

OPEN CLUSTERS

Open clusters are strongly concentrated toward the Milky Way. They form a flattened disklike system 3,000 light-years thick with a diameter about 30,000 light-years; the younger clusters serve to trace the spiral arms of the Galaxy since they are found invariably to lie in them (see GALAXY, THE). Very distant clusters are hard to detect against the rich Milky Way background. A classification based on central concentration and richness (see Figure 4) is in use and has been extended to 852 open clusters. Probably about half the known open clusters contain fewer than a hundred stars, but the richest have a thousand or more. The largest have apparent diameters of several degrees, the diameter of the Taurus cluster being 400′ (nearly 7°), and the Perseus cluster 240′.

The linear diameters run from the largest, 75 light-years, down to five. Increasingly, it is found that a large halo of actual cluster members surrounds the more noticeable core and extends the diameter severalfold; cluster membership is established through common motion, common distances, and so on. Tidal forces and stellar encounters lead to the disintegration of open clusters in long periods of time, as stars "evaporate" from the cluster.

Contents. Stars of all spectral classes from O to M (high to low temperatures; see STAR) are found in open clusters, but frequency of types varies from one cluster to another, as does concentration near the centre. In some (O or OB clusters) the brightest stars are blue and very hot, spectral types O or B, while in others they are type F, whitish yellow and cooler. High luminosity stars are more common than in the solar neighbourhood and dwarfs are much scarcer. The brightest stars in some open clusters are 150,000 times as bright as the Sun. The luminosity of the brightest stars at the upper end of the main se-

Luminosity of stars in open clusters

quence varies in clusters from about −8 to −2 visual absolute magnitude (visual magnitude is that seen by the eye, as opposed to that registered on ordinary photographs; see STAR).

Because of the high luminosity of their brightest stars, some open clusters have a total luminosity as bright as that of some globulars (absolute magnitude −8), which contain thousands of times as many stars. In the centre of rich clusters, the stars may be only 1½ light-years apart. The density may be 100 times that of the solar neighbourhood. In some, such as the Pleiades and the Orion cluster, nebulosity is a prominent feature, while others have none. Masses of neutral hydrogen have been detected with radio telescopes in clusters younger than 25,000,000 years extending over three times the optical diameter of the cluster. Many of the OB clusters mentioned above contain globules, relatively small, apparently spherical regions of absorbing material. The most numerous variables connected with open clusters are the T Tauri type and related stars which occur by the hundreds in some nebulous regions of the sky. Conspicuously absent from open clusters is the type most common in the globular clusters, the RR Lyrae stars. Other variables include: eclipsing binary stars, both Algol type and contact binaries; Cepheids; flare stars and spectrum variables, such as Pleione. The last named, one of the Pleiades, is known to cast off shells of material from time to time, perhaps a result of its high rotational speed (up to 200 miles per second).

Colour–magnitude and spectrum–magnitude diagrams. The colour– or spectrum–magnitude diagram derived from the individual stars holds vital information. Colour–magnitude diagrams are available for 189 clusters on the UBV photometric system; in this system the colour is measured from the amount of light radiated by the stars at ultraviolet, blue, and visual (yellow) wavelength regions. In young clusters, stars are found along the luminous bright blue branch, while in old, beyond a turnoff only a magnitude or two brighter than the Sun, they are red giants and supergiants (see Figure 5).

From A. Sandage and O. Eggen, *The Astrophysical Journal* (1969); The University of Chicago Press

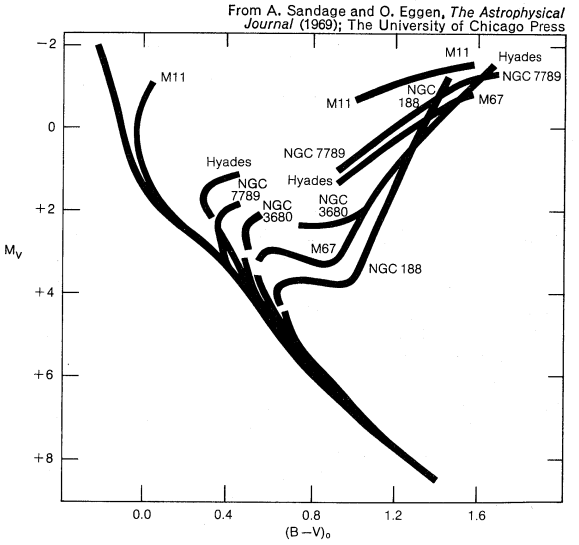

Figure 5: Composite colour–magnitude diagram for six open clusters fitted to the main sequence for very young stars (zero-age). M_V is visual magnitude; $(B-V)_0$ is the colour (blue magnitude minus visual magnitude) for the zero-age stars.

Distances and motions. Distances can be determined by many methods; geometric, photometric, and spectroscopic, with corrections for interstellar absorption. For the very nearest clusters, direct (trigonometric) parallaxes may be obtained and these are inversely proportional to the distance (see PARALLAX, ASTRONOMICAL). Distances may be derived from proper motions, apparent magnitudes of the brightest stars, and spectroscopically from individual bright stars. Colour–magnitude diagrams, fitted to a standard plot of the Main Sequence, give a common and reliable method of determining distance. The nearest open cluster is the nucleus of the Ursa Major group at 75 light-years; the most distant clusters are thousands of light-years away.

Motions, including radial velocities and proper motion, have been measured for thousands of cluster stars. The radial velocities are much smaller than for globular clusters, averaging tens of kilometres per second, but the proper motions are larger. Open clusters share in the galactic rotation. Used with galactic rotation formulas, the radial velocities give another means of distance determination.

Moving clusters

A few clusters are known as moving clusters because the convergence of the proper motions of their individual stars toward a "convergent point" is pronounced. The apparent convergence is caused by perspective; the cluster members are really moving as a swarm in almost parallel directions and with about the same speeds. The Hyades is the most prominent example of a moving cluster. (The Hyades stars are converging with a velocity of 45 km/sec toward the point in the sky with position coordinates, right ascension 94°, declination +7° .6.) The Ursa Major group, another moving cluster, occupies a volume of space containing the Sun; but the Sun is not a member. The cluster consists of a compact nucleus of 14 stars and an extended stream.

Stellar groups are composed of stars presumed to have been formed in a batch together, but the members are now too widely separated to be recognized as a cluster.

Noteworthy individual clusters. The Pleiades is the best known and perhaps the most thoroughly studied. This cluster, with a diameter of 35 light-years at a distance of 400 light-years, has about 500 stars and an age of 150,000,000 years. Near the Pleiades in the sky, but not so conspicuous, the Hyades is the second nearest cluster at 130 light-years. Its stars are similar to those in the solar neighbourhood, and it is an older cluster, with an age of 2,000,000,000 years. Measurements of the Hyades form a basis for astronomical determinations of distance and age because its thoroughly studied Main Sequence is used as a standard. A "poor" cluster with few stars is Coma Berenices at a distance of 260 light-years, containing only about 40 stars. Of the extremely young clusters, that associated with the Orion nebula is the nearest, 1,500 light-years away, with an age of 3,000,000 years. A still younger cluster is NGC 6611, whose age after formation is 800,000 years. At the other end of the scale some open clusters have ages approaching those of the globular clusters and seem to be of intermediate type. Messier 67 in Cancer, at a distance of 3,000 light-years, with 500 solar masses, is 5,500,000,000 years old. NGC 188 in Cepheus is the oldest open cluster at 8×10^9 or 9×10^9 years.

ASSOCIATIONS

The chief distinguishing feature of the members of a stellar association is that the large majority of its stars have similar physical characteristics. The OB association consists of large numbers of hot, blue giant stars, spectral classes O and B, and relatively small numbers of other objects. A T association consists of cooler dwarf stars, many of which exhibit irregular variations in brightness. The stars clearly have to be relatively near to each other in space, though in some cases they may be widely dispersed in the sky and are less closely placed than in the open clusters.

OB associations. The existence of an OB association is usually established through a study of the space distribution of early type O and B stars. It will appear as a concentration of points in a three-dimensional plot of galactic longitude and latitude and distance. Seventy are catalogued, designated by constellation abbreviation and number; *e.g.*, Per OB 1 in the constellation Perseus. In dimensions they are larger than open clusters, from 100 to 700 light-years, and usually contain one or more open clusters as nuclei. They frequently contain a special type of multiple star, the Trapezium, named for its prototype in Orion, as well as supergiants, binaries, H II regions and globules. Associations are relatively homogeneous in age. Best distance determinations are from spectroscopic parallaxes of individual stars; *i.e.*, estimates

of their absolute magnitudes made from studies of their spectra. Most of those known are nearer than 10,000 light-years, with the nearest, named Sco OB 1, at 650 light-years.

Associations appear to be almost spherical, though rapid elongation would be expected from the shearing effect of differential galactic rotation. It has been suggested that expansion, which is of the order of 10 kilometres per second, masks the tendency to elongate, and this is confirmed in some. Tidal forces will break up an association in less than 10,000,000 years through differences in the attraction by an outside body on members in different parts of the association.

Lifetime of an association

A good example is Per OB 1 at a distance of 6,000 light-years, spreading out from the double cluster *h* and Chi Persei. A large group of 20 supergiant stars of spectral type M belongs to it. Associations with red supergiants may be in a relatively advanced evolutionary stage, almost ready to disintegrate.

T associations. The T Tauri associations or T associations are formed by groups of T Tauri stars generically associated with the clouds in which they are found. About three dozen are recognized. A T Tauri star is characterized by irregular variations of light, low luminosity, and hydrogen line (H-alpha) emission. It is a newly formed star of intermediate mass that is still in the process of contraction from diffuse material. The small motions of the T Tauri stars relative to the nebula indicate that they are not field stars passing through the nebula. They are found in greatest numbers in regions with bright O and B stars. T associations are found only in or near regions of galactic nebulosity, either bright or dark, and only in obscured regions, showing the presence of dust. Besides T Tauri stars, they include related variables, nonvariable stars, and Herbig-Haro objects. The last-named are small nebulosities 10,000 astronomical units in diameter; each contains several starlike condensations in configurations similar to the Trapezium, Theta Orionis, in the sword of Orion. These objects are considered to be star groups at the very beginning of life.

The constellation of Cygnus has five T associations and Orion and Taurus four each. The richest is Ori T2 with over 400 members, with a diameter 50 by 90 light-years, at a distance of 1,300 light-years, around the variable T Ori.

RELATIONSHIP AND SIGNIFICANCE

Seen from intergalactic space the Galaxy would appear as a giant luminous pinwheel, with more than a hundred globular clusters dotted around it. The richest parts of the spiral arms of the pinwheel would be marked by dozens of open clusters. If this panorama could be seen as a time-lapse movie, the great globular clusters would wheel around the galactic centre in elliptical orbits with periods of hundreds of millions of years; open clusters and associations of stars would be seen to form out of knots of diffuse matter in the spiral arms, gradually disperse, run their life cycle and fade away, while the Earth's Sun pursued its course around the galactic centre for thousands of millions of years.

Young open clusters and associations, occupying the same region of space as clouds of ionized hydrogen, help to define the spiral arms. A concentration of clusters in the bright inner portion of the Milky Way between galactic longitudes 283° and 28° indicates an inner arm in Sagittarius. Similarly, the two spiral arms of Orion and Perseus are defined between 103° and 213°, with a bifurcation of the Orion arm. Associations show the existence of spiral structure in the Sun's vicinity. Older clusters, whose Main Sequence does not reach to the blue stars, show no correlation with spiral arms because in the intervening years their motions have carried them far from their place of birth.

All the O and B type stars in the Galaxy may have originated in OB associations. The great majority, if not all, of the O stars (5,000) were formed and still exist in clusters and associations; though only 10 percent of the total number of B stars are now in OB associations or clusters, it is likely that all formed in them. At the other (fainter) end of the range of stellar luminosities, the number of dwarf variable stars in the nearby T Tauri associations is estimated at 12,000. These associations are apparently the main source of low luminosity stars in the Sun's neighbourhood.

While large numbers of associations have formed and dispersed and provided a population of stars for the spiral arms, the globular clusters have survived relatively unchanged except for the evolutionary differences that time brings. They are too massive to be disrupted by the tidal forces of the Galaxy, though their limiting dimensions are set by these forces when they most closely approach the Galactic centre. Impressive as they are individually, their total mass of 10,000,000 suns is small in comparison to the Galaxy—only about 1/10,000. Their substance is that of the Galaxy in a very early stage. The Galaxy may have collapsed from a cloud of gas made up almost entirely of hydrogen and helium. Between 12×10^{12} and 13×10^{12} years ago, before the last stages of the collapse, material forming the globular clusters may have separated from the rest. The fact that metal-rich clusters are near the galactic nucleus while metal-poor clusters are in the halo or outer fringes may indicate a nonuniform distribution of elements throughout the primordial mass.

In a study of star clusters a time panorama unfolds—from the oldest things existing in the Galaxy, the globular clusters, through clusters in existence only half as long, down to extremely young open clusters and associations that have come into being since the ancestors of man first trod the Earth.

CLUSTERS IN EXTERNAL GALAXIES

Clusters have been found and studied in at least eight external galaxies, mostly members of the Local Group. At their great distances the classification is difficult, made from studies of the colours of the light from the whole cluster (integrated colours) or, for a few, from colour magnitude diagrams. An electronograph (image tube) on a large telescope in the uniquely good observing conditions of Chile has extended studies to cluster stars of apparent magnitude 23, that is a factor of 10^{10} fainter than the bright star Sirius.

Clusters have been found by the hundreds in some of the nearest galaxies. At the distance of the Magellanic Clouds, a cluster like the Pleiades would appear as a faint 15th magnitude object, subtending 15 seconds of arc instead of several degrees, and would perhaps not yet have been found. In the Small Magellanic Cloud, at a distance of 200,000 light-years, about 120 clusters are known. In the Large Magellanic Cloud, at a distance of 180,000 light-years, nearly 1,200 have been catalogued. Most of them are young open clusters, but about 60 have globular characteristics. In both clouds, the brightest clusters are the young blue giant open clusters such as NGC 330 and NGC 1866. The open clusters contain some Cepheid variables, and in chemical composition are similar to, but not exactly the same as, those of the Galaxy. The globular clusters fall into two distinct groups. Those of the first group, the red, have a large metal deficiency similar to those in the Galaxy; RR Lyrae variables have been found in some. Those of the second group are large, circular in outline, with colours much bluer than normal galactic globular clusters, and ages of about 10^6 to 10^9 years. They are similar to the open clusters of the Clouds but very populous. The observed differences between clusters in the Galaxy and the Magellanic Clouds are due to small differences in helium or heavy-element abundances. There are 122 associations with a mean diameter of 250 light-years, somewhat richer and larger than in the Galaxy. Sixteen of the associations contain coexistent clusters. Also 15 star clouds are recognized.

Cluster characteristics

In the great Andromeda spiral galaxy, M 31, 2,200,000 light-years away, more than 300 clusters are known, of which, perhaps, two-thirds are globular. Colour studies of 46 show them to have a higher metal content than galactic globulars. A total of 188 OB associations is known with distances up to 80,000 light-years from the nucleus. Diameters of their dense cores are comparable to those of galactic associations. NGC 206 (OB 78) is the richest star cloud in M 31, with a total mass of 200,000 suns and

a strong resemblance to the double cluster in Perseus. Around the dwarf elliptical companions to M 31, NGC 185, and NGC 205, some globular clusters have been found.

M 33 in Triangulum, a late-type spiral galaxy, has about 300 known clusters, not many of which have globular characteristics. Of the six dwarf spheroidal galaxies in the Local Group, only the one in the constellation Fornax has clusters. Its five globular clusters are similar to the bluest galactic globular clusters. In the irregular galaxies NGC 6822 and IC 1613 no clusters have been found.

Beyond the Local Group, at a distance of 45,000,000 light-years, the giant elliptical galaxy M 87, in the Virgo cluster, is surrounded by an estimated 2,000 globular clusters. Inspection of other ellipticals in Virgo shows that they too have globular clusters whose apparent magnitudes are similar to those in M 87 although their stellar population is substantially smaller. There is indication that the mean absolute magnitudes of globular clusters are constant and independent of the absolute luminosity of the parent galaxy.

The total number of clusters now known in external galaxies far exceeds the number known in the Galaxy.

State, The

The "state," as the term refers to the political organization of society, is used in two ways, one more general, meaning the whole body of persons who are politically organized, the other more specific, meaning the institutions of government. In the first usage the state comprehends all the citizens; in the second, it may be contrasted with the citizens. Since the second meaning is just as well, if not more clearly, expressed by the term government, it is best, for purposes of exposition and understanding, to concentrate on the idea of the state as being the whole body politic. Modern political theorists generally define the state as a special form of association (an association being a deliberately organized social group). It is distinguished from other forms of association by its purposes, by the methods it employs to carry out those purposes, by having territorial limits, and by its sovereignty. The primary purpose of the state is to maintain order and security. It does so by means of a system of law backed by force. The exercise of its jurisdiction is limited to a definite geographical area, but within that area the state is sovereign; that is to say, it has supreme and exclusive authority.

THE CONCEPT OF THE STATE

The use of the word state for politically organized society is relatively recent. It became prominent in the 16th century, being first popularized by the Italian political theorist Niccoló Machiavelli in *The Prince* (1513). The ancient Greeks spoke of the *polis* ("city-state"). In classical Latin —as, for example, in Cicero—*res publica* ("commonwealth") was the most favoured expression, though *civitas* ("community of citizens") was also used. Medieval writers tended to prefer the terms *civitas* and *regnum* ("realm" or "kingdom"). The Greek *polis* differed from a modern state not only in being smaller but also in embracing more of social life. The Greek conception of the *polis* included religious and cultural activities as well as government, so that the later distinction between church and state could not be expressed in terms of church and *polis*. The Roman *res publica* was a larger entity, for it extended beyond the city of Rome to Roman citizens throughout Italy and the provinces. Another difference, at least in Cicero's usage, was that the Roman idea of *res publica* emphasized the legal structure of political association. In medieval political writings the words *regnum* and *civitas* were used sometimes indiscriminately but often with a distinction, *civitas* referring to the city-state that existed in some parts of Europe and especially in Italy, *regnum* referring to the larger type of monarchy that was growing up in other parts of Europe. The term *res publica* came to be used for a larger entity still, *res publica christiana*, the community of Christendom.

Earlier terms for the body politic

In the political philosophies of Plato and Aristotle, the *polis* was treated as the ideal form of community, because it was self-sufficient in providing for economic and social needs and for moral development. The ideas of value that were included in the Greek concept were continued in the connotations of *res publica* and of its English translation, "commonwealth." Self-sufficiency, which Aristotle called the essence of the *polis*, is quite different from sovereignty, the essential feature of the modern state. Machiavelli thus used a new word for a new idea.

Sovereignty and the state. Sovereignty is the most fundamental of the distinctive attributes of the state as it has been conceived and understood since the 16th century. Some theorists have emphasized sovereignty in its legal aspect, supreme and independent authority for making, interpreting, and applying a system of law over a defined territory. Other theorists have laid more stress on "political" sovereignty, the possession of coercive power sufficient to enforce obedience internally and to maintain independence in external relations. The two forms of sovereignty in fact go together, because the effectiveness of legal authority depends in the last resort on its being backed by coercive power superior to any possessed by individuals or groups within the state.

The word state is used to refer to some politically organized communities that are not sovereign states, notably the constituent members of a federal union, such as the constituent states of the United States of America or of the Commonwealth of Australia. In such instances the feder-

al union is the sovereign state; it not only has a superior authority in internal affairs, but it alone has the right to treat with foreign states and international bodies. Other types of political unit that possess some of the powers of a state but lack sovereignty are protectorates, self-governing colonies, and trust territories.

Other attributes of statehood. Certain other distinctive attributes of the state emerged during the 16th, 17th, and 18th centuries. First, there must be a considerable measure of stability and continuity in respect of defined borders and consequently of population. Since states recognize each other's sovereign jurisdiction over their respective territories, these territories need to be clearly defined. Uncertain or frequently shifting borders are a source of friction and hostility. Men need to know that a particular area and its inhabitants owe political allegiance to one definite authority. Stable borders and populations go along with the growth of a common nationhood. The state in the modern world tends to be a nation-state, although there are many exceptions. A nation is a community that shares a number of attributes such as a common language and culture; it is a community of persons who feel that they belong together because of shared interests and history. To some extent the bonds of nationhood have contributed to the formation of states, but it is equally true that the experience of being a state, of being ruled by the same authority and the same laws, has caused a community gradually to feel a sense of common nationality.

State and nation

The primary function of a state, maintaining order and security by means of law backed by force, naturally entails a number of permanent institutions. There must be governmental bodies for forming policies and making laws; a civil service for carrying out governmental policy; a judicial system with police and penal services to apply the law; and armed forces for defense against external enemies and, if need be, for putting down internal riot. It is all these organs of administering a state that are referred to when the word state is used in the narrower of the two senses described at the beginning of this article.

THE POLITICAL PHILOSOPHY OF THE STATE

Since sovereignty is the feature of the modern state that distinguishes it most markedly from earlier conceptions of political society, it is not surprising that political theory should initially stress the importance of absolute authority. The French and English political philosophers Jean Bodin and Thomas Hobbes are the first who made explicit the idea of state sovereignty. Machiavelli, who preceded them, took it for granted.

Machiavelli. Machiavelli was not a political philosopher in the ordinary sense. He did not try either to define the state or to justify its existence. His views about the state, as about much else, are implied as a matter of course when he describes how a ruler may retain or acquire firm control, how he is liable to lose it, which qualities are necessary for a republic to remain strong, or how precarious a thing is its liberty. Medieval thinkers had taken the political authority of any prince or king in the community of Christendom to be necessarily limited —by the supposedly superior authority of the emperor, by the parallel authority of the church in spiritual matters, and by the authority of natural law (that is, universal moral principles), which determined the bounds of justice. Machiavelli did not argue against this theoretical position. He simply ignored it, writing as if it were an obvious matter of fact that a state has absolute authority. He thought that the value of religion lies purely in its contribution to social order and that the ordinary rules of morality must go by the board if security requires it.

Machiavelli's absolutist assumptions

Machiavelli again differed from medieval thinkers in taking it for granted that the power of the state is a single whole and can be centrally controlled, irrespective of whether a particular state has the form of a monarchy or a republic. He preferred a republic because he preferred liberty. But he believed that the liberty of a republic can be sustained only if the people have the "virtue"—that is, the vitality, courage, and independence—that the ancient Romans possessed, but which, as he thought, existed hardly anywhere in the Europe of his own day except among the Germans. Where the people are "corrupted," especially by the power of nobles, the state needs a single ruler with a strong hand, ready to be ruthless in preserving order.

Bodin. Bodin was the first political theorist to isolate the concept of sovereignty and to see it as the essential feature that distinguishes the state from other organizations. He defined sovereignty as the absolute and perpetual power of making and unmaking laws. By "absolute" he meant unlimited, and by "perpetual" he meant not confined to any fixed period of time. If the right to legislate were of limited duration, Bodin argued, the holder of it would be merely a trustee for the real sovereign, the possessor of permanent authority. Bodin also implied that sovereignty is indivisible, although this is not included in his definition. He followed the traditional classification of forms of government into monarchy, aristocracy, and democracy, and said that in an aristocracy or democracy the sovereign is the ruling group as a whole; sovereignty cannot be shared. In consequence, he believed that there cannot be a state with a mixed constitution, in which the sovereign authority is divided among different offices. The sovereign often has to act through agents, but the agents do not thereby share in the sovereignty. Their authority is strictly subordinate.

Bodin's limitations on state sovereignty

Bodin, nevertheless, did not make as clean a break with medieval thought as did Machiavelli. There is a real sense in which his conception of sovereignty is not absolute but is limited by natural law, by constitutional law, and by property rights. In the first place, Bodin was not prepared to treat arbitrary power as political authority. The chief of a robber band who holds absolute sway over his associates and obeys no superior is not a sovereign, in Bodin's view, because his rule is not law; it is not based on justice; sovereign authority must have a moral foundation in natural law. Secondly, Bodin made sovereignty subject to the constitutional law that determines succession. And thirdly, Bodin held that sovereignty may not interfere with property rights. Legislation pertains to the state, property to the family. The sovereign has an "absolute" power to legislate, but he may not levy taxes without consent.

The fact is that, when Bodin described the sovereign's authority as absolute, he meant unlimited by the authority of any other office. The sovereign's commands are subordinate to natural law but not to the interpretation of natural law by the church; the sovereign is perfectly capable of seeing for himself what natural law requires. Bodin's purpose was to deny that feudal lords, whether temporal or spiritual, had any final right of jurisdiction independent of the king's authority.

Hobbes. Philosophical justification of an absolute state reached its acme in the political theory of Hobbes, who painted a grim picture of what life would be like without political order. Since men are largely selfish, are roughly equal in strength, and are liable to compete with each other in satisfying their wants, the "natural condition" of mankind is a "war of every man against every man," in which there is "continual fear, and danger of violent death; and the life of man, solitary, poor, nasty, brutish, and short." The only way to avoid this, Hobbes argued, is to maintain a state ruled by a sovereign (man or assembly) with absolute authority. Supreme authority must be absolute and undivided, because otherwise there may be conflict between the holders of different offices (such as Hobbes saw before and during the English Civil War between Charles I and his Parliament), and that is to be back in the natural condition of war. Absolute rule may be oppressive, but at least it secures men from the worst of evils, a state of war.

Hobbes's concept of natural right

In the hypothetical condition of nature, according to Hobbes, every man has a "natural right" to do whatever he thinks fit. It must be assumed that, when men form or accept the political order of a state, they have given up the major part of their natural right, they have authorized a sovereign to issue laws, and they have promised to obey those laws. The consequence is that the citizens, in place of their former natural right or freedom to do as they like, are under obligation to the sovereign.

The sovereign retains the whole of his natural right; unlike the citizens, he makes no promise and so does not limit his freedom of action by undertaking any obligation. In addition, since the citizens have obliged themselves to obey his commands, he is entitled to their support when he orders it.

Although the sovereign, in Hobbes's theory has an absolute right to issue whatever commands he thinks fit, the subjects do not have an equally absolute obligation to obey any and every command. Some parts of their original natural right cannot be given up. Hobbes believed that the fundamental motive in all men, as in other living creatures, is the desire for self-preservation. This is what induces men to accept political society in place of the natural condition, in which life is apt to be short. But then one cannot suppose that a man who promises political obedience for the sake of self-preservation intends to promise obedience to *any* command, such as a command that he should kill himself or that he should not resist an attempt to execute him. There are therefore certain things that the sovereign cannot expect of his subjects.

The implicit promise of obedience that the subjects have given, moreover, is for the sake of protection; and, if the sovereign is in fact unable to protect them, their obligation ceases. This is not to say that there is a contract of mutually dependent obligations between sovereign and subjects. The sovereign has not promised to provide protection in return for the subjects' promise to obey. But he has a duty of prudence to provide it. A wise sovereign knows that his power will last only so long as he can maintain order and protection. He, like everybody else, wants to avoid a relapse into the condition of nature, and for this reason he should follow the moral principles called laws of nature, which, in Hobbes's view, are maxims of prudence. In practice, therefore, a sovereign's freedom of action is limited if he wishes to retain his power. But his formal authority, what he is entitled to do, is absolute.

Locke. Absolute sovereignty for the state need not mean absolute monarchy. Machiavelli thought that a monarchy was the only practical regime for most peoples; Bodin positively preferred it to aristocracy and democracy; and Hobbes wrote as if his sovereign were more likely to be an individual than an assembly. All three, nevertheless, regarded popular forms of government as perfectly legitimate. The idea that absolute monarchy is the only proper form was put forward in the 17th century by certain other writers, notably Sir Robert Filmer in England and Jacques-Bénigne Bossuet in France. Both supported their view with the doctrine of the divine right of kings. It naturally provoked reactions and of more than one kind.

The English philosopher John Locke, for example, built his political philosophy upon the natural rights of all men, as did Hobbes, but with a different conception of natural right. By a right Hobbes meant the absence of obligation, a freedom or license to act as one wishes. Locke meant a justified claim on another person, correlative to an obligation or duty that that other person has toward the one who has the right. Locke's natural rights arise from the traditional view of natural law as a moral law imposed upon men by God. If God commands all men to do no murder, the consequence is that every man has a duty not to kill others, and correspondingly every man has a right or justified claim against others that they should not kill him. This is the natural right to life. Locke wrote the three main natural rights: to life, liberty, and property. Unlike Hobbes, Locke believed that a state of nature is not a state of war or one in which there is no sense of community. The state of nature is, however, inconvenient, because it lacks an impartial judge to arbitrate disputes and to punish breaches of natural law. Men are therefore willing to set up a state or political society, the function of which is to protect their natural rights.

Locke differed from Hobbes again in believing that rebellion is sometimes justified, as in the revolution of 1688 against James II. To avoid Hobbes's supposition that the overthrow of a sovereign means the dissolution of the state, Locke distinguishes the state's source of authority from that of the government. The state rests on a social contract, government on a trust. A government is entrusted with power in order to protect life, liberty, and property. If it fails to do so, it forfeits its claim to obedience, and the citizens are entitled to set up a different government instead.

Influence of Locke's ideas

Locke's theory had a considerable influence on the basic political ideas of the American Declaration of Independence, except that the pursuit of happiness replaced property as the third of the cardinal natural rights. Although Locke himself said that property, understood in a wide sense, comprises all natural right, it would be more accurate to regard liberty as the most comprehensive of his natural rights. The state for Locke has the negative function of preventing men from encroaching on each other's proper sphere of liberty in regard to their persons, property, and desires generally. From this perspective Locke's political theory marked the beginning of liberalism. The same tendency (albeit qualified) appears in his arguments for the toleration of religious dissenters. But Locke's distinction between the legislative and executive functions of government is less significant for the development of ideas about liberty. It was the 18th-century French theorist Montesquieu who saw the separation of the legislative, executive, and judicial powers as the best guarantee of liberty in the state. The explicit separation of powers in the American Constitution is due to the influence of Montesquieu.

Rousseau. While the American conception of the state owes much to Locke and Montesquieu, the French one owes more to Jean-Jacques Rousseau. The French Declaration of the Rights of Man and of the Citizen begins, like the American Declaration of Independence, with an assertion that the purpose of political association is to preserve natural rights, but it then goes on to the novel principle that sovereignty resides in the nation and that law expresses the general will. These are the views of Rousseau, who went further than Locke in limiting the powers of the executive but who insisted that the sovereign authority to legislate lay with the whole people and could be neither transferred nor even deputed to representatives. This last idea, rejecting representative democracy and requiring that laws be made by all the citizens, is of course impractical in any modern state and is not followed in the declarations and constitutions of the French Revolutionaries.

In many ways Rousseau's political theory was a reversion to Greek ideas and especially to those of Plato. Whereas Locke restricted the functions of the state, Rousseau went back to the notion of an all-embracing political order that provides the only environment in which men can develop their moral capacities. Having himself been born in the city-state of Geneva, Rousseau thought of the small city-state as the ideal form of political community, and his theory of popular sovereignty reflects his view of the ideal rather than the actual. Like Plato again, Rousseau was a collectivist in his ideas about the moral character of man and society. He disagreed with the individualist notion of Locke that men in a state of nature would have natural rights and moral relationships. All rights are social for Rousseau. It is only in society, and this means political society, that men can realize their moral—indeed, their human—qualities. One can become a man only by being a citizen.

Rousseau's theory of popular sovereignty and the general will is a novel method of dealing with the relation between liberty and authority. Hobbes limited liberty to make way for authority, and Locke limited authority to leave scope for liberty. Rousseau believed that the two can go together. He regarded freedom as essential to morality and so as essential to being a man; and, since citizenship of a state is equally essential to being a man, it must be possible to retain freedom when accepting political authority. Now if the authority is exercised by all citizens, who legislate for themselves, then submission to the laws is following decisions that are as much one's own decisions as they are those of other people; it is doing what one has willed to do oneself, and so it is a voluntary or free act. This would be clear and

simple enough if all decisions were unanimous, but if decisions were unanimous there would be no problems of political order at all. Rousseau had to argue that a man is free even when the law that he is required to obey is one with which he disagrees. Hence, Rousseau distinguished the "general will" from particular wills. The general will is a moral will, a will that aims at the common good. Rousseau assumed that all men are capable of taking the moral standpoint of aiming at the common good and that if they did so they would reach a unanimous decision. But men are also prone to judge things from the particular standpoint of aiming at their own good, and then of course they are liable to disagree. In an ideal state, laws express the general will. An individual who disagrees with a law must be failing to look at things from the moral standpoint. The general will that the law expresses is what that individual, no less than others, would share if he took the moral, the truly human, view. Further, since moral action depends upon freedom of choice, that freedom is true freedom and shows itself in the general will. Freedom to do as one wants for one's own particular interests is not true freedom. Rousseau thus concluded that obedience to the law is following the true freedom of the general will, and even went so far as to say that an individual who is forced by the state to obey the general will is being "forced to be free."

Rousseau's concept of the general will

Hegel. Such a doctrine, which begins with democratic sentiments, can clearly lead to a more authoritarian attitude, an attitude that was developed by the German philosopher Georg Wilhelm Friedrich Hegel, who took up some of Rousseau's ideas and molded them into a political theory of a very different character. He elaborated Rousseau's concept of freedom, speaking of a universal or rational will instead of a general will but without the notion of popular sovereignty. He admired great leaders such as Napoleon, and he advocated monarchy. Rousseau's popular sovereignty was intended for a city-state, and this was bound to seem unrealistic to Hegel, who took history to be the guide to theory and practice alike. The history of Germany in particular led Hegel to idealize the nation and to venerate the state as the embodiment of national aspiration.

Hegel, like Rousseau, rejected the individualistic notion of freedom as the facility to do as one likes. Complete freedom in that sense is impossible. True freedom is the freedom of moral choice, expressing a universal or rational will. Hegel meant by this that, if a man acts as a moral agent, his aims coincide with those of others; he does not think of his own particular interest but of justice and the public good. Since there is no conflict in aims when people act morally, their aims can be fully satisfied, which implies that they can be completely free. Freedom, therefore, like morality, is possible only in a moral community, the highest form of which is the state. Hegel's concept of freedom does not drown the individual in the collective. His view is that genuine human individuality can exist only within the milieu of civilization. Freedom as he understood it involves conscientiousness, and he was ready to admire reformers such as Socrates or Martin Luther who stood up against conventional views for conscience' sake, but the general tenor of his theory of the rational will made him speak as if the requirements of the state must necessarily be right. He had no sympathy with democratic individualism and would build the state on groups such as classes, estates, and corporations. Hegel thought of the state as being like an organism whose parts can have no life or significance except in relation to the whole. The overall effect of Hegel's political theory, therefore, is to subordinate the individual to the state.

Restriction between the state and civil society

Hegel drew a sharp distinction between the state and "civil society." This is partly due to the "dialectical" logic of the whole of his philosophy, the idea that all process contains three elements, thesis, antithesis, and synthesis; in his political theory the state fills the role of synthesis, combining and transcending the values of the family (thesis) and civil society (antithesis). Partly, however, the distinction is intended to show the supposed superiority of Hegel's theory to those of earlier thinkers who had used the expression civil society for the state. By civil society Hegel meant the set of institutions that meet the needs of economic life and regulate people's pursuit of their private affairs. All the mundane business of administering the law and providing public services falls within the sphere of civil society. Civil society is society as conceived by individualists and Utilitarians, a means to the satisfying of private interests. The state, by contrast, is society conceived as a moral order, in which private interest is merged into public. The state is not a means, as civil society is; it is an end—indeed, the ultimate end for social action. It is "the march of God in the world."

Hegel thought of the state as divine, not only for its ethical character but also for its power. In his discussion of international relations and war he glorified power and war as much as justice and was evidently unmoved either morally or intellectually by the prospect of continuing conflict between states. His general philosophy should have led him to envisage a universal political community as the proper embodiment of universal spirit, but he rejected the vision of "perpetual peace" and a league of nations outlined by Immanuel Kant, his predecessor in German philosophy.

The political thought of Hegel stands in striking contrast to the philosophy of individual liberalism initiated by Locke and continued by Utilitarians and radicals, especially in Britain and in France. The Utilitarians rejected the idea of natural rights quite as firmly as did Rousseau and Hegel; the English Utilitarian Jeremy Bentham called it nonsense and insisted that the only rights were those of positive law. The Utilitarians nevertheless regarded society as made up of individuals and the public good as made up of the happiness of individuals. Like Hegel, they posited an identity of private and public interest in the state. The difference is that they regarded the state as a device to produce this identity of interests artificially. The state for liberals is a means to the ends of its members. For Hegel the state is an end in itself. Hegelianism entered into the thought of some liberal thinkers, such as Thomas Hill Green in England and Benedetto Croce in Italy, tempering the somewhat mechanistic and negative concept of the state that the Utilitarians inherited from Hobbes and Locke. Generally speaking, however, the tempering of liberalism has come more from radical and Socialist traditions, which add the aims of equality and fraternity to that of liberty.

Influence of Hegel's ideas on the state

Hegel's theory of the state both reflected and strengthened the rising nationalism of the 19th century. It has had a profound influence on later political thought and on practical political movements. Hegel's dialectical and historical approach was adopted by Karl Marx but with economic Materialism replacing Idealism and with a strongly internationalist instead of a nationalist outlook. Nationalism became conservative and reactionary, culminating in the Fascism and National Socialism that led to World War II (1939–45). Prussian militarism in the 19th century owed the whole of its ideology to Hegel, as may be seen especially in the writings of its spokesman, Heinrich von Treitschke. Modern Fascism and Nazism have a more mixed ancestry, but the influence of Hegel is clear in their exalting of the nation and the nation-state, of the heroic leader, military power, and war.

Marxist analyses. While Hegel saw the state as the matrix of justice and ethical value, Communists and Anarchists see it as a mechanism of exploitation or as an institution for perverting man's natural goodness or capacity for development. This is partly because they take a different view of the history of society but partly also because they assign a different meaning to the word state. Hegel saw the state as the whole society unified by ideas of moral community; it was, of course, organized, but the essence of the state for Hegel lay in its moral spirit, not in its institutions. In the political theories of Marxism–Leninism and of Anarchism the state figures as the institutions of government.

Karl Marx said that in Hegel's philosophy "dialectic stands on its head" and that he himself turned it the right way up by substituting Materialism for Idealism. For Marx the apparatus of the state forms part of the superstructure of society, along with religion, morality, and culture gen-

erally. This superstructure depends on and is less "real" than the substructure constituted by economic facts. Hegel had held that "the real is the rational," meaning that the highest value attaches to the realm of the mind. Marx's Materialism attributed the greatest importance to the work that men do and their economic relations. Marx thus inverted Hegel's order of value as between the state and the mundane life of civil society. But he went further than that. In Hegel's philosophy the state is necessary for true morality and the realization of freedom. For Marx the state is an instrument of class rule and robs men of their freedom. It consists of institutions of oppression in the form of law, police, prisons, an army, all designed to maintain the existing economic system. Marx argued that capitalism, like earlier forms of social organization, develops internal contradictions and so nurtures the seeds of its overthrow by revolution. In this revolution the workers will seize the means of production and make its ownership public. They will thus acquire economic and also political power.

The "withering away" of the state in Marxist theory

The Marxist theory of what happens to the state after the Socialist revolution was explained by Marx's friend and collaborator Friedrich Engels and then elaborated by Lenin. The Socialist stage of society that follows capitalism is not yet a classless society, because the bourgeoisie, although stripped of its possessions and power, still retains its former outlook. Socialist society therefore still has the apparatus of the state in the form of "the dictatorship of the proletariat." In time this Socialist society will be followed by a truly Communist stage of society, in which at last men will have complete freedom, because there will be no need for the enforcement of law. The members of a Communist society are classless and free, because all voluntarily seek the good of the whole society, instead of the interest of a limited section. Engels said that the state will "wither away" and that in a Communist society "the government of persons is replaced by the administration of things and the direction of the process of production." He meant that economic life will still be organized, and there will still be rules as under a system of law, but there will be no need for institutions of enforcement, because everyone will obey the rules willingly and readily, knowing that they are for the common benefit and are not a means of exploiting one group for the private interests of another. But the withering away of the state, Lenin insisted, cannot happen without a Socialist revolution to place the means of production under public ownership. The state cannot just be abolished; there must first be a period of the dictatorship of the proletariat; that is, of the continuance of forceful political rule.

Anarchist analyses. Lenin was here arguing against the Anarchists of his time. Some Russian Anarchists, such as Peter Kropotkin, believed that the state would gradually disappear with the growth of voluntary cooperation, even in a capitalist society. Others, such as Mikhail Bakunin, agreed with the Marxists that revolution was needed but thought that the state could be abolished immediately. Others again, such as Leo Tolstoy, advocated a merely passive resistance to state authority.

Kropotkin's view of the state

Kropotkin is the clearest exponent of Anarchism—the doctrine that government is unnecessary and undesirable. He noted that people engaged in art, science, industry, and commerce can go about their business successfully by voluntary agreement. Indeed, he argued, the freedom that they enjoy through the absence of state control means that they show greater energy.

According to Anarchism, the state is both harmful and unnecessary. It is harmful because power corrupts those who govern and divides those who are governed. It is unnecessary because it is inefficient. Kropotkin argued that the state is less successful than voluntary effort in providing services or security. Even in the conduct of war, Kropotkin asserted, voluntary groups are more effective than standing armies. As for internal security, the state, far from protecting citizens, creates criminals by its unjust economic system and hardens them by its prisons. Kropotkin thought that private associations would naturally cooperate together to do all that the state does and to do it better.

The state as a legal order. Any theory of the state must take account of the relation between government and law. It has been left to the Austrian legal philosopher Hans Kelsen to put forward the view that the state is nothing other than a centralized legal order. Kelsen's "pure theory of law" is a landmark in the history of jurisprudence. His theory of the state, though less influential, is an original and noteworthy development in the history of political philosophy.

Kelsen compared the notion of the state with that of a legal person. A legal person is not the same as a natural person, as may be seen from the fact that a corporation is a legal person. On the other hand, there is no need to postulate a special metaphysical entity over and above natural persons. A legal person, in Kelsen's view, is the set of legal rights and obligations that are commonly said to belong to that person; the person consists of the rights and obligations. So, too, with the state. The state cannot simply be identified with society, the set of natural persons whose behaviour is the subject matter of sociology. Yet, on the other hand, it is idle to postulate an additional metaphysical entity over and above the members of the state. The state, in Kelsen's view, is the centralized legal order regulating the conduct of the inhabitants of the territory; it is the set of legal norms and the acts performed by natural persons (legislators, judges, officials) in their capacity as "organs of the state."

Kelsen rejected the doctrine of state sovereignty on the ground that it is illogical. It implies, he said, that each state or legal order recognizes only itself as authoritative, and he compared this position with solipsism, the philosophical theory that each person has certain knowledge only of his own existence and experience. Kelsen maintained that supreme authority must be accorded to international law.

The welfare state. The concept of the welfare state, applied to a number of liberal democratic states since World War II, involves a widening of the functions assigned to the state by individual liberalism. For Locke and the early Utilitarians the business of the state is confined to order and security; the state should protect each man's freedom to act as he chooses, provided he does not infringe upon the like freedom of others. This notion highlights liberty but does nothing to help those who cannot help themselves. Aid for the needy is left to the voluntary action of religious and philanthropic institutions and is not thought to be the business of the state. In the welfare state, however, it is. The state has the job of ensuring the means of subsistence and a basic minimum of welfare for all its members.

This change means a move toward the doctrine of collective responsibility held by Socialists and Communists. Something of the new attitude is found in the 19th century in the social theory of the English philosopher John Stuart Mill, who saw virtue in parts of Socialist doctrine despite his being the most influential spokesman of the Utilitarian philosophy and the most powerful advocate of individual liberty. The philosophy of the welfare state was, however, first clearly enunciated in Great Britain in the Beveridge report of 1942, a document of proposals for a unified system of social insurance presented to the government by Sir William (later Lord) Beveridge. Beveridge may have been unconsciously influenced by the ideas of Mill, and, like Mill, he was essentially a radical liberal, not a Socialist.

Enlarged role of the welfare state

The philosophy of the welfare state, as enunciated by Beveridge, involves a more general view of state responsibility. The basic necessities of life are defined so as to include a decent measure of education, health, and housing. Schemes of social insurance redistribute wealth in the interests of social justice. A welfare state has the positive function of promoting justice and welfare as well as the old negative function of protecting liberty and security.

The old function still remains, however, and the political philosophy of the welfare state still regards individual liberty and individual responsibility as fundamental. Individuals continue to be themselves responsible for rising above the level of welfare provided by the state, and that level is deliberately kept to a basic minimum of bare sub-

sistence in order to give people an incentive for effort to go beyond it. The welfare state draws on the ideas of socialistic collectivism but retains the essence of individual liberalism.

THE STATE IN CONTEMPORARY POLITICS

A political philosophy usually reflects and reinforces a tendency that is making itself felt in practice. In the 16th and the 17th centuries the notion of sovereignty came to the fore in the writings of Machiavelli, Bodin, and Hobbes because a new form of political structure was emerging and was needed as a result of the breakdown of the medieval order of society. By the middle of the 20th century, however, state sovereignty was beginning to be something of an impediment for the development of international order, and this is reflected in the theory of Kelsen. The liberal and democratic ideas of Locke and Rousseau are indicative of the rising tide of revolt against monarchical rule. Hegel mirrors and strengthens the movement toward national unity in Germany. Marxism brings into sharp focus the social effects of the Industrial Revolution. The philosophy of the welfare state epitomizes changes that have been growing up for some time in the character of liberal democratic society.

The state and the individual. The introduction to this article began by saying that "the state" has both a wider meaning, the politically organized society as a whole, and a narrower one, the institutions of government. The foregoing survey of leading philosophical theories has indicated why it was natural for the narrower meaning to arise. The authority of the state must be exercised through particular offices, and these come to be identified in thought with the state. Thus, Marxism and Anarchism see the state as the institutions for enforcement of rules —that is to say, the institutions of government—and as something separable from the society as a whole.

One result of this tendency is that some kinds of political conflict come to be viewed in terms of a conflict between the state and the individual, for an individual who is against a law or a governmental policy and is prepared to demonstrate or to use violence in support of his beliefs thinks of his conflict with the powers that be as a conflict with the state. Not all political disputes take on this character—political conflict between rival parties or between rival factions within a party, for example, does not take this form. But in a totalitarian state, in which only one party is permitted, views opposed to the policy of that party are necessarily and permanently opposed to the government and are therefore regarded as being opposed to the state. In a multiparty state, an opposition party that has a reasonable opportunity of gaining power in the future will not see its conflict with the government as a conflict with the state. It is different with a minority group that has no chance of gaining political power, such as a racial minority that is socially depressed or a group of young people who oppose governmental policy on matters of war and peace. Such a group is often liable to think of its opposition to the government in terms of a contest with the state.

Ameliorative influence of the separation of powers

The separation of powers in democratic states helps to reduce this polarization of state and individual. Although an individual who takes a minority view is liable to find himself at odds with the legislature, executive, and judiciary alike, the courts may nevertheless protect such an individual from the excessive exercise of power by the executive.

A further situation in which political conflict may polarize into conflict between the state and the individual is when "reason of state" is invoked as a justification of executive action. The phrase reason of state (a translation of the French *raison d'état*) means a purely political reason for justifying the action of a government. It was used especially when normal moral justifications were conspicuous by their absence, when the action involved some patent injustice, dishonesty, or concealment. Nowadays the expression national interest is more commonly used. In time of war or other emergency the national interest is invoked to justify forms of discrimination that would otherwise be unfair, as in the selection of conscripts for the armed forces or to excuse departures from normal legal procedure, such as detention without trial of persons suspected of being potentially dangerous. Even in time of peace, government departments are liable to appeal to the national interest as a justification for actions that would not otherwise be tolerated, such as a refusal to provide information to a court or to a legislature. There is always a temptation for the executive to find an easy excuse for the exercise of power.

Here again the division of powers acts as a check on the executive and as a protection for the rights and freedoms of the individual. The courts may require the head of a government department to show "good cause" why someone should be detained or why some information should be withheld. The executive's use of its power can be restrained by other checks also, such as criticism or questioning in the legislature or examination of a grievance by an ombudsman.

Attempts to counter the growth of governmental control are also seen in the tendency toward decentralization achieved by increasing the scope of local and regional government. Decentralization does not, of course, limit state power, but it diffuses the exercise of that power and so gives more opportunity for the voice of individual citizens and representative groups to be heard and heeded.

The state in international society. Despite the doctrine of sovereignty, states have never been entirely free in law to do whatever they like. When the international society of medieval Christendom was replaced by sovereign states, the modern system of international law emerged at the same time as a restraining factor. The new political entities, which acknowledged no superior authority, needed some agreed principles for regulating their relations with each other both in peace and in war. Much of international law is rather like the customary law of a tribal society. States that break the rules cannot be coerced by the power of an international police force. They nevertheless have obligations under international law, and they conform to those obligations to a certain extent, if only because general conformity is to the advantage of all states.

Some theorists, drawing upon Hegel, consider that the obligations of states under international law arise from the "auto-limitation of sovereignty." They mean by this that the sovereignty of a state can be limited only by the decision of that state itself. This view implies that a state is free at any time to revoke the limitation and to be no longer bound by international law. On the basis of the actual behaviour of states, however, it would appear that only part of international law is treated as subject to consent. A state gives its consent to international obligations when its government signs a treaty or ratifies a convention or agrees to accept the jurisdiction of the International Court of Justice. But there are many rules of international law that do not arise from treaties or conventions; they reflect customary practices of international society or else general principles recognized by all civilized peoples. Nowadays there are also the precedents of important decisions by the International Court of Justice. Newly formed states are not given the option of accepting or rejecting the existing body of rules of international customary law. They are assumed as a matter of course to be bound by these rules, the tacit acceptance of which is a condition of their diplomatic recognition by other states.

International protection of human rights

Public international law and the United Nations are mainly concerned with the relations between states. A state's treatment of its own citizens was until recently held to be entirely its own business. The peace treaties concluded at the end of World War I, however, contained clauses to guarantee protection for certain minorities, and in 1948 the United Nations adopted the Universal Declaration of Human Rights. This document does not lay any legal obligations upon member states, but it has inspired several conventions, which have obligatory force, on particular topics such as the status of refugees, the political rights of women, and the removal of discrimination in employment or education. In addition, a num-

ber of European states have adopted a more general European Convention for the Protection of Human Rights and Fundamental Freedoms (but restricted to civil and political rights, while the Universal Declaration includes economic, social, and cultural rights also). The most striking development in this regard is the setting up of the European Commission of Human Rights and the European Court of Human Rights, which have the power to investigate alleged breaches of the convention. Under this procedure a complaint can be made against a state not only by another state but also by an aggrieved citizen—a remarkable, if as yet undeveloped, modification of the historical supremacy of the state over its members.

BIBLIOGRAPHY. Virtually all books on general political theory deal with the state as one of the main topics. Among recent works, ALESSANDRO PASSERIN D'ENTREVES, *La dottrina dello stato* (1962; Eng. trans., *The Notion of the State*, 1967) is especially useful in combining analysis with the history of ideas. JOHN D. MABBOTT, *The State and the Citizen*, 2nd ed. (1967), is a lucid philosophical introduction. ERNEST BARKER, *Principles of Social and Political Theory* (1951), though a more general treatise, is largely concerned with the state. ALEXANDER DUNLOP LINDSAY, *The Modern Democratic State*, vol. 1 (the only volume published, 1943, reprinted 1959), relates political philosophy to political, social, and economic history. HUGO KRABBE, *Die Moderne Staatsidee* (1915; Eng. trans., *The Modern Idea of the State*, 1922, reprinted 1930), stresses a juristic approach; ROBERT M. MACIVER, *The Modern State* (1926), is more sociological; EDWARD JENKS, *The State and the Nation*, rev. ed. (1935), is anthropological and historical. HAROLD J. LASKI, *The State in Theory and Practice* (1935), gives a Socialist view. Views of the contemporary relation between state and individual are given by WILLIAM ERNEST HOCKING, *Man and the State* (1926, reprinted 1968); and by JACQUES MARITAIN, *Man and the State* (1951). The changing position of the state in relation to international law is described in JAMES LESLIE BRIERLY, *The Law of Nations*, 6th ed. revised by HUMPHREY WALDOCK (1963); and in IAN BROWNLIE, *Principles of Public International Law* (1966); and FREDERICK L. SCHUMAN, *International Politics*, 7th ed. (1968).

(D.D.R.)

Statistics

Statistics is the art and science of gathering, analyzing, and making inferences from data. Originally associated with numbers gathered for governments, the subject now includes large bodies of method and theory.

Applied fields have stimulated extensive theoretical and practical work. For example, trying to improve the accuracy of physical measurements led the 19th-century German mathematician Carl Friedrich Gauss to develop the method of least squares (a method of analyzing experimental data; see below), which today has evolved to a flexible general theory that is applied and adapted to nearly every quantitative area. This work also contained the seeds of what the 20th-century British statistician Sir Ronald Aylmer Fisher later developed into the design of experiments, a branch of statistics widely used in agriculture for the improvement of crop yield and used to improve the precision of the results obtained in medical, biological, and industrial experimentation.

The ideas of effective design for data gathering are also basic to the construction of sample surveys, a branch of statistics most popularly known for its contributions to public opinion polling, to pre-election forecasting, and to market research. Perhaps even more significant is this branch's service to government through, for example, estimates of amount of unemployment and cost of living, which have become indispensable in attempts to regulate the economy. Sample survey methods have found uses in accounting, inventory control, and other areas.

For modern manufacturing, methods of controlling the quality of manufactured product have been essential. The statistical foundations of sequential analysis were provided by Abraham Wald in 1947 in order to handle problems in quality control.

In psychology and education, the statistical theory of tests and measurements has been extensively developed to compare achievement by individuals from diverse places and backgrounds.

THE BASIC PRINCIPLES OF STATISTICAL INFERENCE

Statistical experiments. The basic principles of statistical inference involve the notions of experiment, outcome, sample space, event, and probability. The idea of an experiment includes such examples as tossing a coin, measuring a length, or asking a person which party he or she will vote for at an election. Such experiments have a number of possible outcomes, perhaps infinitely many. When an ordinary die is thrown there are six possible outcomes, corresponding to the numbers 1, 2, 3, 4, 5, and 6. In statistics this collection of all possible outcomes is called a sample space. For the die the sample space can be written as the set {1, 2, 3, 4, 5, 6}. Any single outcome of an experiment, such as the throwing of a 6, is called a point. Certain specified sets of outcomes are called events. The throwing of an even number on a die would be an event, denoted by {2, 4, 6}.

Die throwing and coin tossing

Sets of events are frequently studied. For example, in tossing a coin twice, one possible outcome is "heads first time, tails second time," which is abbreviated to (H, T). Four possible outcomes make up the sample space—(H, T), (H, H), (T, H), and (T, T). If the experimenter asks only whether he gets the same result on both throws, the natural events chosen would be {(H, H), (T, T)} and {(H, T), (T, H)}.

In statistics the results of a large number of experiments form the data used. Sometimes it is assumed that each outcome is independent of any preceding one, as the number thrown on a die is independent of any preceding throws. It is also assumed that there is an underlying probability mechanism determining the nature of the data, as the probability of a coin's coming up heads determines the outcomes of experiments in which a coin is thrown twice. If the underlying probability mechanism is known, then the probability that certain outcomes occur can be calculated. This is the concern of probability theory (see PROBABILITY, THEORY OF).

Statistics is concerned with the application of probability theory to data. If only partial information is available —for example, if the underlying mechanism is one of several—it may be possible to use the data to infer which mechanism generated it and to associate probabilities or degrees of confidence with the various mechanisms. It is possible to perform the experiment a number of times and obtain a sequence of outcomes. Dividing the number of times an outcome of an experiment falls in event A by the number of experiments gives an estimate of the probability of event A. As the number of experiments grows large, the estimate becomes more likely to be close to the true probability $\mathbf{P}(A)$. In mathematical terms, if $x_1, x_2, \cdots$ is a sequence of outcomes and A an event, and $N(x_1, x_2, \cdots, x_n; A)$ denotes the number of times the outcome falls in A during the first n experiments, then as n tends to infinity, the chance that $N(x_1, x_2, \cdots, x_n; A)/n$ is close to $\mathbf{P}(A)$ tends to certainty.

Although this fact, known as the law of large numbers, tell the experimenter that he will arrive at the right answer eventually, it does not tell him how close he will be to the right answer after having performed the experiment a certain number of times. This is where statistical methods come in. Under certain conditions statistical methods give an estimate of the error that might possibly be made by performing the experiment a finite number of times.

An experiment is described completely by its sample space S, which is the set of possible outcomes, by a family B of events, and by a probability assignment $\mathbf{P}$ that governs the outcome of the experiment. The independence of two events means that the outcome of one does not imply anything about the outcome of the other. As a practical matter, separation of events in space and time often ensures independence. The concept of statistical or probabilistic independence is intended to extend the common meaning of independence to chance situations in which the occurrence of one event does not change the probability of occurrence of another event.

When events are independent, the probability that they jointly occur is the product of their probabilities: If the events are $A_1, \cdots, A_n$ and the associated probabilities

are $\mathbf{P}(A_i)$, $i = 1, \cdots, n$, the probability that all occur is $\mathbf{P}(A_1) \cdots \mathbf{P}(A_n)$.

When a die is tossed twice, for example, the sample space can be written as the set $\{(1, 1), (1, 2), \cdots, (1, 6), (2, 1), \cdots, (2, 6), \cdots, (6, 6)\}$; each of the 36 points in this sample space is composed of an outcome on the first toss and an outcome on the second. Thus, (4, 3) denotes a 4 on the first toss and a 3 on the second. The events A_1 and A_2 are independent and the probability of "A_1 and A_2" may be computed as the product of the individual probabilities (see Box, calculation 1), yielding a probability of ⅓.

These ideas of independence apply to statistical investigations in which the data are generated by repetitions of the same elementary operation, each carried out independently of the others.

Random variables

To develop models for numerical data, a real number or a vector with real components is associated with each outcome in the sample space. The function mapping the outcome to the number or vector is called a random variable. Capital letters are often used to designate the random variable itself and lower-case letters for an unspecified value of a random variable. Thus $\mathbf{P}(X = x)$ represents the probability that the random variable X takes the value x. It is often convenient to forget the functional origin of the idea of random variable and regard the set of values of X as the basic sample space.

For example, when a coin is tossed, the outcome may be heads or tails, and heads may be associated with $X = 1$ and tails with $X = 0$. X, the number of heads, is called a random variable and its values are 0 and 1 with equal probabilities of ½ (see 2).

Using random variables to describe outcomes of experiments gives systematic ways to describe the assignment of probability to sets. In practice, the sample space of the random variable is either a discrete set of values (as in tossing a die) or a continuous set (as in measuring a length). In both cases the sample space consists of a set on the real line. In the discrete case, it may be convenient to give a probability for each point x in the sample space S. Thus for the random variable X a probability mass function f is defined such that its value at x is a probability (see 3). Then the probability of an event A may be computed by summing $f(x)$ for all values of x in A (see 4). For all x, $f(x) \geq 0$ and $\mathbf{P}(S) = 1$.

For example, if p is the probability of success on a single trial, if the outcomes of trials are independent, and if the random variable X is the number of successes in n trials, then (as mentioned in PROBABILITY, THEORY OF) the value of f at x is a term in a binomial expansion (see 5). The probability that the experiment produces all successes or all failures is $p^n + (1 - p)^n$. The distribution of probability represented by the values of $f(x)$ is called the binomial distribution. A more complete representation would use $f(x|n, p)$ (read "f of x given n and p") rather than $f(x)$ so as to specify the parameters n and p of the distribution.

When probability is smoothly distributed over continuous sample spaces, a difficulty in representing the probabilities is that each point has probability zero, yet the total probability must be one: a line segment consists of points, each of zero length, and yet it has a nonzero length. Developing probability through measures on Borel sets resolves such difficulties (see ANALYSIS, REAL).

Distribution functions and their properties. For the continuous random variable X with values $x \in S$, a cumulative distribution function F is defined so that its value at x is the probability (see 6) for the random variable to be less than or equal to x. $F(-\infty)$ and $F(+\infty)$ are also defined by: $F(-\infty) = 0$ and $F(+\infty) = 1$ (the symbol ∞ denotes infinity). The probability in an interval, say $a < x \leq b$, is given by the difference in the values of F evaluated at the endpoints of the interval (see 7).

If F has a derivative $dF(x)/dx = f(x)$ for almost all x, then f is called the probability density function of the random variable X, or more briefly the density function. This brings the integral calculus into play because now, from the fundamental theorem of calculus, the definite integral of f is a probability (see 8). For example, for the uniform distribution on the interval $a < x \leq b$, the density and cumulative are given by specific functions (see 9) that are constant and of constant slope, respectively, over the interval.

The approach via the cumulative distribution function F makes it possible to unify mathematically discrete and continuous distributions as well as mixed ones by employing the Lebesque-Stieltjes integral.

The problem of finding the value of x such that $F(x) = p$ often arises. Such a value of x is called the pth quantile, or $100p$th percentile, of the distribution; the notation x_p is used. The median of the distribution is $x_{0.5}$, and $x_{0.25}$ and $x_{0.75}$ are the first and third quartiles.

When the random variable X has a distribution with density f, the mean of the distribution, if it exists, is given by the integral (see 10) over the whole real line of the product $xf(x)$. Its value μ is also called the first moment of the distribution. More generally, if it exists, the integral (see 11) of the product $x^r f(x)$ is the rth raw moment of the distribution. Moments about the mean are also used, and the rth moment about the mean is obtained from a similar integral (see 12) involving the rth power of $(x - \mu)$. In the discrete case the integrations are replaced by summations over $x \in S$.

Variance

The second moment about the mean is much used in both statistics and probability. It is called the variance of the distribution, or the variance of the random variable X, abbreviated var X, or σ_X^2, or when the name of the random variable is understood, σ^2. Its square root, σ, is the standard deviation.

In addition to moments defined as average values of the functions X^r and $(X - \mu)^r$, the average values of other functions of random variables frequently arise. If h is a function of X, then when it exists, the expected value of $h(X)$ is defined to be the integral over the whole real line (see 13) of the product of $h(x)$ and the probability density function. Therefore, the mean is $\mathbf{E}(X)$, and $\sigma^2 =$

(1) $$\begin{cases} A_1 = \{\text{first toss even}\}, \\ A_2 = \{\text{second toss 4 or less}\} \\ \mathbf{P}(A_1 \cap A_2) = \mathbf{P}(A_1)\mathbf{P}(A_2) = \frac{3}{6} \times \frac{4}{6} = \frac{1}{3} \end{cases}$$

(2) $$\mathbf{P}(X = 1) = \mathbf{P}(X = 0) = \tfrac{1}{2}$$

(3) $$f(x) = \mathbf{P}(X = x), \quad x \in S$$

(4) $$\mathbf{P}(A) = \sum_{x \in A} f(x)$$

(5) $$f(x) = \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x}, \qquad 0 \leq x \leq n$$

(6) $$F(x) = \mathbf{P}(X \leq x), \qquad -\infty < x < +\infty$$

(7) $$F(b) - F(a) = \mathbf{P}(a < X \leq b)$$

(8) $$\int_a^b f(x)\,dx = F(b) - F(a) = \mathbf{P}(a < X \leq b)$$

(9)

	$x \leq a$	$a < x \leq b$	$b < x$
$f(x)$	0	$1/(b-a)$	0
$F(x)$	0	$(x-a)/(b-a)$	1

(10) $$\mu = \int_{-\infty}^{+\infty} xf(x)\,dx$$

(11) $$\nu_r = \int_{-\infty}^{+\infty} x^r f(x)\,dx$$

(12) $$\mu_r = \int_{-\infty}^{+\infty} (x-\mu)^r f(x)\,dx$$

$\mathbf{E}[(X-\mu)^2]$. It should be noted that $\mathbf{E}$ is an operator, not a notation for a function.

For example, the expected value of the number of successes, X, for the binomial distribution is the product of the number of trials n and the constant probability p of success in each trial (see 14), derived by evaluating a binomial summation. The variance of X is $(1-p)$ times the mean (see 15).

For the normal distribution (see 16a), upon integration the mean μ of the random variable X is θ_1 (see 17), and the variance σ^2 is θ_2 (see 18). Consequently, the parameters of the normal distribution are said to be μ and σ^2. These results (see 16b) make clear that the normal density decreases exponentially, the exponent being proportional to the square of $(x-\mu)/\sigma$, the distance from x to the mean measured in standard deviation units. The coefficient $1/\sqrt{2\pi\sigma}$ assumes that the total density integrates to unity so that the total probability is 1. [In (16a), (16b), and (16c), π (pi) equals 3.14159 $\cdots$.]

If $Y = aX + b$, in which a and b are constants, and X any random variable with mean μ and variance σ^2, then the mean of Y, written μ_Y, bears the same linear relation to the mean of X that Y bears to X, and the variance of Y is the product of a^2 and the variance of X (see 19).

From any random variable X with mean μ and variance σ^2 a new random variable $Y = (X-\mu)/\sigma$ with mean 0 and variance 1 can be constructed. Such a Y is called a standardized random variable, and, if X is normally distributed, it is said to have the standard normal distribution (see 16c).

To generalize the concept of distribution function to several random variables $X_1, \cdots, X_k$ in a k-dimensional Euclidean space, the joint cumulative distribution function F is used. By definition the joint cumulative distribution function (see 20) is the probability of the common occurrence of k events of the type $(x_k \leq x_k)$. If any x_i is replaced by $-\infty$, then F takes the value zero. When all x_i are replaced by $+\infty$, $F = 1$. If F is differentiable with respect to all the variables, then there is a joint probability density function f such that F is the indefinite multiple integral (see 21) of f. If A is a set in the sample space and $x = (x_1, \cdots, x_k)$, then the probability that x belongs to the set A is the multiple integral (see 22) of the density extended over A. Formally the same equality is expressible in terms of a Stieltjes integral (see 23). When integration is performed over all variables but x_i, the cumulative gives $F(+\infty, \cdots, +\infty, x_i, +\infty, \cdots, +\infty)$, which represents the marginal cumulative distribution of X_i alone. More generally, when exactly r $(1 \leq r < n)$ coordinates are set at $+\infty$, the $(k-r)$th-order marginal distribution of the remaining $k-r$ random variables is obtained.

When the X_i are independent with $F_i(x_i) = \mathbf{P}(X_i \leq x_i)$, $i = 1, \cdots, k$, and have probability density functions $f_i(x_i)$, then the joint cumulative can be represented as the product of the separate distribution functions (see 24), and the joint density as the product of the separate densities (see 25). To represent the distribution of repeated measurements, X_i is allowed to represent the ith measurement, and the f_i is taken to be equal to f_0, so that the products above take a particularly simple form, expressible as a product extended over k index values (see 26) of $f_0(x_i)$.

If two random variables X and Y have a joint density f and if their means are μ_X and μ_Y, the covariance between X and Y (if it exists) is defined as an integral of the product of the differences $(x-\mu_X)$ and $(y-\mu_Y)$, weighted with the joint density (see 27).

Sums of random variables have special interest for statisticians. If X_i has mean μ_i and variance $\sigma_i^2 = \sigma_{ii}$ and if cov $(X_i, X_j) = \sigma_{ij}$, then if $Y = \Sigma X_i$, the mean of Y is the sum of the means of the X_i (see 28) and the variance of Y is the double sum over σ_{ij} (see 29). (In the summation defining Y the sum is from 1 to n.) In other words, the mean of a sum is the sum of the means, and the variance of a sum is the sum of the variances plus twice the covariances. The correlation coefficient between variables X_i and X_j is defined as the ratio of σ_{ij} to the product $\sigma_i\sigma_j$ (see 30). When all pairs of variables have $\rho_{ij} = 0$, then $\sigma_Y^2 = \sum_{i=1}^{n} \sigma_i^2$. Independence between all the random variables guarantees $\rho_{ij} = 0$, but having all $\rho_{ij} = 0$, $i \neq j$, does not guarantee independence.

The correlation coefficient

An important exception is the joint multivariate nor-

(13) $$\mathbf{E}(h(X)) = \int_{-\infty}^{+\infty} h(x) f(x)\, dx$$

(28) $$\mu_Y = \mathbf{E}(Y) = \mathbf{E}\left(\sum_{i=1}^{n} X_i\right) = \sum_{i=1}^{n} \mathbf{E}(X_i) = \sum_{i=1}^{n} \mu_i$$

(29)
$$\begin{cases} \operatorname{var} Y = \mathbf{E}[(Y-\mu_Y)^2] = \sigma_1^2 + \cdots + \sigma_n^2 + 2\sigma_{12} + \\ \qquad + 2\sigma_{13} + \cdots + 2\sigma_{n-1,n} \\ \qquad = \sum_{j=1}^{n} \sum_{i=1}^{n} \sigma_{ij} \end{cases}$$

(30) $$\rho_{ij} = \frac{\sigma_{ij}}{\sigma_i\sigma_j}$$

(31)
$$\begin{cases} f(x_1, \cdots, x_n | \mu_i, \sigma_i^2, i = 1, \cdots, n) \\ \qquad = \prod_{i=1}^{n} (2\pi\sigma_i^2)^{-1/2} \exp[-\frac{1}{2}(x_i-\mu_i)^2/\sigma_i^2] \end{cases}$$

mal distribution, the only parameters of which are the means, variances, and covariances of the variables. When $\rho_{ij} = 0$ for all $i, j, i \neq j$, the joint density can be represented by a product (see 31) of normal densities with typical mean μ_i and variance σ_i^2. For the general joint multivariate normal distribution density is proportional to the exponent of a quadratic form (see 32). If $||\sigma_{ij}||$ is the covariance matrix of the n random variables ($||a_{ij}||$ denotes the matrix with elements a_{ij}) and σ^{ij} the elements of its inverse, then the quadratic form is expressible (see 33) in terms of the collection $\{\sigma^{ij}\}$, and the constant factor that multiplies the exponential is expressible (see 34) in terms of $|\sigma^{ij}|$, in which $|a_{ij}|$ is the determinant of the matrix with elements a_{ij}. If $\Sigma = ||\sigma_{ij}||$ and the vector $(x - \mu)$ is defined (see 35), the quadratic form Q can be written more simply in vector and matrix notation, in which T stands for transpose.

Under a variety of conditions, the distribution of sums of random variables tends to a normal distribution as the number of random variables tends to infinity. The statements of conditions leading to these distributions are called central limit theorems. To illustrate, if $X_1, X_2, \cdots$ is a sequence of random variables and $Y_n = X_1 + \cdots + X_n$, and if $\mathbf{E}(Y_n) = \mu_n$ and var Y_n exists, then as n becomes large the sequence of distributions of the standardized random variables Z_n (see 36; each with mean 0 and variance 1) has a limit that is the standard normal distribution (see 37). One set of conditions guaranteeing this limiting distribution is independence of the X_i and identical distributions with finite variances, but other conditions are also available that do not require identical distributions, equal variances, or even independence.

This limiting distribution is also shared by many functions of random variables and is one reason for the importance of the Gaussian or normal distribution in statistical theory. In applications, sums of even a few random variables of the types ordinarily met have distributions the central portions of which can be well approximated by normal distributions.

If $Z_1, \cdots, Z_k$ are independent standard normal random variables, the sum of their squares (see 38) forms a new random variable, χ_k^2; its distribution is called the chi-square distribution with k degrees of freedom.

If Z, a standard normal random variable, and χ_k^2 a chi-square random variable with k degrees of freedom, are independent, then the new random variable, written t_k, which is proportional to Z divided by the square root of the chi-square (see 39), has the distribution known as Student's t distribution with k degrees of freedom. Student was the scientific pseudonym of William Sealy Gosset, the statistician and chemist who discovered the form of the distribution by a combination of mathematical work and empirical work with random numbers, an early application of what is now called the Monte Carlo method.

The chi-square and t distributions are frequently used in interval estimation and in testing hypotheses.

(32) $$\begin{cases} f(x_1, \cdots, x_n | \mu_i, \sigma_i^2, \sigma_{ij}, i, j = 1, \cdots, n) \\ \quad = K \exp(-\frac{1}{2}Q) \end{cases}$$

(33) $$Q = \sum_i \sum_j \sigma^{ij}(x_i - \mu_i)(x_j - \mu_j)$$

(34) $$K = [\,|\sigma^{ij}|/(2\pi)^n\,]^{1/2}$$

(35) $$\begin{cases} (x_1 - \mu_1, \cdots, x_n - \mu_n) = (x - \mu) \\ Q = (x - \mu)^T \Sigma^{-1} (x - \mu) \end{cases}$$

(36) $$Z_n = \frac{Y_n - \mu_n}{\sqrt{\text{var } Y_n}}$$

(37) $$\lim_{n \to \infty} \mathbf{P}(Z_n < z) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{z} e^{-\frac{1}{2}x^2}\, dx$$

(38) $$Z_1^2 + \cdots + Z_k^2$$

(39) $$t_k = \frac{Z}{\sqrt{\chi_k^2/k}}$$

(40) $$f(x|\theta) = \theta e^{-\theta x}, \qquad x \geq 0, \theta > 0$$

(41) $$\mu = \mathbf{E}(X) = \theta \int_0^\infty x e^{-\theta x}\, dx = 1/\theta$$

(42) $$L(x_1, \cdots, x_n | \theta) = \prod_{i=1}^{n} f(x_i|\theta)$$

ESTIMATION

Point estimation. For a random sample with values $x_1 \cdots, x_n$ independently drawn from a distribution F the parameter of which is θ, the problem of estimation is to find a function of the x's, $\hat{\theta}$, that comes close to θ. Here "close" is a vague word that can be given many meanings. If the sample is regarded as composed of random variables $X_1, \cdots, X_n$, and the estimator $\hat{\theta}$ as a function of those random variables, then $\hat{\theta}$ is itself a random variable. Some desirable properties for an estimator $\hat{\theta}$ are (A) that its average error be small: indeed, if the average error vanishes, $\mathbf{E}(\hat{\theta} - \theta) = 0$, and the estimator is said to be unbiassed; (B) that the mean square error $\mathbf{E}(\hat{\theta} - \theta)^2$ be small: this measure combines, in a somewhat arbitrary way, variability of $\hat{\theta}$ with its bias $b = \mathbf{E}(\hat{\theta} - \hat{\theta}$, because $\mathbf{E}(\hat{\theta} - \theta)^2 =$ var $\hat{\theta} + b^2$. (C) Another attractive property is small variance. If, among several unbiassed estimators, one has smallest variance, it is known as the minimum-variance unbiassed estimator. Which of several estimators may be more desirable depends, among other things, upon the costs of errors $(\hat{\theta} - \theta)$ of various sizes.

Samples contain information about the parameters of a family of distributions, but different families can profitably use different functions to extract this information. Several methods of estimation offer general techniques for finding estimators for parameters. Three techniques are considered here: the method of moments, the method of maximum likelihood, and Bayesian methods.

Method of moments. The moments of a family of distributions are functions of the parameters of the family. If there are only a few parameters, it may be possible to use the first few moments of the distributions together with the sample moments to get estimates of the parameters. If the observed values of the sample moments are equated with the corresponding population moments, expressed as functions of the parameters, the resulting equations for estimates of the parameters may be solved. Thus the estimators choose that member of the family whose moments match the sample moments.

The method of moments may be used, for example, to estimate the parameter θ of an exponential distribution having probability density function proportional to the exponential of $-\theta x$, the values of x being non-negative (see 40). The population mean is calculated (see 41) to be $1/\theta$. The value of the sample mean is $\bar{x} = (x_1 + \cdots + x_n)/n$, and so the method of moments would derive the estimate of θ from $\bar{x} = 1/\hat{\theta}$ and give $\hat{\theta} = 1/\bar{x}$.

The method of maximum likelihood. A widely used method that has attractive large-sample properties is the method of maximum likelihood. For families of discrete distributions, the probability of getting the particular sample that has been observed can be computed, and then those values of the parameters that maximize the probability can be chosen as estimates. If the sample $x_1, \cdots, x_n$ has been independently chosen from a distribution with probabilities $\mathbf{P}(X = x \mid \theta) = f(x \mid \theta)$, in which θ may be a vector, then that probability, called the likelihood, is defined as the product of n probability mass functions, one evaluated at each sample value (see 42).

For continuous distributions the corresponding approach is again to maximize the likelihood function, which is given above (see 42) except that the right-hand side is the product of the values, $f(x_i \mid \theta)$, of the density function evaluated at the sample points. Although symbolically the same, the likelihood in the discrete situation is a probability, but in the continuous case it is a measure of the density of probability at the sample point. The one-parameter case is considered. Under broad regularity conditions (dealing with the differentiability of f with respect to θ, and the existence of integrals of functions of f and its derivatives), the estimator $\hat{\theta}$, the value of θ that maximizes L for the given sample, is the maximum likelihood estimator of θ. Asymptotically (*i.e.*, as n tends to infinity) $\hat{\theta}$ tends to be normally distributed with asymptotic mean θ and asymptotic variance expressed in a simple formula (see 43) in terms of the reciprocal expectation of the second derivative (with respect to θ) of the log of the density.

For example, a sample of size n from the normal distribution with mean 0 and variance θ (or σ^2) has a likelihood function and its derivative given by the equations that are exponential and algebraic in form, respectively (see 44). If the derivative is set equal to zero and the equation solved for θ, the maximum likelihood estimate of θ is given by the sum of the squares of the x_i divided by n (see 45). Because the second derivative of the log of the density is a simple expression that is linear in the square of the variable (see 46), and $\mathbf{E}(X^2) = \theta$, the asymptotic variance is found to be proportional to the reciprocal of n (see 47).

Some attractive asymptotic properties of the maximum likelihood estimator when the regularity conditions are met are:

A. That it converges in probability to the true value of θ as $n \to \infty$. (Estimators that do this are said to be consistent.)

B. That it is asymptotically unbiassed.

C. That among asymptotically unbiassed estimators, no other has smaller asymptotic variance. (Unbiassed estimators having finite variance at least as small as that of any other estimator are said to be efficient.)

D. The maximum likelihood estimator of a function of θ is the same function of the maximum likelihood estimator of θ.

In the example given above the maximum likelihood estimate of θ (or σ^2) was $\Sigma x_i^2/n$. The maximum likelihood estimate of σ is the square root of this expression (see 48).

The extension of this method to vector random variables and vector parameters is straightforward providing further regularity conditions hold. If a sample point consists of the vector $x_i = (x_{1i}, \cdots, x_{ri})$, and the joint distribution of the r variables has k parameters $\theta = (\theta_1, \cdots, \theta_k)$, then one forms the likelihood function that is formally the same as before but now involving vectors (see 49). To find the relative maximum (assumed unique), the partial derivatives with respect to θ_i are taken, they are set equal to zero, and the resulting equations for the maximum likelihood estimates $\hat{\theta}_i$ are solved. Asymptotically the estimators are jointly normally distributed with mean $(\theta_1, \cdots, \theta_k)$ and covariance matrix $||nB_{pq}||^{-1}$, in which the $\{B_{pq}\}$ are expectations of second partial derivatives of the log of the density (see 50). The vectorial nature of the observations is not central to maximum likelihood estimation, and so the method is illustrated by a one-variable probability distribution with two parameters.

As an example, consider the vector parameter. If the sample is drawn from the normal distribution with mean θ_1 and variance θ_2, so that the normal density is specified (see 51) as before, then it is found that the maximum likelihood estimator of the population mean is the sample mean, and of the population variance is the sample variance (see 52). Furthermore, the covariance matrix is diagonal (see 53), so that asymptotically $\hat{\theta}_1$ and $\hat{\theta}_2$ are independently normally distributed with means (θ_1, θ_2) and variances θ_2/n and $2\theta_2^2/n$, respectively.

For a sample of n independent normally distributed observations, the sample mean $\bar{X}$ is exactly, not just asymptotically, normally distributed with mean θ_1 and variance θ_2 as before (see 54).

Interval estimation. The discussion of estimation has emphasized point estimates for parameters, but it may also be useful to give an interval within which a parameter is likely to lie, together with the chance that the interval includes the parameter. More generally, if the parameter were a vector, a region would be given.

The confidence interval

An important illustration gives the confidence interval, based on a sample size of n, for the unknown mean μ of a normal distribution with known standard deviation σ. The probability is $1 - \alpha$ that the sample mean X falls (see 55) within a specified distance, $|z_{\alpha/2}|\,\sigma/\sqrt{n}$, of μ, in which $z_{\alpha/2}$ is the $100\alpha/2$ percentage point of the standard normal distribution.

The sample mean X is normally distributed with mean μ and standard deviation $\sigma/\sqrt{n}$, so that a rearrangement of the inequalities gives upper and lower bounds for the parameter μ that involve the random variable $\bar{X}$ (see 56). This statement (in 56) is true $100(1 - \alpha)$ percent of the time. If the random variable $\bar{X}$ is replaced

(43) $$\operatorname{var}\hat{\theta} = \frac{1}{-n\mathbf{E}\left[\dfrac{\partial^2 \log f(x|\theta)}{\partial\theta^2}\right]}$$

(44) $$\begin{cases} L(x_1, \cdots, x_n|\theta) = [2\pi\theta]^{-\frac{n}{2}}\, e^{-\frac{1}{2}\Sigma x_i^2/\theta} \\ \dfrac{\partial \log L}{\partial\theta} = -\dfrac{n}{2\theta} + \dfrac{\Sigma x_i^2}{2\theta^2} \end{cases}$$

(45) $$\hat{\theta} = \sum_{i=1}^{n} x_i^2/n$$

(46) $$\frac{\partial^2 \log f(x|\theta)}{\partial\theta^2} = \frac{1}{2\theta^2} - \frac{x^2}{\theta^3}$$

(47) $$\operatorname{var}\hat{\theta} = \frac{2\theta^2}{n}$$

(48) $$\hat{\sigma} = \sqrt{\hat{\theta}} = \sqrt{\Sigma x_i^2/n}$$

(49) $$L(x_1, \cdots, x_n|\theta) = \prod_{i=1}^{n} f(x_i|\theta)$$

(50) $$B_{pq} = -\mathbf{E}\frac{\partial^2 \log f(x|\theta)}{\partial\theta_p \partial\theta_q}, \qquad p, q = 1, \cdots, n$$

(51) $$\begin{cases} f(x|\theta_1, \theta_2) = (2\pi\theta_2)^{-1/2} \exp[-(x-\theta_1)^2/2\theta_2] \\ -\infty < x < \infty, \qquad -\infty < \theta_1 < \infty, \qquad 0 < \theta_2 < \infty \end{cases}$$

(52) $$\hat{\theta}_1 = \frac{\Sigma x_i}{n} = \bar{x}, \qquad \hat{\theta}_2 = \frac{\Sigma (x_i - \bar{x})^2}{n}$$

(53) $$\begin{Vmatrix} \dfrac{\theta_2}{n} & 0 \\ 0 & \dfrac{2\theta_2^2}{n} \end{Vmatrix}$$

(54) $$\theta_2/n = \sigma_X^2/n$$

(55) $$\mu - |z_{\frac{1}{2}\alpha}|\sigma/\sqrt{n} \leq \bar{X} \leq \mu + |z_{\frac{1}{2}\alpha}|\sigma/\sqrt{n}$$

(56) $$\bar{X} - |z_{\frac{1}{2}\alpha}|\sigma/\sqrt{n} \leq \mu \leq \bar{X} + |z_{\frac{1}{2}\alpha}|\sigma/\sqrt{n}$$

(57) $(\bar{x} - |z_{\frac{1}{2}\alpha}|\sigma/\sqrt{n}, \bar{x} + |z_{\frac{1}{2}\alpha}|\sigma/\sqrt{n})$

(58) $\mathbf{P}(\hat{\theta}_l \leq \theta < \hat{\theta}_u|\theta) = 1 - \alpha$

(59) $\text{var } X' = \dfrac{1}{4n[f(x_{0.5})]^2}$

(60) $c(x|\mu, \sigma^2, \gamma) = (1-\gamma)n(x|\mu, 1) + \gamma n(x|\mu, \sigma^2)$
$\sigma > 1$

(61) $L(x_1, \cdots, x_n|\theta) = \prod_{i=1}^{n} f(x_i|\theta)$

(62) $h(x_1, \cdots, x_n, \theta) = g(\theta) \prod_{i=1}^{n} f(x_i|\theta)$

(63) $p(\theta|x_1, \cdots, x_n) = kg(\theta) \prod_{i=1}^{n} f(x_i|\theta)$

by the observed sample mean $\bar{x}$, then the statements (in 56) are true or false. They are true in $100(1 - \alpha)$ percent of the times this method is used. The limits $\bar{x} \pm |z_{\alpha/2}|\sigma/\sqrt{n}$ are called upper and lower $100(1 - \alpha)$ percent confidence limits, and $100(1 - \alpha)$ is called the confidence level or confidence coefficient and is expressed either as a percent or a proportion, $1 - \alpha$. The interval composed of the points (see 57) between the upper and lower confidence limits is called a confidence interval. A commonly used confidence level is 0.95, and then $|z_{\alpha/2}| = 1.96$, or about 2.

If, in general, an upper function $\hat{\theta}_u$ and a lower function $\hat{\theta}_l$ of the sample values can be found—so that the probability for these functions to bound θ is $1 - \alpha$ (see 58), then the values of $\hat{\theta}_u$ and $\hat{\theta}_l$ obtained from the sample provide upper and lower $100(1 - \alpha)$ confidence limits for θ.

In a sample of size n drawn from a normal distribution with unknown mean μ and unknown variance σ^2, having sample mean $\bar{x}$ and variance $s_{\bar{x}}^2$ of the mean given by $\Sigma(x_i - \bar{x})^2/n(n - 1)$, symmetrical $1 - \alpha$ confidence limits on μ are given by $\bar{x} \pm |t_{\alpha/2}|\, s_{\bar{x}}$, in which $t_{\alpha/2}$ is the $\alpha/2$ percentage point of the t distribution with $n - 1$ degrees of freedom.

In some investigations, the researcher continues sampling until his confidence limits have been reduced to a preset size. Finding appropriate stopping rules and setting the limits are problems in sequential estimation.

Interval estimation can be used not only for reporting uncertainty in the value of the parameter, but also for hypothesis testing. If a specific value of the parameter θ, say θ_0, has a reasonable chance of being the true value, and if $1 - \alpha$ confidence limits can be set on θ, then if θ_0 is in the confidence region, it can be accepted as possibly being the true value. Otherwise this hypothesis can be rejected.

For example, in a sample of size $n = 3$ from a normal distribution, $\bar{x} = 2$, $s_{\bar{x}} = 0.5$, symmetrical 95 percent confidence limits are set on μ, and a test applied as to whether $\mu = 0$ is a reasonable value. This problem has two degrees of freedom, and $t_{0.025} = -4.30$. From the above formulas, the confidence limits are $2 \pm 4.30(0.5) = -0.15, +4.15$, and the hypothetical value 0 is in the interval (though barely). Consequently, 0 is not rejected as the value for μ at the 5 percent level of significance.

Robust estimation. In real data, the appearance of observations that seem not to belong with the rest of the measurements (such as 22.19 in the set 10.01, 10.04, 10.03, 22.19) is so commonplace that systematic methods are required to defend the analyses against them. Setting observations aside has always been a touchy step, especially to those who believe that good work never leads to bad data. One reasonable attitude is that wild observations should be set aside and studied separately so as not to destroy the information in the main body of the data. A few standard methods are applied to afford protection against temptation to make a special analysis to reach a foregone conclusion—and against the criticism that this has been done.

One estimator of location is the sample median, the middle-sized observation if the sample size is odd, or the average of the middle two if it is even. The large-sample distribution of the sample median X' is approximately normal with asymptotic mean $x_{0.5}$, the 50th percentile point of the distribution, and asymptotic variance expressed in terms of the density function evaluated at $x_{0.5}$ (see 59). When f is a normal density function, the population mean and median are both μ. The sample mean $\bar{X}$ is exactly, and the sample median X' approximately, normally distributed. As n grows large, $\text{var } \bar{X} \approx \frac{2}{\pi} \text{var } X'$, and X' is said to have asymptotic efficiency $2/\pi \approx 0.63$ compared with $\bar{X}$. Thus it takes a sample of 100 using the median to get the accuracy of a sample of 63 with the mean. If wild observations contaminate a distribution, however, the efficiency soon favours the median.

For example, a density function c formed as the weighted sum of two normal densities is expressed in terms of a function n and a weighting parameter γ (see 60), in which $n(x|\mu,\sigma^2)$ is the ordinate at x of a normal probability density function with mean μ and variance σ^2. For small γ, c is said to be a contaminated distribution, and γ is the fraction of contamination by data having variance σ^2. When $\gamma = 0.09$ and $\sigma = 3$, X' has a smaller variance than $\bar{X}$, and thus X' would be preferred to $\bar{X}$ as an estimator of μ.

Trimmed means

Trimmed means are also resistant to contamination; they are formed by setting aside a fraction α of the largest and smallest measurements, 2α in all, and averaging the middle $1 - 2\alpha$. Empirical studies suggest that, for a large class of distributions, trimming with $\alpha \approx 0.25$ seems to be satisfactory for estimating location. For the normal this trimmed mean has asymptotic efficiency of about 0.83 compared with $\bar{X}$ before contamination. For a contaminated distribution c with $\gamma = 0.05$ and $\sigma = 3$, the mean $\bar{X}$ has efficiency only 0.92 of that of the trimmed mean. With $\alpha = 0.25$ and $\gamma = 0.10$ this decreases to 0.775.

Bayesian methods. The methods of estimation described above are often referred to as classical in the sense of standard. The Bayesian approach offers an alternative that gives an especially convenient way of incorporating prior information about the parameters and also of adding further information when it arrives. One disadvantage is that the method apparently cannot proceed without a prior distribution for the parameters. The main device for inference is the posterior distribution of θ, given the data.

For a distribution of the random variable X given parameter θ with probability density function f, the likelihood of a sample of size n is, as before, a product of densities (see 61) each evaluated at sample points. If the prior distribution of θ has density $g(\theta)$, then the joint density of the sample and θ can be represented as the product (see 62) of this density and the likelihood of a sample. The posterior distribution of θ is required, given the sample. It has the density constructed as k times the joint density of the sample and θ (see 63), in which k is a normalizing constant that makes the integral of the function $p(\theta \mid x_1, \cdots, x_n)$ equal to 1, the integral extending over the possible values of θ.

In this present discussion θ is a random variable, whereas in methods of estimation discussed earlier it was regarded as a constant. The interpretation of $p(\theta \mid x)$ is of interest. It tells what the thoughtful observer who provided the prior distribution would believe about the state of the world after he received the data x. If his prior was largely based on personal subjective judgment, then the degree-of-belief interpretation is paramount, and others may prefer different priors and therefore different $p(\theta \mid x)$. When the prior comes from substantial frequency-based observations closely related to the real world, the poste-

rior distribution may well approximate an objective relative frequency distribution. Many practical situations fall between these extremes.

Much of the controversy over Bayesian methods has concentrated on the philosophy of the choice of the prior distribution and the difficulty of attaining agreement or unanimity. After completing a large Bayesian study, the U.S. statisticians Frederick Mosteller and David L. Wallace (1964) concluded that a neglected difficulty in Bayesian inference, as in methods of inference based on likelihood, is the sensitivity of the conclusions to the chosen family of data distributions; that is, to the functional form of f.

For a given $p(\theta \mid x)$, point or interval estimates can be obtained, or $p(\theta \mid x)$ can be used to make decisions. For example, the mean, mode, or median of the posterior distribution might be used as a point estimate for the true value. Alternatively, an interval (u, v) could be set up, like a confidence interval, that includes most of the probability, so that the integral with respect to θ from u to v of $p(\theta \mid x)$ equals $1 - \alpha$.

(64) $$p(\pi|x) = k\pi^{a+x-1}(1-\pi)^{b+n-x-1}$$

(65) $$\mu_{post} = \frac{a+x}{a+b+n}, \qquad \sigma^2_{post} = \frac{\mu_{post}(1-\mu_{post})}{a+b+n+1}$$

(66)

State of Nature	Action a_0 (accept H_0)	Action a_1 (accept H_1)
θ_0 (H_0 true)	$l(\theta_0, a_0)$	$l(\theta_0, a_1)$
θ_1 (H_1 true)	$l(\theta_1, a_0)$	$l(\theta_1, a_1)$

(67) $$\begin{aligned} \text{Risk}(\theta_0) &= l(\theta_0, a_0)\,\mathbf{P}(a_0|\theta_0) + l(\theta_0, a_1)\,\mathbf{P}(a_1|\theta_0) \\ &= \mathbf{P}(a_1|\theta_0) = \alpha \end{aligned}$$

(68) $$\begin{aligned} \text{Risk}(\theta_1) &= l(\theta_1, a_0)\,\mathbf{P}(a_0|\theta_1) + l(\theta_1, a_1)\,\mathbf{P}(a_1|\theta_1) \\ &= \mathbf{P}(a_0|\theta_1) = 1 - \gamma \end{aligned}$$

(69) $$\frac{L(x|H_0)}{L(x|H_1)} \leq c$$

(70) $$\int_W L(x|H_0)\,dx = \alpha$$

(71) $$f(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}(x-\mu)^2}, \qquad -\infty < x < +\infty$$

An example is a machine setup in which the proportion of defective parts produced in the initial setting is π and prior data suggest that π is distributed according to a beta distribution $g(\pi) = c\pi^{a-1}(1-\pi)^{b-1}$, in which c is the normalizing constant and $a > 0$, $b > 0$, $0 \leq \pi \leq 1$. After a setup, a sample of size n with x defectives has likelihood $f(x \mid \pi) = \pi^x(1-\pi)^{n-x}$. The posterior distribution of π given x defectives in the sample is proportional to the product of g and f (see 64). The posterior mean and variance of π are then calculable (see 65).

If both the prior distribution and the data distribution are normal with prior mean and variance μ_0 and σ_0^2, and the data observation and variance are x and σ^2, then the posterior distribution is again normal with mean μ_1 and variance σ_1^2. Their values can be computed from the relations $\mu_1 = \dfrac{h_0\mu_0 + hx}{h_0 + h}$, and $h_1 = h_0 + h$, in which $h_i = 1/\sigma_i^2$, $h = 1/\sigma^2$, so that $\sigma_1^2 = 1/h_1$.

When little information about θ is available, prior distributions for θ might be diffuse so that in the neighbourhood of any particular value of θ, the distribution is nearly flat. This would give the data greater weight in determining the posterior. Such a distribution is called a gentle prior distribution.

One's prior distribution of the length of a dimly seen and unfamiliar distant object would have a very large standard deviation compared to that of one direct measurement taken with a steel tape. If measurement errors were normally distributed with $\sigma = 0.1$ in inches and a gentle prior were used on the true value, the posterior distribution would be approximately normal with mean x and standard deviation 0.1.

HYPOTHESIS TESTING

When the probability model for the mechanism generating the observed data is known, hypotheses about the model can be tested. This involves the question: Could the present set of data reasonably have come from the model if the hypothesis is correct? Usually a decision must be made on the basis of the available data, and some degree of uncertainty is tolerated about the correctness of that decision. These four components (data, model, hypothesis, and decision) are basic to the statistical problems of hypothesis testing.

Use of the null hypothesis

In such problems a null hypothesis is formed (usually denoted H_0) that the assumption to be tested is correct. Then a significance level α $(0 < \alpha < 1)$ is chosen to indicate how improbable a set of data must be if H_0 is to be rejected. The particular samples to be considered improbable make up the critical region W, a subset of the sample space that has $\mathbf{P}(W \mid H_0) \leq \alpha$. In developing a test of a hypothesis, the central task is to construct the critical region.

When the null hypothesis is rejected, an alternative hypothesis, usually denoted H_1, is accepted in its place. The probability that a sample will lead to this action when the true value of the parameter is in H_1 is called the power, γ, of the test. If testing a hypothesis is viewed as a decision problem, there are two possible actions—"accept H_0" and "accept H_1"—and each has a corresponding loss depending on the true state of nature. (The terms "accept" and "reject" may give a rather unrealistic impression of finality, but they are the ones conventionally used in statistics as standard labels for the two actions; they owe part of their currency to one development of these ideas in the field of quality control, in which manufactured lots of material are accepted or rejected on the basis of samples.)

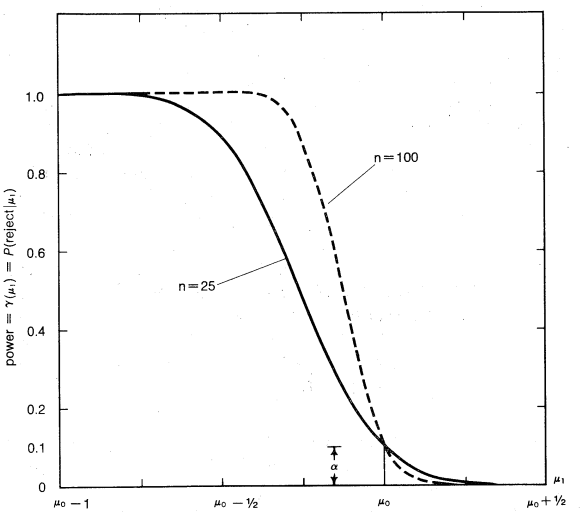
Many hypotheses concern values of a parameter (θ) in the probability model. In the most basic case both H_0 and H_1 involve a single value of θ (θ_0 and θ_1, respectively) and are said to be simple hypotheses. In this case the loss function may easily be displayed in a table: the two states of nature and the two possible actions determine four distinct values of the loss function (see 66). Here the concepts of decision theory provide a generalization of the classical formulation of hypothesis testing in which the losses are $l(\theta_0, a_0) = l(\theta_1, a_1) = 0$ and $l(\theta_0, a_1) = l(\theta_1, a_0) = 1$.

Risk is defined as the expected loss, given the state of nature. In that formulation the values of the risk are α at θ_0 (see 67) and $1 - \gamma$ at θ_1 (see 68). Thus among all tests with significance level α in a given problem, the one with the greatest power γ has the least risk.

To construct a test of H_0 with maximum power against H_1, a general technique, given in 1933 by the Romanian-born U.S. statistican Jerzy Neyman and the British statistician Egon Sharpe Pearson, may be used. The basis for this technique is the likelihood function $L(x \mid H)$, in which x denotes the sample and H a simple hypothesis. The critical region W for the test is that subset of the sample space for each element of which the ratio of the likelihood function for H_0 to the likelihood function for H_1 is less than or equal to c (see 69), with c chosen to give the desired significance level: the probability of W, assuming H_0 to be true (see 70), is required to be α. The quotient $L(x \mid H_0)/L(x \mid H_1)$ is referred to as the likelihood ratio.

For example, a hypothesis about the value of the mean μ of a Gaussian (normal) distribution with variance 1 might be tested (see 71). On the basis of a random sample of n observations $X_1, \cdots, X_n$, the null hypothesis H_0 that $\mu = \mu_0$ is tested against the alternative hypothe-

sis H_1 that $\mu = \mu_1 < \mu_0$. If a prescribed significance level α is used, $\alpha = 0.1$, say, then the appropriate critical region may be constructed. The likelihood function for any value of μ is formed from a product of normal densities each evaluated at sample points (see 72), and the likelihood ratio for the test is a ratio of two such products that differ in the value selected for the parameter μ (see 73). It is more convenient to work with the logarithm of the likelihood ratio, so that $(x_1 \cdots, x_n)$ lies in the critical region when the difference of two sums of squares (namely the quadratics that appear in the exponentials of the normals) yields a value that is less than or equal to $\log_e c$ (see 74). An algebraically equivalent condition is an inequality that sets an upper bound (dependent on c, μ_0, μ_1, and n) on the sum of sample values (see 75). Here c remains unspecified, but that causes no difficulty. In this problem the critical region does not require any distinction between samples that have the same sum. The critical region is described in terms of the sample mean $\bar{x}$: it is composed of the set of n-dimensional points for which the mean is less than or equal to a simple function of z_α (see 76).



As might be expected from the assumption that $\mu_1 < \mu_0$, the critical region is composed of samples with means to the left of μ_0. For this test, the power is calculated (see 77) to be the function Φ evaluated at the sum of z_α and $\sqrt{n}(\mu_0 - \mu_1)$, in which Φ is the standard Gaussian cumulative distribution function. In the Figure power curves are plotted showing how the power depends on the separation between μ_1 and μ_0 and on the sample size n.

In the example, the critical region W depends only on having $\mu_1 < \mu_0$. Thus, in this problem the alternative hypothesis H_1 that $\mu < \mu_0$ could be used. Such hypotheses, involving more than one value of the parameter, are called composite. The power γ of the test is now a function of the true value of the parameter within the set of alternatives.

The curves in the Figure represent the power function $\gamma(\mu)$ for the two values of n. In general any attempt to construct a test with maximum power against a composite alternative hypothesis involves the formation of a power function $\gamma(\theta)$ that lies above other possible power functions for all values of θ within H_1. In some problems this is not feasible, and a considerable body of theory has been created to deal with such problems in great generality.

The descriptive level of significance

In practical significance testing, instead of presetting the significance level, the investigator may report the level of significance that would have just rejected the null hypothesis for his data. This level, called the descriptive level of significance or the nominal level of significance, has the advantage of giving a more complete report on the test and allows the reader to set his own significance level.

Plot of power curves for the example for $\alpha = 0.10$ and $n = 25$ (solid curve) and 100 (dashed curve; see text).

$$L(x_1, \cdots, x_n|\mu) = \prod_{i=1}^{n} f(x_i) = (2\pi)^{-n/2} \exp\left[-\tfrac{1}{2}\sum_{i=1}^{n}(x_i - \mu)^2\right] \tag{72}$$

$$\frac{L(x_1, \cdots, x_n|\mu_0)}{L(x_1, \cdots, x_n|\mu_1)} \tag{73}$$

$$-\tfrac{1}{2}\sum_{i=1}^{n}(x_i - \mu_0)^2 + \tfrac{1}{2}\sum_{i=1}^{n}(x_i - \mu_1)^2 \leq \log_e c \tag{74}$$

$$\sum_{i=1}^{n} x_i \leq \frac{\log_e c}{\mu_0 - \mu_1} + \frac{n}{2}(\mu_0 + \mu_1) \tag{75}$$

$$W = \left\{(x_1, \cdots, x_n) : \bar{x} \leq \frac{z_\alpha}{\sqrt{n}} + \mu_0\right\} \tag{76}$$

$$\begin{cases} \mathbf{P}(W|H_1) = \mathbf{P}\left(\bar{X} \leq \dfrac{z_\alpha}{\sqrt{n}} + \mu_0 | \mu = \mu_1\right) \\ \qquad = \mathbf{P}(\sqrt{n}(\bar{X} - \mu_1) \leq z_\alpha + \\ \qquad\quad + \sqrt{n}(\mu_0 - \mu_1)|\mu = \mu_1) \\ \qquad = \Phi(z_\alpha + \sqrt{n}(\mu_0 - \mu_1)) \end{cases} \tag{77}$$

$$\lambda(x_1, \cdots, x_n; \theta_{01}, \cdots, \theta_{0r}) = L_0(x_1, \cdots, x_n|\theta)/L_1(x_1, \cdots, x_n|\theta) \tag{78}$$

$$W = \{\lambda : \lambda \leq c\} \tag{79}$$

In more complicated situations a critical region in the original sample space may often be difficult to use because the region is defined by complicated functions of the data. When this happens, a technique that is based directly on a likelihood ratio may be used. The following illustration suggests some of the generality of the technique.

Suppose the parameter is $\theta = (\theta_1, \cdots, \theta_k)$, the null hypothesis is H_0: $(\theta_1, \cdots, \theta_r) = (\theta_{01}, \cdots, \theta_{0r})$ with $r \leq k$, and the alternative is H_1: $(\theta_1, \cdots, \theta_r) \neq (\theta_{01}, \cdots, \theta_{0r})$. These hypotheses are not concerned with $\theta_{r+1}, \cdots, \theta_k$. The approach is to determine the maximum value of the likelihood subject to the constraint imposed by H_0 and then use its ratio to the unconstrained maximum as the test statistic. This procedure, known as the likelihood ratio test, plays a role in hypothesis testing analogous to the role of maximum likelihood in estimation. For a random sample of n the test statistic is a function λ that is a ratio of likelihood functions L_0 and L_1 (see 78), in which L_0 is maximized over θ with the constraints that $\theta_i = \theta_{0i}$, $i = 1, \cdots, r$, and L_1 over all θ. From this definition it is clear that $0 \leq \lambda \leq 1$, and the cirtical region contains values of λ that are too small for H_0 to be reasonable: it is composed of values of λ that are less than or equal to c (see 79), with c chosen so that $\mathbf{P}(W \mid H_0) \leq \alpha$. When the exact distribution of λ is a function of the random sample $X_1, \cdots, X_n$, it is easy to choose c for the desired significance level. Otherwise the distribution of λ must be approximated. Fortunately, a remarkable asymptotic result may be employed: as n becomes large, the distribution of $-2 \log_e \lambda(X_1, \cdots, X_n; \theta_{01}, \cdots, \theta_{0r})$ when H_0 is true approaches a chi-square distribution with r degrees of freedom.

When data can be collected on a continuing basis, the techniques for testing a hypothesis should attempt to reach a decision as soon as the evidence is strong enough. Considered as a decision problem, this situation has three actions: "accept H_0," "accept H_1," and "continue sampling." Such methods are part of the field of sequential analysis.

When hypothesis testing was first mentioned, it was assumed that the probability model underlying the data was known. There is no reason to expect that this will always be the case; the reasonableness of a particular model may be exactly what is to be tested. Alternatively, it may be necessary to test whether the mean of one population is equal to the mean of another, without assuming a particular probability model for either. These are typical of the problems that form the subject of nonparametric hypothesis testing. Ordinarily, nonparametric methods depend less on the detailed shape of the sampling distributions than do methods called parametric. Nonparametric methods when used with measurements typically depend on signs of differences, or on counts, ranks, and permutations, rather than on the specific values.

STRUCTURE IN DATA

Many sets of data arising in actual practice are more complex than the situations and examples that have been described. The data may be collected according to a plan, and its structure must be considered in any analysis. Several properties may be measured for each observation in the sample, and their relationship may be of central importance. A process may be observed over a period of time, and it may be desired to discover or correct for cyclical aspects of its behaviour. These three types of situation are examples, respectively, of experimental design, of regression and correlation analysis, and of time-series and spectrum analysis. There are almost as many techniques of analysis as kinds of structure in data, but the most widely used are those of linear regression.

Regression analysis

The general setting for regression analysis is as follows. Each observation consists of a value of Y, which is regarded as a response, and a value of each of $X_1, \cdots, X_k$, which are regarded as factors affecting the response. A model that restricts Z to equal a linear combination of $\{U_i\}$ plus ε (see 80) is built, for example, in which Z is some function of Y, the U's are functions of the X's, and ε is random error, attributable to measurement error or natural variation. Z may be regarded as a response; it is often called the dependent variable. The U's, which are called carriers, may depend on the X's in ways prescribed by theory or suggested by preliminary examination of the data; they are often called independent variables, even when they may not be probabilistically or functionally independent. The parameters $\beta_1, \cdots, \beta_r$ in the model are usually called regression coefficients. Such a model is said to be linear because Z depends linearly on the U's.

At an early stage in analyzing data according to this linear or multiple regression model the β's are estimated, whether or not their numerical values are the primary goal of the analysis. One standard method for fitting the model to the data is least squares: given n observations $(y_i, x_{1i}, \cdots, x_{ki})$, estimates ($b$'s) for the β's are chosen that result in the smallest value of the sum of squared deviations from the fitted model (see 81). This sum is differentiated with respect to each of the b's, and the minimization problem is reduced to one of solving a set of r simultaneous linear equations in r unknowns. This can be done without consideration of the probability model for the random error ε, but when that error follows a normal distribution, the least-squares estimates of the b's are the same as the maximum-likelihood estimates.

Ordinarily, it is assumed that the random errors $\varepsilon_1, \cdots, \varepsilon_n$ are independent and have mean 0 and common variance σ^2; it is also assumed that they are the only source of random variation in the data. As a result, the estimated coefficients $b_1, \cdots, b_r$ vary randomly with mean values $\beta_1, \cdots, \beta_r$. When the ε's are normally distributed, the vector $b = (b_1, \cdots, b_r)$ will have a multivariate normal distribution. This fact can be used in setting a confidence region for β or a confidence interval for any single β_j.

Certain hypotheses about the model may be tested: is the carrier U_j necessary (usually posed as H_0: $\beta_j = 0$ versus H_1: $\beta_j \neq 0$)? Does the model adequately describe the data? The basis for many such tests is the component of the data that remains when the fitted model is subtracted. For each observation this component is called the residual: it is a typical term (see 82) that appears squared in the sum of squared deviations. The relationship between the residuals and other elements of the model is often examined graphically. Systematic patterns in such plots can show that assuming a common variance σ^2 for the ε's is suspect, that the data have additional structure (to be fitted by adding a carrier to the model), that some U's should have a different form, or that another function of Y is more nearly linear in the U's than the present Z.

$$(80) \quad Z = \beta_1 U_1 + \cdots + \beta_r U_r + \varepsilon$$

$$(81) \quad \sum_{i=1}^{n} [z_i - (b_1 U_{1i} + \cdots + b_r U_{ri})]^2$$

$$(82) \quad z_i - (b_1 U_{1i} + \cdots + b_r U_{ri})$$

$$(83) \quad \hat{y} = A(b_1 x_1 + \cdots + b_k x_k) + B$$

While fitting by ordinary least squares, assuming the common variance σ^2 for the ε's, is usually the first step in regression, it is quite sensitive to the presence of contamination or wild observations in the data. Consequently, a different analysis can be undertaken, based on a pattern of unequal variances or fitting the model by minimizing the sum of absolute-value deviations instead of the sum of squares.

For these calculations, as well as in graphical examination of the data and the model, the computer has become an indispensable tool. The discriminant function illustrates one use of linear regression in biology, medicine, the humanities, and the social sciences.

When no one property correctly classifies objects into their populations, measures on several properties may improve the process. The linear discriminant function applies multiple regression for this purpose. If $X_1, \cdots, X_k$ are the variables used to aid the classification, $Y = 0$ is defined for objects in population Π_0 and $Y = 1$ for those in population Π_1. Using data for objects that can be correctly assigned to Π_0 and Π_1, least squares is applied to predicting y from $(x_1, \cdots, x_k)$. The discriminant function is a linear function, with parameters A and B, of a linear combination of the $\{x_i\}$ in which the coefficients are $\{b_i\}$ (see 83). The parameters A and B are arbitrary scaling factors chosen for convenience, and the b_i are the least squares regression coefficients. These b_i, it can be shown, separate the y scores of the populations as widely as possible. To classify new objects, one chooses a cutoff score y_0, and values above it are classified as belonging to Π_1, below it to Π_0.

For example, the rates of use of the words *and, in, of, the,* and *to* by Alexander Hamilton and James Madison in political writing led to the discriminant function

$$\hat{y} = -3.014 - 0.0195x_1 + 0.0301x_2 + 0.0547x_3 - 0.0167x_4 + 0.0420x_5.$$

Here a piece of writing by Hamilton is scored 1 and a piece by Madison 0. The rate of use per 1,000 words of the word numbered i above is x_i. A cut-point, here 0.5, is chosen, and a piece of writing scoring higher is assigned to Hamilton, lower to Madison. Thus a new paper known to be written by one of these two authors having rates $x_1 = 30$, $x_2 = 20$, $x_3 = 60$, $x_4 = 100$, $x_5 = 40$ would score $\hat{y} = 0.295$ and be classified as by Madison.

Steam Power

Steam, or vaporized water, is a basic power source for industrial civilization. Steam power is indispensable in the manufacture of steel and other metals, in oil refining, and in the production of chemicals and many other products. It is used to drive the turbogenerators that furnish the major portion of electric power, to convert nuclear energy into mechanical energy, and to operate heavy transportation machinery.

HISTORY

Steam power before the Watt engine. The first recorded use of steam to produce motion was a simple reaction turbine built by Hero of Alexandria about AD 100.

Though Hero's demonstration of the reactive power of steam had tremendous potential, it was centuries before any attempt was made to give it practical value. In 1784 Baron von Kempelen of Pressburg (modern Bratislava, Czechoslovakia), attempted to develop a reaction turbine similar to the reaction water, or undershot, wheel. When James Watt in Scotland heard of von Kempelen's work, he correctly concluded that a wheel capable of moving fast enough to absorb the energy from steam could not be made with then-existing technology.

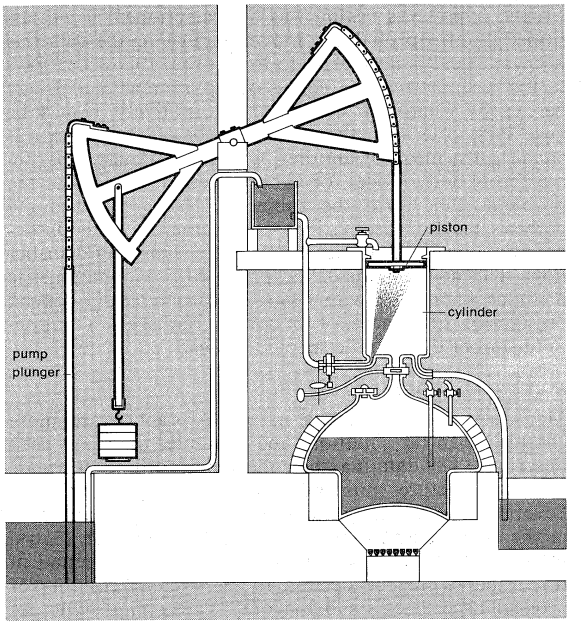

Figure 1: Newcomen engine (see text).

Savery pump and Newcomen engine

Meanwhile, an entirely different line of development led to Watt's steam engine. The problem of raising water from mines had long attracted engineering attention when, in 1698, Thomas Savery, an English military engineer, patented a pump for "raising water by the impellent force of fire." Savery's pump consisted of a boiler, a closed vessel called a receiver, one-way valves in the water inlet and the outlet of the receiver, a steam supply line from boiler to receiver with a shutoff valve, and a waterline with a cock for spraying water on the exterior of the receiver. The pump was operated by hand manipulation of the steam-supply and water-spray valves. When the steam valve was opened to supply steam to the water-filled reservoir, steam pressure forced the water out through the one-way-outlet valve. When the water was all expelled from the reservoir, as indicated by the clatter of the outlet valve, the steam valve was closed. The water cock was then opened and water sprayed over the surface of the reservoir, condensing the steam and creating a vacuum. Atmospheric pressure in the mine caused water to flow into the reservoir. The vacuum created in the reservoir was not perfect, so atmospheric pressure was capable of lifting water only about 20 feet (6 metres). The steam-powered discharge was also limited, owing to the inability of the boilers of that day to withstand high pressure. Direct contact of the steam and water within the reservoir not only caused a heat loss but the steam pressure had to be at least equal to the pressure represented by the height to which the water was pumped.

Thomas Newcomen of Dartmouth, Devon, England, and his assistant, John Calley, developed the first piston-operated steam engine in 1712.

The Newcomen engine (Figure 1) consisted of a cylinder fitted with a piston. When the cylinder was filled with steam the counterweighted pump plunger moved the piston to the extreme upper end of the stroke. With the admission of cooling water, the steam condensed, creating a vacuum. The atmospheric pressure acting on the piston caused it to move down in the cylinder, and the resulting force acting upon the beam lifted the pump plunger. The steam was condensed, at first, by applying the cooling water to the exterior of the cylinder. When this was found to be too slow, the water was sprayed inside the cylinder. Another problem was that air and other noncondensable gases accumulated within the cylinder causing

the engine to stop after a few strokes. This difficulty was overcome by allowing some steam to blow out each time the cylinder was filled. The valves for admitting steam and condensing water to the cylinder were first operated by hand. Later they were operated by the motion of the engine so that after start-up the engines became self-actuating.

Savery and Newcomen probably worked independently in the development of their quite different types of engines. Since, however, Savery's patent included a reference to "creation of a vacuum by the condensation of steam," it was necessary for Newcomen to enter into a partnership with him. Before Newcomen's death in 1729, numerous pumping engines were in use in England and in several other European countries.

The practical success and usefulness of the Newcomen engines is proven by their long service record. A few with separate condensers and other features introduced by Watt were built as late as the 1800s. As mining operations changed, the pumps were moved to new locations and sometimes modified. Some are known to have remained in operation until the early part of the 20th century when they were replaced with electric pumps.

Watt's engine. In 1765 James Watt, an instrument maker in Glasgow, modified a Newcomen engine with a separate condenser to make it unnecessary to heat and cool the cylinder with each stroke. Because the cylinder and piston remained at steam temperature while the engine was operating, fuel costs dropped 75 percent. In 1769 Watt obtained a patent for his "new method of lessening the consumption of steam and fuel in fire engines." He entered into a partnership with Matthew Boulton who owned the Soho Manufactory at Birmingham, England. In 1775 the House of Commons extended the patent for 25 years.

Boulton and Watt sold engines on a basis that was to give them one-third of the saving in fuel from that required by a Newcomen engine. Watt made extensive tests to establish the comparative steam requirements of his engine with those of the common engine.

At Boulton's insistence, Watt applied his great inventive ingenuity to developing a new kind of engine which rotated a shaft instead of providing simple up-and-down motion. Watt found a way to obtain an inflexible connection between piston and piston rod (beam), and invented special gear arrangements to convert the up-and-down movement of the beam into circular motion. A heavy flywheel was added to smooth out the variations in the force delivered to the engine shaft by the action of the piston in the cylinder. An ingenious governor, connected to the flywheel, regulated the flow of steam to the engine. Watt, furthermore, applied steam to both sides of the piston to produce greater uniformity of effort and increased power, and invented packing glands which sealed against steam leakage where the piston rod passed through the cylinder head. Though far more difficult to build, Watt's rotative engine created an entirely new field of application. The rotative engine was immediately accepted, and it is estimated that by 1800 the partnership had built 500 engines, of which 38 percent were pumps and 62 percent were of the rotative type.

Owing to the inherent weakness of the boilers and Watt's emphasis on safety, steam pressures remained at five pounds per square inch. Though Watt understood the advantages of the use of the expansive powers of steam within a cylinder and the use of compound engines, neither was economically attractive at the low steam pressures Watt employed. In a compound engine, high pressure steam is supplied to one cylinder, the exhaust from it is then admitted to a second, the exhaust from the second to a third, and in some cases from the third to a fourth. Each cylinder is larger than the preceding one because of the increase in steam volume as the pressure is reduced.

Watt's pressure indicator

Watt also invented a device which graphically indicated the pressure inside the cylinder of the engine. This invention is still used to test the performance of engines and to adjust them for maximum efficiency.

Development of high-pressure boilers. The first instance of the successful generation of steam for a practical application was the pressure cooker invented in 1680. From this beginning developed the steam boiler, soon widely used in conjunction with the Newcomen and Watt engines. Early boilermakers observing that a hollow vessel usually assumes a cylindrical or spherical shape in response to internal pressure, designed their boilers accordingly. Flat plates, required where water and steam tubes were connected, were supported to prevent bulging.

Shells were constructed of steel plates joined together by rivets. The technique of joining boiler plates by rivetting was highly developed before welding replaced it in the 20th century.

Since Watt's engines used low-pressure steam, simple boilers were adequate and there was but little development in design. By the latter part of the 18th century, two types of boilers had developed. In one, the fire-tube boiler, hot gases in tubes heated the surrounding water. In the other, the watertube boiler, the fire is external to the tube.

Though these first watertube boilers were not very successful, they showed great promise, and development of them continued throughout the 19th century. By the beginning of the 20th century, quite sizable watertube boilers were in common use.

GENERATION OF STEAM

Steam boilers. The modern boiler, like its earliest forerunners, is basically a closed vessel supplied with water which is transformed into steam by heat. But because the pressure at which the steam is generated determines the temperature of the water inside the boiler, the ability of the boiler to withstand pressure is critically important. The application of more heat to the boiler produces additional steam at a constant temperature, provided the pressure does not change.

Pressure requirements

Required operating pressure is a major consideration in the selection of a boiler. If the steam is to be used for heating purposes, the required temperature determines the operating pressure. When steam is used to generate power the pressure must be sufficient to meet the requirements of the steam engine or turbine. Generally, higher pressure results in greater efficiency of conversion from heat to mechanical energy. Pressure is an important consideration when steam from the same source is used both for power generation and heating.

Boilers must be selected to meet specific pressure requirements, and pressure rating determines design. All components must withstand not only the pressure but also the accompanying high temperatures. Though the steam piping and valves on a high-pressure boiler are smaller than those on a low-pressure boiler of comparable capacity, they must withstand higher temperatures. Other considerations include provisions for circulation of the water in the boiler to carry away the heat transmitted through the surfaces and separation of steam from the water to assure that the steam discharged from the boiler is as free of water particles as possible.

Superheated steam

Steam is designated as superheated when it is heated beyond the temperature at which it is produced by boiling water. Superheated steam is produced by passing the steam discharged from the boiler outlet, usually the steam drum, through tubes that are exposed to hot gases. Superheaters, usually installed within the boiler casing, absorb radiant and convective heat from the boiler furnace. In some instances, however, separately fired superheaters are used. The amount of superheat must be controlled since piping systems, engines, and turbines are designed for a given temperature.

Superheaters add to boiler cost since they must be constructed of nickel or molybdenum steel and because additional controls are required, but this added cost can be justified by improved economy.

The heat, absorbed by the boiler in generating and in superheating, is produced by burning fuels such as coal or oil or from hot gases discharged from industrial processes. In order for it to operate at maximum efficiency, as much heat as possible must be transferred from these gases to the water inside the boiler. This is accomplished by providing as much internal heating surface in the boiler as possible, consistent with initial costs.

At high pressures the water in the boiler is at a correspondingly high temperature, so the heating gases leave the boiler at elevated temperatures and much heat may be wasted. To prevent this, heat-recovery equipment is employed. Such equipment may be designed to heat the water before it is fed into the boiler drum, or to heat the air for combustion before it is introduced into the furnace. The equipment used to heat the feedwater is referred to as an economizer, while that which heats the combustion air is an air preheater. In some plants both economizers and air preheaters are installed. The type and size of a heat-recovery unit used depends on fuel costs, fuel analysis, the extent to which the plant will be operated at or near capacity, and other considerations.

Fire-tube boilers. Fire-tube boilers, so-named because the hot gases circulate through tubes to heat the water surrounding the tubes, are extensively used. Tube arrangement may be vertical, horizontal, or inclined. For applications in which weight and space limitations exist, the boiler and combustion equipment (firebox) are constructed in a single unit. The firebox is made of a double wall of steel plates arranged to leave a space between the plates for water. These plates must be internally reinforced to resist steam pressure. The horizontal-return tubular boiler (Figure 2), a fire-tube boiler formerly widely

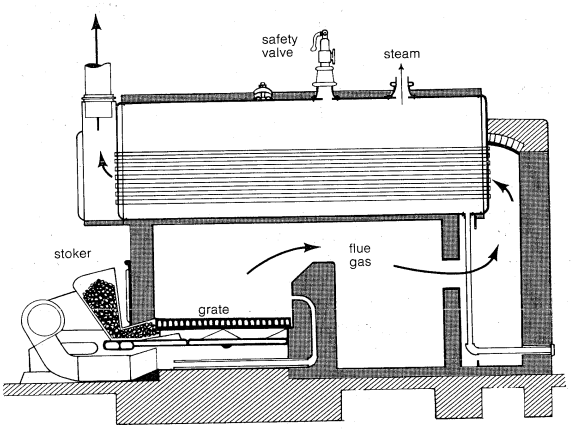

Figure 2: Early horizontal-return fire-tube boiler with single-retort-underfeed stoker.

used in plants for heating and power generation, has a cylindrical shell of steel plates. Tubes that extend through the shell from one head (flat end) to the other provide the major part of the heating surface and serve as stays for a section of the heads.

The shell is placed in a brick-walled enclosure, lined with refractory materials capable of withstanding high temperatures. Boilers may be fired with solid fuels by hand, or mechanically with stokers, or oil or gas can also be used. Combustion of the fuel begins in the front of the unit and continues as the gases pass over a low separating wall made of firebrick, called the bridge wall, and under the boiler shell. Thus, the shell is exposed to the radiant heat from the solid fuel bed on the grate, or flame from the oil or gas burner. The hot gases (combustion products) pass through the tubes and out the stack. These boilers, though limited in maximum pressure and capacity, are very reliable.

Package boiler

The fire-tube principle has been adapted to present-day requirements in the low-cost, prefabricated, and easily installed package-type boiler, which consists of a large shell mounted on a steel foundation, with flat heads (tube sheets) welded to each end. A flue (large tube) and a number of smaller tubes extend through the shell from one tube sheet to the other. The ends are secured to prevent the tube sheet from bulging from the pressure and to resist leakage. This assembly provides the complete unit for the section of the boiler subjected to steam pressure. Since the flue is exposed to the intense heat of combustion, it is usually corrugated around its circumference to allow for expansion.

The oil- or gas-burner flame is directed into the flue that serves as the combustion chamber. Some of the heat is absorbed by the water by transfer through the walls of the combustion chamber; the remaining heat is discharged in the products of combustion (gases) that enter a compartment at the rear of the boiler and are directed back through a section of tubes toward the front, where they are again reversed and pass through another section of tubes toward the rear, completing three passes through the boiler. Some boilers are designed for four gas passes. Three-pass boilers have flue connections in the rear; four-pass boilers in the front. In some designs the compartments in the rear of the boiler, where the gases reverse direction, are lined with heat-resistant materials while in others they are constructed of water-cooled steel plates.

The package boiler has burners, air-supply fan, and controls mounted directly on its front. The fan supplies pressurized air for the burner, where the fuel and air are mixed in correct proportions for efficient combustion. The pressure developed by the fan not only delivers the air to the burner but also forces the products of combustion through the combustion chamber, tubes, and out the smoke stack, which need be only high enough to prevent a nuisance and meet antipollution requirements.

These boilers may be made essentially automatic in operation with controls that vary the fuel supply to meet the steam demand and regulate the air supply to maintain efficient combustion. Safeguards are provided to prevent the boiler from starting up if safe conditions do not exist and to shut the unit down if unsafe conditions develop in the course of its operation. There is a wide variation in legal requirements for boilers and plants, most of which are based on steam capacity and pressure.

Packaged fire-tube boilers are extensively used in supplying steam for space heating and for industrial process requirements. Completely factory-assembled, they may be transported as a single unit, lowering costs. Installation time is reduced since no special foundations are required, and it is necessary only to connect the water, fuel and electric power supplies, drain, and steam and flue gas outlets. The compactness of these units is also an advantage.

Watertube boilers. The watertube boiler, in which the hot gases surround the tubes and the water flows through the tubes, permits the designer to provide almost any amount of heating surface required. The steam drum containing the reserve supply of water is relatively large in diameter and must, therefore, be made of thick plates to withstand the pressure. Advantages of watertube boilers include adequate circulation so that steam formed on the tube surfaces is rapidly carried to the steam drum, reduced hazard in the event of tube failure, and less costly repairs.

Optimum heat transfer

The drum or drums and tubes are the essential components which must be made to withstand steam pressure. Many arrangements are used to provide optimum transfer of heat from the hot gases, circulation of water within the boiler, separation of water from the steam before it leaves the drum, and expansion of the drums and tubes owing to variations in temperature.

Early watertube boilers were encased in brick settings that enveloped the pressure section, provided space for the furnace where the fuel was burned, and directed the hot products of combustion around the exterior of the tubes. To maximize heat transfer, restrictions (baffles) were installed. These forced the products of combustion to flow through the bank of tubes several times before being discharged to the stack.

Boiler tubes originally were installed close to the furnace to maximize heat transfer from the high-temperature bed of burning fuel. It was found, however, that this arrangement did not allow enough space and time for complete combustion; gases leaving the fuel bed entered the tube bank and were cooled before all combustible material had been burned. Part of the heating value of the fuel was lost, smoke was discharged from the stack, and soot formed on the tube surfaces retarding the rate of heat transfer.

Design was directed toward boilers with larger capacity and improved efficiency. These larger boilers were set

higher above the fuel bed, permitting the gases to travel further before coming in contact with the tubes. The increased distance, however, meant that less heat was radiated to the tubes. This resulted in a higher temperature in the fuel bed and furnace. When temperatures exceeded the softening point of the ash in the fuel, clinkers formed in the fuel bed, restricting the flow of air. High temperature combined with the action of the ash resulted in the rapid deterioration of the furnace refractory (firebrick) walls. Particles of ash adhered to the boiler tubes, decreasing heat transfer and, in extreme cases, restricting the flow of gases.

Large steam-generating units are now made by combining adequate space for fuel combustion with a furnace able to withstand the high temperatures developed (Figure 3). Experience with different fuels dictates the required furnace configuration and volume. The furnace enclosure is made of tubes placed side by side, sometimes welded to form a solid steel wall. These tubes (waterwalls) contain water and are actually part of the boiler. The waterwall tubes absorb heat and thereby reduce the furnace temperature, while adequate furnace volume is provided to obtain efficient combustion of the fuel.

By courtesy of the Babcock & Wilcox Co.

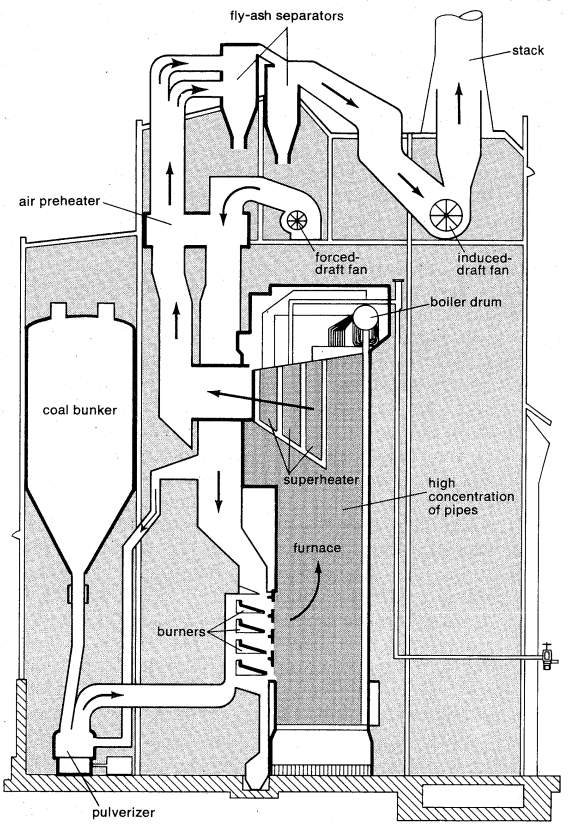

Figure 3: Cross section of a typical central-station boiler.

These large watertube boilers with waterwall furnaces provide adequate furnace volume, reduce furnace maintenance, permit the use of preheated combustion air and decrease the required building size. Such a design allows highly preheated air to be employed for combustion, thus permitting the use of air preheaters and increasing overall efficiency. The large quantities of fuel burned in these boilers justify the use of such heat-recovery equipment; both air preheaters and economizers are frequently installed on the same boiler. Superheaters are also an integral part of such units. After leaving the drum the steam passes through the superheater tubes and is heated to the specified temperature before being discharged into the station piping system.

Water supplies and treatment. Water must be supplied to the boiler in quantities equal to the rate at which steam is being generated. The water normally available contains impurities in the form of suspended solids, dissolved solids, and gases. Oxygen contained in the feedwater and carbon dioxide produced within the boiler may leave with the steam. These gases cause corrosion and other problems. The boiler may corrode, or become embrittled, losing strength. Impurities may produce scale, which by impeding the flow of heat causes the tubes to become overheated and to fail. Foam may form on the surface of the water in the drum and cause moisture and impurities to leave with the steam, creating deposits in the steam lines. Impurities cannot be tolerated in cases in which the steam comes in contact with the product.

To prevent these conditions from arising, the boiler water must be conditioned. Such conditioning includes treatment before it enters the boiler, the addition of chemicals to the boiler, and draining some water from the boiler to prevent excessive buildup of impurities. Pretreatment of water includes settling to remove suspended solids and the addition of chemicals to remove dissolved impurities or to convert them to a less objectionable form. Dissolved gases are removed, and chemicals are added to the water in the boiler to prevent its impurities from forming scale and to prevent it from corroding or foaming.

Recycling water

Recycling the water in a power plant is accomplished by returning the condensed steam (condensate) from the heating coils and condenser to the boiler. Except for possible leakage of cooling water into the condenser and leakage into the heating coils, the condensate is free from impurities. The use of condensate vastly reduces the amount of water that must be treated in a steam-generating plant.

Fuels. Fossil fuels such as coal, oil, and gas contain carbon and hydrogen as essential heat-producing elements. One pound of carbon combines with oxygen to develop 14,540 British thermal units of heat, while one pound of hydrogen develops 62,000 British thermal units. A British thermal unit (BTU) is the quantity of heat required to raise the temperature of one pound (453 grams) of water 1° Fahrenheit at or near 39.2° F (4° C). Air (about 23 percent oxygen and 77 percent nitrogen by weight) is used to supply the oxygen.

Boiler furnaces bring the fuel and air into contact at elevated temperatures in order to effect a complete chemical reaction (combustion) of the carbon and hydrogen. To obtain complete combustion more air must be added than that theoretically required. This excess air results in the presence of oxygen and additional quantities of nitrogen in the products of combustion (flue gases).

Coal is the principal fossil fuel used in steam generation. Combustion of coal leaves ash, an inert material that must be disposed of. Moreover, ash frequently forms into large chunks called clinkers and the fine particles (fly ash) are carried along with the flue gases, thereby leading to possible pollution of the atmosphere. Coal burning plants therefore include ash-handling equipment and collectors for removing a large portion of the ash from the gases before they are discharged from the stack. Sulfur, another troublesome impurity in coal, provides only a small amount of heat, but the sulfur dioxide and sulfur trioxide in the products of combustion are highly corrosive and objectionable atmospheric pollutants.

In early plants, coal, burned on stationary grates, was introduced into the furnace by hand. The air required for the combustion came up through the grates, from which the ashes were removed by hand. As boilers increased in size, hand firing became impractical and mechanical means of conveying fuel to the boiler and feeding it into the furnace were devised. Three basic types of mechanical feeders, or stokers, are in common use.

Basic types of stokers

1. The chain- or travelling-grate stoker consists of a front and a rear sprocket (circular-toothed gear) and a moving grate on which the fuel bed slowly moves through the furnace. Fuel is fed on the grate from a hopper located at the front of the furnace. Upon entering, the fuel is ignited and continues to burn as it moves through the furnace. The ash is discharged as the grates pass over the rear sprocket. Feed rate is varied by adjusting the speed of travel and the depth of coal on the grate.

2. The underfeed stoker employs a ram pusher or screw to force the coal into the furnace, injecting it beneath the

burning fuel bed. Fuel is distributed inside the furnace by moving or inclining the grates. Ash is removed from smaller units by periodic dumping of a section of the grates. In larger units, ash is removed continuously by a power-driven rotary ash discharge (clinker grinder).

3. The spreader stoker simulates continuous hand firing. Coal is supplied at a controlled rate to a power-driven rotary distribution mechanism that throws it into the furnace. Some combustion takes place while the fuel is being thrown through the high-temperature furnace, and the remaining combustion takes place after the fuel falls on the grates. In smaller installations, ash is removed by hand cleaning of stationary or dumping grates. Multiple feed and distribution units must be used since one must be out of service during cleaning. Large spreader-stoker units employ moving grates; ash removal is continuous.

Large watertube boilers with waterwall furnaces utilize pulverized fuel to generate heat. Particles of various degrees of fineness are employed, depending on the specific fuel and the combustion equipment. The fine particles are blown into the furnace by a stream of primary air. Here the fuel is ignited and the required secondary air is added. In this way the fine fuel particles are thoroughly mixed with the air and are burned in suspension as they pass through the furnace.

Fuel oil used to generate steam is divided into several classes according to its specific gravity (that is, its density compared to water). Lighter grades are used in domestic furnaces and for standby service to supplement other fuels. Heavier grades are burned in power boilers. In order to obtain efficient combustion, the oil is broken up into fine particles (atomized), so that it will mix with the combustion air. Heavy oils are heated in order to reduce their viscosity and improve their pumping and atomizing characteristics.

Gas, either natural or man-made, is another fuel widely used for steam generation. Natural gas is widely distributed by pipeline systems. In some instances gas is manufactured as a by-product from coke ovens, blast furnaces, and oil refineries. The gas is introduced into the combustion chamber and burned to provide heat.

In addition to the conventional fuels, certain waste products such as scraps from sawmills and woodworking plants, paper-mill sludge, sugarcane fibres (bagasse), and combustible material in rubbish are employed.

Heat for steam generation is also produced by nuclear reactors. In this case, the boiler and furnace which utilize fossil fuel are replaced by a reactor (see also NUCLEAR REACTOR).

STEAM ENGINES

Development and operating principles. Though relatively inefficient, the steam engine is, nevertheless, a most important device for the conversion of heat into mechanical energy. A piston moving back and forth within a cylinder uses steam to perform work. When steam pressure is exerted on one side of the piston, the resulting force causes it to move the length of the cylinder. Then the steam is applied to the other side of the piston and it moves in the opposite direction. This reciprocating motion is changed into rotary motion of the engine shaft by means of a connecting rod and crank. During the operation the cylinder is alternately filled with steam from the high-pressure supply line and exhausted at a lower pressure. In this way a portion of the heat in the steam is converted into work.

The amount of work delivered by one stroke of the engine (one traverse of the piston within the cylinder) is the product of the average force on the piston times the distance of travel. The force can be increased by the application of higher-pressure steam or by discharging the exhaust steam at a lower pressure.

Simple and compound reciprocating engines. A conventional double-acting steam engine admits steam alternately to each end of the cylinder, resulting in two power-producing strokes for each rotation of the crankshaft. Steam is alternately admitted to and discharged from each end by means of a D-slide valve, so-named because it has a cross section shaped like the letter D. This valve is moved back and forth over the steam passages (ports) to the cylinder by a connection to the engine shaft. The arrangement is adjusted to open and close the ports when the piston is in the correct position to receive and exhaust steam.

Engine speed is controlled by a flyball governor (so-named because it employs two small spinning balls to actuate the valve-controlling mechanism) driven by a belt from the engine shaft. When engine speed increases, the governor slowly closes the steam supply valve, reducing the pressure of the steam admitted to the cylinder and, when speed decreases, the governor slowly opens the steam supply valve.

Engine efficiency

Engine efficiency is improved by having the steam supply to the cylinder shut off, before the piston reaches the end of the stroke. After the supply is cut off, the steam in the cylinder expands and continues to push the piston, but with a continuous decrease in pressure. The power output from a cylinder can be effectively controlled by varying the point of steam cutoff.

Control of the point of steam cutoff cannot be obtained with a simple D-slide valve without also changing other valve functions. This and other disadvantages prompted modification of the D-slide valve and development of other types of valves. The piston valve, for example, permits the use of higher pressures and more superheat. By adding an extra component called a riding cutoff to a D-slide and piston valve, the cutoff can be controlled without varying the other functions of the engine cycle; an engine with a riding cutoff controlled by a flywheel governor is called an automatic engine.

A type called a Corliss-valve engine employs separate intake and exhaust valves at each end of the cylinder (four valves per cylinder) to permit separate control of steam admission and exhaust. The admission valve is not cooled by the exhaust steam. The design also provides for quick closing of the admission valves. Poppet- (perpendicular-) valve engines, which also have separate valves for intake and exhaust, can use highly superheated steam.

The flow of steam in and out of an engine cylinder results in the loss of heat from the heating and cooling of the cylinder (cylinder condensation). The greater the temperature difference between the steam supply and exhaust, the greater the heat loss. This loss is reduced, therefore, by the use of compound or multiple-expansion engines in which high-pressure steam passes through three or four successively larger cylinders. When each cylinder has a connecting rod and crank to deliver its power to a common shaft it is called a cross-compound engine. Tandem-compound engines have the cylinders located in line and a common piston rod, connecting rod, and crank.

The uniflow engine provides another means of reducing cylinder condensation. Steam enters at the end of the cylinder and leaves through exhaust ports located near the middle of the cylinder. Perpendicular or poppet valves admit the steam; the piston uncovers the exhaust ports. Only steam flows through the supply ports and exhaust through the discharge, thus eliminating the repeated heating and cooling which occurs in other designs.

Turbines. The steam turbine changes the heat energy in steam into mechanical energy by discharging the steam through nozzles, where its heat energy is transformed into energy due to velocity. The stream of high-velocity steam strikes vanes on the moving element of the turbine (rotor) causing the rotor to turn. For a given steam supply and exhaust system, the identical amount of heat is available for conversion into mechanical energy whether a moving-piston engine or a steam turbine is used. Thus the useful output of energy depends upon the efficiency of the engine or turbine.

Impulse and reaction turbines

The steam turbine employs both the impulse (forward) and reactionary (backward) forces resulting from the discharge of steam through nozzles and both principles are frequently employed in different sections of the same turbine. In impulse turbines, the nozzles are stationary and the high-velocity steam expends its energy moving

the blading. In a reaction turbine the steam is discharged from moving nozzles against stationary blades or vanes.

Steam supply pressure, superheat, and exhaust pressure all determine the amount of heat energy available to a turbine. The turbine's ability to convert the energy into useful work depends upon many factors involved in turbine design. The best transfer of energy occurs when the turbine blade is traveling about half as fast as the steam discharged from the nozzle. To achieve this velocity ratio, the designer regulates pressure drop in the first set of nozzles and employs several sets of nozzles arranged in sequence to utilize the full amount of the steam pressure. Optimum blade shape, and the use of finely ground and polished surfaces contribute to improved efficiency. When the exhaust steam is used for heating, the conversion efficiency is less important and the added cost for multiple sets of nozzles cannot always be justified.

The energy output of a turbine, and hence its speed, is controlled by a governor. In its simplest form a single valve governor regulates the pressure of steam supplied to the first set of nozzles. When the turbine is operated at less than rated capacity, efficiency may be improved by the use of multivalve control, in which the governor opens a series of valves in sequence as load requirement increases. Each valve supplies steam to a nozzle or set of nozzles. Full pressure is applied to one set before steam is admitted to the next. Turbine governors are very responsive and capable of maintaining the accurate speed control required to drive alternating current generators.

Steam turbines are ideally suited to use high pressure, highly superheated steam, since the steam does not come in contact with lubricated surfaces. Steam temperatures are limited by the material used in construction of the turbine. Provision must be made to reduce leakage around the shaft at the inlet, outlet, and between stages. Small- and medium-sized turbines for moderate steam conditions use carbon-seal rings held against the shaft by springs. Large turbines using high-pressure and high-temperature steam have packing consisting of a grooved shaft running with close clearance inside a grooved sleeve. Because of the close clearances, careful consideration must be given to movements resulting from expansion and to vibration. The rotating elements must be accurately balanced. Minimum vibration is the goal of every turbine manufacturer. Pressure lubrication in which oil is supplied to the bearing under pressure and is then cooled contributes to low maintenance costs.

The versatility of the steam turbine makes it suitable for many industrial applications. Turbines are used to drive fans, pumps, air compressors, presses, and similar equipment; their speed may be controlled to meet almost any requirements. Efficiency decreases, however, when turbines are operated at partial load and reduced speed. Mechanical steam-drive turbines are especially attractive in installations in which the exhaust steam can be used for process and/or space heating, because the heat energy changed to power is very small. Mechanical drive turbines are also used for emergency electric generators and fire pumps. These may be arranged to start automatically when an emergency arises.

The most extensive use of steam turbines is in central electric power stations in which they are used to drive electric generators (see also ELECTRIC POWER). High initial steam pressures and temperatures and low exhaust pressures are used to obtain optimum efficiencies. Further economy is obtained by reheating the steam. When steam has expanded part way through the cycle, the temperature and pressure having been reduced, it passes through a superheater (reheater) in which heat is added and the temperature increased before expanding through the final stages of the turbine.

Regenerative cycle

Since pressure is reduced in the consecutive stages of a turbine, steam at any desired pressure can be removed if connections are provided in the casing. This feature provides a versatile means of balancing power and heating requirements since the steam can be expanded in the turbine until it reaches the pressure required for heating. This principle is applied in electric generating plants to what is called a regenerative cycle. Steam from several stages of the turbine is used progressively to heat the condensate (water discharged from the condenser) on its way back to the boilers. This improves efficiency by reducing the steam flow to the condenser, and hence the heat rejected to the cooling water. The required extraction points to meet steam heating requirements must be incorporated in turbine design.

Utilization of high-pressure and more efficient condensers. Sadi Carnot (1796–1832), a French engineer, established the relation between the temperature of the working fluid and its mechanical effect. In 1824 he published a paper stating that the optimum conversion of heat energy to mechanical energy is the absolute temperature leaving the boiler less the absolute temperature of the vapour in the condenser, divided by the absolute temperature leaving the boiler. Stated in a formula: Efficiency $= (T_1 - T_2)/T_1$. Applied to steam power, T_1 is the absolute temperature (degrees Celsius +273, or degrees Fahrenheit +460) leaving the boiler, and T_2 is the absolute temperature of the vapour in the condenser. This represents the maximum possible theoretical efficiency and serves as a useful means of evaluating results. It cannot be attained in practice owing to losses which are inherent in physical equipment.

The efficiences of power generation have been continually increased by the use of higher and higher steam temperatures. This, in turn, has been made possible by the use of heat-resistant steel alloys in superheater tubes, piping, and turbine components. Temperatures in excess of 1,000° F (538° C) have been successfully employed. Because of the increased cost of material and more rapid deterioration of metals requiring costly maintenance and interruption to service, however, 1,000° F is the nominal upper limit of temperature.

As Watt discovered, a separate condenser is a satisfactory method of reducing the final (exhaust) temperature. The exhaust steam is condensed, the volume reduced, and a vacuum created. The pressure depends upon the temperature of the cooling water, efficiency of the noncondensible gas-removal equipment, and the heat transfer rate in the condenser.

There are two principal types of condensers, a jet condenser in which the cooling water and steam come into direct contact; and a surface condenser in which the cooling water flows through tubes that are surrounded by steam.

Jet condensers are seldom used in generating plants because the condensate is mixed with, and therefore contaminated by, the cooling water. This cannot be tolerated in high-pressure plants because of complications and the cost involved in conditioning the water supplying the boilers.

Widely used in steam electric generating plants, surface condensers contain thousands of small tubes, surrounded by vapour and through which water flows. The amount of cooling water required is from 50 to 100 units per unit of steam, depending upon the temperature rise which takes place in the condenser.

Since the pressure inside a condenser is below that of the atmosphere, there is a tendency for air to leak into it. This air, along with some gases carried along with the steam, collects in the condensers and is noncondensible, since it is not removed by the cooling action of water and must be exhausted by vacuum pumps.

Auxiliary equipment (valves, governors, etc.). Auxiliaries to steam engines and turbines include pumps, lubricating systems, condensers, and heaters. Accessories include piping, shutoff valves, governors, and safety devices.

Function of the throttle valve

The throttle valve admits steam for starting, and stops the engine or turbine by shutting off steam flow. In addition to hand operation for starting, the throttle valve is equipped with a tripping device, which causes it to close in the event an undesirable or hazardous condition develops. Some of the conditions which cause the throttle valve to close are excessive speed, loss of lubricating oil pressure, excessively high temperatures, reduced vacuum, and excessive vibration. During start-up, the throttle valve is opened by hand until the unit attains design speed, at which time the governor starts to function,

controlling the flow of steam and thereby the speed. Once in operation the engine or turbine is controlled automatically to run at nearly constant speed. The simplest type of governor throttles the steam supply and so regulates the steam flow to meet the demand for power. To improve the efficiency at partial load, more elaborate control is used. Engine governors vary the length of time during which steam is admitted to the cylinder and in this way make use of the expansive properties of the steam. Turbine governors admit full line-pressure steam to an increasing number of nozzles as the demand for power increases. In hydraulic-control systems, a centrifugal governor senses the shaft speed and regulates the oil flow to or from a hydraulic cylinder, which in turn positions the steam-supply mechanism. Failure to maintain the oil pressure in this system will cause the throttle valve to close and shut down the unit.

STEAM TRANSPORTATION

Locomotives. Early in the 19th century, English experimenters attempted to use steam engines to run vehicles on tramways. In 1802 Richard Trevithick, an English engineer, obtained a patent for his high-pressure engine and its application for driving carriages but progress was retarded by a boiler explosion alleged to have been caused by an operator having shut off the safety valve.

In 1829 the "Rocket" locomotive, invented by George Stephenson, an English engineer, proved superior in a trial involving three locomotives. At this time development was rapid, and in 1833 Robert Stephenson, the son of George, and himself an engineer, built a locomotive incorporating many features that were retained in future developments. The Stephenson link was a single lever by means of which the locomotive could be made to run either forward or backward, and intermediate positions of the lever controlled the point of cutoff and gave high-steam economy at light loads. These features were incorporated in larger locomotives operating at high pressures and with superheated steam. The steam locomotive retained its importance in transportation until the mid-20th century when it was replaced by diesel-powered locomotives (see also RAILROADS AND LOCOMOTIVES).

Ship propulsion systems. The steam engine has made many contributions to industrial progress, but none has been more important than that made to navigation. Of the many experimenters, the American, John Fitch (1743–98), was one of the first to obtain some degree of success and public recognition. He built several steamboats between 1786 and 1798.

In 1803 Robert Fulton, an American mechanical engineer, successfully operated a steamboat on the Seine River in Paris, but it was rejected in both France and England. In 1807 Fulton's side-wheeler, "Clermont," made a successful trip up the Hudson River from New York to Albany, a distance of 150 miles (241 kilometres) in 32 hours. In the same year Robert L. Stevens, an American engineer and naval architect, and his father, John Stevens, an engineer, constructed a successful paddle-wheel steamer, which was put in service between New York and New Brunswick, New Jersey (see also SHIP).

Reciprocating engines. A reciprocating engine built by Boulton and Watt was used to power Fulton's "Clermont." Improved reciprocating engines were subsequently used, and with the introduction of watertube boilers, referred to as "safe boilers," higher pressures were used. Higher pressures and the use of condensers prompted the use of multiple-expansion engines as a means for reducing fuel consumption. Evaporators were used to condition the seawater for use in the boilers.

Geared turbines. When turbines became practical they were quickly applied to ship propulsion, because they offered a means of developing the increased power required, weighed less, and occupied less space. Gear reducers are required to adapt the economical high-speed turbines to the low optimum speed of the ship propellers.

Road vehicles. The use of steam to propel road carriages dates from 1770 when a French artillery officer built a massive machine. The boiler was inadequate and it stopped every few hundred feet because of a lack of steam. In 1801 Richard Trevithick, a rival of James Watt, built a steam-driven carriage that operated on the streets of London.

Between 1824 and 1828, several coal-burning steam-powered coaches capable of carrying 20 passengers and attaining a speed of 20 miles (32 kilometres) per hour were operated in and around London. Progress on the development of steam-driven carriages was essentially stopped when Parliament passed a law requiring that a self-propelled wagon be proceeded by a man carrying a red flag in the daytime and a red lantern at night. Steam-powered coaches

The invention of the pneumatic tire and the discovery of liquid fuel resulted in great interest in motor vehicles in France, Germany, and the United States. In 1897 F.E. and F.O. Stanley, American inventors in Newton, Massachusetts, completed their first steam-driven car. Their success in competition in Boston, Massachusetts, in 1898, prompted them to continue to develop and build the steam cars. Their car won a speed trial by travelling one mile (1,609 metres) in 2 min 11 sec, not only exceeding the speed of the gasoline powered De Dion car but also the world's record of one mile in 2 min 32 sec. Furthermore, the Stanley was the only car capable of negotiating a 30 percent grade. In 1906 a Stanley steamer attained a speed of 127 miles per hour in the Dewar Cup race on the beach at Ormond Beach, Florida.

By the early 20th century there were several makes of steam-powered automobiles including Eclipse, Grout, Lane, Locomobile, Mobile, Stanley, Stearns, and White. In 1900, 34 cars were exhibited in Madison Square Garden, New York and of this number seven were steam-powered. In 1906, by carrying some supplies and tools, and with even limited mechanical ability, steam cars could be successfully driven on extensive tours.

Much ingenuity and technical knowledge was applied to the early steam-powered automobiles. Steam pressures in excess of 1,000 pounds per square inch were developed in the boilers. Some designs employed flash-type once-through boilers consisting of a single coil in which water supply to the coil and fuel feed to the burner were proportioned to evaporate all of the water in the first part of the coil with the remainder used to superheat the steam. Early engines exhausted the steam to the atmosphere, and additional water had to be supplied to the boiler. Condensers were introduced about 1915 and the resulting water recycled to the boiler. Some manufacturers connected the engine directly to the rear drive axle, while others located the entire power plant under the hood and transmitted the power to the rear wheels.

The steam-driven automobile is characterized by speed, smooth operation, and hill-climbing ability. The time required to develop steam pressure in the boiler, however, is a disadvantage. Extensive application of automatic controls and other advances have decreased the amount of attention required by the operator. The internal-combustion engine, however, requires even less attention.

Interest in steam-driven automobiles has continued. Consideration has been given to the use of steam drive to reduce the air pollution caused by the exhaust from the internal-combustion engine. Working substances other than steam have been tested to eliminate the problem of freezing in cold climates (see also AUTOMOBILE).

STEAM POWER PLANTS

Early individual plants. A steam-power installation consists of boilers, engines, and auxiliary equipment that uses fuel as raw material and produces mechanical power. The general use of steam power in mills began in 1782 when Watt developed the double-acting rotative engine. One of the first of these engines was installed in the Albion Mill at Blackfriars, London. Its success revolutionized the flour-milling industry and rotative engines were soon in use in many industries.

The replacement of waterpower by steam power was a great advantage to mills and industries. It meant that the mill or factory could be located close to raw materials, transportation, and markets rather than where there was waterpower. Whereas the availability of water to turn the waterwheel frequently had limited the size and output of

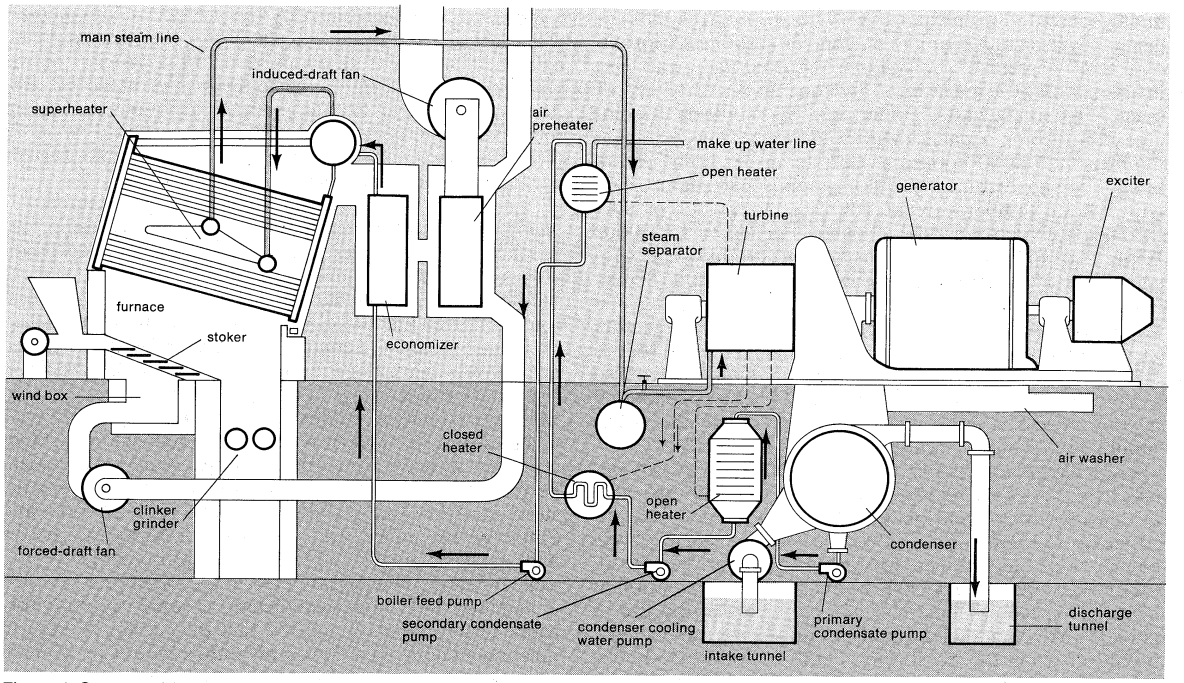

Figure 4: Steam turbine generating station with heat recovery equipment.

a mill, a steam plant could be built to meet the power requirements.

The use of steam to provide power for mills and factories was further enhanced by rapid development of the engine. By mid-19th century engine design was essentially standardized. Steam plants had become more compact, easier to operate, and more reliable and efficient.

Development of standardized design

The early use of steam engines in flour mills was extended to cotton gins, sugarcane mills, lumber mills, and grain-threshing machines. During the harvest season, portable threshing machines were moved from one farm to another; at first horse-drawn, they were later self-propelled. Steam-power tractors were used on large farms to cultivate the land and at harvest to pull combines which cut, threshed, cleaned and delivered the grain ready for market in one operation. Steam tractors were also used to replace horses and mules on construction work involving the moving of soil from excavations and for building dams. These steam-driven tractors were widely used from mid-19th century to mid-20th century, when they were largely replaced by internal-combustion engine drives.

Modern fossil-fuel plants. The power developed by steam engines was transmitted to the driven mill or machine by belts, shafting, or gears. The application of electricity created a new use for steam power. Steam engines were used to drive the electric dynamos. At first used only for lighting, electricity was soon found to be an excellent means of transmitting power. Power plants were increasingly used for generating electricity that could be readily transmitted to the mills and factories where it supplied motors that powered the machinery.

In 1880 Thomas A. Edison constructed a power station with a capacity of 7,200 lamps at 110 volts. An increasing demand for electricity resulted in the rapid development of a central steam plant. The service provided mill and factory operators with adequate power without requiring them to invest their capital in power plant equipment.

In a noncondensing power plant, typical of an early plant used for supplying steam for space heating and for industrial processing, in addition to electricity for power and lighting, the steam generated by use of fossil-fuel supplies the engine which generates electricity. The engine runs at constant speed and automatically admits sufficient steam to develop the required electric power. Exhaust steam from the engine flows to the heating system, process equipment and feedwater heater. When the exhaust steam is insufficient, steam is admitted from the boiler outlet through a pressure-reducing valve. Should the exhaust steam exceed the demand, the excess is wasted to the atmosphere through the back pressure regulating valve. A feedwater heater raises the temperature of the water supply to the boiler by the application of heat from the exhaust steam which would otherwise be wasted. The plant operates most efficiently when the electrical power demand on the engine results in an amount of exhaust steam equal to the combined heating requirements.

Central stations

The conventional central station, having only a limited use of steam for heating, must employ techniques for obtaining maximum amounts of electrical power from the fuel. These include (Figure 4) economizers and air preheaters to recover heat from the flue gases, superheaters to obtain a high-temperature steam supply to the turbines, condensers to reduce the turbine back pressure (pressure at the turbine exit), and heaters which use steam extracted from the turbines to raise the temperature of the condensate being returned to the economizers. The practice of using steam extracted from the various stages of turbines to heat the condensate is generally practiced in central stations.

Central station plants must be located accessible to the fuel and condensing-water supply. The electricity can be transmitted relatively long distances over high voltage lines. In a modern central power plant, coal received in railroad cars is dumped into hoppers and conveyed to overhead bunkers. The coal flows from bunkers to pulverizing mills and the resulting fine coal particles are then blown into the furnace. Radiant heat from the flame is absorbed by the water in the tubes which form the furnace walls and by the steam in the superheater. Additional heat is removed from the gases as they pass through the superheater-convection section of the boiler and the air preheater. Following the air preheater in the system, the precipitator removes dust particles from the gases before they pass through the fan and are discharged out the stack. Steam from the superheater drives the turbine and flows to the condenser where the latent heat is transferred to the condenser cooling water. A portion of the steam that flows through the turbine is, however, diverted from the condenser for use in the regenerative feedwater heating cycle. The returning condensate passes through the deaerating heater for removal of oxygen before being pumped through the economizer into the boiler. The electric power generated at 13,800 volts is stepped up to 114,000 volts for long-distance transmission.

An international survey of plants being designed and

under construction in the early 1970s dramatizes the tendency toward larger units for central stations. Approximately 40 percent of the turbines reported had a capacity in excess of 500 megawatts and one had a capacity of over 1,000 megawatts. Boiler size also reflects the increase in turbine capacity, with some exceeding 5,000,000 pounds (2,270,000 kilograms) of steam per hour. Steam is supplied to turbines at 3,500 pounds per square inch with a total temperature of 1,000° F and, after passing through the high-pressure turbine, is reheated to 1,000° F. Some of these plants are designed to produce one kilowatt-hour of electric energy on less than 8,000 British thermal units of fuel.

Nuclear power plants. Nuclear fuel is used in reactors to develop heat, producing steam that is then used to drive turbines. The reactors replace the fossil-fuel-fired boilers used in the conventional plant. The heat generated by the reactor is controlled so as to regulate the steam supplied to meet the requirements of the turbines.

In nuclear plants it has been quite difficult, if not impractical, to obtain highly superheated steam comparable to that used in conventional plants. In most cases saturated steam is used. This results in a decrease in the cycle efficiency of the turbines. In some cases separately fossil-fuel-fired superheaters have been used. Consideration is being given to methods of superheating steam by use of nuclear fuel. The nuclear plant produces less atmospheric pollution than the fossil-fuel plant but they both discharge large quantities of heat to the condenser water. The heat discharged is low level and not capable of generating power but adds thermal pollution to lakes and rivers. To eliminate this contamination, large cooling towers are being used to receive this rejected heat that is then dissipated to the atmosphere.

Almost all nuclear power central stations utilize the nuclear power to generate steam, which is then used to drive steam turbines. In some, steam is generated within the reactor (boiling-water reactor); in others, the water used to cool the reactor is pressurized to prevent boiling, and the steam generated in a separate heat exchanger (pressurized-water reactor). In western Europe some of the reactors are cooled by gases (high-temperature gas reactor), and gas turbines are used to generate electricity.

The nuclear-powered central station has proven to be a safe and dependable means of generating electricity. When compared with a conventional plant, however, costs are marginal, except in areas where fossil-fuel costs are high. Installations of nuclear-powered stations have been delayed by the reluctance of the public to accept the proposed sites, uncertainty regarding future fuel costs, and long-term delivery of equipment. Surveys show 11,000 megawatts of nuclear-powered central stations on order or being designed in the United States and 20,000 megawatts in western Europe. It has been estimated that of the 12,000 megawatts which will be installed in the United States by the year 2000, one-half will be nuclear powered, and the ratio will be even higher in western Europe.

OTHER APPLICATIONS OF STEAM POWER

Injector. The injector is a device that uses the energy derived by expanding steam through a nozzle to lift water and force it into the boiler from which the steam was obtained. The essential parts of an injector are the steam and suction jets, combining and delivery tube and ring, overflow and discharge tube. The velocity of steam discharged from the jet causes the water to be drawn into the combining chamber where the steam is condensed. The kinetic energy in the steam is transferred into the water which flows through the delivery tube into the boiler. Injectors, because of their compactness and simplicity, were widely used to supply water to small portable boilers, tractors, and locomotives.

Ejector. The ejector makes use of the kinetic energy developed by discharging steam through a nozzle to produce a vacuum. In modern power plants ejectors are used to remove noncondensible gases from surface condensers.

Ejectors are also used in processing operations where a product must be exposed to a vacuum.

Water can be refrigerated by the use of a steam ejector. The water is sprayed into a vacuum created by a steam ejector. This results in evaporation of a portion of the water and a lowering of the temperature of the remainder. For a chamber maintained at 0.12 pounds per square inch the temperature of the chilled water would be 40° F (4.5° C). This chilled water is then available for air conditioning or other cooling applications.

Pumps. The first practical application of steam power was for pumping water and this remains an important function. Steam pumps may be broadly classified as direct-acting and power-driven or rotary.

Direct-acting pumps have a steam piston and water piston or plunger that are directly connected by a rod. When the steam piston is actuated by steam, the water piston also moves, and water is admitted to and discharged from the water cylinder.

Piston or plunger pumps can be driven by engines or turbines, but in modern practice the high-speed turbines are used to drive centrifugal pumps. This arrangement permits a wide range of selection of turbine throttle, steam pressure, and temperature and exhaust pressure. Similarly, the centrifugal pump may be chosen to meet a wide range of capacity and pressure requirements.

Pulsometer. The pulsometer is an adaptation of Savery's pump and, though inefficient, is sometimes used because of its simplicity and the fact that it can be used in locations where other types of pumps would be difficult to install. The pulsometer consists of a casting containing two chambers, a steam-admission valve, two water-inlet and two water-outlet valves. Steam flows into one of these chambers, pushing out the water. When nearly empty the continued flow of steam through the outlet valve disturbs the remaining water, causing the steam to condense and produce a vacuum within the chamber. This vacuum shifts the steam supply to the second chamber where it forces the water out while the vacuum is causing the first chamber to refill. The cycle is repeated and an almost constant stream of water is discharged. The maximum suction lift is 25 feet (7.6 metres), but the practical range is 7 to 15 feet (2.1 to 4.5 metres). The required steam pressure is 50 percent higher than the total discharge pressure of the water.

Fire engines. Steam-driven pumps replaced the bucket brigades and hand-operated fire pumps commonly used in the 1830s and before. In 1829 the first heavy and cumbersome steam-operated fire pumps were developed in London. Similar units were used in New York in 1841. Some of these early fire engines were self-propelled, but it was found advantageous to use horses to pull the engines to the location of the fire and utilize the time enroute to develop steam pressure. Inventiveness and ingenuity were exercised in developing compact and light-weight equipment, and boilers that would steam rapidly.

Horse-drawn fire engines

By the end of the 19th century, these steam driven pumping engines were universally adopted in large cities. By 1925 internal-combustion engines were being used to propel the fire-fighting equipment to the fire and to operate the pumps. Thereafter, horse-driven steam engine pumpers were soon replaced.

Pile drivers. It is an age-old practice to support building structures on wooden poles (piles) driven into the ground. Steel and reinforced-concrete piling is now used. Before the use of steam, a heavy weight was lifted by various hand-powered devices and then dropped on the pile.

At first a steam engine was used to turn a winch that raised a hammer ranging in weight from 1,000 to 8,000 pounds (450–3,600 kilograms). This hammer was then dropped on the piling. Much faster but less forceful blows were obtained by a single-acting steam hammer. Steam pressure is applied directly to lift the weight and, upon release of the steam pressure, the weight falls by gravity and strikes the pile. Additional striking force is obtained by the double-acting steam hammer in which steam is applied not only to lift the weight but also to add to the force of gravity to intensify the striking force. Additional speed and striking force is obtained by use of the differential steam hammer which employs two pistons.

Since World War II diesel-powered hammers have been

developed. Although lacking in some of the versatility of the steam hammer, they are more easily transported because the boiler is eliminated.

Catapults. Steam is used as a means of accelerating airplanes to attain airborne speed when being launched from the deck of carriers. A tube or cylinder extending the length of the carrier deck is provided with a piston. A protrusion from the piston engages the airplane. When steam is introduced into the cylinder the piston moves forward accelerating the plane to 70 miles (112 kilometres) per hour. By an ingenious arrangement the slot in the cylinder, through which the protrusion from the piston moves, is sealed against steam leakage as the piston moves forward.

BIBLIOGRAPHY. LAMMERS, *Steam Plant Operation*, 3rd ed. (1967), a description of power plant boilers, engines, turbines, auxiliaries, and accessories, with an explanation of operating procedures to obtain optimum results.

(E.B.Wo.)

Steel Construction

Steel construction refers to a broad range of building construction in which steel plays the leading role. Most steel construction consists of large-scale buildings or engineering works, with the steel generally in the form of beams, girders, bars, plates, and other members shaped through the hot-rolled process. Despite the increased use of other materials, steel construction remained a major outlet for the steel industries of the U.S., U.K., U.S.S.R., Japan, West Germany, France, and other steel producers in the 1970s.

Early history. The history of steel construction begins paradoxically several decades before the introduction of the Bessemer and Siemens-Martin (open-hearth) processes made it possible to produce steel in quantities sufficient for structural use. Many of the problems of steel construction were studied earlier in connection with iron construction, which began with the Coalbrookdale Bridge, built in cast iron over the Severn River in England in 1777. This and subsequent iron bridge work, in addition to the construction of steam boilers and iron ship hulls, spurred the development of techniques for fabricating, designing, and joining. The advantage of iron over masonry lay in the much smaller amounts of material required. The truss form, based on the resistance of the triangle to deformation, long used in timber, was translated effectively into iron, with cast iron being used for compression members —*i.e.*, those bearing the weight of direct loading—and wrought iron being used for tension members—*i.e.*, those bearing the pull of suspended loading.

The technique for passing iron, heated to the plastic state, between rolls to form flat and rounded bars, was developed as early as 1800; by 1819 angle irons were rolled; and in 1849 the first I beams, 17.7 feet (5.4 metres) long, were fabricated as roof girders for a Paris railroad station.

Two years later Joseph Paxton of England built the Crystal Palace for the London Exposition of 1851. He is said to have conceived the idea of cage construction—using relatively slender iron beams as a skeleton for the glass walls of a large, open structure. Resistance to wind forces in the Crystal Palace was provided by diagonal iron rods. Two features are particularly important in the history of metal construction: first, the use of latticed girders, which are small trusses, a form first developed in timber bridges and other structures and translated into metal by Paxton; and second, the joining of the wrought-iron tension members and cast-iron compression members by means of rivets inserted while hot.

In 1853 the first metal floor beams were rolled for the Cooper Union Building in New York. In the light of the principal market demand for iron beams at that time, it is not surprising that the Cooper Union beams closely resembled railroad rails.

Introduction of structural steel

The development of the Bessemer and Siemens-Martin processes in the 1850s and 1860s suddenly opened the way to the use of steel for structural purposes. Stronger than iron in both tension and compression, the newly available metal was seized on by imaginative engineers, notably by those involved in building the great number of heavy railroad bridges then in demand in Britain, Europe, and the U.S.

A notable example was the Eads Bridge, also known as the St. Louis Bridge, in St. Louis (1867-74), in which tubular steel ribs were used to form arches with a span of more than 500 ft (152.5 m). In Britain, the Firth of Forth cantilever bridge (1883–90) employed tubular struts, some 12 ft (3.66 m) in diameter and 350 ft (107 m) long. Such bridges and other structures were important in leading to the development and enforcement of standards and codification of permissible design stresses. The lack of adequate theoretical knowledge, and even of an adequate basis for theoretical studies, limited the value of stress analysis during the early years of the 20th century, as occasional failures, such as that of a cantilever bridge in Quebec in 1907, revealed. But failures were rare in the metal-skeleton office buildings; the simplicity of their design proved highly practical even in the absence of sophisticated analysis techniques. Throughout the first third of the century, ordinary carbon steel, without any special alloy strengthening or hardening, was universally used.

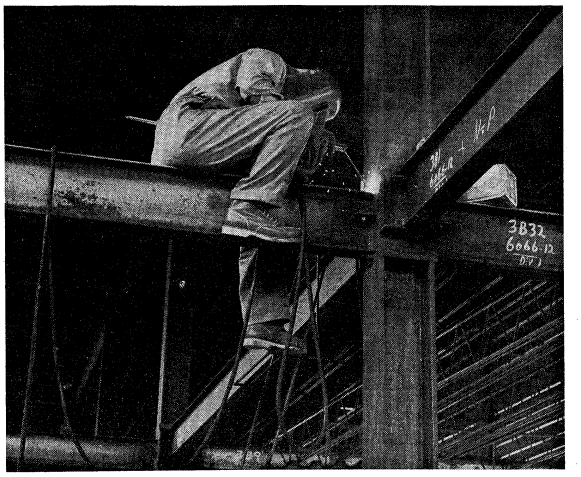
The possibilities inherent in metal construction for high-rise buildings was demonstrated to the world by the Paris Exposition of 1889, for which Alexandre-Gustave Eiffel, a leading French bridge engineer, erected an openwork metal tower 300 m (984 ft) high. Not only was the height —more than double that of the Great Pyramid—remarkable, but the speed of erection and low cost were even more so, a small crew completing the work in a few months. At the same exhibition the huge, single-story Galerie des Machines, housing some of the exhibits, also contributed significantly to the advance of metal construction. Its roof was supported by latticed steel arch ribs spanning 114.3 m (375 ft).

The first skyscrapers. Meantime, in the United States another important development was taking place. In 1884–85 Maj. William Le Baron Jenney, a Chicago engineer, had designed the Home Insurance Building, ten stories high, with a metal skeleton. Jenney's beams were of Bessemer steel, though his columns were cast iron. Cast iron lintels supporting masonry over window openings were, in turn, supported on the cast iron columns. Solid masonry court and party walls provided lateral support against wind loading. Within a decade the same type of construction had been used in more than 30 office buildings in Chicago and New York. Steel played a larger and larger role in these, with rivetted connections for beams and columns, sometimes strengthened for wind bracing by overlaying gusset plates at the junction of vertical and horizontal members. Light masonry curtain walls, supported at each floor level, replaced the old heavy masonry.

Though the new construction form was to remain centred almost entirely in America for several decades, its impact on the steel industry was worldwide. By the last years of the 19th century, the basic structural shapes—I beams up to 20 in. (0.508 m) in depth and Z and T shapes of lesser proportions—were readily available, to combine with plates of several widths and thicknesses to make efficient members of any required size and strength. In 1885 the heaviest structural shape produced through hot-rolling weighed less than 100 pounds (45 kilograms) per foot; decade by decade this figure rose until in the 1960s it exceeded 700 pounds (320 kilograms) per foot.

Coincident with the introduction of structural steel came the introduction of the Otis electric elevator in 1889. The demonstration of a safe passenger elevator, together with that of a safe and economical steel construction method, sent building heights soaring. In New York the 286-ft (87.2-m) Flatiron Building of 1902 was surpassed in 1904 by the 375-ft (115-m) Times Building (renamed the Allied Chemical Building), the 468-ft (143-m) City Investing Company Building in Wall Street, the 612-ft (187-m) Singer Building (1908), the 700-ft (214-m) Metropolitan Tower (1909) and, in 1913, the 780-ft (232-m) Woolworth Building.

The rapid increase in height and the height-to-width ratio brought problems. To limit street congestion, building setback design was prescribed. On the technical side, the problem of lateral support was studied. A diagonal bracing system, such as that used in the Eiffel Tower, was not architecturally desirable in offices relying on sunlight for illumination. The answer was found in greater reliance on the bending resistance of certain individual beams and columns strategically designed into the skeleton frame, together with a high degree of rigidity sought at the junction of the beams and columns. With today's modern interior lighting systems, however, diagonal bracing against wind loads has returned; one notable example is the John Hancock Center in Chicago, where the external X-braces form a dramatic part of the structure's facade.



World War I brought an interruption to the boom in what had come to be called skyscrapers (the origin of the word is uncertain), but in the 1920s New York saw a resumption of the height race, culminating in the Empire State Building in 1931. The Empire State's 102 stories (1,250 ft. [381 m]) were to keep it established as the highest building in the world for the next 40 years. Its speed of erection demonstrated how thoroughly the new construction technique had been mastered. A depot across the bay at Bayonne, N.J., supplied the girders by lighter and truck on a schedule operated with military precision; nine derricks powered by electric hoists lifted the girders to position; an industrial-railway setup moved steel and other material on each floor. As the building rose, the hoist engines were lifted outside the building to successively higher stages. Initial connections were made by bolting, closely followed by riveting, followed by masonry and finishing. The entire job was completed in one year and 45 days.

The Empire State Building

The worldwide depression of the 1930s and World War II provided another interruption to steel construction development, but at the same time the introduction of welding (see photograph) to replace rivetting provided an important advance.

Joining of steel parts by metal arc welding had been successfully achieved by the end of the 19th century and was used in emergency ship repairs during World War I, but its application to construction was limited until after World War II. Since then it has gained steadily, especially in shop fabrication. Another advance in the same area has been the introduction of high-strength bolts to replace rivets in field connections.

Steel frame being welded.

Since the close of World War II, research in Europe, the U.S., and Japan has greatly extended knowledge of the behaviour of different types of structural steel under varying stresses, including those exceeding the yield point, making possible more refined and systematic analysis. This in turn has led to the adoption of more liberal design codes in most countries, permitting freer, more imaginative design made possible by so-called plastic design and by the use of the higher strength materials, with significant savings in cost. The introduction of the computer, by short-cutting tedious paperwork, made further advances and savings possible.

Resistance to earthquakes. While its interior was gutted by fire, the 16-story Call Building in San Francisco, erected in 1898, withstood the 1906 earthquake and was subsequently rehabilitated. Nevertheless, the construction of much higher buildings in areas subject to strong seismic forces was postponed until midcentury. That they can be designed to resist strong ground motion without damage was demonstrated by the 43-story Latino-Americano Tower during the 1957 earthquake in Mexico City. Similar performance was observed with comparable buildings in Los Angeles in 1971.

Stiff-wall framing. The 1950s saw a new development in steel-skeleton design that was, paradoxically, a return to an older, presteel building system—that of bearing walls. Exterior wall skeletons were built of closely spaced steel members arranged and proportioned with sufficient rigidity to function as the stiff sides of a box, capable of carrying all interior loadings, and resisting wind forces. The advantage of such an arrangement in modern office buildings is that it provides column-free interior space around the central service core. The office space can be organized by light partition walls to suit individual tenants' requirements.

The first such structure built was the IBM Building, erected in Pittsburgh in 1962. Its novel diamond-pattern exterior walls were designed to deliver their entire load to a pair of trellis-like supports under the centre of each exterior wall. Three different grades of structural steel were used on the diamond frame so that the wide range in stresses could be borne without disturbing the uniformity of the pattern. The structural members, which had a yield strength ranging from 36,000 to 100,000 lb/sq in. (2,531 to 7,030 kg/sq cm), were covered with stainless steel.

The success of the IBM Building led to the adoption of

the same bearing-wall principle elsewhere, most spectacularly in the 110-story twin towers of the World Trade Center in New York City, completed in the early 1970s. Unlike the Empire State Building, which they exceed in height by 100 ft (30 m), the towers maintain the same cross section (209 sq ft [19.4 sq m]) from ground level to roof. The 350-ft (107-m) TV antenna mast on the north tower carries the total height to just short of a third of a mile. Stiffness in the exterior walls is provided by closely spaced columns rigidly connected to deep spandrel beams, which are located between window units at successive floor levels. Steel in the columns ranges from ordinary grade at the top to heat-treated low-alloy at ground level, where extraordinary compressive strength is needed. Steel also is basic to the floor construction; corrugated steel forms, supported on steel joists spanning from the exterior walls to the interior service core framing, support the poured concrete slab. The slabs are mechanically anchored to the joists to act integrally with the joists in supporting the floor loads.

Specialized structures. Improved research facilities available since World War II have expanded and refined the understanding of steel as a structural material; combined with improved fabrication techniques and the computer, this has resulted in a proliferation of unusual applications of steel in construction. Three notable buildings at world's fairs of the 1950s and 1960s provide examples: the U.S. Pavilion at the 1958 Brussels, Belgium, exposition, in which the roof was supported by a wire rope system resembling the spokes of a wheel, stretched in tension between a ring hub and a rim made as a circular latticed girder; the 600-ft- (183-m-) high Space Needle of the Century 21 Exposition in Seattle, Washington, in 1962, in which three legs, built up of heavy rolled beam sections, surrounded a central core, providing access to a revolving restaurant and observation level at the top; and the 275-ft-diameter geodesic, spherical dome enclosing the U.S. Exhibition Building at Expo 67 in Montreal.

Other examples of unusual steel construction include the movable 575-ton (575,000-kg) feeder platform supported on cables 500 ft (152.4 m) above the dished reflector antenna at the ionospheric observatory in Arecibo, Puerto Rico; the 2.7-mile (4.3-kilometre) Sandia Peak Aerial Tramway near Albuquerque, New Mexico, with its 7,720-ft (2,353-m) catenary (suspension cable) between Tower No. 2 and the summit; the 630-ft- (192-m-) span Gateway Arch at St. Louis; and the Vertical Assembly Building at Cape Kennedy, Florida, used for assembly of space rockets, and enclosing more space than any other scientific building in the world.

GAYLORD, *Structural Engineering Handbook* (1968), a comprehensive reference text covering all phases of structural engineering; *Bauen in Stahl 2*, (1962), a description, in French and German, of 147 structures of all types erected in 15 countries since 1956; profusely illustrated, presenting a well-rounded report on modern steel construction.

(T.R.H.)

Steele, Sir Richard

English essayist, dramatist, journalist, and politician, Richard Steele is best known today as principal author, with his friend Joseph Addison, of the essay periodicals *The Tatler* and *The Spectator;* but his stage comedies had a great effect on the sensibility of the 18th century, all but one of them retaining a considerable popularity for several decades and his work as a political pamphleteer and editor on behalf of the Whigs during the last years of Queen Anne's reign brought him national importance and a knighthood. Both as man and writer Steele is one of the most attractive figures of his time, much of his writing—easy, rapid, slipshod, but deeply sincere—reflecting his personality. "There appears in his natural temper," wrote his contemporary, the philosopher George Berkeley, "something very generous and a great benevolence to mankind." An emotional, impetuous, good-natured, and idealistic man, he always found it easier to get money than to keep it, and his career can be seen as in part shaped by the constant need to keep his head above the waters of debt.

Steele, oil painting by Sir Godfrey Kneller, 1711. In the National Portrait Gallery, London.

Early life and works. Steele was born in Dublin early in 1672. His father, an ailing and somewhat ineffectual attorney, died when Steele was about five (a moving passage in *Tatler* No. 181 records what were probably his memories of this); and the boy was taken under the protection of his uncle Henry Gascoigne, confidential secretary to the Duke of Ormonde, to whose bounty, as Steele later wrote, he owed "a liberal education." He was sent to study at Charterhouse in 1684 and to Christ Church, Oxford, in 1689. At Charterhouse he met Addison, and thus began one of the most famous and fruitful of all literary friendships, which lasted until disagreements (mainly political) brought about a cooling and a final estrangement shortly before Addison's death in 1719. Steele moved to Merton College in 1691 but, caught up with the excitement of King William's campaigns against the French, left in 1692 without taking a degree to join the army. No doubt he intended to make this his career, or one of his careers; he was commissioned in 1697 and promoted captain in 1699, but, lacking the money and connections necessary for substantial advancement, he left the army in 1705.

Beginning of Steele's friendship with Addison

Meanwhile, he had embarked on a second career, as a writer. Perhaps partly because he gravely wounded a fellow officer in a duel in 1700 (an incident that inspired a lifelong detestation of duelling), partly because of sincere

feelings of disgust at the "irregularity" of army life and his own dissipated existence, he published in 1701 a moralistic tract, "The Christian Hero," of which ten editions were sold in his lifetime. This tract, asserting "that no Principles but those of Religion are Sufficient to make a Great Man," inevitably led to Steele's being accused of hypocrisy and mocked for the contrast between his austere precepts and his genially convivial practice; but, even if Steele occasionally deluded himself about his moral worth, he was unquestionably sincere, and this early work foreshadowed much of his later writing. Sensitive to the jeers of his fellow officers, however, Steele turned his literary talents to a very different kind of production and in the same year (1701) wrote his first comedy, *The Funeral*. Performed at Drury Lane "with more than expected success," it made his reputation and helped to bring him to the notice of King William and the Whig leaders. Late in 1703 he followed this with his only stage failure, *The Lying Lover*, which ran for only six nights, being, as Steele said, "damned for its piety." Sententious and ill-constructed, with much priggish moralizing, it is nevertheless of some historical importance as one of the first "sentimental comedies" and is of interest in that there is much of Steele in it—an emotional protest against duelling, a solemnly tender regard for "the fair sex," and a wry allusion to the gullible author's having recently squandered a good deal of money in an alchemical project. Steele was, indeed, always ready to entertain moneymaking ventures, having an indefatigable faith that something would turn up, and from 1717 he was to spend much time, energy, and money on a scheme for transporting live fish in specially constructed boats.

First comedy

A third play, *The Tender Husband*, with which Addison helped him (1705), had some success, but Steele continued to search for advancement and for money. In the next few years he secured various minor appointments, such as that of gentleman-waiter to the Queen's husband, Prince George, and in 1705 he married a widow, Margaret Stretch, who owned considerable property in Barbados. Little is known of this marriage, but it is difficult not to believe that Steele's motives were at least partly mercenary. Almost immediately the estate was entangled in his debts (he lost two actions for debt, with damages, in 1706), but, when, late in 1706, she conveniently died, Margaret left her husband with a substantial income. Steele's second marriage, contracted within a year of Margaret's death, was very different, though again he married a woman of means: Mary Scurlock, his "Dear Prue," was completely adored by Steele, however much he might at times neglect her. His hundreds of letters and notes to her provide a vivid revelation of his personality during the 11 years of their marriage. Having borne him four children (of whom only the eldest, Elizabeth, long survived Richard), she died, during pregnancy, in 1718.

Mature life and works. Steele's other important appointment in the early part of Queen Anne's reign was that of gazetteer—writer of *The London Gazette*, the official government journal. Although this reinforced his connection with the Whig leaders, it gave little scope for his artistic talents, and, on April 12, 1709, he secured his place in literary history by launching the thrice-weekly essay periodical *The Tatler*. Writing under the name (already made famous by the satirist Jonathan Swift) of Isaac Bickerstaff, Steele created the mixture of entertainment, and instruction in manners and morals, that was to be perfected in *The Spectator*. "The general purpose of the whole," wrote Steele, "has been to recommend truth, innocence, honour, and virtue, as the chief ornaments of life"; and here, as in the later periodical, can be seen his strong ethical bent, his attachment to the simple virtues of friendship, frankness, and benevolence, his seriousness of approach tempered by the colloquial ease and lightness of his style. Addison contributed some 46 papers and collaborated in several others, but the great bulk of the 271 issues were by Steele himself; and, apart from bringing him fame, it brought a measure of prosperity. The exact cause of *The Tatler*'s demise is uncertain, but probably the reasons were mainly political: in 1710 power had shifted to the Tories and Steele, a Whig, had lost his gazetteership and had come near to losing his post of commissioner of stamps. *The Tatler* had contained a good deal of political innuendo, some of it aimed at Robert Harley, the Tory leader, himself, and Harley may well have put pressure on Steele to discontinue the paper.

Launching of *The Tatler*

The Tatler's greater successor, first appearing on March 1, 1711, was avowedly nonpolitical and was enormously successful. *The Spectator* was a joint venture; Steele's was probably the more original journalistic flair, and he evolved many of the most celebrated ideas and characters (such as Sir Roger de Coverley), although later Addison tended to develop them in his own way. Steele's attractive, often casual style formed a perfect foil for Addison's more measured, polished, and erudite writing. Of the 555 daily numbers, Steele contributed 251 (though about two-thirds made up from correspondents' letters).

Of Steele's many later ventures into periodical journalism, some, such as *The Englishman*, were mainly politically partisan. *The Guardian* (to which Addison contributed substantially) contains some of his most distinguished work, and *The Lover* comprises 40 of his most attractive essays. Other, short-lived, periodicals, such as *The Reader*, *Town-Talk*, and *The Plebeian*, contain matter of considerable political importance. Steele became, indeed, the chief journalist of the Whigs in opposition (1710–14), his writings being marked by an unusual degree of principle and integrity. His last periodical and his last extended literary work was *The Theatre*.

Steele's political writings had stirred up enough storms to make his career far from smooth. He resigned as commissioner of stamps in 1713 and was elected to Parliament; but, as a consequence of his anti-Tory pamphlets "The Importance of Dunkirk Consider'd" and "The Crisis," he was expelled from the House of Commons for "seditious writings." Calmer weather, however, and rewards followed on George I's accession: Steele was appointed to the congenial and fairly lucrative post of governor of Drury Lane Theatre in 1714, knighted in 1715, and re-elected to Parliament in the same year.

Last years

Steele's health was gradually undermined by his cheerful intemperance, and he was long plagued by gout. Nevertheless, he busied himself conscientiously with parliamentary duties and, more erratically, with his part in the management of Drury Lane. One of his main contributions to that theatre's prosperity was his last and most successful comedy, *The Conscious Lovers*—one of the most popular plays of the century and perhaps the best example of English sentimental comedy.

In 1724 Steele retired to his late wife's estate in Wales and began to settle his debts. His closing years were quiet; but his health continued to deteriorate, and, on September 1, 1729, the genial and charming writer, whose burly figure, brown face, and brilliant eyes had long been part of the London scene, died at Carmarthen.

MAJOR WORKS

PERIODICAL ESSAYS: in *The Tatler* (1709–11); *The Spectator* (1711–12); *The Guardian* (1713); *The Englishman* (1713–14; second series, 1715); *The Lover* (1714); *The Reader* (1714); *Town-Talk* (1715–16); *The Theatre* (1720).

POLITICAL WRITINGS: "The Importance of Dunkirk Consider'd" (1713); "The Crisis" (1714); "Mr. Steele's Apology for Himself and His Writings" (1714). Some of Steele's periodical journalism was purely political; many of his essays and pamphlets were gathered in *Political Writings* (1715).

MISCELLANEOUS: "The Christian Hero" (1701).

PLAYS: *The Funeral* (performed 1701, published 1702); *The Lying Lover* (performed 1703, published 1704); *The Tender Husband* (1705); *The Conscious Lovers* (performed 1722, published 1723).

BIBLIOGRAPHY. There is no systematic bibliography of Steele's works. Aitken's *Life* has a bibliography, as does Blanchard's edition of *The Christian Hero* (see below). The major collections of Steele material are in the British Museum and the Bodleian Libraries; there are many documents relating to him in the Public Record Offices of London and of Dublin and in Somerset House, London. A definitive edition of the works is in progress. RAE BLANCHARD has edited *The Christian Hero* (1932), the *Correspondence* (1941, reprinted 1968 with additional letters), *Tracts and Pamphlets* (1944, reprinted 1967), *Occasional Verse* (1952), *The Englishman* (1955), and *Periodical Journalism, 1714–16* (1959). JOHN

LOFTIS has edited *The Theatre, 1720* (1962); and SHIRLEY STRUM KENNY, *The Plays* (1971). DONALD F. BOND has edited *The Spectator*, 5 vol. (1965), and is preparing an edition of *The Tatler;* the latter was edited by G.A. AITKEN, 4 vol. (1898–99). The most fully documented biography is G.A. AITKEN, *The Life of Richard Steele*, 2 vol. (1889); more up-to-date are the biographies by WILLARD CONNELY, *Sir Richard Steele* (1934); and CALHOUN WINTON, *Captain Steele: The Early Career of Richard Steele* (1964) and *Sir Richard Steele, M.P.: The Late Career* (1970). See also JOHN LOFTIS, *Steele at Drury Lane* (1952). Critical studies include WALTER J. GRAHAM, *The Beginnings of English Literary Periodicals: A Study of Periodical Literature, 1665–1715* (1926); F.W. BATESON, *English Comic Drama, 1700–1750* (1929); and A.R. HUMPHREYS, *Steele, Addison, and Their Periodical Essays* (1959).

(R.P.C.M.)

Steel Production

The name steel is applied to an enormous variety of alloys in which the principal ingredient is the chemical element iron. Carbon is the most important alloying element, although other alloying elements may be present in higher concentrations. The carbon content can range from approximately 0.03 percent to 1.5 percent and in a few cases may go as high as 2.25 percent. Iron alloys containing less than 0.03 percent carbon are called irons, and those containing carbon above 1.5 percent are usually called cast irons or, in the crude form, pig iron.

Three classes of steels

Broadly, there are three commercial classes of steels: carbon steels, low-alloy steels, and high-alloy steels. In addition to carbon, the carbon steels contain up to 1.65 percent of manganese and possibly small quantities of silicon, aluminum, copper, and other elements. The low-alloy steels also include a total of from 1 to 5 percent of common alloying elements such as nickel, chromium, molybdenum, tungsten, titanium, niobium (columbium), and often other elements. The high-alloy steels contain over 5 percent of at least one alloying element, principally chromium, nickel, manganese, molybdenum, or tungsten. The stainless steels constitute a major class of the high-alloy steels. Usually a steel with more than 5 percent chromium is called a stainless steel. By common practice, an alloy containing less than 50 percent iron is not considered to be a steel. Carbon steels are used extensively for automobile bodies, appliances, machinery, ships, containers, and the structure of buildings. The low-alloy steels are used most often in applications in which special properties are needed, but cost is of considerable importance. Examples are forged products for highly stressed parts of machines, aircraft landing gear, shafts, hand tools, gears, and high-strength structural steels. The high-alloy steels are used for their unusual properties: typical are the stainless steels, used when resistance to corrosion and oxidation and good appearance are required; *i.e.*, as parts of jet engines, chemical equipment, tableware and cooking utensils, and cutting tools.

The world production of all kinds of raw steel in the second year of the present decade was over 642,000,000 tons, (excepting Tables 1 and 2; and Fig. 13 amounts in tons refer to short, or net, tons of 2,000 pounds), with the United States, the Soviet Union, and Japan together producing almost 60 percent of the total, excluding that produced by China. Great quantities of iron ore, coal, fuel oil, electricity, natural gas, limestone, oxygen, and air are needed as raw materials by the industry. In the United States an average of 1,750 pounds of iron ore, 1,050 pounds of steel scrap, 1,600 pounds of coal, 800 pounds of limestone, 150 kilowatt-hours of electrical energy, and 16,000 gallons of water are required to produce one ton of raw steel. The equivalent amounts in metric units per metric ton of steel are 875 kilograms of ore, 525 kilograms of steel scrap, 800 kilograms of coal, 400 kilograms of limestone, and 66 cubic metres of water. The steel industry of a modern industrial nation constitutes an important segment of the economy.

Properties of iron

The physical and chemical properties of the element iron make it one of the most interesting in the periodic table (see TRANSITION ELEMENTS AND THEIR COMPOUNDS). The metal forms solid and liquid alloys with most of the metallic elements and forms compounds with most of the nonmetallic elements; those of particular interest in steel production are the oxides, carbides, nitrides, and sulfides of iron. Iron occurs in two crystallographic forms: so-called face-centred cubic structure, in which the atoms are arrayed at the corners of a cube and at the centre of each face of the cube; and body-centred-cubic structure, in which the atoms are located at the corners of the cube and one at the centre of the cube. The tremendous variety possible in the properties of steels arises principally because of the effects of atoms of elements such as manganese, chromium, nickel, molybdenum, and vanadium substituting for atoms of iron in the crystal lattice and by elements such as carbon and nitrogen, which can lodge interstitially in holes between the atoms of iron. The importance of these interstitial elements can be seen from the fact that in many commercial steels the carbon content must be controlled within 0.01 percent and nitrogen within 0.001 percent.

The general course of the chemical changes that iron undergoes in the conventional conversion of iron ore to steel is as follows. Oxygen is removed from the ore by reactions with carbon, carbon monoxide, and hydrogen. The resulting metallic iron is melted, and in this state it will dissolve carbon and other impurities. Most of these impurities are removed from the liquid iron in the steelmaking furnace by reacting the metal with oxygen; the process is controlled, however, to prevent the iron from being oxidized again to the oxide. After the liquid metal has been refined, the necessary alloying elements are added, and the steel is solidified. In the subsequent rolling, forging, pressing, and processing of the solid steel, care is again taken to prevent undue oxidation of the steel and loss of carbon from the surface.

This article is divided into the following sections:

I. History
  The Iron Age
  Mass production of steel
II. Modern steel technology
  Raw materials
  The basic steelmaking process
  Types of steelmaking processes

V. World steel production

I. History

THE IRON AGE

Early uses of iron. Iron is found in the metallic state only in small quantities and only in a few places in the Earth's crust. Principally, it is associated with basaltic rock on the west coast of Greenland. It has also been found in very small quantities in a few places in middle Europe; in the Don district, in the southern U.S.S.R.; in Scotland; and in Canada. Occasional pieces of iron of meteoric origin also have been found in many places in the world. It seems probable that iron objects made from these sources entered ancient commerce before 4000 BC, though there is no evidence for this, because iron corrodes relatively rapidly, so that iron objects disappeared, whereas those of gold and silver have survived until today. Most probably, iron came into more general use in primitive times through the accident of iron-bearing stones being exposed to the hot charcoal in a fire. The action of the charcoal converted the stones to spongy pieces of iron, which were later recovered from the residue of the fire. The association of certain kinds of rock with charcoal and fire and the presence of metallic iron in the ashes may have been discovered at various times in many places. It would seem, however, that development

Native iron

of the technology by which iron was forged, welded, and worked into useful objects took many centuries and occurred in only a few locations. It is known that iron objects were used in ancient civilizations in China, India, the Near East, Egypt, and Greece. Iron is mentioned a number of times in the Old Testament, the earliest references being in Genesis and Deuteronomy. It is also mentioned in Homer's *Iliad*.

The Catalan forge. Iron weapons and implements were apparently made by hammering and welding sponge iron by 1000 BC. The sponge iron was produced in shallow, clay-lined, bowl-shaped hearths into which were placed charcoal and the iron-bearing stones. Intense heat was generated by a jet of air directed onto the charcoal through a nozzle, or tuyere. The Catalan forge, *c.* AD 700

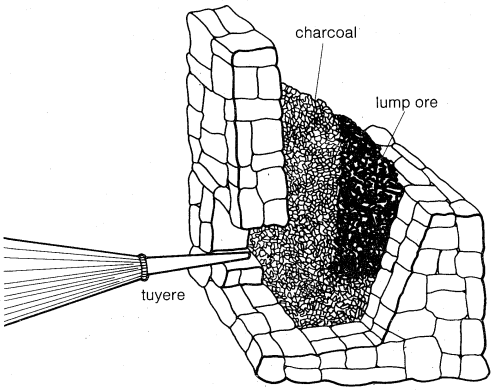

Figure 1: Catalan hearth or forge used for smelting iron ore until relatively recent times. The method of charging fuel and ore and the approximate position of the nozzle supplied with air by a bellows are shown (see text).

(see Figure 1), was a short shaft furnace for producing sponge iron directly from iron ore. A blast of air produced with a stream of falling water or with a bellows powered by hand, animal, or waterpower was introduced into the charcoal at the bottom of the hearth. It was possible to obtain much higher temperatures with this type of air supply than could be reached with more primitive furnaces that used natural draft or the force of the prevailing wind directed into the furnace opening. Though the temperature reached was not hot enough to melt the sponge iron (the melting point of iron is 1,538° C [2,800° F]), it did melt the impurities in the ore and the ash in the charcoal to form a liquid slag. After sufficient sponge iron was formed, the hot lump was withdrawn from the hearth and hammered vigorously to expel most of the slag, to weld the pieces of sponge together, and to shape the resulting piece of metal into a rod, bar, or plate. The metal of this type of product, called wrought iron, was relatively pure, having no more than about 0.1 percent impurities alloyed with the metal and up to 3 percent entrapped slag (see IRON MINING AND PROCESSING).

Production of steel objects. By 1200 BC it was possible to produce steel objects that could be hardened by quenching them in water or oil to develop a hard edge for cutting, picking, or chiselling. This required that the carbon content of wrought iron be increased by holding the sponge iron in contact with hot charcoal or other carbonaceous material away from the air blast for several hours. Alternatively, a wrought-iron object would be packed in a bed of hot charcoal in a clay box or jar. The whole assembly would be heated above a red heat for days so the carbon content of the metal surface was raised sufficiently to obtain the desired hardness when the object was quenched. This latter technique is called the cementation process, and the product is cemented steel.

Development of the blast furnace. With the passage of time, the sides of the smelting hearth grew higher and the bed of ore particles and charcoal deeper. Greater production and economy in fuel consumption was realized, because the gases from the hot region passed upward through the bed to preheat and prereduce the ore. As a consequence, the iron absorbed more carbon, so that it liquified and trickled down into the hearth to form a puddle of impure iron. This iron has a melting point in the range of 1,150° to 1,200° C (2,100 to 2,200° F) and could be cast readily into convenient shapes, such as kettles and plates. It is probable that cast iron was first produced in China during the 6th century AD. The tall furnace, known as a blast furnace, was in general use throughout Europe by the 14th century and was introduced into Britain late in the 15th. The first blast furnace erected on the North American continent was in Falling Creek, Virginia, in 1620. Early furnaces were about 20 to 26 feet (six to eight metres) high. The fuel was charcoal, and the air blast was supplied by bellows driven by a waterwheel. Sixteenth-century furnaces produced about one ton (900 kilograms) of iron a day. By the middle of the 17th century some English furnaces produced two to three tons a day. The product of the blast furnace was called pig iron, because liquid metal flowing from the furnace was conveyed into a sand bed in which was formed a long trough to lead the metal into numerous smaller troughs. The feeder trough was likened to a sow and the side bars to piglets, hence the name pig iron. As a result of the extensive use of charcoal in the production of pig iron, wrought iron, and steel, much of the forests in Great Britain had been destroyed by the middle of the 17th century, and until the end of the 18th century Great Britain had to import iron from Sweden, Russia, and her American colonies. It was only after the successful commercial use of coke in the blast furnace in 1740 that the production of pig iron returned to Great Britain.

Pig iron

In the 18th century and the early part of the 19th century, blast furnaces grew rapidly in size and capacity. With coke as the fuel, blowing capacities greater than were available from water-driven bellows were required. In 1776 James Watt's steam engine was applied to pump air for a blast furnace in England, and the replacement of charcoal by coke proceeded rapidly thereafter. An 1816 invention by which the hot waste gases from an industrial process were used to preheat incoming air for combustion was applied to the iron blast furnace in 1828 in Scotland. There resulted a saving of at least one-third in the fuel required to smelt iron.

Indirect process for making wrought iron. Although pig iron was cheap to produce and easy to cast, it was brittle, because it contained at least several percent of carbon and appreciable concentrations of silicon, manganese, phosphorus, and sulfur. Wrought iron could be produced from it by an indirect process, to which there were so many variations that only its general character can be described here. Pigs of cast iron from the blast furnace were melted gradually on a hearth filled with charcoal. The liquid collected in a puddle, which was exposed to a blast of air from a tuyere. The air oxidized the silicon and carbon out of the metal, and, without these elements, the melting point of the metal rose. As a result, the puddle became a pasty lump. When a large enough ball of metal and slag was collected, the mass was removed from the furnace and hammered to obtain a ball of wrought iron. Early in the 17th century a brick roof was put over the hearth, and heat for puddling the iron was provided from a combustion chamber that was separated from the hearth by a brick wall. The heat and flame from this combustion chamber were reflected, or reverberated, from the roof down upon the charge in the hearth. This type of furnace has come to be known as a reverberatory furnace. In 1784 Henry Cort of England was granted a patent for an improved method of producing puddled wrought iron in this type of furnace. During the latter part of the 18th century the use of wrought iron for machinery and implements expanded rapidly. In 1777 the first bridge made of wrought iron was erected in Coalbrookdale, Shropshire.

Reverberatory furnace

Crucible process. The crucible process for making steel reappeared in 1740. Pieces of cemented wrought iron and slag-making ingredients were charged into a fireclay crucible (see Figure 2). The crucible was tightly sealed and then placed in a heating furnace. In this way the fuel could be burned under highly oxidizing condi-

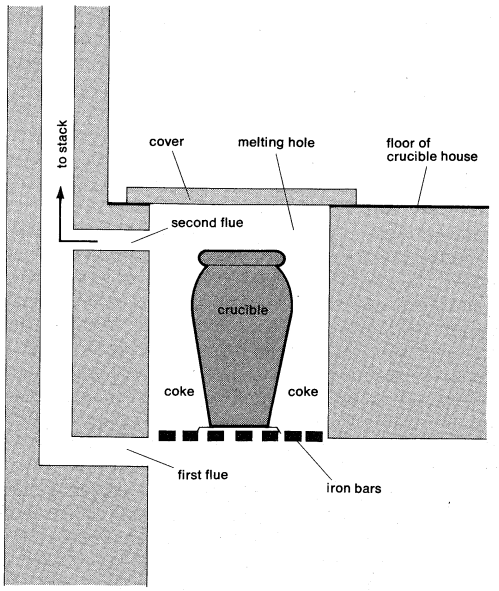

Figure 2: Position of crucible in melting hole in the crucible process.
From A.K. Osborne, *An Encyclopaedia of the Iron and Steel Industry;* Technical Press, London

tions, so that temperatures high enough to melt the steel were reached, but the charge was not oxidized. After several hours of heating, the crucible was withdrawn from the furnace and its contents cast in a mold of the desired shape. Because the steel had been melted, the internal structure of the product was much superior to the steel products obtained directly by cementation of wrought iron. A crucible could contain not more than 100 pounds (45 kilograms) of charge, so that castings of greater weight had to be obtained by combining the product from several of them. Silicon, the chief alloying element in the steel, was obtained by a reaction between carbon in the liquid and silica (SiO_2) in the crucible wall and in the slag. Carbon monoxide gas (CO) was also produced. The process was completed in 2½ to four hours, after which there was no further evolution of carbon monoxide. In 1801 a British steelmaker introduced manganese into the charge, and later the additions of nickel, chromium, and tungsten in the charge permitted the production of a wide range of alloy steels.

Early steelworking machinery. Objects of iron and steel have been worked by hand hammering since antiquity. With the development of the production of wrought iron on a large scale, water-driven hammers came into use. Water-driven mills with two rollers for slitting iron bars were first developed in Liège, Belgium, early in the 16th century. A mill of this type for the production of rods and bars used in the manufacture of nails was installed at ironworks at Saugus, Massachusetts, in 1648. Water-powered mills for rolling larger plates and sheets were used in Sweden and Great Britain early in the 18th century. Rolls with grooves for rolling bars of various cross sections, such as rounds and squares, came into use in the middle of the 18th century; perfection of a mill with grooved rolls in 1783 marks the beginning of modern rolling mills. In England in 1786, Watt's steam engine was first used to drive a slitting and rolling mill; in subsequent years, however, the steam engine was used more widely to drive forge hammers.

MASS PRODUCTION OF STEEL

Late 19th and early 20th centuries. The rapidly rising demand for iron and steel in the middle of the 19th century resulted from the use of these materials in the construction of railroads, ships, buildings, and machinery, required by the rapid industrialization of western Europe, Great Britain, and the United States. War and advancing military technology also demanded steel.

Improvements in steelworking machinery. Advances in machinery for working and rolling wrought iron and steel made it possible to produce a wide variety of useful products. The steam hammer that came into general use between 1850 and 1860 had a steam-driven piston that actuated the hammer directly, permitting rapid operation with precise control. Two rolling achievements of note were the production of an iron rail 62 feet (19 metres) long in 1851 at Port Talbot, Wales, and the installation of a mill at Dowlais, Wales, capable of rolling 18-inch- (46-centimetre-) deep H beams 50 feet (15 metres) long and rails up to 120 feet (37 metres) long. The universal mill with both vertical and horizontal rolls, which was invented in England in 1829, was first used in 1848. The first I beams were rolled in France in 1840. The so-called three-high mill, which first appeared in England in the early 1820s and came into general use after 1850, when it became possible to build bearings, gears, and drive systems of satisfactory quality and precision, has three rolls placed one above the other, and a bar or sheet can be passed back and forth through the mill. The rolling can be accomplished in both directions without the need for reversing the mill. The advantage of this mill over the two-high mill (see Figure 3) was that the piece did not have to be passed back over the mill by hand after each rolling operation.

From A.K. Osborne, *An Encyclopaedia of the Iron and Steel Industry;* Technical Press, London

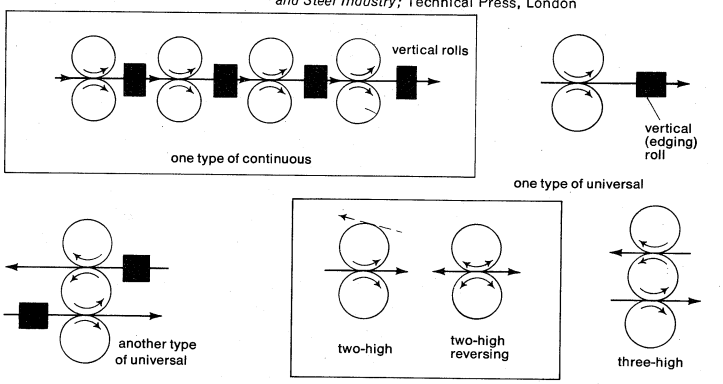

Figure 3: Representative roll arrangements.

Continuous rolling mill

The continuous mill for rolling rods for wire first appeared in England in 1861. It has several consecutive two-high stands of rolls that are alternately vertical and horizontal. A bar passing through the mill is in several stands at once, and its speed increases as its cross section is reduced. The multiple-stand continuous rolling mill for producing large coils of steel strip from hot slabs of low-carbon steel was first used in 1923 in the United States. The multiple-stand continuous mill for rolling these coils cold at high speed into thin sheets began to replace old hand-operated mills in the 1930s.

To reduce waste as well as the amount of rolling required and the size of mill needed, equipment and methods have been developed for casting steel continuously into bars, rods, and slabs. Employed successfully since 1950, these strand-casting methods have been used to make lengths of steel with round or square cross sections called blooms.

First techniques of mass production. By 1850, relatively large quantities of liquid pig iron were being produced by the blast furnace, but the existing processes for making wrought iron and steel, principally the puddling furnace and the crucible process, could produce metal in batches of not more than a few hundred pounds each. In addition, these operations involved heavy manual labour and the exposure of workers to high temperatures. This situation and the growing need for large tonnage of wrought iron and steel stimulated the invention of methods for the mass production of steel. Work on a pneumatic means for producing steel from liquid impure iron by blowing a blast of cold air up through the molten mass was begun by William Kelly of Kentucky, in 1846. In England, Henry Bessemer's efforts along the same lines led to the patenting of the Bessemer process in 1856. At first, Bessemer's and Kelly's process could not be used

Patenting of the Bessemer process

to make good steel from common English and American liquid crude iron. It was soon discovered, however, that the addition of manganese to the blown metal from the converter would make the steel ingots dense and easily workable by rolling and forging without cracking. In 1856 William and Friedrich Siemens, German-born scientists who also lived in England, invented a regenerative system for preheating the air supplied to a furnace so that flames of very high temperature could be produced. A chamber filled with open brickwork is heated for a time by the hot gases from the furnace. Then, for a period subsequently, the air supply for combustion is heated by passing it through this chamber. In this way the chamber is alternately heated and cooled in cycles; normally, a furnace is equipped with two regenerator chambers. In 1858 a patent was issued to the Siemens brothers for the use of regenerators with a shallow-hearthed furnace for melting and refining steel. The Siemens furnace used a grate for burning solid fuel, however, and the ductwork necessary to convey the gases from one end of the furnace to the regenerator chambers and the hot air to the grate at the other end was complex and inefficient. Pierre and Émile Martin in France in 1864 built a furnace that was fired by gas and placed a set of two Siemens regenerator chambers at each end of the furnace; one heated air, and the other heated the fuel gas. By firing the furnace with the gas alternately at one end and then the other, each set of chambers alternately was heated by waste gases and then heated the incoming air and fuel gas. As a consequence, it was possible to operate with a flame whose temperature was sufficiently hot to melt steel scrap. This furnace became known as the Siemens–Martin furnace, or, more commonly, as the open-hearth furnace. The regenerative system was also applied to the crucible process.

Open-hearth furnace

Native ores in Europe and in England contain considerable phosphorus, and pig iron produced from these ores, upward of 1 percent phosphorus, is unsuitable for steelmaking by Bessemer's process or the Siemens–Martin furnace. In 1876 S.G. Thomas and Percy Gilchrist, also in England, invented a modification of Bessemer's process by which satisfactory steel could be made from high-phosphorus pig iron. Instead of silica, a lining of lime was used; this permitted operation with a slag high in lime that could absorb phosphorus from the metal. Very shortly after this discovery, open-hearth furnaces were also built with their hearths lined with lime or magnesia instead of silica. Thus, the basic open-hearth furnace came into being.

The new methods for making steel were utilized rapidly in the commercial production of steel on the European continent, in Great Britain, and in the United States. The first commercial production of Bessemer steel in the United States was in Wyandotte, Michigan, in 1864, and in 1868 the first commercial open-hearth operation was started in Trenton, New Jersey. These processes produced steel in batches, or heats, that ranged in size from one or two to 15 tons or more. Thus, steel products in the form of rails, structural members, plates, and castings could be made cheaply and in relatively large quantities. The expansion of railroads in the United States following the Civil War depended largely on the availability of steel for rails. In the 1880s and 1890s buildings were built using steel members as the skeletons. Though the electric motor came into use for many purposes between 1880 and 1890, it did not completely replace the steam engine in the large rolling mills for many decades.

Use of the electric dynamo in steelmaking

As soon as the dynamo became a practical reality, chemists and metallurgists put electricity to work as an energy source for steelmaking. William Siemens is credited with having first used electric power to make steel (1878). The heat source was the electric arc. P.-L.-T. Héroult in France in 1899 operated the first commercial electric furnace for the production of steel. His design was the forerunner of the modern high-powered arc furnace. This type of furnace was enlarged in an installation in the United States in 1904 with a capacity of four tons (3,600 kilograms) per charge. The electric arc furnace is well suited to the production of high-quality special and alloy steels, and it rapidly replaced the crucible process for making these steels.

Development of fuels. As has been noted, fuels have been of great importance in the production of wrought iron, pig iron, and steel. Charcoal was virtually the only fuel employed from antiquity until early in the 16th century. Coal appears to have been used only occasionally before 1000, and heap coking of coals was practiced in the Middle Ages. The beehive coke oven was first used in 1620, but heap coking of coal for metallurgical purposes persisted. Attempts to develop ovens from which by-products could be obtained from the materials volatilized from the coal began in 1781. The modern retort oven was developed in 1861 and has been the chief means for producing coke for metallurgical use since about 1910. The beehive ovens continued to be operated for many years, particularly in times of high demand for coke. An important step in the development of fuels for steelmaking involved the use of gas as a fuel in the open hearth. This permitted all of the combustion to occur over the charge, a condition that could not be achieved with the combustion of solid fuel in a grate. Between 1880 and 1900, heavy oils, atomized with steam or air under pressure to form a long, nonturbulent flame over the hearth, also came to be used as fuels in the open-hearth furnace. The Bessemer converters and the basic oxygen process are said to be autogenous, because all the heat required is supplied by oxidation of elements in the charge, and no fuel is required. An important advantage of the electric furnace is that there is no possible contamination of the charge by impurities from the source of the energy at the generating station, such as can result from fossil fuels or nuclear power. Supplies of low-sulfur coal and fuel oils are being depleted rapidly, however, and the steel industry will face greater problems of contamination of steel with sulfur from fuels in the 1970s and 1980s.

Use of gas in open hearth

New steels. The growth of steel production in the world was rapid between 1870 and 1950. By 1910 the use of the acid Bessemer process had begun to decline in the face of competition of the basic open-hearth furnace, and the acid open hearth came to be used for the production of special steels for such items as forgings and bearings. The basic Bessemer process was used extensively in Europe for refining pig iron produced from certain low-grade (minette) ores. The electric-arc furnace became the principal method for producing alloy steels by 1920, and the use of the crucible process declined rapidly thereafter. Wrought iron continued to be produced in appreciable quantities, but there was a gradual decline in output in the face of competition from steel. The Aston process was developed in the United States for producing a "synthetic" wrought iron starting with low-carbon iron from an acid Bessemer converter and was used commercially until 1971.

The principal changes in the methods of producing steel in the early part of the 20th century were the rapid increase in the capacity and number of producing units of the iron blast furnace and of the basic open-hearth furnace. In 1950 a large blast furnace produced 1,500 to 1,800 tons of iron a day; and a large open hearth, 400 tons of steel in a heat time of eight to ten hours. The types of steels being produced expanded greatly, and the highly alloyed steels, such as the stainless steels (1915), came into use.

Post-World War II period. The enormous demand for steel created by World War II, the destruction of steel-producing facilities in a number of countries as a result of the conflict, and the economic changes in the immediate postwar era had a profound effect on the steel industry in most countries. The mines that supplied high-grade iron ores that could be used in the blast furnace with little or no processing were seriously depleted and could no longer supply the rapidly rising requirements for iron and steel in the postwar years. In consequence, it became necessary to process low-grade ores to obtain high-grade concentrates. Because these concentrates were very fine, they were agglomerated to obtain a granular product of uniform size (see ORE DEPOSITS for a description of iron-ore occurrence; see IRON MINING AND PROCESSING for in-

formation about mining and ore dressing or beneficiation).

Improvements in ore supply

The development of supplies of iron ores of carefully controlled size and composition has resulted in a very large increase in the output of a blast furnace since 1950. A furnace that produced 1,500 to 1,700 tons of iron a day in 1950 using an unprepared burden, for example, is expected to produce 3,500 to 4,000 tons a day today with an ore supply of good quality. Other improvements have aided in making this increase in productivity possible: increased pressure and temperature of the air blast, injection of fuel with the air, enrichment of the air blast with oxygen. Many mechanical improvements in equipment have also helped to increase the output. The availability of high-grade raw materials have made it practical to build very large furnaces with capacities of 10,000 tons of iron a day. Several of these furnaces were under construction in Japan in 1970.

Use of pure oxygen. Metallurgists have dreamed since Bessemer's time of using pure oxygen instead of air to refine liquid pig iron into steel. Although the fractionation of air to produce pure oxygen was developed in 1889, oxygen remained too costly for many years for it to be used as a primary oxidant in ironmaking and steelmaking. The first large-scale use of oxygen occurred in Germany immediately prior to World War II, following the development of a process for extracting oxygen from air in 1937. Immediately before and after the war, experimentation of the use of oxygen in steelmaking began in Germany, Switzerland, England, Sweden, and the United States. In 1949 a new process came into being as a result of experimental work in Austria. The furnace for the process is a roughly pear-shaped steel vessel lined with a basic refractory (Figure 4). The mouth of the vessel is

"Oxygen and Steelmaking Processes: A Comparison of Open Hearth, LD, Kaldo and Rotor Processes," by E.F. Kurzinski, *AISE Yearly Proceedings, 1960*, p. 99

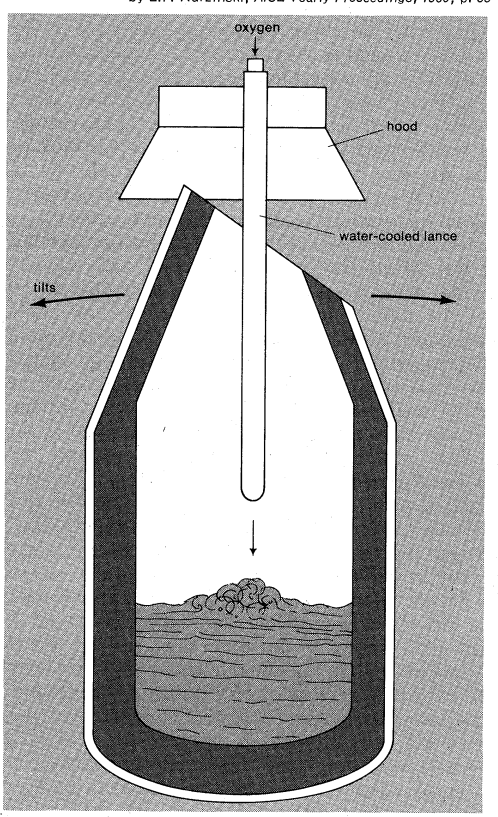

Figure 4: Elements in the L–D, or basic oxygen, furnace (see text).

open and faces upward. The liquid metallic charge placed in the vessel is oxidized by a supersonic jet of oxygen from a water-cooled lance that directs the oxygen vertically downward onto the charge of scrap and liquid hot metal. Depending on where it is located, this process is known as the L–D process, from the towns of Linz and Donawitz, in Austria, the basic oxygen furnace, the basic oxygen process, or the basic oxygen steel process. The first commercial oxygen furnaces had a capacity of 38 tons, but successive installations became larger, and furnaces with capacities of over 275 tons per heat have been in operation in Italy, the United States, and Germany since 1964. A plant with one furnace of this size in regular operation can produce over 2,500,000 tons of steel a year.

The basic oxygen furnace produces carbon steels at least the equivalent in quality to basic open-hearth steel. Many new installations of this process have been made throughout the world, and it is virtually the sole method used in making carbon steels in Japan. In 1970 it surpassed the basic open hearth in the production of raw steel in the United States, and it has been installed in a number of the major steel plants in the Soviet Union. It is also being operated extensively in Europe as a result of the greater use of low-phosphorus ores from overseas. Several modifications of the basic oxygen process are used to refine high-phosphorus pig iron on the European continent and in Great Britain.

Direct reduction. For several hundred years, metallurgists have argued the relative merits of the indirect and the direct processes for producing steel. The indirect process consists of producing a crude, relatively impure iron in the blast furnace and then refining it in the liquid form in one of the steelmaking processes, such as Bessemer, basic open hearth, or basic oxygen. The indirect process is commonly employed in virtually all modern steel plants throughout the world. Its detractors point, however, to the complicated processing sequence and the enormous capital investment for the facilities. In the direct process, relatively pure iron ore is reduced to the solid-metallic state by hydrogen, carbon, or carbon monoxide. The solid metal is then melted, alloyed, and cast into ingots or strand-cast bars and slabs for subsequent processing into finished products. If the reduced solid iron is pure enough, it can be compacted and formed into a bar of iron without the metal having been melted. The problems, however, of finding large quantities of iron ore of very high purity and of controlling the composition of the product have prevented large-scale use of this type of process. In the past century a large number of schemes have been proposed and patented for the direct production of steel. Many of them have been sound technically, but, except in unusual circumstances, none has been able to compete economically with the indirect route of the blast furnace and steelmaking furnace.

Interest in direct methods revived between 1965 and 1970 for a number of reasons. The initial cost of a single blast furnace and its auxiliaries with a capacity of 6,000 to 7,000 tons of pig iron a day is over $70,000,000. It is not practical in most countries to build a small unit with a capacity of 500 to 1,000 tons a day. In addition, relatively large supplies of high-quality ores suitable for direct processing have become available commercially, and the modern high-powered electric-arc furnace is well suited to economical melting of solid reduced ore. Finally, direct processing is suited to small-scale production of steel in the range of 500 to 2,000 tons a day away from the large-scale producing centres. It remains to be seen whether the improved technology for direct reduction will alter the century-old economic advantage of the indirect processing.

In the two decades since World War II the production of steel has spread to many countries of the world. The changing technology by which steel can be produced economically from scrap on a relatively modest scale of a few hundred tons a year has favoured this expansion. Also, a country often desires a steel industry as a mark of its industrialization and as a means of reducing its expenditures abroad.

Alloy steels. The use of alloying elements to obtain special properties in steels began on a commercial basis in 1861, when a patent was issued to cover the use of tungsten in tool steels. Chromium-bearing steels began to appear in the United States, Britain, and France in the

Steel used in construction

1870s. Chromium was used in tool steels; its first employment in constructional steels was in the Eads Bridge built in St. Louis, Missouri, 1867–74. This was the beginning of widespread use of the high-strength, low-alloy steels for constructional purposes. Steel containing 12.5 percent manganese and 1.2 percent carbon was found to be exceptionally tough and resistant to impact and wear. Invented by Sir Robert Abbott Hadfield in England in 1883, this steel is used for railway tires, railway crossings, and the tips and cutting edges of excavating equipment. Hadfield also assisted in the development of silicon-bearing steels for electrical machinery. These steels came into use just after 1900. Late in the 1880s there was a rapid development of the use of nickel as the alloying element in steels used in guns, armour plate, and projectiles in Britain, France, and the United States. Improved armour plate was obtained with the addition of chromium to nickel steels by the French in 1891. Soon after, the use of nickel–chromium steels spread to all types of forgings and machine parts. High-speed tool steels that retain a cutting edge at high temperatures and permit high cutting speeds were first developed in the United States about 1900. These steels contain tungsten, chromium, and vanadium. The appearance of the motorcar in considerable numbers about that time also accelerated the use of alloy steels for crankshafts, gears, springs, and shafts. Vanadium is used extensively in these steels because it imparts resistance to shock and fatigue. The appearance of the electric furnace not only led to improved methods for making alloy steels but also resulted in the production of numerous kinds of ferro-alloys required in the manufacture of these steels. Shortly after 1900, ferro-alloys containing silicon, chromium, tungsten, titanium, molybdenum, and vanadium became readily available to the alloy steelmakers. Stainless steels, which contain over 5 percent chromium, were first developed in Great Britain (1912). These steels have superior resistance to corrosion and were first used in cutlery. Between 1909 and 1912 the more familiar chromium–nickel stainless steels resulted from research work in Germany. The best known composition contains 18 percent chromium and 8 percent nickel; hence, it is known as 18–8 stainless.

Although many alloy steels were developed for munitions and military purposes, during wartime the shortage of materials made it necessary to economize on the use of alloying elements. In World War I a number of special alloy steels were developed that required reduced levels of alloying elements to obtain the desired properties. This was also true during World War II, when additional economies in the use of alloying elements were achieved by adding boron to steels. Boron is a potent agent, and 0.0005 percent of it permits the reduction of other alloying elements by half without loss of strength, ductility, and hardness. Subsequent to World War II, metallurgists throughout the world have been seeking ways of making and solidifying steels and processing them to reduce the amounts of expensive alloying elements that have been used in the past to impart special properties. To a large measure, the efforts have been successful, and in many places low-alloy steels or coated carbon steels are being used in place of more highly alloyed steels.

Protecting steel

Steel can be protected from corrosion and rusting by coating it with tin, zinc, chromium, lead, or copper. Tinning of iron was first practiced in Bohemia in the 17th century. The iron was cleaned in acid and then was dipped into a pot of molten tin to form a thin, adherent layer of tin. This method of coating iron and steel with tin, zinc, or lead containing some tin has been followed for centuries. Galvanized steel has a coating of zinc, and so-called terne plate has a lead–tin coating. To conserve tin, which was scarce in World War II, the electrolytic method was developed for making tinplate. A very thin coating of tin is applied continuously to the surface of a strip of sheet steel by the electrolysis of tin from an aqueous solution. The layer is then melted quickly and cooled to form a bright, adherent coating. The production of galvanized steel was made continuous just after World War II. A strip of sheet steel moves continuously through a furnace, which prepares the surface, and then the strip is passed through a pot of zinc alloy. Subsequently, the strip is cooled to solidify the zinc. Between 1960 and 1970 a wide variety of coatings have been developed for steel sheets; aluminum coatings by hot dipping or deposited from the vapour and a large variety of organic coatings are examples.

II. Modern steel technology

For information on the occurrence of iron-ore deposits, see ORE DEPOSITS. Extraction of iron ore and its treatment are described in IRON MINING AND PROCESSING. For additional information, see MINING AND QUARRYING.

RAW MATERIALS

Pig iron. Virtually all large steel plants in the world have blast furnaces for producing liquid pig iron, which usually constitutes over 50 percent of the metal-bearing part of the charge for the steelmaking furnace. In these large plants, a small quantity of cold pig iron may also be included in the charge for steelmaking, but hot metal is preferred, because no extra heat is required to melt it. Usually the cold pig iron is obtained from discarded ingot molds and the excess hot metal, which is cast into pigs from time to time. Pig iron may constitute up to 15 percent of the metallic charge of electric and open-hearth furnaces that operate on a completely cold charge, as it is an essential source of carbon for the system in these cases. Hot metal is transported from the blast furnace to the steel-producing shop in ladles of various types that are carried on special railway trucks. Common forms for these ladles are either a simple refractory-lined bucket (having a heat-resistant lining) with an open top or the submarine-shaped refractory-lined tank having an opening in the top central portion. There is also equipment for tilting the ladle so that metal can be poured from it and slag and refuse can be dumped out. The capacities of submarine ladles range from 100 to 300 tons, and iron will remain molten in them for periods as long as 24 hours. At the steelmaking shop, hot metal is poured from these ladles into an open-top ladle, which is used to transfer the metal to the furnace. In some plants, especially the older open-hearth shops and Bessemer shops, the metal will first go to a large refractory-lined tank or mixer that serves as a reservoir. A mixer usually has a capacity of 1,000 to 1,500 tons of hot metal. Liquid metal is taken from the mixer as needed by the steel furnaces.

Steel scrap. Steel scrap is the second most important source of iron in the charge to the steel furnace. Generally speaking, scrap has constituted between 48 and 50 percent of the total tonnage of metallic raw materials used in steel production throughout the world in recent years. There are three primary sources of scrap: revert scrap is the material discarded within the steel plant in the production of steel products such as plates, sheets, tubing, and wire from the raw cast steel; industrial scrap is the discarded steel from the plants and factories that process steel into useful objects, such as automobile bodies, machinery, and appliances; and reclaimed scrap is the ferrous materials obtained from refuse, worn-out objects, old buildings, and other discarded objects. Revert scrap varies greatly in size and thickness, because it consists of discarded ingots, crops removed from the ends of bars, billets and blooms during rolling, and clippings and trimmings from all kinds of products as they are cut to the required dimensions. It includes rejected products that may be found unsatisfactory at any point in the production process. Approximately 30 percent of the raw steel produced by the steel furnaces is recycled for remelting within the steel-producing plant. Thus, it is imperative for economic reasons that the steel-melting facilities be able to consume this scrap. Where possible, the steel plant segregates scrap from special alloy steels to use when making new steel having a similar composition.

Sources of scrap

Industrial scrap from factories and plants is generally of very good quality. Usually it is clean, its composition is known, and it is baled, or compacted into bundles of a size suitable for charging to the steelmaking furnace. The amount of this scrap produced varies greatly, depending upon the nature of the operation in the factory.

Many new manufacturing techniques have been developed, however, that tend to reduce the amount of steel lost as scrap. In consequence, the fraction of the finished steel produced by the steel industry that returns as industrial scrap to the steel plant also will probably be reduced in the years ahead. The physical condition and composition of reclaimed scrap varies widely. It may be contaminated with undesirable substances (*e.g.*, paints, coatings, cement, and dirt) containing zinc, copper, tin, sulfur, arsenic, or silica that cause difficulties in steelmaking and may be deleterious to many grades of steel. An element such as copper or nickel, for example, may be valuable in certain kinds of steel but quite undesirable in others.

Metallized ore. Metallized ore, the solid metallic product obtained by the direct reduction of iron ore, is becoming an important raw material, particularly for the electric arc furnace. It is of great value in the charge for high-grade steels because of its freedom from contaminants such as copper and tin. It has the disadvantage that the worthless rock (gangue) it carries from the ore increases the slag volume of the melting furnace. The reduced product must be processed and handled so it does not reoxidize extensively between the time it leaves the reduction system and the time it is melted in the steel furnace. In some cases the spongy metallic product is compacted under high pressure to form dense briquettes. These briquettes can be handled and stored under cover without reoxidation being a serious problem. The usual practice has been to transfer the reduced product, either hot or cold, directly to the furnace for melting with a minimum of delay. Provisions for a cover of an inert gas may be included in the handling facilities and storage bins to prevent contact of the metallized ore with air and moisture. Metallized ore may constitute part or all of the initial charge to a furnace, and it may also be fed continuously as the furnace operates. In the latter case, special handling facilities are required.

Fluxes. Limestone, lime, and fluorspar (CaF_2) are important as fluxes for forming a slag of the correct composition and consistency in the steelmaking furnace. The amounts used vary with the different steelmaking methods and will be considered later when each process is described. Lime and limestone must have low levels of sulfur, in the range of 0.04 percent, and silica of under approximately 2 percent to be satisfactory. They must also be crushed and sized by screening to eliminate dust and large pieces. The most desirable burnt lime is as completely calcined as possible without becoming hard and dense due to its being overburned. Similarly, fluorspar should be coarsely granular to prevent loss by dusting when it is shipped, transported within the steel plant, and added to the furnace. Relatively large quantities of fluorspar are required in oxygen steelmaking to assist in the formation of the slag, and there has been a worldwide shortage from 1968 to 1971.

Preparation of fluxes

Liquid iron. The cylindrical-shaped cupola furnace has been used since Bessemer's time to melt pig iron and scrap to provide liquid iron high in carbon for steelmaking. High-quality coke is used as a fuel. During the early years of the Bessemer process, all of the iron from the blast furnace was pigged, and this cold iron remelted in a cupola to provide liquid iron for steelmaking. Several decades elapsed before liquid iron directly from the blast furnace could be used. Since World War II the hot-blast cupola has been used to melt scrap to provide a supply of liquid pig iron for oxygen steelmaking in steel plants where the demand for steel is insufficient to support a blast furnace.

Oxygen. Enormous quantities of gaseous oxygen are used in steelmaking throughout the world. Produced by the fractionation of air (see GASES, INDUSTRIAL AND DOMESTIC), the gas is usually 99.5 percent pure to avoid contaminating the steel bath with nitrogen. In most cases the gas is transmitted by pipeline from the producing plant to the steel furnace. The basic oxygen furnace consumes more oxygen per ton of steel made than does the basic open hearth, and, as the former has replaced the latter, the consumption of oxygen in steelmaking has risen rapidly.

Refractory materials. Large quantities of costly high-grade refractory materials are consumed in steelmaking. Every steel plant must have facilities for storing and handling these refractories and for relining ladles and converters and for rebuilding furnaces. The consumption of refractories by the basic open-hearth process is much greater than it is for the basic oxygen process, because the furnace structure is more complex. As the basic oxygen process has replaced the basic open-hearth process, the requirement of basic refractories in steelmaking has declined markedly.

THE BASIC STEELMAKING PROCESS

Virtually all the world's annual production of 642,000,000 tons of steel is made in a process that begins with the production of an impure liquid bath from a charge that is principally steel scrap, hot metal, pig iron, and, perhaps, a small amount of ore. The bath is then refined to obtain the desired carbon content and to remove impurities. Finally, alloying elements are added to the refined bath to adjust its oxygen content and to bring its composition to the formulation required for a given steel product. The major impurities in the bath removed during refining are carbon, silicon, manganese, phosphorous, and sulfur. These are oxidized to form a gas containing carbon monoxide and carbon dioxide from the carbon and a liquid slag containing the oxides, silica (SiO_2), manganese oxide (MnO), and ferrous oxide (FeO), which react with lime (CaO) in the charge. Undesirable materials introduced with the charge that also enter the slag are sand, dirt, bits of cement, small quantities of blast-furnace slag, and gangue (worthless rock) in the ore. Materials such as lime, limestone, and fluorspar (CaF_2) may be added to assist in the formation of the slag and to give it the desired composition.

Impurities in the liquid bath

Types of furnaces. Contemporary steelmaking furnaces can be classified broadly in terms of their shape and the way in which heat is provided. The open-hearth furnace has a broad, shallow hearth to contain the pool of metal and slag. Heat is supplied from a large, luminous flame that plays over the surface of the slag. The electric-arc furnace also has a shallow hearth; heat is supplied from arcs struck between graphite electrodes and the metal bath. The converter is a pear-shaped vessel into which an oxidizing gas is injected. Heat to support the process is provided by reactions between the gas and materials in the charge. An induction furnace is also used on a small scale: the scrap charge is contained in a cup-shaped crucible, and heat for melting and refining is supplied from electric currents induced in the metallic charge from an external coil in which an electric current is circulated.

Slags and refractories. Steelmaking processes may also be differentiated on the basis of the type of slag necessary for refining the steel and the type of refractory used in the furnace. Broadly, there are two types of oxides used in slags: acids, such as silica (SiO_2) and phosphorus pentoxide (P_2O_5), and bases, such as lime (CaO) and magnesia (MgO). Ferrous oxide (FeO) and alumina (Al_2O_3) are essentially neutral in steelmaking slags, and manganous oxide (MnO) tends to be basic. Acidic steelmaking slags contain an appreciable concentration of silica with very little lime, and basic slags contain an appreciable concentration of lime and up to about 20 percent silica. The decision whether to use an acid or basic slag depends on the levels of sulfur and phosphorus to be contained in the charge to the furnace. If the amount of either is greater than that which can be tolerated in the final steel product, it is necessary to use a basic slag, because it is able to absorb both of these elements. The nature of the slag also determines the type of refractory materials that are used to contain the slag and metal. An acid slag will attack and rapidly dissolve basic refractories, while a basic slag will destroy acid refractories. Silica is the principal refractory used in acid steelmaking furnaces. Basic refractories are composed chiefly of pure magnesia (MgO), calcined dolomite ($CaO \cdot MgO$), or lime. In some cases, chromite ($FeO \cdot Cr_2O_3$) may be used as a hearth lining if steels high in chromium are to

Acidic and basic slags

be made. It is usual to choose a refractory with a low solubility in the slag. Only a few percent of magnesia, for example, will dissolve in basic steelmaking slags. The pure oxides from which refractories are made have melting points well above the operating temperatures of the steelmaking system. In most processes, the composition of the slag must be adjusted so that it is completely liquid at the operating temperature of the furnace.

Amount of nitrogen. The amount of nitrogen introduced into the steel during processing also plays an important part in the choice of a steelmaking process. Actual levels are very low; 0.005 percent or less is desired in sheet steel, and values above 0.009 percent are desired only in selected types of steel. (The effect of nitrogen on the properties of steel is described below.) Nitrogen is introduced into liquid steel during melting and refining if the liquid metal is exposed to air or other gas that contains nitrogen. The rate of absorption rises rapidly as the temperature of the liquid metal increases and is particularly rapid when the metal is exposed to an electric arc operating in air or when a jet of air or of oxygen carrying small concentrations of nitrogen impinges on the metal surface. The practical steps necessary to minimize the uptake of nitrogen by the metal are to keep the metal covered with a slag that is impervious to nitrogen, to exclude nitrogen from the furnace atmosphere and be certain that the oxygen used in refining has a very low nitrogen content, and to obtain a vigorous boiling action of the bath by the formation of carbon monoxide as bubbles of these gases carry nitrogen out of the system.

Refining reactions. Liquid impure iron and steel can be refined rapidly by reactions with oxygen from an oxygen jet, from iron oxides such as ore added to the furnace, and from iron oxide dissolved in the slag. The reactions between ferrous oxide in the slag and silicon, manganese, and phosphorus in the crude iron can be written:

$$2FeO\ (slag) + Si\ (metal) = SiO_2\ (slag) + 2Fe\ (iron)$$
$$FeO\ (slag) + Mn\ (metal) = MnO\ (slag) + Fe$$
$$5FeO\ (slag) + 2P\ (metal) = P_2O_5\ (slag) + 5Fe.$$

The first two reactions occur very early in the refining process, and usually all but minute quantities of silicon and manganese go into the slag, particularly if it contains more than about 10 percent ferrous oxide. The oxidation of carbon by iron oxide in the slag is written:

$$FeO(slag) + C(metal) = CO(gas) + Fe$$
$$2FeO(slag) + C(metal) = CO_2(gas) + 2Fe.$$

The gas formed will contain only a few percent carbon dioxide. Pure liquid iron at 1,600° C (2,900° F) in the presence of pure liquid ferrous oxide will dissolve 0.24 percent oxygen. Since solubility rises very rapidly as the temperature increases, the steel bath will absorb oxygen from ferrous oxide in the slag and from a jet of oxygen gas impinging on the surface. As oxygen is added to the bath, it will react with carbon to form carbon monoxide and carbon dioxide. A steel bath at 1,600° C containing 1 percent carbon will have to contain approximately 0.002 percent oxygen to be able to eliminate carbon as carbon monoxide in a bubble of gas passing through the metal. As the carbon content of the bath is reduced during refining, the oxygen content of the bath necessary to drive carbon out into the gas phase rises rapidly. At 0.1 percent carbon, a minimum of 0.02 percent oxygen in the steel is needed, and, at 0.05 percent carbon, 0.04 percent oxygen is required. During refining of the steel bath the actual oxygen level is about twice the minimum. Since the solubility of oxygen in solid steel is very low, the oxygen in the liquid steel evolves very rapidly, chiefly as carbon monoxide, during solidification. Liquid steel containing 0.2 percent carbon and 0.02 percent oxygen may evolve over 100 times its own volume of hot carbon monoxide as it solidifies. Unless the release of gas is controlled, sound ingots and castings of the steel cannot be obtained. Control is effected after refining by adding deoxidizing agents such as aluminum, silicon, titanium, and manganese to the liquid; these combine with most or all of the oxygen. The products of the deoxidation reactions are small particles of the oxides of these elements. Some will float out of the steel, but many will remain in the solidified steel. If a metal serves as an alloying agent and will also deoxidize the steel, only a small excess need be added for deoxidation, because the amount consumed by the reaction with oxygen is usually only a few hundredths of a percent of the weight of the steel.

Removing sulfur from the bath

Sulfur can be removed from the steel bath only if a basic slag is present. Very little sulfur is carried off in the waste gases. The chief requirements for control of sulfur are that the ratio of lime to silica in the slag be greater than 2.8, that the slag be fluid and hot, and that the slag and metal be stirred together actively. Strongly reducing conditions in the furnace also favour desulfurization. The concentration of sulfur in a basic slag ranges between 0.05 and 0.20 percent in normal commercial oxidizing steelmaking operations such as the open hearth and the basic oxygen furnace. Since the final steel should contain from about 0.01 to 0.025 percent sulfur, control of this element is a major problem of the steelmaker.

TYPES OF STEELMAKING PROCESSES

Acid Bessemer process. The converter developed by Bessemer and Kelly is lined with a siliceous refractory material and operated with an acidic slag and, therefore, cannot be used if phosphorus must be removed from the charge. Its use grew rapidly in the United States, where pig iron low in phosphorus was produced from plentiful supplies of low-phosphorus ores. On the other hand, it found little use in Europe and Great Britain, where most steelworks produced hot metal high in phosphorus from local ores high in phosphorus. Even in the United States, however, the open-hearth process enjoyed advantages because of superior control of sulfur and the avoidance of nitrogen in the steel from the air blast.

The acid Bessemer converter is either a pear-shaped or a cylindrical vessel with a slightly constricted nose that has an opening at the top (see Figure 5). Waste gases leave

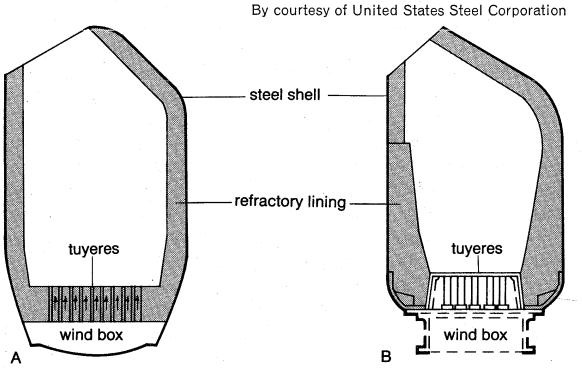

Figure 5: *Bessemer vessels.*
(A) Bottom-blown acid converter; (B) bottom-blown basic converter.

through this opening. The vessel also has a perforated bottom for admission of the air blast. The furnace is mounted in a steel ring around its middle, and this ring is supported by two horizontal shafts, or trunnions, fixed at a right angle to the longitudinal axis of the vessel so it can be tipped for charging and tapping. All charge materials enter through the mouth of the vessel, and finished steel is poured from the mouth as well. Compressed air for the blast is led through a tube in one trunnion and then into a steel box on the bottom of the vessel, from which it passes into the vessel through holes (tuyeres) in the bottom refractory lining.

The refractory lining of the vessel walls, usually composed of sandstone or micaceous schist, will usually last over a thousand heats. The bottom refractory, however, is subject to severe wear and survives only 25 to 35 heats. Accordingly, the bottom of the vessel is constructed for ready removal to be relined and replaced. Spare bottoms are kept on hand and can be installed in 30 minutes.

In the United States a Bessemer shop was usually equipped with two or three vessels that stood in the open. One vessel was available for relining and repair while the

other one or two were in use. A vessel was usually ten to 12 feet in diameter by 20 feet high (approximately three by six metres) and produced from 25 to 30 tons of steel each blow. Ladles of hot metal and chutes for charging scrap were carried by overhead cranes or on railcars. Ladles for the finished steel and pots for the slag were mounted on railcars while being filled. Usually the ladle of steel was transferred by an overhead travelling crane to the teeming platform, where the steel was poured into ingot molds. The operation was controlled by an operator in a pulpit so positioned as to permit an unobstructed view of the vessel. Hot metal was stored in a large mixer with a capacity of between 800 and 1,200 tons. Such a reservoir was needed because hot metal came from the blast furnace infrequently and in large batches but was used in small quantities and at much more frequent intervals. The mixer also provided a supply of hot metal that was relatively uniform in composition and temperature. The shop included facilities for scrap preparation, relining of the vessel and bottoms, storage and weighing and ferro-alloy additions, and a compressor to provide air blasts at a pressure of 20 to 25 pounds per square inch.

The hot-metal reservoir

The usual hot metal for acid Bessemer operations contains 1.1 to 1.5 percent silicon, 0.4 to 0.7 percent manganese, about 4 percent carbon, 0.09 percent maximum phosphorus, and 0.03 percent maximum sulfur. A typical charge is approximately 90 percent hot metal and 10 percent scrap. Sometimes small quantities of high-quality iron ore or roll scale are added to decrease the blow time. When this is done it is also necessary to reduce the amount of scrap because of the extra heat required to reduce the iron oxide. The furnace is charged in the horizontal position, the air blast is turned on, and then the furnace is rotated to the vertical position, a procedure that prevents plugging of the tuyeres. The cold-air blast oxidizes manganese and silicon and some iron to form a slag in the first four minutes of the blow. During this time, the flame emerging from the mouth of the vessel is short and transparent. Then the carbon is oxidized, producing a bright flame about 30 feet (ten metres) long. This flame results from carbon monoxide burning in the surrounding air. When most of the carbon is burned out of the steel, the flame drops. An operator learns from experience to judge the carbon content and temperature of the steel by the character of the flame. A blow lasts 12 to 15 minutes, and the final slag contains iron oxide, manganese oxide, and silica, the amount being approximately 7 percent of the weight of the steel made. Additional scrap, iron ore, cold pig iron, or steam in the blast can be used to cool a hot heat; the temperature of a cold heat can be raised by blowing with the vessel turned on its side. This oxidizes iron into the slag, which generates considerable heat, but reduces the amount of steel produced from the charge. Deoxidizing agents and alloying additions to bring the steel to the desired composition are added to the ladle as the steel is tapped from the furnace into the ladle. For a long time, high-carbon steels such as rails were made by recarburizing the steel with hot metal. The practice led, however, to a product of poor quality.

The basic Bessemer process. Developed to produce steel from the low-grade ores of Europe and similar ores in Britain, the basic Bessemer, or Thomas, process has had an existence in those areas similar to that of the acid Bessemer process in the United States. Production of Thomas steel rose rapidly until 1910 and, except for the period of high demand during World War II, declined as a result of competition from basic open-hearth steel. The process is suffering further decline as a result of the increased importation of high-grade ores that also are low in phosphorus.

In most external aspects, the basic Bessemer steel shop is similar to the acid Bessemer plant. There are essential differences in the way the process operates, however, because a basic refractory and a basic slag are employed.

The basic and acid Bessemer vessels are similar in shape, except that in the basic vessel the nose is usually concentric with the longitudinal axis. The capacity of basic furnaces and the relatively deep bath requires a blast pressure of 35 pounds per square inch. The lining is a plastic mixture of tar and calcined dolomite or lime that is rammed into place. The wall and nose lining lasts up to 400 heats and the bottom refractory to about 40.

Thomas process in operation

The operation of the Thomas process varies so widely from plant to plant that only the general pattern can be described: the vessel is charged with hot metal, the composition of which is 1.5 to 2 percent phosphorus, 0.6 to 1 percent manganese, 0.2 to 0.4 percent silicon, about 3.8 percent carbon, and a maximum of 0.05 percent sulfur. It should be noted that the regular basic Bessemer process cannot operate successfully on pig iron containing less than 1.5 percent phosphorus, because insufficient heat is generated to meet the needs of the process. The weight of lime charged is approximately 15 percent of the weight of the finished steel. This lime is charged with the hot metal. Only about 10 percent of the metallic charge is steel scrap, and it is usually added late in the blow, because much of the heat is generated by oxidation of the phosphorus occurring late in the heat. The reactions proceed much as they do in the acid process, with silicon and manganese being oxidized first, followed by oxidation of carbon. The flame drops when the carbon reaches about 0.04 percent. About three minutes before the flame drops, scrap is added to the vessel, and the blow is continued for two to three minutes more. During this time, the principal reaction is oxidation of phosphorus into the slag. At the end of the blow, the carbon, manganese, and silicon levels in the metal are very low, and the phosphorus content is about 0.04 percent and nitrogen 0.01 percent. The carbon must always be brought to a low level to obtain a dephosphorizing basic slag with 15 to 20 percent ferrous oxide. Thus, it is necessary to add to the ladle large amounts of ferromanganese, other carbon-containing additions, and a deoxidizer as the heat is tapped to obtain steel of the desired final composition.

The final weight of the basic Bessemer slag is about 20 to 22 percent of the weight of the steel made. This slag contains 16 to 18 percent phosphoric acid and up to 50 percent lime, so that it has been sold profitably as a fertilizer. The recent production of less expensive fertilizer from phosphate rock has meant the loss of revenue to the steel plant from the sale of this slag.

Low-nitrogen steel

A number of special practices have been developed to permit the production of steels low in nitrogen by the basic Bessemer process. These consist of keeping the bath cool and shortening the afterblow by adding roll scale or ore (up to 2.5 percent of the metal weight) just before the flame drops, by first blowing half of the charge to completion in order to develop a slag containing considerable iron oxide and then adding the balance of the hot metal and completing the blow, and by equipping the vessel with tuyeres on the sidewall so that the air has a shorter path through the metal and is in contact with the bath for a shorter time. Use of a blast of oxygen and hydrocarbon gas permits refining of hot metal containing little or no phosphorus. Oxygen is used in some plants to enrich the air blast. This practice permits the use of hot metal with less phosphorus, because, with a lower level of nitrogen in the blast, less heat is carried from the system by the waste gases. Alternatively, the use of oxygen permits the percentage of scrap that dilutes the phosphorus in the hot metal and also shortens the afterblow.

Steels produced by the basic Bessemer process are used extensively except where high ductility and formability are required in low-carbon sheet steels. With special practices in the afterblow, particularly blowing with oxygen and steam, low-carbon steels, with low levels of phosphorus and nitrogen, can be made that are competitive in properties with open-hearth steels.

The basic oxygen process. Though the basic oxygen furnace was developed in form from the basic converter, the chemistry of the process is more closely related to that of the basic open-hearth process. The basic oxygen furnace is a large, cylindrical steel vessel with a conical nose and a solid bottom. The opening in the nose is usually concentric, and a taphole is placed about halfway up the conical portion. The refractory lining of the walls and nose cone is made of a mixture of tar and calcined dolomite. The refractory on the bottom may also be made of

tar–dolomite brick or plastic mix rammed in place. A supersonic jet of oxygen is projected down onto the central portion of the charge by a large water-cooled lance inserted vertically through the mouth of the vessel. The vessel is mounted on trunnions so it can be tilted for charging, tapping, and repair of the refractories. Two or three vessels are usually installed together in a row, and one vessel is relined while the other one or two operate. The building housing the furnaces is tall to accommodate bins and weighing equipment for delivering lime, limestone, calcined dolomite, and spar to the vessel as required. The lance-support system and replacement lances are also located above each furnace. Waste gases and heavy red fumes from the furnace are collected in a hood, passed through cleaning equipment, and discharged through a tall stack. Often the hood is water-jacketed so the heat of the hot gases and that resulting from the combustion of the waste gases with air is used to generate low-pressure steam: a hood system has been developed in Japan that is sealed to the mouth of the vessel, and the waste gases are collected for use as a gaseous fuel in other areas of the steel plant.

Charging the vessel

The vessel is charged with hot metal from a large ladle carried by an overhead crane. Scrap may also be charged from a chute carried by the same crane or may be added from a large box mounted on a very large tilting device that travels on rails. The ladle for the steel and a pot to collect the slag are carried under the furnace by a car that travels on rails. This car moves the steel ladle and slag pot out from under the furnace on the side opposite to the charging side. The ladle of steel is then carried by another overhead crane to the place where the steel is poured into ingots or into a strand-casting machine. There are several positions from which the furnace is operated. The controls for the furnace, oxygen lance, waste-gas system, and bins for additions to the furnace are located in a small, well-protected building on the level of the furnace trunnions and where the operator can see the mouth of the vessel during blowing. There are usually auxiliary control stations for tilting the vessel on the charging side and on the tapping side.

The charge to a furnace is usually 27 to 33 percent scrap, with the balance being hot metal. The amount of scrap will be a little higher if the metal is hotter and the level of silicon is high. Scrap in the charge has been increased up to 40 percent by preheating the scrap and by the use of an auxiliary fuel such as silicon carbide. The furnace will operate successfully on a broad range of compositions of hot metal—3.5 to 4.3 percent carbon, 0.2 to 2.0 percent silicon, 0.1 to 2.5 percent manganese, up to 0.45 percent phosphorus, and up to 0.06 percent sulfur. When making steels with sulfur below 0.025 percent, however, it is necessary that the sulfur in the hot metal be less than 0.04 percent. The operation of the process is not particularly sensitive to the kind of steel scrap in the charge. The oxygen required is approximately 0.07 tons per ton of steel made (1,750 cubic feet per net ton [55 cubic metres per metric ton]). Gaseous oxygen is delivered to the lance at a pressure of ten to 13 atmospheres gauge (150 to 180 pounds per square inch). The amount of lime and calcined dolomite required varies depending upon the silicon content of the iron, but an average figure is 8 percent of the weight of the finished steel. Fluorspar (CaF_2) is used almost universally as a fluxing agent to help dissolve the lime in the slag and to produce a thin, fluid slag. The amount used also varies widely and increases as the level of manganese in the hot metal decreases. An average figure for U.S. practice is 0.7 to 0.8 percent of the weight of steel. The slag produced is 10 to 15 percent of the weight of the steel. The scrap is usually charged to the vessel first, and then the hot metal is poured in. The oxygen lance is lowered to within five to nine feet (1.5 to three metres) of the metal surface, and the oxygen jet is turned on. The blowing rate depends primarily upon the size of the furnace, the rates being approximately 0.035 ton of oxygen a minute per ton of steel capacity; *i.e.*, a 200-ton furnace is blown at a rate of 0.7 ton of oxygen per minute. Usually within seconds after the oxygen is turned on, flame and fumes appear at the mouth of the vessel, and the refining reactions begin. Shortly thereafter the desired amounts of lime, calcined dolomite, fluorspar, and ore, if used, are added. Within four to six minutes an early slag is formed by oxidation of iron and of impurities in the charge. After eight minutes, oxidation of carbon begins and continues until the flame drops. If the reaction becomes too violent, slag and metal may be ejected from the furnace, and the operator adjusts the lance position and oxygen flow to correct the condition. Usually the amount of the charge and the blowing rate are designed to give a blow time of from 15 to 20 minutes. In most furnaces, the flame drops when the carbon is about 0.06 percent. If the heat of steel is to have a higher concentration of carbon, the blowing is stopped earlier. When the blow is ended, the furnace is turned down, a thermocouple is inserted into the bath to measure its temperature, and a sample of metal is taken for chemical analysis. Often a sample of the slag is also taken. The carbon content of the bath is determined within a minute or two, and the contents of metals such as manganese, phosphorus, sulfur, copper, tin, and nickel can, if needed, be determined by a spectroscope in a few minutes. The ferrous-oxide content of the slag and the lime–silica ratio may also be obtained. If there is too much carbon, sulfur, or phosphorus in the steel or if the temperature is too low, the heat is reblown for an interval of from one-half to three minutes. If the steel is too hot, limestone or scrap is added. As the steel is poured into the ladle, ferro-alloys and deoxidizers are added to bring it to the desired composition.

Heat times

The time from the beginning of charge of one heat to the beginning of charge of the next heat ranges from just under an hour for large furnaces to less than 30 minutes for small furnaces. There is vigorous competition among furnace crews, steel plants, and nations for the fastest furnace; a good performance is 30 heats a day for one furnace, but an average of 50 heats a day for a month has been achieved. The composition of a typical slag from a low-carbon heat is 55 percent lime, 25 percent ferrous oxide, 16 percent silica, 2 percent magnesia, and a few percent each of manganous oxide and phosphorus pentoxide. The sulfur content would range from 0.05 to 0.20 percent.

The reactions among silicon, manganese, and carbon proceed in much the same manner as in the acid and basic Bessemer converters. Silicon and manganese oxidize rapidly to silica and manganous oxide. Some ferrous oxide is formed, and these oxides react with the lime, calcined dolomite, and fluorspar to form a slag within four or five minutes after the fluxes have been added. As soon as a slag has formed, some phosphorus is oxidized to phosphorus pentoxide and is absorbed by the slag. After approximately eight minutes of blowing, only a trace of silicon is left in the metal, and most of the manganese that will oxidize is in the slag. At this point the reactions with carbon become much more vigorous, and the slag and metal are highly agitated and mixed by the release of very large volumes of gas. The high speed of the basic oxygen process results from this agitation. When the carbon in the bath has reached 1 percent, the phosphorus in the bath is usually under 0.05 percent, so satisfactory steel with a carbon level as high as 1 percent can be made. As the carbon drops, the ferrous oxide in the slag rises, and the lime becomes fully dissolved to produce a fluid, basic slag that will dissolve sulfur and more phosphorus. Nitrogen is not absorbed by the metal in the process, because high-purity oxygen containing less than a 0.1 percent of nitrogen is used, and the vessel nose is designed to prevent any air from entering the converter when the metal is being agitated violently. Levels in the final steel between 0.003 and 0.005 percent nitrogen are obtained.

A great deal of attention has been devoted to finding means for automatic control of the process. Instruments have been developed for determining the temperature and carbon content of the bath and the amount of carbon in the waste gases during the blow. Computer programs have been developed that calculate the charge for a heat and determine such things as the lance position, oxygen delivery rate, and time to stop blowing. Although much

has been learned, a wholly complete and automatic control system has not yet been devised.

The original furnaces installed at Linz and Donawitz, Austria, in 1952 and 1953 had capacities of 39 tons. Since then the size of furnaces has grown rapidly, and many vessels with capacities of as much as 200 and 300 tons are now in operation in Europe, North America, Australia, Great Britain, Russia, and Japan. The basic oxygen furnace is rapidly replacing the basic open-hearth furnace and the Thomas converter for producing carbon steels. Virtually all production of carbon steels in Japan is by oxygen converter. The first oxygen converter was installed in the United States in 1956, and, by 1970, 50 percent of the steel made was by the process. Large plants have also been installed in Great Britain, Italy, France, The Netherlands, the Soviet Union, and India. Installed capacities of basic oxygen furnaces in 1970 in millions of tons were: Japan, 105; United States, 78; European Economic Community, 75; Soviet Union, 23; and the United Kingdom, 23. The total capacity for the world is reported to be 336,000,000 tons, with an additional 116,000,000 tons being planned.

Two-slag operation

A special two-slag operation is carried out when the basic oxygen furnace is used to refine high-phosphorus hot metal, which previously required the use of the Thomas process. An early slag that is high in phosphorus is formed by carrying powdered lime into the vessel along with the oxygen stream in a special lance. A fluid slag is formed, the blow is interrupted, and this slag is poured off. The blow is continued, and more lime is added, to form a second slag typical of normal operations. The first slag can be sold as fertilizer because of its high phosphorus content. In some cases, the second slag is retained in the vessel after the steel is tapped and becomes the first slag in the next heat. This two-slag practice is used in Luxembourg, Belgium, France, and Great Britain.

The open-hearth process. *Open-hearth furnace.* The open-hearth furnace has a large, rectangular, shallow hearth that contains the molten pool of metal and the liquid slag floating on its surface (see Figure 6). Walls of

brick and an arched brick roof confine the large flame that is the source of heat in the process and reflect heat from the flame down onto the hot steel and slag. This brickwork is held in place by a framework of heavy steel members. Brick ducts at each of the short sides of the rectangle—*i.e.*, the ends of the furnace—permit the passage of air and gases between the furnace chamber and the brick regenerator chambers located one floor below the hearth level. A large water-cooled burner is mounted at each end of the furnace and, when in operation, projects natural gas or atomized heavy fuel oil, pitch, or tar down the furnace chamber. This spray of fuel is burned by the stream of hot air from the regenerator. A jet of oxygen gas may also emerge from the burner under the fuel jet to increase the rate at which the fuel is burned. The furnace is charged through a number of openings on the front side of the furnace. These openings are closed by water-cooled, refractory-lined doors that slide up and down. It is probable that the name open hearth is derived from the fact that these openings extend the full length of the hearth to make the furnace chamber accessible for charging, working of the heat, and making repairs. Equipment for servicing the furnace operates on the charging floor at hearth level in front of these doors. The materials to be charged are brought to the furnace in large steel boxes carried on small railway cars. A charging machine that also runs on rails is equipped to pick up a charging box, thrust it through an open door, dump its contents on the hearth, and return it to the small car. Hot metal is poured into the furnace from a ladle carried by an overhead travelling crane. The metal is poured in through a movable spout inserted in one of the open doors.

The burner

Draining the furnace

A taphole for draining steel and slag from the furnace is built into the bottom of the furnace on the side opposite the doors. This hole is plugged with refractory, and when the heat is to be tapped the plug is partially dug out and then blasted open with a small explosive charge. The metal flows through a short trough called a launder and falls into a large ladle. The slag also flows into this ladle and floats on top of the liquid steel. When the ladle is full of steel, the slag cascades into a cast-steel slag pot set beside the ladle. The full ladle is transported by another overhead travelling crane to a stand where ingot molds are filled, or teemed. In some shops the ladle is moved in this fashion to a strand-casting machine.

Most modern furnaces are equipped with one or more oxygen lances that project down through the roof. A lance can be lowered so that its tip is close to the slag and the jets of oxygen from numerous small holes in the tip impinge on the surface of the metal bath. A lance also can be withdrawn completely from the furnace so as not to interfere with other operations, such as charging. These lances are smaller than those used in the basic oxygen furnace and deliver oxygen at a much lower rate to avoid heavy splashing of slag and metal. The waste gases leaving the furnace carry large quantities of fume, particularly when oxygen is being used. Gas-cleaning systems have been installed on many modern furnaces to collect this fume before the gases are discharged into the atmosphere.

The regenerators

The regenerators for each furnace are two large chambers, each of which may be as big as the furnace itself, located below the furnace and under the charging floor. Each chamber is partially filled with refractory brick stacked to form many small vertical flues. Air from a blower passes into the lower part of one of the chambers. It then turns and passes up through the flues. The checker brickwork is hot, and the air is heated from 1,200° to 1,550° C (2,200° to 2,820° F) in the passage. The air then passes up into the furnace, where it burns fuel. The gases from the flame and from the reactions in progress in the furnace pass out of the opposite end of the furnace and down into the other regenerator chamber. The ductwork has several abrupt changes in direction and cross section to cause particles of slag, soot, and iron oxide to settle out of the stream of gas before it enters the regenerator chamber. This very hot gas heats the brick flues in the chamber but still retains some heat when it leaves the regenerator chamber. To remove this heat, the gas is passed through a waste-heat boiler. It then goes to the gas-cleaning system and out the stack. The gas flow through the regenerator system and furnace is reversed at approximately 20-minute intervals to keep the air for combustion hot.

The capacities of furnaces range from 200 to 650 tons per heat. Eight to 12 furnaces are usually installed in a long row so that auxiliary equipment can service several furnaces. Hot metal is usually brought from the blast furnace in submarine-type (enclosed) ladles. It may be put in a mixer and transferred to the furnace; or the submarine ladle may serve as a reservoir, and the hot metal may be transferred directly to the open-hearth furnace as needed. Because of its complex shape and regenerator chambers, an open-hearth furnace requires large amounts of costly refractories, and considerable plant space

and staff are devoted to the repair and reconstruction of the furnaces. Most furnaces are basic, and the hearth is formed by ramming a plastic magnesite (MgO) mixture into the desired form. In modern shops the walls and roof are made of chrome–magnesite ($Cr_2O_3 \cdot MgO$) bricks, each of which has a thin steel casing. This steel oxidizes in use and functions as mortar to seal the bricks in place. The hearth requires frequent repairs but will last 3,000 to 6,000 heats. The roof will last between 500 to 1,000 heats; its life depends on the care of the operator running the furnace. Each time a new roof is put on, the furnace is repaired, and the regenerators are cleaned out. The whole structure may be rebuilt when the hearth is replaced.

The furnace is able to melt virtually all kinds of scrap, ranging from discarded ingots and odd pieces that formed in the ladle from a cold heat to very lightweight clippings and trimmings left in the processing of steel and miscellaneous iron-bearing waste obtained from refuse.

Production of a heat. The production of a heat of steel starts with an inspection of the furnace and sealing of the taphole with a refractory plug. The charge usually consists of limestone, steel scrap, iron ore, and hot metal. The weight of the limestone is determined by the weight of silicon in the hot metal and normally ranges from 6 to 9 percent of the weight of steel made. The hearth is first covered with a light layer of plate scrap, and then limestone is spread over the hearth. Iron ore, if used, is spread over the limestone. The amount of ore required ranges from 0 to 25 percent of the weight of steel made and is determined principally by the percentage of hot metal and cold pig iron in the metallic charge. If more than 45 percent hot metal is used, some ore will be needed, and the amount is increased as the percentage of hot metal increases above this level. Charging of these materials may take up to 2.5 hours. The flame is kept on during this time to heat the charge, and much of the scrap is melted by the time charging is finished. During melting, some of the scrap is oxidized, and an early slag high in iron-oxide forms. The hot metal is poured in as soon as possible after charging is complete. The desired composition of the hot metal is 0.8 percent silicon, 1 percent manganese, less than 0.03 percent sulfur, less than 0.15 percent phosphorus, and about 4 percent carbon. A wide range of compositions is possible. If there is ore in the charge, the hot metal reacts with the hot ore and early slag causing a vigorous boiling action of the metal and slag because of the large amount of gas (principally carbon monoxide) generated. It is desired that the ore boil be vigorous so that an appreciable portion of slag is flushed from the furnace through a special port or out one of the doors. If there is no ore in the charge, no slag will be flushed from the furnace. The ore-boiling period will take up to 2.5 hours, during which virtually all of the silicon, much of the manganese, and approximately 60 percent of the phosphorus in the hot metal will have been oxidized into the slag. When the ore boil is almost completed, calcination of the limestone in the charge begins, and a heavy boiling action results from liberation of carbon dioxide from the limestone. The lime boil lasts one to 1.5 hours. At its termination, the slag is heavy and lumpy because of the presence of particles of undissolved lime. The metal is all molten, however, and relatively cold. The charge to the furnace is designed so the level of carbon in the bath at this time is 0.2 to 0.4 percent above the carbon level desired in the steel when the heat is tapped. Much heat is required to finish melting the scrap and to calcine the limestone so the flame is maintained in the furnace during the lime boil. The oxygen lances may be lowered and used to assist in melting the scrap; their action also speeds the ore and lime boils. With the lances in operation, the action in the furnace may become so vigorous and the rate of gas evolution so high that the fuel may be turned off to prevent overtaxing the waste-gas system.

The ore boil

The refining period begins at the end of the lime boil. At this point the bath is cold, the slag is lumpy and raw, and the levels of carbon, sulfur, and phosphorus in the bath are higher in the steel than is desired at the end of the heat. A sample of the bath is taken for chemical analysis to determine the levels of carbon, copper, nickel, tin, phosphorus, and sulfur. Continued heating, use of the oxygen lances, and judicious additions of burnt lime and small amounts of fluorspar developed a fluid basic slag suitable for the removal of sulfur and phosphorus. Iron oxide in the slag and oxygen from the lances react with the carbon in the bath to form carbon monoxide. The heat from these reactions and from the flame raises the temperature of the bath. A skillful operator will bring the bath to the desired temperature and carbon levels simultaneously and will have both sulfur and phosphorus levels below the specified limits.

Refining the steel

Heat times range from seven to nine hours and depend on the kind of steel being made, the use of oxygen, and the type of charge. The heat time does not vary appreciably with the size of the furnace. The amount of slag produced depends upon the amount of hot metal in the charge and on the silicon content of the hot metal. The weight will be from 10 to 15 percent of the final weight of the steel bath. The composition of the slags will be very similar to the range given for the basic oxygen furnace. The fuel composition will range from 6 to 12 percent by weight (fuel oil) of the steel made.

Many of the older basic open-hearth plants have been closed down, and most of the rest were expected to cease operation in the 1970s in the face of competition from the basic oxygen furnace. It would appear, however, that existing modern, well-equipped shops will continue to operate for years to come. The reason is that the open hearth enjoys the advantages over the basic oxygen furnace of greater flexibility in the amount of scrap that can be used in the charge and the ease with which it can make all kinds of carbon steels. It also has the advantage over the electric furnace of being able to produce steels that are low in nitrogen.

The electric process. Steelmaking processes employing electricity as the chief source of heat are utilized in the production of most highly alloyed and specialty steels. The advantages of electric furnaces in steelmaking are absence of contamination of the steel with elements, such as sulfur, that are present in most fuels; flexibility of the system, which permits special slags to be made and removed easily; excellent control of temperature and very high temperatures obtainable; and less loss of expensive alloying elements.

Advantages of electric furnaces

Electric arc furnace. The most commonly used electric furnace (Figure 7) for steelmaking employs an arc struck between graphite electrodes and the metal charge as the source of heat for the system. The furnace has a dish-shaped circular hearth, vertical sidewalls, and an arched roof. It is mounted on a large rocker assembly so it may be tilted forward for tapping and backward for charging, working the heat, and removing slag. Three cylindrical graphite electrodes (two are shown in the figure) are inserted through holes in the roof and are positioned at the apexes of an equilateral triangle. The electrodes are carried on arms projecting from a vertical mast located on one side of the furnace. The electrodes can be moved up and down individually by these arms. Each electrode is connected to the terminal of a large transformer by a heavy cable and a (copper) bus bar. Electrical energy is supplied to this transformer, usually at 22,000 volts, from another transformer and a high-tension line leading to the power generating system. An elaborate set of terminals and switching equipment on the furnace transformer permit energy to be supplied to the furnace in a range of from 50 to 700 volts. Modern furnaces are equipped with a mechanism that lifts the roof, electrode-support system, and electrodes and swings them clear of the furnace, to permit charging from the top by a large steel bucket with a drop bottom. Most furnaces are also equipped with a water-cooled oxygen lance that is inserted into the furnace chamber through a port in the sidewall or in the roof. An electric furnace also has two openings in the sides that are closed by water-cooled sliding doors. One port is opposite the taphole, and the other is 90° from it on the side opposite the electrode mast. These openings permit access to the furnace for adding materials, for removing the slag, and for "working the heat." Machinery for making additions

From C.E. Sims (ed.), *Electric Furnace Steelmaking;* the Metallurgical Society of AIME

to the furnace and for service and repairs operates on the charging floor at the hearth level. Large furnaces are usually located with the hearth level 20 to 30 feet (six to nine metres) above ground level. The support structure is located below the furnace, and the slag pots and the steel ladles are carried on railcars at ground level. Charging buckets are carried by an overhead crane. The steel ladles and slag pots are carried by another overhead crane on the tapping side of the furnace. A plant usually has several furnaces in a line, with the centre line through the tap hole and front door of each furnace at right angles to the line of furnaces. The overhead cranes travel parallel to the furnace line.

Virtually all of the electric-arc furnaces employed for steelmaking have basic hearth refractories and utilize basic slags. The hearth is usually a layer of rammed grain magnesite (MgO) over magnesite brick, or chrome–magnesite materials ($Cr_2O_3 \cdot MgO$) are used when steels high in chromium, such as the stainless steels, are being made. The sidewalls are chrome–magnesite brick, and the roof is made of high-alumina or high-silica brick.

The electrodes

The electrodes are cylindrical lengths of graphite connected together by threaded graphite nipples. As an electrode is consumed, an additional section is added to the end outside the furnace, and the assembly is slipped a distance through the support clamp. Though electrode size is determined by furnace size, furnaces of more than 100 tons capacity usually employ 610-millimetre- (24-inch-) diameter elements; these are the largest practical size commercially available. Either carbon or graphite electrodes may be used. Carbon electrodes are cheaper, but the best quality graphite electrodes are required to meet the severe operating conditions of high-speed, large-capacity modern furnaces. Electrodes are consumed by oxidation, by the action of the arc, and by breakage. The weight of electrodes consumed is 0.4 to 0.75 percent of the steel produced. A modern 200-ton furnace is powered with a 50,000 kilo-volt-ampere transformer, and each electrode carries up to 60,000 amperes at full power. A furnace of this size would have a shell 7.3 metres (24 feet) in diameter.

Considerable fume and smoke are generated when the arc furnace is in operation; therefore, to maintain air quality a furnace must be equipped with gas-collecting and cleaning equipment.

Single-slag oxidizing practice. An oxidizing practice is employed for producing plain-carbon and low-alloy steels in electric-arc furnaces of all sizes. Many recently installed large furnaces use this method to produce ordinary carbon steels in competition with the open hearth. Prior to charging, the furnace is inspected, the electrodes are raised, the roof is swung away from the furnace and the scrap is discharged from a large bucket containing the charge. Some heavy scrap is placed on the bottom of the charge, and light scrap is positioned to fall against the furnace walls to protect them from exposure to the arcs during melting. Hot metal is rarely included in the charge. The burned lime, ore, and fluorspar necessary for the heat are added on top of the scrap. The roof and electrodes are repositioned on the furnace, and the electrodes are lowered, and the power is turned on at about one-third the rated capacity. The electrodes, on automatic control, strike arcs against the scrap and burn holes down through the pile. The power is then turned off, and the electrodes are raised slightly and then lowered again with a higher power setting. This is repeated until full power is reached. The arcs are then deep into the pile of scrap, so that all of their energy is absorbed by the pile. This method also produces a pool of steel in the hearth for the arcs to play on, which also expedites melting. If the charge is mostly light scrap, a second bucket of scrap is added to the furnace after the first is almost completely melted. The full charge is melted in from 60 to 120 minutes. At this time it is necessary to reduce the power to 20 to 30 percent of normal rating of the furnace to prevent severe damage of the roof and wall refractories because of their exposure to direct and reflected radiation from the arc. The bath is cold, and the level of carbon is 0.1 to 0.3 percent above the desired final value for the steel. A sample of the metal is withdrawn for composition analysis. The slag contains undissolved lime and is high in iron oxide from oxidation of the scrap that occurred during melting. The operator then adds ore, lime, and fluorspar as required to assist in obtaining a basic, oxidizing fluid slag, and he may also add the necessary alloying elements—nickel, molybdenum, and copper—that do not oxidize. These may be added either as the metal or as the oxide, because the oxides are reduced by reaction with carbon in the bath. The oxygen lance is also employed to speed the refining reactions and to assist in the formation of a fluid slag. About 30 to 60 minutes are required to reach the desired temperature and carbon level in the

Melting the scrap charge

bath. If a heat of low-carbon steel is being made, the furnace is tilted, and the steel and slag are tapped into the waiting ladle. Although additions and deoxidizers such as ferromanganese, ferrochromium, ferrovanadium, and ferrosilicon and aluminum are added to the ladle as the steel is tapped. The full ladle is then moved to the pouring stand, where a train of ingot molds is waiting or where the steel is strand cast (explained below).

Two-slag practice. Many alloy and plain carbon steels that must be manufactured to very high standards of cleanliness and quality are made exclusively in the electric furnace using what is called a two-slag practice. First the charge is melted and refined with the oxidizing practice described above. At the end of the refining period, the oxidizing slag is removed by tilting the furnace back and letting the slag drain into a pot beneath the furnace. Removal of the slag is assisted by rabbling (stirring the surface by hand) to drag as much as possible of the slag out of the furnaces. Some furnaces are equipped with induction stirrers that induce currents in the pool toward the door and thereby carry the slag to the door. Small amounts of graphite, ferro-silicon, and aluminum are then added to the bath to deoxidize and recarburize it. A new slag, formed by adding burned lime, silica sand, and fluorspar to the furnace, contains less than 1 percent iron oxide; it is very basic and very effective in removing sulfur from the metal. Once the slag is formed, the alloying elements, such as titanium, zirconium, and chromium, that normally oxidize readily can now be added to the bath without serious loss. The bath is stirred gently by rabbling or with the induction stirrer, and then the heat is tapped into the ladle. The steel produced in this way is very clean, because the bath is quiet so that the particles of slag and dirt float to the surface, and levels of sulfur below 0.005 percent can be reached.

Stirring to remove slag

The level of nitrogen in electric-furnace steels tends to be much higher than in open-hearth or basic-oxygen steels, because the bath is exposed to the atmosphere in the region of the arc. By contrast, there is virtually no nitrogen in the furnace gases of the basic oxygen furnace, and in the open hearth the bath is isolated from the atmosphere by a layer of slag. Electric-furnace steels may contain between 0.006 and 0.012 percent nitrogen. Ordinary carbon steels made with the single-slag practice generally stand at the lower end of this range.

The oxidizing slags employed are similar to basic open-hearth slags, except that the iron oxide content usually is lower at a given level of carbon in the bath. The reason for this is that the oxygen level in the furnace atmosphere is kept low because of the reducing action of the hot graphite electrodes in the furnace chamber. Accordingly, phosphorus removal presents a more serious problem in the electric furnace than in the open-hearth or basic oxygen furnace. On the other hand, the phosphorus content in the original charge to the electric furnace is usually very low, so the limitation is not a serious one. The high temperature of the arc makes it possible to obtain a very hot slag; it is relatively easy to produce very basic slags that are fluid if needed. This is advantageous when working with the reducing slag, which is low in iron oxide and silica. The ratio of lime to silica in these slags ranges between 2.5 and 4.5. A typical reducing slag has the following composition: lime, 60 to 65 percent; silica, 18 to 22 percent; magnesia, 7 to 9 percent; calcium carbide (CaC_2), 1 to 2 percent; ferrous oxide, 0.5 percent; sulfur, 0.3 percent; and small amounts of alumina and manganous oxide.

Production of stainless steels. The electric furnace is used extensively in the production of steels high in chromium, especially the stainless steels that contain over 5 percent chromium. To economize on chromium, many plants use a large percentage of stainless scrap in the charge. At ordinary steelmaking temperatures around 1,600° C (2,900° F), oxidation of the bath to eliminate carbon to the low levels necessary in many types of stainless steels results in most of the chromium being oxidized into the slag and therefore wasted. By copious injection of oxygen into the bath, however, the temperature of the system can be raised as high as 1,850° C (3,360° F), which favours elimination of carbon and avoids much of the chromium loss. The slag is deoxidized and removed. The bath is cooled to 1,600° C subsequently, and a deoxidizing slag is formed. The heat is finished as described above for the normal two-slag practice. Two alternatives to the use of high temperatures are available to avoid loss of chromium, which also causes extensive wear of the furnace refractories. The first is to melt the charge and oxidize it modestly to reduce the carbon level of the bath without serious loss of chromium. After the bath has been refined, it is transferred to a ladle in a vacuum chamber in which the metal can also be heated by induction. The application of a vacuum and the use of some oxygen gas reduces the carbon level of the bath as desired, and the necessary additional chromium is then added to obtain the desired composition, and the steel is ready for pouring. A second alternative, coming into use in the United States and Japan, involves bubbling a stream of argon and oxygen through the metal, reducing the carbon in the bath to the desired level without the need for very high temperatures. This method avoids excessive loss of chromium into the slag.

Avoiding chromium loss

Vacuum processing. If liquid steel comes into contact with moisture or water, hydrogen from the water may dissolve in the metal in the ensuing reaction. The usual levels encountered range from one to ten parts per million by weight. On cooling, the solubility of hydrogen in the steel diminishes. If the steel is cooled too rapidly for the hydrogen to migrate to the surface and escape, pockets of hydrogen gas may form at weak points within the structure, and small internal ruptures will result. The problem is particularly acute with very large ingots of electric-furnace steel cast for big forgings used in turbines and electric generators, and is also generally present with alloy steels containing from 2 to 10 percent nickel used for smaller forgings. The presence of these ruptures make a casting unusable. Moisture in the furnace additions, moist runner and ladle refractories, and moisture on the ingot-mold walls contribute hydrogen to the steel. By carefully drying all additions and refractories and by cooling the ingots very slowly in special furnaces, the problem of hydrogen in forgings can be minimized but not eliminated.

Internal rupturing

A number of techniques have been devised in which the liquid steel is exposed to a vacuum in a chamber, and the hydrogen is pumped out to a level ranging from 1.5 to two parts per million. If the steel then does not come into contact with moisture until it is solidified, the problem of internal rupturing can be avoided. One method of preventing such contact is to place the ingot mold in a large steel chamber connected to vacuum pumps. The chamber is evacuated, and the ladle containing the steel is set on top of the chamber. The nozzle is sealed to a fitting closed with a thin metal disc. When the stopper rod is raised, the steel stream cuts through the disc, and the stream and the steel in the mold are exposed to the vacuum. Several alternative methods are also employed.

Vacuum processing is also used to eliminate oxygen from liquid steel. Carbon and oxygen react to form carbon dioxide gas at a low pressure maintained by the vacuum pumps. Under this condition carbon itself acts as a very strong deoxidizer, and no products of deoxidation are left to contaminate the steel. With a good vacuum and a clean system, the level of oxygen dissolved in the steel can be reduced to as low as ten to 20 parts per million, a level that may not be reached with strong deoxidizers such as aluminum.

SOLIDIFICATION AND CASTING

The quality of the surface and interior and the physical properties such as strength, resistance to impact, and corrosion resistance of a steel product are influenced by the way the liquid steel is solidified. In the usual practice, molten steel is poured into a cast-iron mold from a hole in the bottom of the ladle, the hole is closed by a stopper on a rod extending up through the metal, and the rod is protected from high temperatures and action of the liquid metal and slag by a refractory sleeve. A recent development is a sliding refractory valve with all parts outside the ladle and below the nozzle. Because the cast-iron

mold is colder than the liquid steel, solid steel forms as a shell on the mold wall and bottom. Freezing proceeds inwardly from the wall as heat from the hot steel flows into the mold.

The refined steel in the furnace contains an appreciable amount of dissolved oxygen, as described above. As the liquid cools and freezes, carbon in the steel and dissolved oxygen will combine to form a large volume of gaseous carbon monoxide. If the evolution of this gas is uncontrolled, the metal will boil up and overflow from the mold, and the steel ingot will have a porous, spongy interior. This phenomenon caused serious difficulties in the early days of the Bessemer process until it was discovered that adding manganese to the steel to combine with the oxygen would prevent formation of the gas, so the ingots were sound and satisfactory. Subsequently, it was found that other elements, such as silicon, aluminum, titanium, and calcium, all of which form stable oxides, could also be used to deoxidize the steel. Furthermore, as liquid steel solidifies and cools, its volume shrinks 7 percent. Finally, carbon and many alloying elements and impurities such as sulfur and phosphorus tend to migrate, or segregate, into the unfrozen liquid during solidification, with the result that the final bit of liquid to freeze is much more impure than the portion frozen first.

Types of ingots and their manufacture. The internal structure of an ingot can be controlled by regulating the rate at which carbon monoxide gas is formed during solidification. If all the oxygen dissolved in the steel is removed by the addition of a deoxidizer, no gas will be generated, and a shrinkage cavity will form in the upper central portion of the ingot. This ingot is a killed ingot (Figure 8A), and the cavity is called "pipe." The steel immediately surrounding the lower portion of the pipe is relatively impure because of the segregation of impurities and carbon. As a result, the upper portion of this ingot is unfit for use, and as much as 30 percent must be discarded. This loss can be minimized by casting the steel in tapered molds with the large end up. Another method is to install a brick or clay reservoir on top of the ingot mold that maintains a small pool of liquid metal during freezing of the body of the ingot. The metal in this "hot top" flows down to compensate for shrinkage of the metal in the mold. The top of the ingot is cropped and discarded; loss is only 10 to 15 percent. Killed steels are employed when a dense, uniform product is desired, as is the case with alloy steels used in forging, tubing, and plates for pressure vessels. Most high-grade alloy steels are killed steels. A "semikilled" ingot (Figure 8B) results when the addition of the deoxidation agents is limited to allow the generation of a small amount of gas during the latter stages of freezing. If properly controlled, this gas forms small, well-distributed blowholes to compensate for the shrinkage of the metal, and no pipe appears. These blowholes collapse and weld shut when the ingot is rolled. Since it is not necessary to discard the top portion of the ingot, semikilled steels are less costly to produce than killed steels. Semikilled steels are used for structural members, rails, some types of plates, welded pipe, and ordinary bars and common sections, such as angles and tees. Ingot C in Figure 8 is an example of a poorly controlled semikilled ingot in which pipe formed, gas pressure ruptured the top, and metal bled out. With a greater amount of oxygen in the steel when it is poured, it is possible to cause small bubbles of carbon monoxide to form at the interface between the liquid and solid metal. These bubbles grow, detach themselves, and rise toward the top of the ingot. In rising they sweep the liquid along and generate a flow of metal up the walls and down in the central portion of the ingot. If the circulation is gentle, blowholes will be present in the solidified rim, and if it is very vigorous a dense rim forms. After a period of rimming, the top of the ingot is sealed, and the resulting interior structure is similar to that of a semikilled ingot. Ingots D through H in Figure 8 show the types of structures that can be obtained. With ingot D and E, the rimming action is modest, and the level of the liquid rises because of the large volume of the blowholes in the rim. Within one to two minutes after the mold has been filled, the steel rises and freezes against a heavy cast-iron or steel cap placed on top of it that seals the ingot and stops evolution of the gas because of a rapid rise in internal pressure. This type is called a capped ingot, or a bottle-top ingot, because of its shape. Ingot E is a better structure, because the rimming action was stronger, and the blowholes in the rim are farther from the surface of the ingot. Plain carbon sheet steels containing between 0.04 to 0.20 percent carbon are often cast as capped ingots. Ingots F, G, and H are called rimmed ingots, because the oxygen level in the liquid steel is high enough to sustain a strong rimming action for from 12 to 16 minutes that produces a rim from three to four inches (75 to 100 millimetres) thick. After a rim of the desired thickness is formed, the ingots are usually sealed by placing a heavy steel plate on top of the liquid surface, and the top of the mold is flooded with water. Of the three, ingot G has the best structure for most purposes. In practice, the rimming behaviour is controlled by adding gas-forming agents to the steel to stimulate the action or small amounts of aluminum to reduce the action. Plain carbon steels containing between 0.04 and 0.25 percent carbon can be rimmed successfully. This type of steel has a soft, pure rim and is used when good surface, high ductility, and good formability are desired. Large tonnages of the product are used in automobile bodies.

Minimizing loss of steel

Rimmed ingots

Control of nonmetallic particles. In addition to controlling the structure, control over the nature and composition of nonmetallic particles in steels is needed. In most steels it is desired to eliminate the particles formed by the reaction of the deoxidizer with the oxygen. Furthermore, small particles of slag may be emulsified in the steel, and bits of refractory may be entrained as a result of the flow and churning of the metal when the heat is tapped from the surface. Most of these particles float to the surface of the metal and combine with the slag in ten to 30 minutes between the end of tap and the beginning of pouring of the ingots. Not all do, however, so many special deoxidizers and pouring methods are used to keep the remaining particles small and well distributed throughout the ingot. Free machining steels are excep-

tions where many small uniformly distributed particles of certain types are desired. These particles lubricate the cutting tool, prevent welding of the cut chip to the tool tip, and cause the chip to break into short pieces. Additions of lead, sulfur, manganese sulfide, selenium, and tellurium to the steel improve the machining properties of steels in this manner.

Variation of ingot size. The size of ingots varies enormously depending upon both the type of steel and its ultimate use. Ingots of highly alloyed tool steels may weigh only a few hundred pounds each. Steels for structural, bar, and rod products usually weigh from two to eight tons (1,800 to 7,300 kilograms). Ingots from which slabs are rolled for large plates and large coils of sheet steels may weigh from 15 to 40 tons. These larger ingots are blocks of steel that may be 90 inches tall by 84 inches wide and up to 38 inches thick (2.3 by 2.1 by one metres). Very large ingots for large, thick plates and forgings for turbine shafts, drive shafts, and pressure vessels may weigh as much as 300 tons each; these are cast in enormous cast-iron molds and take weeks to solidify. Forging ingots are from three to five times thicker than the thickness of the product forged or rolled from it to ensure adequate working of the steel. A greater reduction in thickness is desired for plates, structural products, rails, and most other products.

Ingot casting. In large steelmaking shops, two or three ingot molds are carried on a small ingot car; several cars are connected together so that one heat is carried on a train. These ingot molds are filled from the top. If particularly good surface quality is required, ingot molds may be filled from the bottom. Usually a number of molds are stood in a cluster on a large car. The steel is poured from the ladle into a tall, slim, trumpet-like tube. The metal flows from this trumpet through hollow clay brick to the bottom of each mold, filling all simultaneously and more slowly, with less splashing, than is the case with top-pouring single molds. After the ingots have cooled sufficiently, the train of cars is moved to a stripping device, which seizes each mold and frees the ingot from the mold by the action of a powerful plunger. The molds are set aside for cleaning and reuse, and the train of hot ingots is moved to the rolling mill. There they are inserted in a reheating furnace, where they are "soaked" for four or five hours to bring them to a uniform temperature in preparation for rolling. These furnaces are often called soaking pits. Six to a dozen ingots are stood on end in each pit; a gas or oil flame passing above the ingots supplies the heat. The air for combustion is heated in regenerators similar to those described for the open-hearth furnace. The furnace is covered, and a slightly oxidizing atmosphere is maintained so a crust of oxide forms on the exterior of each ingot. Care is taken so the ingots are not heated above the temperature at which any part of the internal structure becomes liquid, because the presence of liquid will result in severe cracking and rupturing of the steel during rolling.

"Soaking" hot ingots

Strand casting. Rapid progress is being made in the use of methods for casting steel in a long, continuous bar, or strand. Once called continuous casting, this method is now called strand casting. The process has long been used in casting nonferrous metals such as copper and aluminum, but many problems peculiar to steel had to be solved. Many highly specialized machines, control methods, and deoxidation methods have been developed for the process. Only the essential aspects of the method need be dealt with here. It has been possible to cast square and rectangular sections of steel for a number of years, but the problems of surface quality, internal structure, and reliability of operation when casting slabs from 150 by 760 millimetres to 280 by 2,000 millimetres (six by 30 inches to 11 by 80 inches) have been resolved only since 1968. Facilities for strand casting the whole output of large basic-oxygen shops and electric-furnace shops are being installed in plants in many countries in the world.

Advantages of strand casting

There are two important advantages of strand casting over ingot casting. A greater yield of useful product from the liquid steel is obtained, because the large pipe in the cast product is avoided and less steel is lost by cropping the ends of the bar of steel during rolling. Also the structure and composition of the bar is uniform along its length, which is not so with a bar rolled from an ingot.

The essential characteristics of the strand-casting system are shown in Figure 9. The steel is poured from the ladle in the customary manner. It flows into a shallow refractory-lined basin (tundish) and then through a nozzle into the water-cooled mold. Flow into the mold is regulated by a stopper in the tundish. The tundish is used to permit precise regulation of the flow of metal into the mold and to allow additional time for nonmetallic particles in the steel to float out. Several molds are usually fed from one tundish. In recently built systems, the metal from the tundish is conducted through a ceramic tube and is discharged below the surface of the metal in the mold. This avoids splashing and further oxidation of the metal by contact with the air. The surface of the metal in the mold may also be covered with a powdery layer of material used for insulation. The layer in contact with the metal melts to form a thin slag, which dissolves particles of oxide that float on the metal and also coats the bar of steel as it is cast. Heat is extracted from the liquid steel by the water-cooled mold; a thin layer of solid steel forms on the mold wall. In most of the strand-casting machines, the mold oscillates rapidly up and down to aid in the separation of the metal shell from the mold wall. Below the mold the steel bar is sprayed vigorously with high-velocity streams of cold water to speed solidification.

The casting operation is started by inserting a large steel bar of the cross section to be cast up into the mold. The liquid metal is poured into the mold and freezes around a large projection on the bar. This bar is withdrawn at the desired rate, and the flow of metal into the mold is regulated to maintain a constant level. The steel bar is supported by several sets of rolls after it emerges from the mold, and some of the rolls are driven at a controlled rate to regulate the speed of withdrawal of the bar. Considerable time is required to complete solidification, and the tapered liquid core may be 6.3 to 13 metres (21 to 43 feet) long. The bar is cut into lengths by a saw or an oxygen torch below the tip of the liquid region. The speed of casting is very fast for small bars: *e.g.*, 10 by 10 centimetres or 15 by 15 centimetres (4 by 4 inches or 6 by 6 inches). Casting speed ranges from one to two metres per minute (three to six feet per minute) for wide slabs that are 230 to 280 millimetres (nine to 11 inches) thick. To reduce the height of the casting machine, some machines bend the bar 90° in the cooling section (Figure 9) so that it comes out horizontally.

From J. Szekely and N.J. Themelis, *Rate Phenomena in Process Metallurgy*, copyright 1971; used with permission of John Wiley & Sons, Inc.

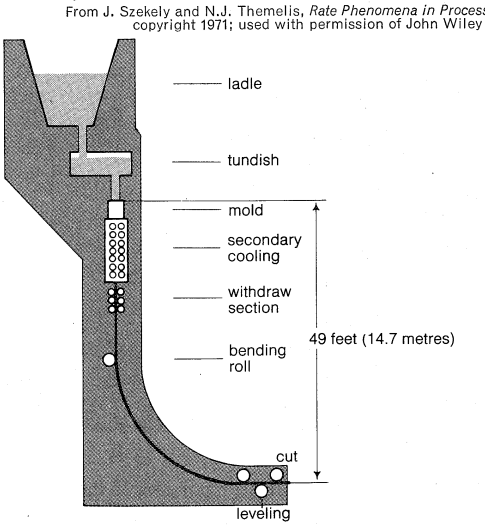

Figure 9: Continuous casting machine.

Other machines have a curved mold that casts a curved bar, in which case the bar is straightened as it emerges from the cooling sections and is horizontal as it leaves the machine. Strand casting avoids the need for large, expensive mills for rolling ingots.

ROLLING AND WORKING OF STEELS

The rolling process. The mechanical properties of a cast steel bar or ingot are improved materially by kneading and working the piece in a press, hammer, or roll stand when it is red-hot and plastic. The nonuniform, coarsely crystalline cast structure is converted to a uniform structure having a fibrous appearance when fractured; there are usually attendant increases in toughness and ductility. The steel is also altered to the desired form. During the working the steel is kept sufficiently hot for the small grains, or crystallites, produced to regrow to form a new structure. Massive gun tubes, drive shafts, and turbine rotors are forged slowly in enormous hydraulic presses. Axles, crankshafts, and heavy engine parts are forged by large steam hammers, while tools and small machine parts are worked by rapid-acting drop hammers.

The rolling mill. Most steel ingots and strand-cast bars are formed in rolling mills. As noted above, rolling mills vary widely in mechanical details depending upon their purpose. The working and shaping of the red-hot piece of steel is accomplished by passing it back and forth through one stand or by sending it through one stand of rolls after another. A bar has its cross section reduced and a sheet is made thinner with each pass through a mill. The rolls of a stand may be grooved to produce a bar with a particular cross section, such as a square bar, a rail, or a beam, or may be cylindrical for rolling flat pieces, such as strips or plates. Though a mill may consist of only one stand, more often several are employed, either in tandem (the steel passes straight from one stand to the next) or side-by-side (the steel bar is looped around to go from one pass to the next). In the latter case, the rolls of each stand may have a number of sets of grooves so that a bar may pass through a stand several times. In the past, a wide variety of arrangements of stand locations have been used in mills.

Mill stands

Modern mills usually have the stands in tandem; the steel passes directly and rapidly through them in a straight line from heating furnace to cooling beds or coiler. The products of rolling mills vary widely in weight and shape, but, in virtually all cases, each piece is uniform in cross section from end to end. Special mills are used to roll steel pieces that vary in cross section along their length. All modern mill stands are driven by powerful electric motors, and the mills are controlled by electronic equipment.

Primary mill. The first reduction of an ingot takes place in a "primary" mill, which may be called a blooming mill if it converts ingots of approximately square cross section into large square or rectangular bars, called blooms. The mill has two large, grooved rolls driven by electric motors of as much as 30,000 horsepower, and the ingot is passed back and forth as the mill is reversed. In each pass the spacing between the rolls is reduced so the bar is reduced in cross section and correspondingly lengthened. The grooves in the rolls also permit rolling blooms with special shapes to be converted into structural shapes, sheet piling, and other forms. This type of mill is called a reversing two-high blooming mill. Some blooming mills are three-high (Figure 3) and roll only in one direction. The ingot can be passed back and forth by alternately using the opening between the middle and upper rolls and then that between the middle and lower rolls. A two-high reversing mill is often used to roll large ingots into slabs for plates and for the production of coils of sheet steel. In a modern steel plant these larger ingots may also be rolled into slabs on a universal mill, which has two stands. One of these stands is a two-high reversing mill for rolling the flat faces of the slab. Adjacent to this stand is another mill, which simultaneously rolls the edges of the slab. Such an installation, with its heating furnaces, shears, controls, and auxiliary equipment, may cost $60,000,000, but it is very fast and can easily roll 4,000,000 or 5,000,000 tons of steel a year. Each mill is equipped with soaking pits to heat the ingots before they are rolled and a shear to crop off the ends of the slab and to cut it into appropriate lengths. Many mills are equipped with a scarfing machine that burns off one to three millimetres (0.04 to 0.12 inch) of each surface of the slab or bloom to obtain a surface free of defects. The burning is accomplished by many jets of gaseous oxygen impinging on the surface of the hot steel.

Second stage of rolling. The blooms and slabs produced by the primary mills receive additional hot work in another mill to convert them into hot-rolled products or to process them further in preparation for cold rolling. The bars and slabs produced by strand casting are introduced into the rolling sequence at this point. Usually the steel is not hot enough to be rolled directly after it leaves the primary mill. Also, it is usually desired to let the steel cool down so it may be inspected and defects on the surface cut out by machining, chipping, or scarfing. The steel is then heated in reheating furnaces, fired by fuel oil or gas. The furnace hearth is inclined and is as wide as the blooms or slabs are long; the pieces of steel are pushed sideways into the furnace. The charge rests on water-cooled skids, and, as one cold piece enters, a hot piece ready for rolling is forced out the other side of the furnace.

Reheating furnaces

Rolled and worked materials. *Rails, bars, and structural steels.* Rails, I beams, H beams, sheet piling, angles, large rounds, and similar products are rolled on a mill having stands with grooved rolls to shape the piece to the desired form. Since special rolls are required for each type of section, the stands are designed so the rolls may be quickly replaced. In modern mills, whole stands may also be changed, inserted, or removed when there is a change in the product being rolled. In a common rolling sequence, a reheated bloom receives an initial pass in a special stand called a scale breaker to remove the scale of iron oxide formed during reheating. The bloom then receives more passes in a two-high reversing stand with grooved rolls. The bar is then brought to its final shape by a number of passes in several subsequent stands. If 12 or more passes are required, it may be necessary to reheat the steel in a second furnace at an intermediate stage. Very close attention is given to the final passes to ensure that the final product is correctly shaped. The hot pieces of steel are sheared to length and cooled on tables. With alloy steels, it may be necessary to control cooling or even to cool slowly in a special furnace. The bars, rails, and beams are then straightened, trimmed, and given a final inspection. For H beams special, massive stands with four rolls arranged to roll the faces of the flanges and each side of the web of the beam are used simultaneously.

Rolling sequence

Mills used for rolling small, simple sections such as round and square bars, angles, and rods also vary widely in the design of the mill and the type of stand used. Blooms may first be reduced to obtain billets having a cross section of under roughly ten centimetres (four inches) square. These billets are then reheated for further rolling. Economical operations require high speed; the most modern mills are continuous, with the stands set in a line. The first several stands are spaced apart sufficiently so the billet is in only one of them at a time, and subsequent stands are closely spaced so the steel passes continuously through all stands simultaneously. To avoid buckling of the steel bar between stands, the speed of the stands must be coordinated and precisely controlled. The steel emerges at a speed of several thousand feet a minute and is either cut to length by a flying shear and cooled on beds or coiled in automatic coilers. These continuous mills may have several of the stands set with their rolls at right angles to the others, or square bars may be twisted 90° as they pass from stand to stand to work all corners of the bar and avoid corner cracks. Some continuous rod mills are equipped to roll four to six bars simultaneously. A very wide range of alloy compositions and types of bars and rods are rolled, and a mill has extensive facilities for inspecting, cutting, straightening, surface preparation, heat-treating, storing, packaging, and shipping.

Plates. The plate mill appears to be very simple in comparison to a structural or rail mill. In some mills, however, the stands and equipment must be massive to be able to roll plates of alloy steels up to five metres (16 feet) wide and smaller plates that may be up to 40 centi-

metres (16 inches) thick. The mills for producing large plates will be described only briefly here. Long plates less than approximately three centimetres (1.2 inches) thick and two metres (80 inches) wide are usually produced on a continuous-type mill, as described below. The production of large plates is a specialized operation because of the many different alloy compositions and sizes that must be made. The mill consists of a storage yard for slabs, several heating furnaces, a scale-breaking stand, the main mill stand and its drive system, run-out tables, a shear, a straightener, furnaces for heat-treating and annealing, and an area for inspection, cutting, trimming, and finishing of the plates.

Plate mill

The main mill stand is usually a four-high reversing mill in which two smaller cylindrical rolls are the work rolls. Slabs of not more than approximately two metres (80 inches) wide can be produced by the primary mill. When making wide plates, it is necessary to give the slabs several passes in its long dimension and then turn the slab 90° and cross-roll it in a few final passes to increase its width. This sequence is required to obtain the desired width, because, in passing through the mill, a slab or bar increases its length but changes its width only slightly. It is found that the ductility of steel is greater in the direction of rolling than it is at right angles to this direction. Hence, cross-rolling is required to avoid the development of the highly directional properties that result when steel is rolled only in one direction.

Continuous-strip mills. Much of the steel from the large integrated steel plants in the world today is produced in the form of long, wide strips, either flat or wound in coils. One large coil usually is obtained from a single slab that may be as much as 250 millimetres (ten inches) thick and 11 metres (36 feet) long and may weigh up to 40 tons. This slab may be strand cast or rolled from a single ingot. Sheet steel for skelp (pipe production), narrow, lightweight plates, and narrow and wide continuous-strip steels are produced on the hot strip mill. Such a mill consists of several heating furnaces, a scale breaker, four roughing stands, a shear, six finishing stands, a run-out table, and coilers. The roughing stands are equipped with edge rolls to control the width of the strip. Except for the scale breaker, the stands are four-high with smaller work rolls backed by two massive rolls to stiffen the work rolls. Each stand of a wide strip mill is driven by an electric motor rated at 3,000 to 6,000 horsepower. The scale breaker is a two-high stand followed by sprays of very high pressure water to carry away the scale loosened by the light reduction of the slab as it passes through the stand. Removal of all scale is essential if a sheet with a surface of good quality is to be obtained. All of the mill stands are set in a line, and the roughing stands are set sufficiently far apart so the slab is in only one of them at a time. The mill may have a slab squeezer, which is a large press located after the first roughing stand to flatten the slab and true up its edges. On leaving the last roughing stand, the strip is about 25 millimetres (one inch) thick. After its ends are squared in a shear, it passes on into the finishing train. The long strip of steel is in all finishing stands simultaneously; the openings of the rolls in the stands are set to obtain the desired final thickness of the strip. These settings and the speed of the stands are controlled automatically. It is remarkable that the stands are only about five metres (16 feet) apart and the strip is travelling several thousand feet a minute as it leaves the last stand. The temperature of the steel must also be carefully controlled to obtain a satisfactory product. The strip then is cooled by water sprays, after which it may be coiled. The thicker strips may be transferred for cooling to another roller table, where they are cut up into long, narrow plates. The final thickness of the hot-rolled strip produced on the continuous hot mill ranges from three to ten millimetres (0.1 to 0.4 inch). A large modern mill producing strips up to two metres (80 inches) wide can roll 4,000,000 to 6,000,000 tons of steel a year.

Removing scale

The product from the continuous hot strip mill has a tightly adhering oxide coating, or scale, covering its surface. This scale may be desired on light plate and sheets taken directly off the mill. For some products, however, the sheets may be pickled to remove the scale and then coated with oil. Pickled products may be sold flat or in coils; wide strips may be split into several narrow strips suitable for making such items as pipe. Much of the product from a wide continuous hot strip mill must be cold rolled to obtain the desired surface quality and physical properties. The coils are first pickled continuously in long tanks to remove the scale. They are then cold reduced 40 to 90 percent in thickness at high speed in powerful mills consisting of four to six four-high stands that are set closely spaced and in tandem. During rolling the strip is kept under tension and driven reels pay out and take up the strip. The product of the mill may be annealed (heat-treated to remove internal strains) in batch furnaces or may be uncoiled and processed continuously through a long annealing furnace. Often coils of either hot- or cold-reduced steel are rolled on single- or double-stand four-high mills to obtain precisely controlled physical and mechanical properties and also a special surface finish. The product is oiled and inspected and may be sold in coil form or may be cut up into sheets. Many steel plants process cold-rolled strip steel into coated products. Coils of tin-plated steel are produced continuously by passing the steel through a bath in which a coating of tin is electroplated onto the surfaces, and this coating is fused to obtain a bright surface. Galvanized sheet is produced continuously by passing the strip through a long furnace to reduce any oxides on the surface and to soften the strip and then passing it into and out of a tank of molten zinc. After cooling, the familiar bright, spangled galvanized steel is obtained. Many other types of coatings, such as paint, chromium, aluminum, and organic coatings, are now being applied to steels.

Pickling to remove scale

Pipe. Pipe in all sizes from six millimetres to 1.3 metres (¼ to 50 inches) in diameter is produced from flat-rolled strip and plate steels. The methods of production vary widely; some of the more common are illustrated in Figure 10 A, B, C, and E. The smaller sizes are produced from narrow strips called skelp by method A. Lengths of skelp six metres (20 feet) long are pointed at one end and are heated flat in a furnace to a white heat.

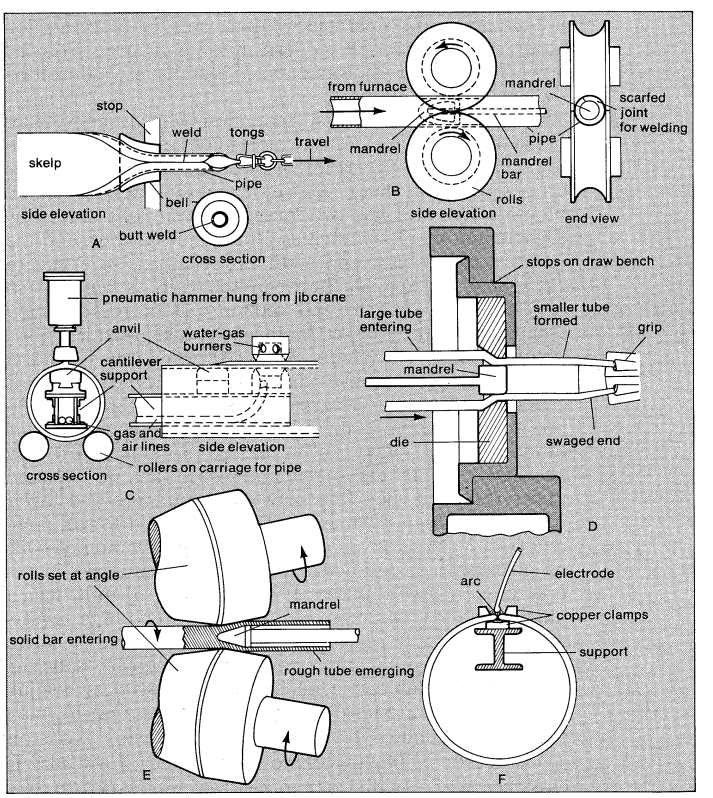

Figure 10: *Various methods of manufacturing pipe.*
(A) Butt welding a two-inch pipe; (B) lap welding; (C) hammer finishing and gas welding of 30-inch pipe; (D) drawing seamless pipe; (E) Mannesmann method; (F) arc welding of 30-inch pipe.

At this temperature the steel is coated with a shiny layer of molten iron oxide and welds easily under pressure. The strip is drawn rapidly through a welding bell, which simultaneously forms the strip into a tube and forms a butt weld. Smaller sizes of pipe with inside diameter ranging from three to seven millimetres (0.1 to 0.3 inch), are made by lap welding (B). The edges of the strip of skelp are first bevelled in a set of rolls, and then the strip is formed into a tube by pulling it through a ring. The tube is then heated to the welding temperature and rolled over a mandrel (core) by a special set of rolls, as shown. The pressure on the overlapping edges from the roll and mandrel causes the steel to weld. The butt-welded or lap-welded pipe is straightened, de-scaled, cut to size, and threaded, if required, tested, and coated with oil, paint, or plastic coating. The steel used in making these pipes is plain carbon steel containing not more than 0.1 percent carbon. The higher carbon and alloy steels do not weld readily by such simple means.

Large-diameter pipe

Large-diameter pipe is produced by forming long plates into tubular form in special presses. First the edges are bent slightly, then the strip is formed into a U shape, and finally the U is bent into an O. The weld is made either by gas (C) or electric (F) means, as shown. After welding, the pipe may be rerolled for shape, heat-treated or annealed if required, cut to size, pressure tested, and given a protective coating. In some plants, pipe of many sizes is produced continuously from strip by electric resistance welding. The strip is formed cold into a tube, with the edges tightly pressed together. Welding is accomplished by passing a heavy current across the joint, which rapidly heats the metal to the welding temperature. The current is supplied by two copper rollers, one on each side of the joint. Because high strength, good corrosion resistance, and other special properties are desired in large pipes, they are made of intermediate carbon and alloy steels.

Seamless tubing. Seamless tubing is usually employed if expected internal pressures are high, service is severe, and reliability is of great importance. Tubing for nuclear reactors, oil wells, and high-pressure chemical equipment are examples. The diameter of the finished tube may be up to 450 millimetres (18 inches), with wall thicknesses as high as 150 millimetres (six inches). The tube is made from a round billet with a total weight of steel that is slightly greater than that of the tube to be made. The billet at a red heat is first pierced by being rotated rapidly between two rolls whose axes are set at a slight angle to each other (Figure 10E). The rotation sets up forces in the billet, causing the centre to rupture. The action of the rolls also forces the billet to advance slowly over a mandrel set between the two rolls. The result is a length of rough tubular blank. After piercing, the tube is reheated and the inner and outer surfaces are smoothed by rolling it over a mandrel as in lap welding (Figure 10B). Subsequently, the tube is straightened, trimmed, and inspected. Tubes may be reduced in size and their strength improved by cold drawing over a mandrel held in a die, as shown in Figure 10D. If a large reduction in diameter or wall thickness is desired, the tubes may be annealed several times during the processing. Tubes produced in this way are certain to be of good quality as only the best quality steel can be pierced successfully. Seamless tubing and other complex shapes are also produced by extruding a hot billet of steel through a die in a powerful hydraulic press. To produce a tube, a billet with a hole down its axis is placed in the cylinder of the press, and the steel is forced to flow out the annulus between a die and a mandrel attached to the piston of the press. The billet is contained in a woven glass sock when it is placed in the press. This sock melts, and the liquid glass acts as a lubricant between the billet and the cylinder of the press. This method was developed in France. Extruded tubes are then processed similarly to the method used for pierced tubes. Steels can also be extruded cold.

Wire and cold-drawn rods. Steel wire is produced by drawing a hot-rolled rod continuously through a number of dies. The reduction in each die ranges from 10 to 40 percent. The rod is first pickled to remove scale and is then given a light coating of lime, phosphate, or copper for lubrication. During the drawing, the dies are also lubricated with soap. Because the steel is drawn cold, the wire becomes stronger and harder with each draw. To prevent breakage, the wire is annealed frequently. Wire is produced in a large number of steel compositions, diameters, stiffness, or tempers, and coatings, depending on its end use, which may be in steel cables, coil springs, nail fencing, or household screening. Hot-rolled rods may be cold reduced slightly by drawing them through several dies. This improves the surface finish and increases the strength of the steel.

CONTROL OF PROPERTIES

Satisfactory production of steel requires that the temperature, composition, and properties of the metal and the processing methods be kept under close surveillance at every step. The compositions of iron ores, sinter, pellets, hot metal, blast-furnace slag, liquid steel, and steel-furnace slag are determined from samples taken during processing. Analyses are obtained by conventional chemical methods and with the use of emission spectroscopy and X-ray fluorescence (see INSTRUMENTATION). The gas content of steel is determined by collecting and analyzing the gases obtained when a sample of steel is remelted under vacuum or in a stream of argon gas. Temperatures are measured by thermocouples inserted in the furnace or in the liquid metal or by optical devices sighted on the steel or into the furnace.

Measuring steel properties

The composition and properties of the solid steel are measured at many stages in processing, from the ingot and strand-cast bar or slab to the final hot- and cold-rolled products. The quality of cast and hot-rolled sections of steel is indicated by the appearance of a fractured surface and by the texture of a cut surface as revealed by etching with acid. Traditionally, the grain size and toughness of a steel bar are judged from the appearance of the fractured surface of the steel. A trained eye is needed for this method to be effective in controlling the production of steel; it has been superseded by many newer and more quantitative techniques.

The general structure and texture of a roughly polished surface cut through a rolled or forged piece of steel is revealed by etching the surface with a hot solution of hydrochloric acid. Lines of flow of the steel from hot working, areas of segregation, and collapsed blowholes and pipe can readily be seen. The distribution of sulfur in the cast or rolled structure can be observed by making a sulfur print of a smoothly ground surface of the steel. A sheet of photographic paper moistened with sulfuric acid is held in contact with the steel for approximately one minute. On being developed, the print shows the texture of the steel and the locations where sulfur is segregated. The structure of hot- and cold-rolled steel products is observed under the optical microscope to determine if the processing has produced the texture and phases necessary for the properties desired of the steel. Many test methods have been developed and are used regularly to determine the hardness, tensile strength, ductility, toughness, and drawability of the steel during processing. These measurements and metallographic examination of the steel are essential in controlling the quality and properties of the steel being made.

Sulfur print

Design of the furnace. The size of a furnace used in heating steel for processing depends very much upon the nature of the product. Furnaces for heat-treating tool steels are small; the batch furnaces for annealing coils of strip steel are refractory-lined boxes of sufficient size to contain six or eight coils in a charge; and furnaces for heating and annealing strip steels and steel parts on a conveyor are block-long horizontal tunnels or may have several vertical sections through which the steel is looped. These furnaces have zones for heating, cooling, and holding the temperature constant so that the steel receives the desired heat-treating cycle automatically. Much attention has been given recently to the design and construction of furnaces of this type for many purposes. Gas, oil, and electricity are used as sources of heat. If reactions between the steel and combustion gases causing carburiza-

tion, decarburization, scale formation, or pickup of sulfur must be avoided, electrical heating is often used. Furthermore, the steel can be isolated from combustion gases by burning fuel oil or gas within tubes of heat-resistant steel or silicon carbide that pass through the furnace. Heat is transferred from these tubes to the furnace charge by radiation and convection of hot gases within the furnace. Mechanical details of a furnace also depend upon the nature of the charge. Furnaces used for heat-treating and annealing large forgings will have large manipulators on wheels or an overhead crane for moving the steel to the furnace and to and from the press, forge, or hammer. Furnaces for treating many steel parts may resemble a tunnel the bottom of which consists of refractory-covered trucks mounted on small wheels that travel on rails. The charge is placed on these trucks, which are pushed through the furnace at the desired rate. Bars and billets may be moved through long or circular furnaces on rollers or conveyors. To conserve heat, many high-temperature furnaces are equipped with recuperators or regenerators for preheating the combustion air by waste heat extracted from the exhaust gases.

Furnace atmosphere. The atmosphere within a furnace is often important to the purpose of the furnace. Soaking pits for heating ingots and the reheating furnaces on primary mills are usually operated with a strongly oxidizing atmosphere to obtain a dry, brittle oxide coating on the steel. This is to assure that the oxide flakes off easily early in the rolling process so as not to blemish the surface of the finished piece. When heating strip steel or annealing tool steels for long periods, the surface must be preserved, so a nonoxidizing atmosphere is obtained by careful control of the ratio of water vapour to hydrogen and the ratio of carbon dioxide to carbon monoxide in the furnace atmosphere. In bright annealing at comparatively low temperatures (650° C [1,200° F]), a small excess of carbon monoxide over carbon dioxide in the atmosphere is employed to obtain a bright metallic lustre on the steel surface. Moisture content of the gas must be kept low, however, to prevent oxidation of the surface during the cooling cycle. Atmospheres that protect the steel from oxidation during heating to higher temperatures must be much more strongly reducing; these are obtained by combustion of natural gas or other gaseous hydrocarbons with a deficiency of air to produce the desired gas composition. Regulation of the ratios of carbon dioxide to carbon monoxide and water vapour to hydrogen permit a gas to be used to add or subtract carbon from the steel. If the steel is to be case carburized (externally hardened by addition of carbon), methane (CH_4) is added to the gas. The addition of both methane and ammonia (NH_3) produces a hard surface on the steel that is high in both carbon and nitrogen. The composition of the gases can also be adjusted in many ways: by partial combustion of a fuel gas, as mentioned earlier, and by cooling a partially burned gas and absorbing carbon dioxide from it or by chilling it sufficiently to condense out most of the moisture.

Non-oxidizing atmosphere

Cooling rate. Rapid extraction of heat from steel to cool it quickly from one temperature to another is important in developing certain desired properties. The cooling rate of the steel is determined by the nature of the quenching medium and the thickness of the piece being treated. An enormous variety of liquids has been employed since antiquity, but relatively few are now utilized. Often used mediums, in order of decreasing severity of quench, are cold water from high-pressure jets onto hot steel, a bath of iced brine, a bath of circulating cold water, a bath of oil (the oil must have a high flash point to be safe), a bath of boiling water, circulating liquid lead, a blast of air, still air, burial in a pit of lime, and slow cooling in a furnace or refractory-lined box.

Quenching media

The cooling rate required to harden a steel is reduced with increased levels of carbon and the presence of alloying elements. Hence, a less severe quench is used with alloy steels. With a given quench medium, however, the cooling rate in the interior of a piece of steel decreases with increased thickness of the steel. Thus, the greater the thickness of the piece, the more severe the quench must be to harden the steel throughout. With carbon steels, air cooling may be sufficient fully to harden thin strips, but water quenching may be inadequate for heavy gears and forgings. Accordingly, alloyed steels are used for the heavier sections both to obtain hardening throughout and to avoid the severe quench rates that cause distortion and cracking. The quenching medium usually has its temperature controlled by a cooling system and is circulated to assure uniformity of quench from piece to piece and over the surface of each piece. Mechanical devices and conveyors are employed to save labour and provide rapid and consistent introduction of metal parts into and removal from the quenching medium. Uniformity and consistency of the quenching operation are essential to obtaining good control of the parts being processed.

Metallography. The nature and structure of a steel can be observed by examining the polished and etched surface of the piece of steel in an optical microscope. The sample is given a high polish and then etched carefully to differentiate the various phases present. The choice of etchant is determined by the composition of the steel and the aspect of its structure under investigation. The magnification employed is also determined by the purpose of the investigation and ranges from one to 1,500 times. Since the latter figure is the approximate limit of ordinary light microscopy, electron microscopy is used if greater resolution is desired. The structures observed may be photographed for further study and to provide a record of the structure of the steel. Considerable attention is being devoted to the use of closed-circuit television and a computer to determine automatically the nature and amounts of various phases present in an image from the microscope. In the long run, this technique should reduce the tedious work of identifying and counting the nonmetallic particles present in steels, but more work is needed to make it practical.

As was pointed out in the section on *Steel metallurgy*, there is a close connection between the heat-treatment given a steel and the structures obtained. Thus, the microscope is important in determining whether the processing was satisfactory. Microscopic examination of a steel, coupled with measurements of tensile strength, ductility, fatigue strength, impact resistance, and other special physical measurements, is used to establish control of processing of all kinds of steels. Hardness is determined by measuring the size of indentation left by a steel ball, diamond cone, or diamond pyramid that is pressed into the surface of the steel with a specified force. Tensile strength is measured by subjecting a standard steel specimen to an increasing load until fracture. Toughness or impact strength is measured by the amount of energy absorbed by the instantaneous fracture of a standardized test piece when struck by a large swinging hammer (see also MATERIALS TESTING).

III. Properties and uses of carbon and alloy steels

CARBON STEELS

Steels can be classified in a number of ways. One of the most common methods is based on the structure produced during solidification; types, already described above, are killed, semikilled, and rimmed steels. Only a few additional comments are needed here. Killed steels are used in applications requiring a dense, uniform structure. Virtually all alloy steels are produced as killed steels, because a high level of deoxidation is necessary to assure control of density and composition. Steels for strand casting must be killed for satisfactory handling during solidification. Thus, a number of kinds of steels that have been cast as semikilled or rimmed ingots must have their compositions and deoxidation practices adjusted for strand casting.

Chemical classification of steels

The primary basis for classifying steels is by chemical analysis. Most major countries have their own methods of classification, which may indicate levels of carbon, manganese, phosphorus, sulfur, or silicon in a steel, depending on type. If other elements, such as aluminum, lead, and copper, are required, their levels also must be specified when a steel is made.

Carbon is both the cheapest and the most effective alloy-

ing agent in steels. Low-carbon steels, containing between 0.08 and 0.15 percent carbon, are used largely where low cost, good surface, good ductility and toughness, weldability, and ease of forming and working are desired. Examples include the sheet steels used for automobile bodies, welded tubing, all kinds of steel containers, and wire and case-hardened machine parts. Mild steels, containing from 0.15 to 0.25 percent carbon, are easily machined and stronger but less ductile than the lower carbon grades. These are used in structural members in buildings and bridges, in truck bodies and railroad equipment, and in boilers, drop forgings, and bolts. Steels in the medium-carbon range, from 0.25 to 0.35 percent carbon, are harder and stronger than mild steel and are used for large tubes, ship structures, shafts, and a variety of machine parts. Steels containing 0.35 to 0.65 percent carbon are used for large forgings for heavy machinery. Steel rails and wrought-steel wheels that require good strength and ductility and good response to heat-treatment are made from steels containing 0.65 to 0.85 percent carbon. These steels respond well to heat-treatment. Steels with 0.85 to 1.2 percent carbon are used in the heat-treated condition when ranges of hardness and ductility are required. Uses include springs, cutting tools, and rock drills.

Ordinary carbon steels constitute the bulk of the steels produced throughout the world. In the United States, for example, in the years just after 1970, 88 to 90 percent of the output of raw steel was carbon steels, 10 percent was alloy steels, and 1.0 to 1.2 percent was stainless steels. Furthermore, flat-rolled products, sheet, strip, and plate, constituted slightly less than half of the total production.

ALLOY STEELS

A very wide variety of compositions of steels is possible with many alloying elements that may be used singly or in combination. It has been found generally that a combination of alloying elements gives better results in cost and properties than is obtained with the use of one element.

Alloying metals. *Nickel and chromium.* The most important alloying elements in steels are nickel and chromium. Nickel dissolves in ferrite (see below *Steel metallurgy*) and imparts strength to the steel but does not increase toughness. Because of this and because of its cost, nickel is no longer used extensively as the sole alloying element.

Chromium and nickel in combination

Chromium at low levels increases the ability of a steel to be hardened by heat-treatment and joins with carbon to form hard, finely dispersed carbides; at levels above 5 percent it imparts corrosion resistance. A number of steels containing from 0.30 to 1.60 percent chromium are used for grinding rolls, roller bearings, and projectiles. Chromium and nickel are often used together or in combination with small quantities of other elements, such as vanadium, molybdenum, and boron. Chromium and nickel are used together because they increase the toughness and strength of a steel and improve its ability to be hardened. The other elements mentioned above aid in these improvements and reduce the amounts of nickel and chromium necessary. The chromium–nickel steels are used extensively for heat-treated machine parts, axles, gears, and armour plate. Rustless irons and stainless steels contain 12 to 18 percent chromium and up to 8 percent nickel. Heat-resisting alloys contain up to 25 percent each of nickel and chromium.

Manganese. Manganese is contained in all steels to ensure good hot-working properties; at levels above 1 percent it is considered an alloying element. Four steel compositions containing 1.75 percent manganese are used in farm implements and automobiles. Higher manganese killed steels are employed in ship construction where brittle fracture is to be avoided. Manganese is an important element in steels used in high-strength castings, rifle barrels, and heat-treated forgings. The tough Hadfield steel, containing 14 percent manganese, is described below in the section on *Steel metallurgy*.

Vanadium. Vanadium is a good deoxidizer. A few tenths of a percent yields steel with a sound structure, a fine grain, or texture, and good response to forging. High-speed steels and tools for hot work contain 0.5 to 2 percent vanadium.

Molybdenum. Molybdenum is an effective alloying addition at low concentrations (0.2 to 0.3 percent). Molybdenum increases the depth of hardening, improves the resistance to creep at moderately elevated temperatures, and permits good control of grain size.

Boron. Boron at a level of 0.0005 percent reduces by half the amounts of nickel, chromium, and molybdenum normally necessary to achieve a desired strength and toughness. Boron was first employed extensively during World War II to economize on scarce alloy elements; its use has continued since that time. Because of its great potency and the very low concentration required, particular skill and care are required when producing, processing, and heat-treating the boron steels.

Advantages of boron

Tool steels. Ordinary high-carbon tool steels must be used carefully to avoid overheating the tip of the tool, which destroys the cutting edge. Modern high-speed steel can be used at six or seven times the cutting speeds possible with carbon-tool steels, and the cutting edge can be allowed to reach a red heat. These steels contain tungsten, chromium, and vanadium and may also contain either molybdenum or cobalt. When forged and annealed, they are soft and can be machined easily into complex forms. The usual heat-treatment first involves preheating to 850° C (1,560° F), followed by rapid heating to 1,300° C (2,400° F), cooling in oil or air to room temperature, and finally a reheat to 600° C (1,100° F), where the steel is held for 30 minutes before it is cooled to room temperature.

There are many compositions of alloy steels used for special purpose tools. Steels containing 1 to 5 percent tungsten are used for woodworking tools. Tool steels that can be hardened with very little distortion contain 1 percent each of carbon, tungsten, chromium, and manganese. Die steels used for forging contain 0.3 percent carbon, 12 percent tungsten, 3 percent chromium, and 0.4 percent vanadium. The tool-steel industry is highly competitive; many proprietary compositions exist.

Stainless steels. The three principal types of stainless steels are austenitic, ferritic, and martensitic (see below *Steel metallurgy* for the identification of these structures). The most familiar is austenitic, which contains 18 percent chromium and 6 percent nickel, is very ductile, and has good resistance to corrosion and staining. It is used in cooking utensils, food-processing equipment, equipment for the chemical industry, hospital equipment, cutlery and flat tableware, and architectural trim. To reduce the cost, manganese may be substituted for some of the nickel. If superior corrosion resistance is required, small amounts of niobium (columbium) may be added. A number of special grades of austenitic steel have been developed for their unique properties.

Martensitic stainless steel, which contains chromium but little or no nickel, is readily formed when annealed; its strength, hardness, and other mechanical properties may be improved by heat-treatment. Martensite steels are used for equipment in the chemical and oil industries. Ferritic stainless steels are similar in composition, except for a low carbon content, and have better corrosion resistance. They are employed for automotive trim and interior architectural trim. Stainless steels containing up to 1 percent carbon are used in cutlery.

Ferritic stainless steels

Alloying agents. Various pure metals and ferro-alloys are added to liquid steel to obtain a desired composition in the final product and to control the levels of oxygen and sulfur in the steel. Pure aluminum, cobalt, copper, chromium, lead, manganese, nickel, and titanium are used when extra-pure alloying elements are required. Generally, aluminum, cobalt, copper, and lead are added in the pure form; the other metals are more expensive as pure metals, however, than when obtained as ferro-alloys. Hence, these ferro-alloys, which are alloys of iron and one or more of the alloying elements, are the principal alloying agents used today. Most contain appreciable levels of carbon, although a number of grades are produced with little or no carbon for use in special situations. An example is low-carbon ferrochromium, which is used in producing extra low-carbon stainless steels; *i.e.*, the steel contains not more than 0.03 percent carbon.

Ferromanganese. Ferromanganese is usually produced in a blast furnace from high-grade manganese ores low in phosphorus, silica, and iron. The usual product contains between 74 and 82 percent manganese, 7.5 percent carbon, not more than 1.25 percent silicon or 0.35 percent phosphorus, and the balance iron. The operation of the blast furnace is somewhat more difficult when producing ferromanganese than when producing hot metal for steelmaking; in consequence, older and smaller furnaces are usually used. The capacity is reduced by about two-thirds, and the coke rate is doubled. Approximately 20 percent of the manganese is lost to the slag. Ferromanganese can also be produced in submerged-arc electric furnaces (described below). Cost of the process is prohibitive, however, except where power is inexpensive, as in Norway.

Ferrosilicon. Ferrosilicon is used extensively in steelmaking both as an alloying agent and as a deoxidizer. Several grades are produced in the submerged-arc electric furnace: 50, 75, 80, and 90 percent silicon, with the balance principally iron. Ferrosilicon contains less than 0.5 percent carbon and less than 0.1 percent each of sulfur and phosphorus. Phosphorus levels must be kept low to prevent the formation of poisonous phosphine (PH_3) when the alloy is exposed to moist air or water. The submerged-arc electric furnace used to produce ferro-alloys is a steel shell having a shallow hearth usually lined with carbon or carbon blocks. Three large carbon electrodes project vertically down into the hearth with their tips well immersed in the furnace charge. Furnaces may or may not have roofs. The electrodes may be preformed or may be made in place by filling thin steel cylindrical shells with a tar–coke mix. This mix is baked as it passes into the hot zone of the furnace. Heat for the process is generated by currents from the electrodes passing through the charge. The charge, consisting of pure quartzite, coke, and iron turnings, is fed in around the electrodes. Silicon is reduced to the metal at a location low in the furnace near the electrode tips, and the charge is heated in part by hot carbon-monoxide gas rising from the reaction zone. The molten iron–silicon alloy collects in the hearth and is periodically drained from the surface.

Submerged-arc furnace

Ferrochromium. Many grades of ferrochromium are produced; the usual commercial alloys contain approximately 65 to 72 percent chromium and between 4.5 and 8.5 percent carbon. This high-carbon product is usually produced in a so-called three-phase Heroult-type electric-arc furnace having a carbon hearth. The charge is high-grade chromium ore, iron or iron ore, and a flux. The reductant is usually anthracite coal. Action of the arc heats the charge, and the oxides are reduced by the carbon. Molten ferrochromium collects in the hearth. When the reactions are complete, the metal is cast into slabs, and when cold these slabs are broken and the pieces crushed and sized for use. Ferrochromium low in carbon is produced by melting high-carbon chromium, chromium oxide, lime, and fluorspar in an electric furnace. The reaction between chromium oxide and carbon in the ferrochromium eliminates the carbon as carbon monoxide. The lime and fluorspar combine to form a slag. The molten metal contains from 0.2 to 2 percent carbon and is processed as described above. Ferrochromium with an intermediate carbon content can be produced in a submerged-arc furnace, but ferrosilicon and ferrochromium with a high level of silicon instead of carbonaceous materials are used as the reducing agents.

Ferrovanadium. Ferrovanadium is difficult to produce, because the metal is highly reactive. It is manufactured from a charge of ore, carbonaceous material, and fluxes in a small graphite-lined arc furnace. The alloy contains between 35 and 55 percent vanadium.

Ferrotungsten. Ferrotungsten is produced in a small, single-electrode arc furnace in which the hearth acts as one electrode. The charge consists of tungsten ore, carbonaceous material, iron ore, or iron and fluxes. The tungsten ore is easily reduced, but the alloy formed has a high melting point. During the heat, a chunk of solid alloy builds up on the hearth. When sufficient alloy has collected, the furnace is shut down and dismantled. The lump of alloy is crushed, cleaned, and prepared for shipment. The usual grade of ferrotungsten contains 70 to 80 percent tungsten and a maximum of 0.6 percent carbon.

Nickel. Nickel is often charged to the steel furnace as nickel oxide, which is easily and rapidly reduced to metal by carbon in the charge. Because nickel does not oxidize into the slag, nickel-steel scrap is usually charged to a heat when a nickel-bearing steel is made. Recently, metallic iron pellets containing 1 percent nickel have been used as a source of nickel when making low-alloy steels.

Other alloys. Alloys of many types are marketed for use in steelmaking. These contain barium, boron, calcium, niobium (columbium), molybdenum, magnesium, phosphorus, sulfur, selenium, tantalum, titanium, zirconium, etc. These metals may be in simple combinations with iron or with another metal, such as calcium silicide, or they may be in complex combinations as proprietary mixtures sold for special purposes.

IV. Steel metallurgy

STRUCTURAL FORMS OF IRON

Pure iron has three structural forms. The structure that is stable from room temperature to 911° C (1,672° F) is called alpha. The iron atoms in this structure are arrayed in a regular fashion on a lattice made up of simple cubes in which iron atoms are at the cube corners and one is at the centre of each cube. Accordingly, the alpha form of iron is said to have a body-centred cubic-crystalline structure. Between 911° C and 1,392° C (2,538° F), the gamma form is stable. In gamma iron the crystalline lattice is composed of identical cubes in which iron atoms are located at the corners and in the middle of each cube face; *i.e.*, the structure is face centred cubic. Between 1,392° C and 1,538° C (2,800° F) the stable structure is again the body-centred cubic form, which is designated delta iron. Iron melts at 1,538° C, and in the liquid there is no well-ordered arrangement of the atoms.

The physical and mechanical properties of a metal are influenced strongly by the nature of the atomic arrangement, and it is found that metals having the face-centred cubic structure are particularly ductile. The properties of a metal are also influenced significantly by defects in the lattice structure; much research has been directed to understanding the nature of these defects. Among the important defects are (1) a vacancy—*i.e.*, one atom is missing from a lattice point; (2) an iron interstitial, in which an iron atom is wedged between the regularly spaced atoms; and (3) large-scale effects called dislocations, one form of which is an extra plane of atoms that extends only partway through the crystal. The crystal structures of iron and steel have been explored by projecting beams of X-rays, neutrons, or electrons through thin foils or powdered specimens and observing the way that these beams are scattered and bent (diffracted) because of the regularity and irregularity of the atomic structure. Many changes in the properties of iron and of metals in general, such as hardening by cold work, brittle fracture, and plastic flow under stress, have been explained in terms of defects.

Structural defects

PHASES IN STEEL

Three phases may be found in unhardened steels: ferrite, austenite, and cementite. Ferrite is the body-centred cubic form of iron (alpha) in which some carbon has dissolved; the maximum amount at equilibrium is 0.025 percent at 727° C (1,341° F). Austenite is the face-centred form of iron (gamma) in which some carbon can dissolve; at 727° C the maximum amount is 0.76 percent, rising to 2.1 percent at 1,147° C (2,097° F). Cementite is a compound of iron and carbon having the formula Fe_3C. Cementite can decompose into ferrite and graphite below 727° C and into austenite and graphite above that temperature. The reactions are so slow, however, that they are not important in the processing of most steels. The iron–cementite phase diagram (Figure 11) shows the regions of stability of the phases found in slowly cooled steels. Below 727° C these steels, containing between 0.025 and 2 percent carbon, consist of ferrite and cementite. As has been noted already, with increasing carbon

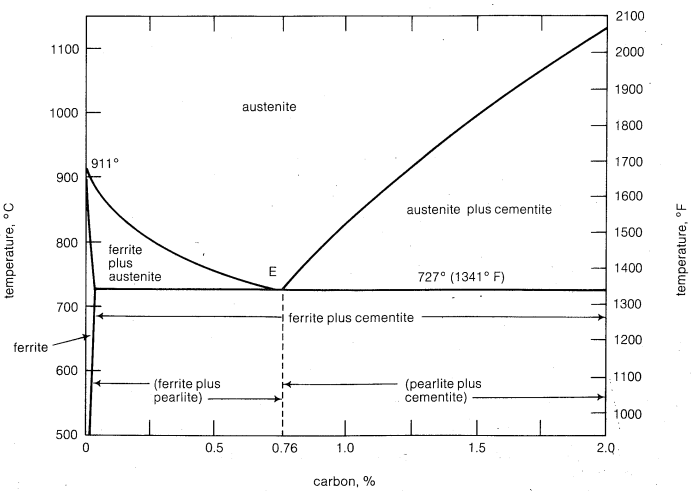

Figure 11: Steel portion of iron—cementite diagram (see text).

content, the amount of ferrite decreases and the amount of cementite increases.

A 0.76 percent carbon steel. The significance of other areas of the phase diagram can be illustrated with steels of three different compositions, beginning with a steel containing 0.76 percent carbon. Below 727° C this steel contains ferrite and cementite. When the steel is heated to just above 727° C (point E), the ferrite dissolves the cementite, and the whole structure is changed to austenite. The temperature at which austenite begins to form on heating is called the Ac_1 temperature (*c* for *chauffage*, or "heating"). Initially the austenite crystals are very small, but either holding the steel at this temperature for a long time or heating it to a higher temperature and holding for a shorter time causes some of the crystals to grow at the expense of others and the crystal size to increase. If this steel is then cooled to a little below 727° C, the austenite will decompose, forming alternate platelets of ferrite and cementite, in a structure called pearlite because of its appearance (see Figure 12A). This reaction of one solid phase decomposing to form two different solid phases is called a eutectoid change, and the temperature at which the austenite decomposition is complete is designated Ar_1 (*r* for *refroidissement*, or "cooling"). Because the reactions are somewhat sluggish, for a given composition, Ac_1 is slightly higher than Ar_1.

The distribution of the ferrite and cementite in pearlite is dependent on the rate of cooling and will be described later.

A 0.3 percent carbon steel. The second steel, one containing 0.3 percent carbon, will also consist of ferrite and cementite below 727° C. When heated just above that temperature, austenite containing 0.76 percent carbon forms by a reaction between the cementite and some of the ferrite. The resulting structure contains only ferrite and austenite. With increased temperature the ferrite dissolves in the austenite until at approximately 810° C (1,490° F) only austenite containing 0.3 percent carbon remains. The temperature at which the transformation to austenite is complete is given the designation Ac_3 (there is no Ac_2).

All carbon steels containing between 0.025 and 0.76 percent carbon undergo this same change on heating; the temperature (Cr_3) at which the steel becomes all austenite rises, however, as the carbon content decreases. This temperature range (see Figure 11) within which the structure changes on heating from ferrite plus cementite to ferrite plus austenite and then to all austenite is known as the critical range for carbon steels. The crystals of austenite again grow in size as the temperature of this steel is increased above 810° C. A steel containing less than 0.76 percent carbon that is slowly cooled from a

Critical range for carbon steels

D. Lloyd Thomas

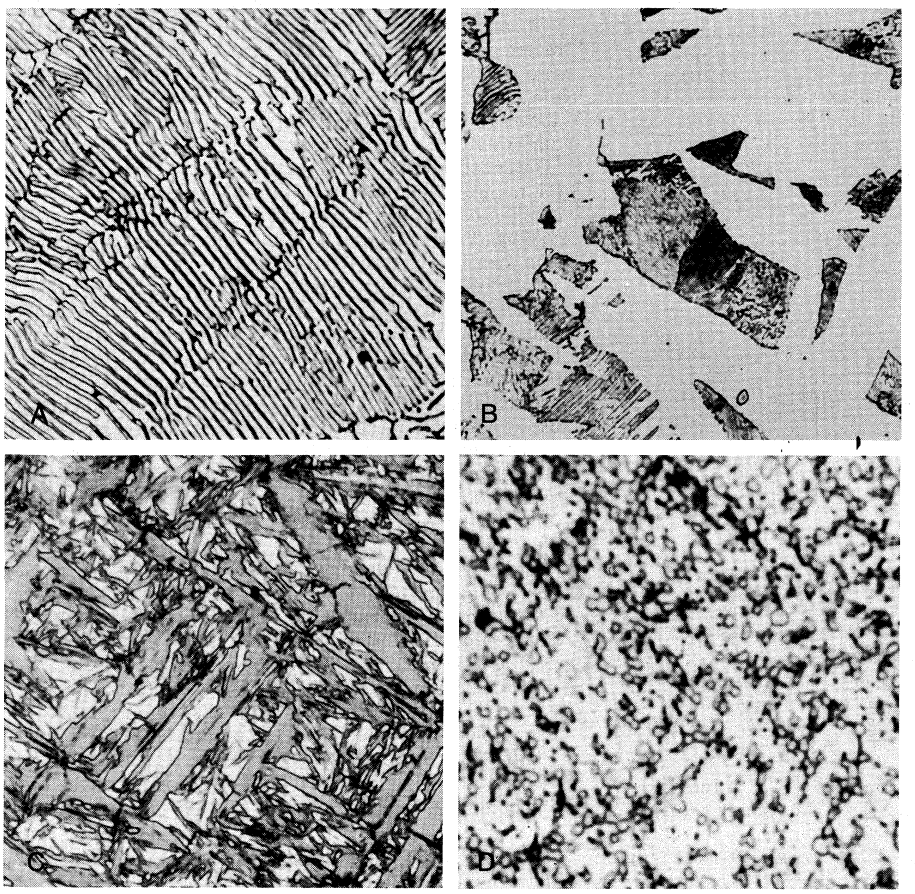

Figure 12: *Microphotographs of various steels.*
(A) Pearlite × 1,000; (B) ferrite (light) and pearlite (dark and lamellar) × 600; (C) martensite × 850; and (D) tempered martensite × 2,000.

temperature above the critical range will begin to form ferrite at the Ar_3 temperature. Very small crystallites of ferrite will form first at the boundaries of the austenite crystals. This ferrite is low in carbon so that the remaining austenite gradually becomes enriched in carbon, reaching 0.76 percent at 727° C (1,341° F).

A 1.1 percent carbon steel. The third steel contains 1.1 percent carbon. If cooled slowly, it, too, will contain only ferrite and cementite below 727° C. If this structure is heated to just above 727° C, the ferrite will react with some of the cementite to form austenite containing 0.76 percent carbon. The structure then will contain only austenite and cementite. With further heating the cementite will decrease, and at 860° C (1,580° F) the steel contains only austenite. When the steel is cooled from a temperature at which it is all austenite, cementite begins to form just below 860° C at the austenite grain boundaries. On further cooling, the amount of cementite increases, and the austenite is depleted in carbon until it reaches 0.76 percent at 727° C. The austenite then decomposes into pearlite, and the final structure is pearlite and cementite or ferrite and cementite, pearlite consisting, as noted earlier, of ferrite and cementite. In steels containing more than 0.76 percent carbon, the temperature at which the solution of cementite in austenite is complete is designated Ac_{cm}, and the temperature at which cementite begins to form from austentite is designated Ar_{cm}.

EFFECTS OF CARBON CONTENT ON STRUCTURE AND PROPERTIES OF STEEL

Slowly cooled steels. At temperatures below 727° C, slowly cooled steels containing more than 0.025 percent carbon contain ferrite and cementite. Ferrite is soft and ductile, and cementite hard and brittle. The amount of cementite seen under the microscope increases with the amount of carbon in the steel. A steel with 0.3 percent carbon contains approximately 94 percent ferrite and 6 percent cementite, whereas at 1 percent carbon these amounts are 85 percent ferrite and 15 percent cementite. In a slowly cooled steel the austenite remaining at 727° C will transform into hard and strong pearlite that consists of alternate layers of ferrite and cementite (Figure 12A).

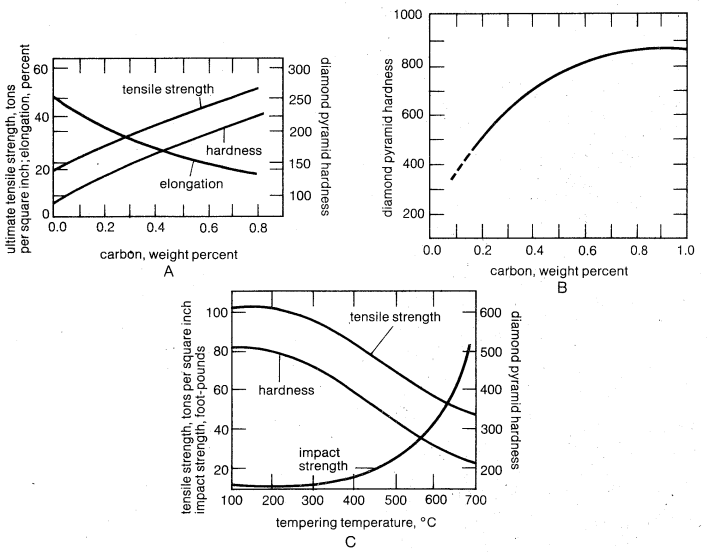

Figure 13: *Effects of composition and heat treatment on mechanical properties of steels.*
(A) Mechanical properties of annealed steel containing various percentages of carbon. (B) Hardness of martensite as a function of carbon content. (C) Effects of tempering temperature on mechanical properties of tempered martensite.

With increased carbon content up to 0.76 percent, slowly cooled steels contain an increased amount of pearlite and less ferrite (Figure 12B); strength and hardness increase, but ductility and toughness are reduced (see Figure 13A). Steels having maximum ductility and toughness are low-carbon steels that have been slowly cooled or annealed below 727° C (1,341° F). The final structure of a steel will be coarse if the austenite crystals were coarse at the beginning of cooling. Hardness and tensile strength are not affected materially by the temperature at which the steel is held before cooling, nor do they depend upon the size of the austenite crystals. The finer the final structure, however, the tougher will be the steel when subjected to shock at and below room temperature. Because recrystallization takes place both on heating (Ac_1 to Ac_3) and cooling (Ar_1 to Ar_3), a coarse structure can be converted to a fine structure by reheating the steel to just above its critical range of temperature and then slowly cooling it.

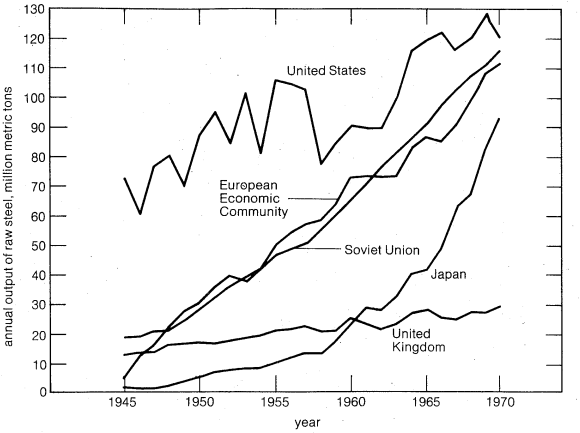

Figure 14: Growth of raw-steel production of major producing countries since World War II.
By courtesy of the American Iron and Steel Institute

A steel containing more than 0.76 percent carbon when cooled from a temperature where it is all austenite will first precipitate cementite at the austenite grain boundaries. With further cooling the structure will consist of grains of austenite surrounded by cementite. Subsequently, the austenite will form pearlite, and the final structure will consist of islands of pearlite in a continuous network of cementite. Though steel formed this way is strong, it is also very brittle, so the cementite is dispersed by kneading the steel. It is important that these steels not be reheated above 760° C (1,400° F) in subsequent heat-treatment; otherwise, the embrittling network will form on cooling.

Hardened steels. *Carbon steels.* The temperature and the nature of the decomposition of austenite into pearlite in plain carbon steels depends strongly upon the rate of cooling. With increased cooling rates the Ac_1 temperature can be lowered progressively to about 550° C (1,022° F), and the pearlite will become so fine that it cannot be resolved under the light microscope. Accompanying this change is increased hardness and strength of the pearlite. With a further increase in the cooling rate, the transformation of austenite to pearlite may be suppressed altogether. A broad range of heat-treatments are used to take advantage of these effects. A steel is annealed by cooling it slowly in a furnace from just above its critical temperature range. The result is coarse pearlite, and the steel is soft. A steel cooled in air from just above its critical temperature range is said to be normalized. The result is a finer pearlite, and the steel is harder, stronger, and less ductile than it would be if annealed. By quenching the steel very rapidly in cold water or brine, the formation of pearlite may be partially or completely suppressed, and austenite can be retained down to about 200° C (400° F). At that temperature, the austenite begins to form a structure called martensite (Figure 12C and D). The transformation from austenite to martensite is complete at about room temperature. The minimum cooling rate necessary to suppress the formation of any pearlite is called the critical cooling velocity for the steel. Quenching to form martensite is often used because of the special properties obtained when the steel is annealed.

Suppression of pearlite formation

Martensite results when face-centred cubic austenite transforms to the body-centred structure without cementite being precipitated. Carbon is retained in the structure, which is stretched slightly so that it is no longer cubic;

Forming martensite

thus, martensite can be thought to be ferrite supersaturated with carbon. This supersaturation results in severe distortion of the lattice, which increases with increasing carbon content of the steel. The hardness of martensite increases to a maximum as the carbon content of the steel increases. To obtain a completely martensitic structure in a steel containing less than 0.8 percent carbon, the steel must be quenched from a temperature above its critical temperature range. This is necessary to suppress the formation of both ferrite and cementite. Steels containing more than 0.8 percent carbon are quenched from 760° C (1,400° F), usually immediately after forging, thus producing a structure of cementite dispersed in a matrix of martensite. The cooling rate necessary to obtain martensite in plain carbon steels very often causes distortion of the part being heat-treated. In severe cases, cracking may also result, especially in a part with a complex shape. Thus, even with the most severe quench in brine or cold water, a maximum thickness of a plain carbon steel that can harden fully to martensite is only about 20 millimetres (0.8 inch), because the cooling rate decreases from the surface to the interior of a part.

Low-alloy steels. Nickel, chromium, manganese, and molybdenum in steels reduce the critical cooling rate necessary to obtain martensite. These elements are said to increase the steel's ability to harden. On the other hand, they do not increase the hardness of the martensite that forms. The use of these alloying elements singly or in combination reduces the tendency for distortion and cracking because a less drastic quench is required to obtain martensite. A quench in oil or air is usually sufficient. Alloy steels containing nickel, chromium, and molybdenum in sections 150 millimetres (about six inches) thick can be made martensitic throughout by an oil quench. Because alloy steels are much more expensive than carbon steels, they are used only when their special properties are required.

Hardened and tempered steels. Martensite is usually much too brittle and too hard for most uses, and residual internal stresses are present in the steel as a result of the rapid cooling necessary to form the martensite. Reheating the steel to a selected temperature in the range of 200° to 600° C (400° to 1,100° F) and then cooling it in air will relieve the internal stresses and decrease the hardness and strength of the steel. A marked increase in toughness is obtained, however. This operation is called tempering. The temperature and time for the tempering operation must be carefully selected on the basis of the type of steel and the final properties desired. A tempering temperature near 680° C (1,260° F) causes the greatest loss in hardness and strength but imparts the greatest toughness as measured by impact strength (see Figures 12D, 13C). Tool steels are tempered in the range of 200° to 250° C (400° to 500° F) to relieve internal stresses without the loss of hardness. Spring steels are tempered at 350° to 500° C (650° to 900° F) to obtain good strength without a serious loss of impact properties. Machine parts subject to impact loadings may be tempered in the range of 500° to 600° C (900° to 1,100° F).

In tempering, martensite decomposes into ferrite and cementite. The amount of decomposition increases as the tempering temperature increases up to 400° C (750° F). In the decomposition, carbon forms small particles of cementite, and the highly stressed martensite relaxes to ferrite. The product is a structure consisting of very fine particles of cementite imbedded in a matrix of ferrite. The structure obtained in tempering at a low temperature is so fine that it can be resolved with the electron microscope but not with the optical microscope. The structure is coarser with higher tempering temperatures, and those obtained at 600° C (1,100° F) can be resolved in the optical microscope at 1,000 magnifications (see Figure 12D).

Mechanical properties of tempered alloy steels

The mechanical properties obtained after tempering alloy steels containing nickel and chromium are much superior to those of the carbon steels. This is because these alloying elements strengthen the ferrite matrix. At the same strength, alloy steels are much tougher than carbon steels. The highly alloyed steels are softened much less by tempering than are carbon and low-alloy steels. High-speed tool steels, for example, are quenched from 1,300° C (2,400° F) and tempered at 500° to 600° C (900° to 1,100° F) with little if any loss in hardness. This resistance to softening at high temperatures makes these steels useful as cutting tools where very high tool temperatures are encountered at high cutting speeds.

The phenomenon known as temper brittleness occurs when steels containing relatively high levels of phosphorus, manganese, or chromium are tempered in the range of 400° to 550° C (750° to 1,000° F). It also occurs if these steels are tempered at a higher temperature and then are cooled slowly through this range. The effect can be avoided by tempering at a temperature above 550° C, followed by a quench from the tempering temperature. Molybdenum in the steel reduces the tendency toward temper brittleness.

SURFACE HARDENING

In many instances steel parts such as gear teeth, the teeth on power shovels, and the tires of railroad wheels are subject to severe wear or abrasion at the surface as well as shock and dynamic loading. The needs for high hardness at the surface and a tough interior are conflicting requirements, but they can be met by treating the surface to obtain a hard "case" while the interior of the steel part remains tough. Common methods for accomplishing this are described briefly below.

Carburizing. Carburizing is the modern form of an old cementation process. The part, made from a carbon or alloy steel low in carbon, is heated to about 900° C (1,650° F) in a bed of carbonaceous material or a carburizing atmosphere. Carbon diffuses into the surface, the amount of carbon added and the depth of penetration depending upon the carburizing medium, the temperature, and the time of exposure. The resulting case will contain about 0.8 percent carbon and be fully martensitic when the part is quenched to room temperature. Because of its lower carbon content, the core will not be fully hard and will be tough. A variety of heat-treatments after carburization are used, depending upon the combination of properties desired for the case and core.

Nitriding. A steel containing small amounts of chromium, molybdenum, and aluminum will form a very hard, thin case on the surface when exposed to an atmosphere of ammonia. This case consists of nitrides of aluminum and chromium formed when nitrogen obtained from the decomposition of the ammonia diffuses into the steel. The depth of the case increases with the duration of the nitriding process. The procedure is first to quench and temper the steel part at 550° to 650° C (1,000° to 1,200° F) to obtain a tough case. The hard case is then obtained by exposing the part to an atmosphere of ammonia for about 80 hours at 500° C (900° F). Nitriding has the advantage over carburizing in that the case remains hard when exposed to temperatures up to 500° C, whereas carburized cases begin to soften at about 200° C (400° F).

Nitriding procedure

Flame and induction hardening. In this method a part is made from a medium-carbon steel, with or without alloying elements. The part is quenched and tempered to produce the desired case properties. Then the portions of the surface that are to be hardened are quickly heated to above the Ac_1 temperature of the steel and quenched in oil or water. The heated region becomes martensitic, and the core retains its toughness. Heating is accomplished by numerous small gas flames or by high-frequency induction.

Other methods. As noted in the history section of this article, Hadfield manganese steels, which contain approximately 1.4 percent carbon and 14 percent manganese, are extremely tough and wear-resistant. These properties are obtained by heating the steel to between 1,000° and 1,060° C (1,800° to 1,940° F), followed by a water quench. This treatment preserves the austenitic structure down to room temperature. Abrasion of the surface and cold work causes the surface to transform to martensite. Thus, the hard surface is continually renewed as the surface wears away.

A number of other methods are also used to obtain a hard surface. One way is to apply a hard facing to a steel part by welding, brazing, or spraying a coating of hard material. Materials used for this are tungsten carbide and Stellite, tungsten, chromium, and carbon.

RESEARCH AND DEVELOPMENT

Steels face vigorous competition in performance and cost from many types of materials, ranging from other metals, such as aluminum and titanium, to plastics, glass, and concrete, and the industry finds that it is constantly necessary to improve processes in use for producing steels and to devise new steel compositions and ways to produce and process them. Much applied research and development work is going on throughout the world to meet these aims.

New methods of processing ores and producing agglomerated products for the blast furnace are being developed. Methods for producing and utilizing directly reduced ores are being tested. Experimentation on methods for continuous production of steel is in progress, and improved methods for operating and controlling the various processes in use for steelmaking are under development. Particular attention is being directed to developing methods for automatic control of basic-oxygen and electric-furnace steelmaking. Improved methods of vacuum process and refining steels have been developed recently and are being further improved. A great deal of effort is being devoted to describing and controlling the solidification of steels. Laboratories are working on new alloy compositions, particularly for the purpose of obtaining improved properties by new processing methods and with the use of lower levels of alloying elements or using less costly alloying elements. In recent years much attention has been devoted to developing new and improved coatings, such as chromium, aluminum, plastic, and thinner tin coatings for flat-rolled products. A strong trend toward the use of plates and sheets instead of rolled sections in the production of such items as structural members and building walls has required the development of improved methods of forming and welding.

Continuous production of steel

Currently, a great deal of money and effort are being directed to means of alleviating the problems of pollution caused in steelmaking. A major task is to avoid air and water pollution associated with conventional methods for coking coal. Modifications in the methods of charging and discharging the ovens are receiving much attention, and alternative methods for processing coke are being tested. The disposal of spent liquor from pickling of steels and pollution arising from sulfur in fuels are also receiving major attention.

Reducing pollution

Research of a more fundamental nature has been devoted to understanding the chemical processes of iron-ore reduction, the chemistry of the reactions in steelmaking, the details of how alloys of iron solidify, the chemical properties of steel, and how the details of the atomic structure of phases present in steels are related to the physical and mechanical properties of steels. Attention is being given to the reactions of steels with various environments and to the mechanisms by which steels corrode.

V. World steel production

During the early 18th century, Sweden was the chief producer of the relatively small volume of steel made in the world. With the development of mass-produced iron and steel, Great Britain became dominant. It has been estimated that the output of pig iron in Great Britain rose from 28,000 tons per year in 1720 to 75,000 tons in 1788 and to almost 3,000,000 tons by 1852 (unless otherwise noted, figures are in short tons). It is notable that in the early part of the 19th century much of this iron was exported: 20 percent in 1806 and almost 50 percent in 1856. Pig-iron production continued its rapid increase to 7,100,000 tons in 1875, when the United Kingdom produced almost half the world's output (see Table 1 for selected world figures). In that year, production in the United States was 2,200,000 tons, or 15 percent of world production. In 1880 British production reached 8,700,000 tons and then rose gradually to about 10,000,000 tons during the remainder of the century. During this time the British share of the world's production of pig iron declined from 42 percent in 1880 to approximately 22 percent as production of pig iron in the United States rose rapidly to over 15,000,000 tons in 1900, making that country's share of world production about 35 percent. Great Britain's annual output of pig iron was first surpassed by that of the United States in 1890, by Germany and France in 1921, when the coal supply was interrupted by a strike, by the Soviet Union in 1931, and by Japan in 1954.

British pig-iron production in the 19th century

Table 1: World Output of Pig Iron for Selected Years

year	metric tons per year (000,000)	year	metric tons per year (000,000)
1820	1.02	1925	76.9
1830	1.83	1929	99.9
1840	2.74	1930	80.5
1850	4.78	1935	74.2
1860	7.34	1940	104.1
1870	12.03	1943	118.8
1880	18.45	1945	80.6
1890	27.2	1950	136.3
1900	40.5	1955	215.8
1910	65.8	1960	264.5
1920	63.9	1965	326.2
		1970	407.5

Great Britain also was pre-eminent in the production of steel in the 19th century. The older methods for making iron and steel products with a great expenditure of labour rapidly gave way to the Bessemer and open-hearth processes after 1870. In 1875 Great Britain produced 790,000 tons of steel, or 40 percent of world production. In 1896 the output rose to about 4,400,000 tons, or approximately 22 percent of the world's total. U.S. production of steel and wrought iron had passed that of the British by 1880. British production continued to rise, however, to about 7,000,000 tons in 1900, 18,000,000 tons in 1950, 27,000,000 tons in 1960, reaching a high of 31,000,000 tons in 1970 but declining in 1971 to less than 27,000,000 tons.

Table 2 shows the production by processes in Great Britain from 1896 to 1906. During the interval, the increase in production was chiefly due to the increased output of open-hearth steel. In 1905 the output of Bessemer steels reached its peak for the 20th century, and, subsequently, the basic open hearth became the primary process for steel production in the United Kingdom.

From 1896 to 1970 the United States was the largest producer of steel in the world. In 1971, however, the Soviet Union surpassed the United States. The rise and decline of processes in use in the United States for the past 100 years illustrates in a general way the changes that have occurred throughout the world. The first production of acid Bessemer steel was in 1867, when 30,000 tons were made. In 1870, production of acid open-hearth steel was begun, and the output was 1,500 tons. In the same year, 42,000 tons of acid Bessemer steel were made, and the output by this process rose rapidly, reaching its all-time peak of 13,800,000 tons in 1906. In the interval from 1870 to 1906 the acid Bessemer was the primary steel-producing pro-

Table 2: Production of Steel and Wrought Iron in Great Britain
(in 000 metric tons)

year	open hearth			Bessemer			total steel	wrought iron
	acid	basic	total	acid	basic	total		
1896	2,180	174	2,354	1,380	465	1,845	4,209	1,234
1900	2,912	298	3,210	1,275	499	1,774	4,984	1,183
1905	3,092	808	3,900	1,418	588	2,006	5,906	954

cess in the country. Subsequently, it has declined in output, becoming of less relative importance each year until production by this method ceased in 1967. Initially, the use of the open-hearth process grew more slowly, because it was operated with acid hearth refractories and an acid slag and, as a result, was not competitive with the acid converter. Its growth quickened after 1884, when it was found that the process would operate satisfactorily with basic refractories. The basic furnace rapidly replaced the acid furnace for most purposes in the United States, because it could treat readily the moderate levels of phosphorus in pig iron made from the ores from the Great Lakes ranges. These ores were used extensively because they were plentiful, cheap, and of good quality. The basic open-hearth process surpassed the acid Bessemer in output in 1908 and was the primary means for producing steel in the United States until 1970, when it was surpassed in output by the basic oxygen process. The reasons for the long ascendancy of the basic open hearth has been its flexibility in producing virtually any type of carbon steel and a number of the low-alloy steels, its flexibility in utilizing scrap, hot metal, and cold iron in virtually any proportion, and its ability to make products of good quality. Between 1928 and 1961 the open-hearth process produced over 85 percent of the steel made in the United States each year.

Growth of oxygen steel

The use of the basic oxygen processes by the U.S. steel industry did not begin until 1955, six years after the basic oxygen furnace (or L–D furnace) had been developed in Austria in 1949. The growth in output of oxygen steel by the basic oxygen furnace has been dramatic in the subsequent 15 years. Production rose from 725,000 tons in 1955 to over 70,000,000 tons in 1971. The primary advantages of the basic oxygen furnace over the open hearth are its rapid operation, lower cost, and ease of control. It is best suited to the production of low-carbon steels, which are used in large quantities today. To meet the disadvantage of its inability to operate normally with more than 35 percent scrap in the charge, a number of steel plants have also installed basic electric furnaces for the production of carbon steels. With the two processes in effect, the inability of the oxygen furnace to melt scrap can be avoided.

High-quality and specialty steels were produced in the United States by the crucible process between 1870 and 1915. Growth was slow, and the peak in output of 146,000 tons was reached in 1907. Production held steady at approximately that level until 1920, but thereafter it declined rapidly to a few thousand tons a year. The commercial use of the electric-arc furnace for producing alloy and specialty steels began in 1906. Output by this process exceeded that by the crucible process in 1916 and increased rapidly to an average of approximately 650,000 tons per year, which was sustained from 1918 to 1938. The demands of World War II pushed production to about 4,500,000 tons in 1943, and the output declined only slightly in the immediate postwar years. The rapid growth in production between 1950 and 1970 resulted from the use of the process for melting carbon steels with scrap as the principal charge. The use of the electric furnace was expected to increase in the decade of the 1970s by increased production of metallized ore and increased recovery of iron and steel scrap from waste as a result of efforts to improve the environment.

In the year 1900 the basic Bessemer process produced 65 percent and the basic open hearth produced 31 percent of the total of 7,500,000 tons of steel made in Germany. In 1905 for France the corresponding figures are 60 percent and 34 percent, respectively, and the total production of steel that year was 2,500,000 tons. The balance of the output was by acid methods. With the increased importation of ores low in phosphorus from abroad in recent years, European steel plants have begun to use the basic oxygen furnace and the Kaldo process more extensively. The basic oxygen furnace with a two-slag operation is also being used to refine the high-phosphorus hot metal obtained from the local ores. Recently, the use of oxygen and steam, and oxygen and hydrocarbons in the basic Bessemer has received renewed interest. In the Soviet Union, the predominant steelmaking process continues to be the basic open hearth. In Japan, where steelmaking facilities were heavily damaged or destroyed in World War II, virtually the whole of the production of carbon steels is by the basic oxygen furnace. Electric furnaces are being used to produce alloy and stainless steels, but a limited tonnage of stainless steel is also produced in the basic oxygen process. Throughout the world the acid processes have given way almost completely to the basic processes, the basic open hearth, the basic Bessemer, the basic oxygen processes, and the basic electric-arc furnace. World production of steel by the basic oxygen furnace was estimated to be 280,000,000 tons in 1971, which was 44 percent of the total production of steel in that year.

World production of iron and steel has maintained an upward trend except for brief periods following World Wars I and II and in 1929 to 1932 during the Great Depression. The production of pig iron has been closely related to the production of steel, because it is used primarily as a raw material in steelmaking. In recent years the large industrial producers of cast-iron products have obtained the iron by melting steel scrap and then carburizing and alloying it. Discarded cast iron from the foundry is sent back to the melting furnace, but there is relatively little pig iron in the charge.

The leadership of the United States in the production of steel was increased after World War II, because the steel-producing facilities of all of the other major industrialized countries had been damaged to some degree in the war. In 1950 the United States produced 48 percent of the world total; in 1960, 27 percent; and, in 1970, 21 percent. The growth in output for each of the principal producing countries and the European Economic Community (Belgium, France, Italy, Luxembourg, The Netherlands, and West Germany) from 1945 to 1970 are shown in Figure 14. In that 25-year span the annual growth rate for the United States was approximately 2.3 percent, and after 1960 the rate was approximately 4 percent. It appears, however, that there has been no growth between 1966 and 1970. In those four years the production of steel in the Soviet Union grew at an annual rate of over 4 percent, that of the European Economic Community almost 7 percent, that of Japan 17 percent, and that of Great Britain slightly over 3 percent. The total world production of steel in 1970 was 634,000,000 tons, and its annual growth rate was approximately 6 percent. The economic conditions in 1971 reduced the rate of growth to a virtual standstill, and the uncertainty of the status of exports and imports of steel for many countries make it difficult to predict whether the growth rates of the 1950s and 1960s can be reached again, or sustained, worldwide.

The place of steel in international trade has changed since World War II. Just after the war, the United States was a major exporter of steel. With the rapid growth of steelmaking capacities in other highly industrialized countries, this has been reversed, and the difference between imports and exports of steel products for the United States has ranged from 6,500,000 to over 16,000,000 tons between 1965 and 1971. The flow of steel products between countries depends strongly on the economic climate and varies greatly from year to year. In the past, major steel-producing countries have always exported steel products to the less industrialized countries. To aid in reducing the drain on their currencies because of the importation of steel products, however, many small countries construct small steel plants using electric furnaces to melt scrap and metallized local ores.

BIBLIOGRAPHY. General information on the production and consumption of iron ores, iron, and steel may be found in publications of the United Nations, the International Iron and Steel Institute, and the United States Bureau of Mines. The best general source on the technology of iron and steelmaking in the United States is H.E. MCGANNON (ed.), *The Making, Shaping and Treating of Steel*, 8th ed. (1964). Excellent coverage of the properties of steels, methods of processing, metallography, and testing and inspection may be found in TAYLOR LYMAN (ed.), *Metals Handbook*, 8th ed. (1970). Treatment of the current technology is covered in the Swedish periodical *Scandinavian Journal of Metallurgy* (bimonthly); the *Journal* of the British Iron and Steel Institute

monthly); the *Journal* of the Japanese Iron and Steel Institute (monthly); *Tetsu to Hagane* (bimonthly); various publications of the American Mining, Metallurgical, and Petroleum Engineers—in particular, the annual proceedings of this society dealing with ironmaking, steelmaking, and mechanical working; and G.J. DERGE (ed.), *Basic Open Hearth Steelmaking*, 3rd ed. (1964); and C.E. SIMS (ed.), *Electric Furnace Steelmaking* (1962). Leading journals of the trade are *Iron Age, Iron and Coal Traders Review, Stahl und Eisen, Magazine 33, Stahl in English,* and *Iron and Steel Engineer*. A.K. OSBORNE, *Encyclopaedia of the Iron and Steel Industry* (1956), will be helpful to the student. Earlier publications that may also be of interest are L. AITCHISON and W.I. PUMPHREY, *Engineering Steels* (1953); H.P. TIEMANN, *Iron and Steel*, 3rd ed. (1933); R. FORSYTHE, *The Blast Furnace and the Manufacture of Pig Iron*, 3rd ed. (1922); and A.W. and H. BREARLEY, *Ingots and Ingot Moulds* (1918).

Stefan Dušan

Stefan Dušan, Serbia's greatest ruler, who added Macedonia, Albania, and large parts of Greece to the Serbian empire in the 14th century, is remembered above all as a conqueror and a codifier of laws.

By courtesy of Jugoslavenski Leksikografski Zavod, Zagreb, Yugoslavia

Stefan Dušan, detail of a fresco in the Monastery Lesnovo, Yugoslavia, 1349.

Stefan Dušan was born in 1308, the son of Stefan Uroš III, who was the oldest son of the reigning king, Stefan Uroš II Milutin. While Dušan was still a boy, his father, who governed the maritime provinces of the Serbian state, rebelled against his own father. Milutin took him prisoner, blinded him in order to make him unfit to claim the throne, and about 1314 exiled him to Constantinople. With his father and mother, Stefan Dušan therefore spent several years in the Byzantine capital. Life in Constantinople as an exile, without any prospect of occupying the throne, had a lasting influence on the formation of his character. In addition to a basic education, he acquired a familiarity with the ways of government of the Byzantine world by which he was later to be guided. The exile in Constantinople ended with the reconciliation of Dušan's father and grandfather and the family's return to Serbia about 1320. After Milutin's death in 1321, Dušan's father greatly increased his chances in the contention for the crown by demonstrating that he was not blind, claiming a miraculous cure. With the support of a great majority of the nobility, he succeeded in defeating his enemies and was crowned king early in 1322. Dušan, still a youth, was crowned "young king," or heir apparent.

Background and early years

Too young to be able to pursue more active policies, Dušan as "young king" governed the maritime provinces of the state. He had to reconcile himself to the loss of Hum (Hercegovina), the most westerly region of Serbia, which the ruler of neighbouring Bosnia conquered in 1326. He gained valuable military experience, however, and the reputation of an able commander in the campaigns against the Bosnians; he particularly distinguished himself in the great battle against the Bulgarians of Velbužd in 1330. Although this victory freed Serbia of the great danger of an allied attack by both the Bulgarian and the Byzantine emperors, dissension soon arose between Dušan and his father. War broke out between them in the fall of 1330. Peace was concluded in the spring of 1331, but soon afterward Dušan rose again against his father and deposed him.

Dušan's reign began on a note of peace in September 1331. He subdued the sporadic revolts of the nobility, who had become more powerful during the period of civil wars, and strengthened his alliance with the new Bulgarian emperor, John Alexander, by marrying his sister Helen in 1332. Relations with Bulgaria remained untroubled to the end of Dušan's reign.

In 1334, however, he began his war of conquest against Byzantium. After taking the border fortresses, Dušan penetrated deep into Byzantine territory to the gates of Salonica, although he did not achieve lasting success in subduing the cities. He made peace with Emperor Andronicus III Palaeologus in August 1334, having extended the territories of his state close to what is today's Yugoslav-Greek border. The next year he secured his northern borders against the Hungarians. During the course of his entire reign, Dušan remained on the defensive in the north, although he succeeded in preventing Hungary from extending its boundaries south of the fortresses on the rivers Save and Danube.

With the death of Andronicus III, in 1341, the Byzantine Empire once more fell prey to family quarrels and civil war. Dušan, arriving before the gates of Salonica, received an unexpected ally in John Cantacuzenus, the late Emperor's general, who took up arms against the regents of the young successor, John V Palaeologus, and proclaimed himself emperor. Dušan aided the Byzantine pretender, but their alliance broke up in 1343, and they became bitter enemies. On his own, Dušan conquered Albania and a greater part of Macedonia in the same year. After conquering the stubbornly defended city of Seres in the fall of 1345, Dušan began to call himself "Emperor of the Serbs and Greeks." He was crowned emperor in April 1346. After subjugating other parts of the Byzantine Empire, Epirus and Thessaly, in 1348, he found himself master of a vast territory from the rivers Save and Danube to the Bay of Corinth and from the Adriatic and Ionian shores to the Aegean. Although Dušan was helped by the weakness of his adversaries, he would never have attained his great successes without the forces provided by the militant nobility of the old Serbian provinces and by his German mercenaries. Dušan regarded the subdued Byzantine lands, "Romania," as his own "imperial lands," whereas the old Serbian provinces were formally the "royal lands" of his son. In reality, he governed both territories himself, but his administrative reforms concerned mostly the Serbian provinces. On the eve of the coronation he raised the Serbian archbishopric to the status of a patriarchate, for in the Orthodox East an emperor was inconceivable without a patriarch. He introduced the Byzantine system of titles and ranks, and the imperial chancellery was organized on the Byzantine model, as was the uniform organization of local authorities. Dušan, moreover, considered the introduction of a law code part of his imperial duties, and in the diets of 1349 and 1354 he promulgated a code containing more than 200 statutes. The code covered mainly criminal law and the relations between the classes.

Emperor of the Serbs and Greeks

From the time he imposed himself as co-ruler of Constantinople with the young emperor John V Palaeologus, John VI Cantacuzenus had posed a serious threat to Dušan, especially after he acquired Turkish auxiliary forces, which had twice defeated the Serbs—in 1344 and in 1352. During Dušan's campaign against Bosnia in 1350, Cantacuzenus' supporters in the Greek cities sent their armies to attack him in the south, thus forcing him to return to Macedonia and to give up his plans for reconquering Hercegovina. Plans for the conquest of Con-

stantinople drew Dušan into close relations with Venice. The republic was sympathetic to him but remained indifferent toward his proposals for direct action against the Byzantine emperors. In his last years Dušan maintained cordial relations with the Pope in Avignon. Like some of his predecessors he showed a readiness to accept a union of the churches, especially since in 1350 the patriarch of Constantinople had proclaimed an anathema on both the Serbian emperor and the patriarch. Enmity between local Orthodox and Catholic clerics stood in his way, as did Hungary's unsuccessful attack on Serbia in 1354, which upset the work of the papal legation. This attack also frustrated Dušan's desire to be designated by the Pope as captain of a crusade against the Turks, who at this time had gained a foothold on European soil and had become a danger to the Christians of the Balkans. Dušan died suddenly on December 20, 1355. He was succeeded by his son Uroš, who was unable to preserve his father's large empire. The peripheral regions of the empire seceded under their powerful governors, and large areas fell to the Turks. Only 15 years after Dušan's death, the territory of Serbia was smaller than that from which he had set out on his conquests.

Assessment

Dušan's popularity was especially great during the era of national awakening and wars for liberation in the 19th century. "Dušan the Mighty" represented at that time a symbol of former glory and greatness, while the restoration of Dušan's empire was stressed as the ideal goal of contemporary Serbian politics. Modern historians stress his accomplishment in elevating the Serbian state to predominance in the Balkans and in introducing internal reforms, transplanted from Byzantine practices and institutions and aimed at centralizing and unifying the administrative system. Outlasting his other accomplishments was Dušan's law code, which remained in use until the end of the medieval Serbian state and later became a valuable source for the study of medieval society.

BIBLIOGRAPHY. There is no modern biography of Stefan Dušan. The chapter on Dušan in CONSTANTIN JIRECEK, *Geschichte der Serben I* (1911) is well documented. Based on Jireček are the following English accounts: H.W.V. TEMPERLEY, *History of Serbia* (1917); and WILLIAM MILLER, "The Medieval Serbian Empire," *Quarterly Review*, 226:488–507 (1916). In the short summary, "The Balkans, 1018–1499," in *The Cambridge Medieval History*, vol. 4, pt. 1, pp. 537–541 (1966), M. DINIC utilized results of recent Serbian scholarship. Dušan has been treated in G. OSTROGORSKY, *Geschichte des byzantinischen Staates*, 3rd ed. (1963; Eng. trans., *History of the Byzantine State*, rev. ed., pp. 499–533, 1969), with selected bibliography. Very useful also is G. SOULIS, "Tsar Stephen Dušan and Mount Athos," *Harvard Slavic Studies*, 2:125–139 (1954).

Steichen, Edward

A pioneer of American photography for over 70 years, Edward Steichen occupied an eminent position at every stage of its development. He was born in Luxembourg on March 27, 1879; but in 1882 his parents moved to the United States and settled in Hancock, Michigan. Later the family moved to Milwaukee, where, at the age of 15, he was apprenticed to a commercial lithographer. He studied painting but became interested in photography, and by 1900 several of his pictures had been shown in Philadelphia and Chicago. Steichen's early photographs were influenced by his training as a painter. He frequently brushed on silver salts and other chemicals to eliminate or add images to negative or paper to achieve prints resembling soft, fuzzy mezzotints or loose wash drawings. These misty pictures were considered by most critics of the day to be the highest achievement of photographic art. Alfred Stieglitz, the best known American photographer of the time—although himself a purist who did not tamper with either his negatives or his prints—concurred. Stieglitz encouraged photographers to experiment, for he believed it justifiable to work on negative or print to obtain the desired image.

In 1902 Stieglitz invited Steichen to join him and 11 other photographers in founding the Photo-Secession, an organization dedicated to promoting photography as a fine art. In the course of time, the Photo-Secessionists did indeed succeed in transforming American photography from a craft that recorded and increasingly embellished to an art that freely experimented and explored. They showed that photographs of ordinary subjects and everyday scenes printed from the negative without manipulation can exert a far greater aesthetic appeal than artificial compositions printed by arcane methods.

Steichen, 1960.
Joanna T. Steichen

Member of Photo-Secession

In 1905 Photo-Secession opened, at 291 Fifth Avenue, New York, its Little Galleries (called "291" for short). It was designed by Steichen, and Alfred Stieglitz was its director. Steichen, who had become a friend of the sculptor Auguste Rodin in 1910 when he was studying painting in Paris, arranged exhibitions of the work of Rodin and that of other friends at the gallery, including paintings by Henri Matisse, Gordon Craig, Max Weher, Paul Cézanne, Pablo Picasso, and sculpture by Constantin Brancusi. Many of these avant-garde artists were shown for the first time in America at "291," starting eight years before the Armory Show of 1913, at which modern European art received its first full-scale display in the United States. The Photo-Secessionist venture was successful; for the first time in the United States, photographs by Photo-Secessionists, Steichen prominently among them, ranked with paintings and drawings as artistic works.

During World War I, Steichen was put in command of the photographic division of the United States Army's air force and retired as a lieutenant colonel in 1918. During the war, realism had been the only purpose of the pictures Steichen took. The experience led to a significant change in his mode of artistic expression—in fact, he made a bonfire of all his paintings. He ceased painting and renounced his impressionistic photography with its broad, simple effects. Instead, he concentrated on creating a precise, clean-cut, more realistic picture. In order to achieve maximum realism, he photographed a white cup and saucer against a black velvet background more than a thousand times in his search for the perfect rendering of the subtle gradations in white, black, and gray. From 1923 to 1938 he operated a commercial studio in New York City that specialized in portraits and advertising illustrations and soon became a successful enterprise. What he knew of art and design as a painter, combined with his masterful photographic technique, enabled him to produce memorable portraits of the literary and artistic personalities and the socially prominent who came to pose. In addition, he was in 1923 induced by Frank Crowninshield, the editor, to become chief photographer for the fashion magazines *Vogue* and *Vanity Fair*. Steichen's photographs of the 20s and 30s form a vital pictorial record. He created such striking images as the veiled Gloria Swanson, the hands-to-head portrait of Greta Garbo, and the smiling Charlie Chaplin.

Perfection of realistic techniques

At the outbreak of World War II, Steichen, rejected by the army because of age, was commissioned by the United States Navy to organize a department to photograph the war at sea. Soon after the Japanese attack on Pearl Harbor in 1941, his photographic exhibition entitled "Road to Victory" was presented in New York's Museum of Modern Art, followed three years later by a similar exhibit, "Power in the Pacific"; both proved to be powerful unifying forces for a nation at war.

After the war, from 1947 to 1962, Steichen was director of photography at the Museum of Modern Art in New York City. In 1955 he organized one of the most popular exhibitions of photographs ever presented, "The Family of Man." It was based on the concept of human solidarity that is the motif of his brother-in-law Carl Sandburg's biography of Abraham Lincoln. Together with his assistant Wayne Miller, Steichen selected 503 from the more than 2,000,000 prints submitted from all over the world. After its opening at the Museum of Modern Art in 1955, the exhibition toured most of the major museums in the world and was seen by more than 9,000,000 people.

"The Family of Man"

Steichen was 76 when "The Family of Man" first appeared, and in 1960 at the age of 80 he married for the third time—to Joanna Taub who was then in her late 20s. To him, "boredom and disinterest and lack of awareness are what characterize a superannuated mind, no matter what the chronological age may be. Happily, growth is not something for children only." He died March 25, 1973 in West Redding, Connecticut.

Early in his career, Steichen rejected the idea that there was one system of aesthetics in American photography. Such a notion, he felt, served only to confine and inhibit the creative photographer. As a consequence, he was always eager to serve as a promoter for American photography, arranging for exhibits, purchasing photographs, and generally acting as patron of younger photographers, regardless of the style of their work. According to Steichen, it is this variety—based on the unique vision of the individual photographer—that has made photography the vigorous art it is today.

(1970); BEAUMONT NEWHALL, *The History of Photography, from 1839 to the Present Day*, rev. ed. (1964), and ed. with NANCY NEWHALL, *Masters of Photography* (1958); *The Family of Man* (1955), a book from the exhibition of the same title for the Museum of Modern Art; *Camera Work*, a magazine of photography, with a Steichen number and special supplement (April 30–May 27, 1906), and a double number devoted to Steichen (April-July 1913). Steichen's photographs may be seen in issues of *Vogue* and *Vanity Fair* (1923–28).

(P.J.P.)

Stein, Karl, Freiherr vom

Heinrich Friedrich Karl, Freiherr vom und zum Stein, Prussian civil servant and minister, one of Prussia's greatest 19th-century statesmen, was the author of epochal reform legislation that liberated the peasants from hereditary servitude and granted self-government to the municipalities. As personal adviser to Tsar Alexander I, he urged that Russia continue the war against Napoleon (1813–14) until the French were defeated. A dedicated educator of his nation, he hoped that through active participation in local self-government the people would acquire a sense of political responsibility in place of their former submissiveness to the sovereign. His later years were occupied in promoting historical research in Germany.

Childhood and youth. Stein was born on October 26, 1757, in Nassau, Germany, into a family of the imperial nobility. His father, although a Protestant, was chamberlain to the Catholic elector and archbishop of Mainz. When not at court, the elder Stein was hunting or taking care of his estate. His mother, also a member of an old aristocratic family, was described by such a competent judge of character as Goethe as a woman of impressive personality: well-informed and original in her thinking, practical, pious, and cultured. Not only did she attend to her household and her large number of children, but she

was also deeply interested in the educational problems of the Enlightenment and had close contacts with the literary circles of her time.

In his autobiography (1823) Stein recounts that he grew up "under the influence of very worthy and devout parents" and that their example imbued his youthful mind with the ideals of piety, patriotism, family and professional honour, and the duty of devoting one's energies to the community's needs and of acquiring the necessary proficiency for such purposes by diligence and effort.

His parents wished him to become a judge at one of the imperial courts of the old German empire, and in 1773 he was accordingly sent to study law at the University of Göttingen, accompanied by a tutor, as was then customary. Stein studied not only law but statistics, economics, and history as well. In contrast to many of his peers "he tackled his work with truly ascetic diligence." He not only attended and reviewed lectures conscientiously, but also took private lessons in English and Italian, in mathematics and music, and in riding, dancing, and fencing. Reading widely and systematically, he was particularly interested in public law, German and English history, English literature, and economics. Austere moral principles guided his personal life and his evaluation of men and situations. He budgeted his time, avoided idleness and empty amusements, selected his friends "according to rigorous standards," seeking them only among "the better, more noble and able young people and avoiding superficial, vain, idle, and empty contemporaries."

Influence of August Rehberg

August Wilhelm Rehberg, whom he met in Göttingen, became such a friend and exercised a greater influence on Stein than any of his academic teachers. Highly cultured, Rehberg was a political thinker and writer of note, who advocated a liberal-conservative policy to preserve the old where it had proved itself and to make reforms where conditions demanded them. In his view, the state was founded in tradition—not on the "social contract" of the Enlightenment theoreticians of natural law—and in 1790 he became one of the most enthusiastic champions of the *Reflections on the Revolution in France* of the English statesman and philosopher Edmund Burke. It was in the constant exchange of ideas with Rehberg that Stein developed his own reform ideas in the quarter century between 1775 and 1800. He attempted to find a middle way between revolution and absolutism that could unite tradition and progress.

In 1777 Stein left the university and used the next three years to study the legal procedures of the imperial supreme courts in Wetzlar and in Vienna and to become familiar with the chief German principalities. In the winter of 1777–78 he stayed at the elector's court in Mainz; in the following summer he visited the capitals of some of the South German princes and attended the imperial diet at Regensburg. He visited Vienna and Austria during 1779, and in January 1780 he was presented to Frederick the Great in Berlin. In the course of his travels he decided against joining the imperial service and to enter the Prus-

sian civil administration instead. In 1780 through his friendship with Friedrich Anton von Heinitz, the Prussian minister of mines, he obtained a suitable post.

Career as Prussian civil servant. Stein began his career in the department of mines and factories, at first stationed for some years in Berlin, then for a long period in Westphalia. Travelling widely in the course of his work, he came to know all the Prussian territories as well as Saxony, Poland, Holland, and England. He was offered the ambassadorships at The Hague and at St. Petersburg, but life in the great world did not attract him, and he rightly regarded himself as a poor diplomat "because of my tendency to be independent, outspoken, and easily irritated." In his work as an administrator, on the other hand, he was content and highly successful: he improved the road network, made the rivers navigable, promoted textile production, and reformed the system of tax collection. When the ecclesiastical principalities were secularized after 1803, Stein was the chief official responsible in Westphalia for merging them into the Prussian state. In keeping with his political principles, he went about his task with such tact and respect that all those concerned were warmly grateful to him. Because of his many years of duty there, Westphalia became his second home.

Marriage and family life

In 1793 he married the countess Wilhelmine Wallmoden. She was the daughter of a Hanoverian general and a granddaughter of England's King George II, through one of his mistresses, the Countess of Yarmouth. On his engagement to Wilhelmine, Stein wrote enthusiastically:

> I should indeed be obtuse and insensitive if I failed to recognize the worth of a girl whose love is so pure . . . I hope that my harshness, hot temper, and impatience will be softened by the sight of this gentle creature and her good sense.

Nonetheless, during the first years of their marriage, Stein felt that his wife did not appreciate his way of life and his goals. As the years passed, however, he became increasingly respectful of his wife's character and abilities. Together they devoted themselves to the education of their two daughters. After the collapse of Prussia in 1806–07 and until the final defeat of Napoleon in 1814–15, Stein was separated from his family for long periods. During these difficult times, his wife took care of his estates, executed his commissions, and brought up the children. In her husband's words, she showed "serenity and nobility of mind." He outlived her by 12 years.

Achievements as minister and prime minister. In 1804 King Frederick William III of Prussia appointed Stein Prussian minister of economics and finance. At about that time he lost the sovereign rights over his hereditary lands in western Germany between the Rhine and the Lahn rivers as a result of the dissolution of the old German empire; his neighbour, the Duke of Nassau, acquired political sovereignty over them. In an angry letter to the Duke, Stein vainly protested this high-handed action.

Once installed as minister in Berlin, Stein gained an insight into the entire Prussian administrative system and realized that it stood in need of reform. His intention to modify the King's absolutist government by having him delegate clearly defined responsibilities to his ministers brought him into conflict with his monarch. Enraged by his "disrespectful, improper behaviour," Frederick William III dismissed Stein in January 1807 as an "intractable, defiant, obstinate, and disobedient servant of the state." Undoubtedly Stein possessed all these traits but viewed positively they spelled energy, civil courage, strength of character, and loyalty to principles. At the time of this clash, however, the King was fleeing from Berlin to East Prussia. War had broken out between France and Prussia, Napoleon had won the first battles, conquered Berlin, taken most of the fortifications and occupied the greater part of the kingdom. Just before the French arrived, Stein, with great presence of mind, had saved the considerable state funds for which he was responsible, by shipping them on river boats via Stettin to Königsberg, in East Prussia.

After his dismissal, Stein retired to his ancestral castle in Nassau in March 1807. Now aged 50, he occupied his enforced leisure by setting down his practical experiences and his political reflections in what was to become known as the famous Nassau Memorandum on the reform of the Prussian state. The program he envisaged was not to remain mere theory. Napoleon compelled the King of Prussia to dismiss his minister Karl von Hardenberg in the summer of 1807, and no successor seemed to be as suitable as Stein. Accordingly, he was appointed first minister in October, given wide powers, and entrusted with the conduct of all the affairs of the state. In this capacity he undertook the reform of the Prussian state. He had excellent men at his side as senior officials inspired by the ideas of the German philosopher Immanuel Kant, the Scottish economist Adam Smith, and the French Revolution. The King, too, was won over.

Nassau Memorandum on reform of the Prussian state

During his 14 months in office, Stein's achievements were outstanding. He emancipated the peasants from hereditary servitude and issued laws permitting both the unrestricted sale of land and the free choice of occupation—acts that represented a decisive step toward the goal of legal and personal equality for all citizens of the Prussian state. Stein's municipal ordinance granted the towns constitutions that enabled them to administer themselves. Beyond that he instituted reforms on all levels of administrative government. Suddenly, in the midst of these labours, one of Stein's letters containing imprudent remarks about Napoleon was intercepted by the French censor, and, yielding to French pressure, the King dismissed Stein.

Last years. Outlawed by Napoleon, Stein found refuge in the Austrian Empire, where his family was able to join him. He spent much of his time in the study of history and wrote a number of historical essays. He remained in close touch with his political friends in Prussia and Germany and as an ardent patriot was continuously concerned with means of freeing Germany from the foreign yoke.

Political adviser to the Tsar

In May 1812 Stein accepted Tsar Alexander I's offer to become his personal counsellor. He joined the Tsar in Vilna and thenceforth accompanied him first to Moscow and St. Petersburg and later, as the Russian army pursued Napoleon, to East Prussia, Germany, and France, and to the peace negotiations in Paris and Vienna. As Russian plenipotentiary he organized the anti-French uprising of the province of East Prussia (February 1813), took part in the Russo-Prussian treaty negotiations at Kalisz (March 1813), was appointed commissioner for the reconquered German territories, and was frequently consulted during the peace negotiations.

In 1815, after retiring from the Tsar's service and from public life, Stein spent most of his time on his estate in Cappenberg in Westphalia. He concentrated his energies on the study of history, his principal private interest. His library, numbering 7,000 volumes, was larger than that of any professional historian. In 1819, in his apartment in Frankfurt, he founded the Gesellschaft für ältere deutsche Geschichtskunde (Society for Earlier German History), which to this day has remained by far the most important organization for the publication of source material on German medieval history. Beyond that Stein hoped that historical research would "nurture our love for our common fatherland." He died at Cappenberg on June 29, 1831.

Almost all his learned contemporaries considered Stein a man of towering stature, whether they admired him or feared his indomitable energy and stormy temper. When, in 1815, the German poet Ernst Moritz Arndt saw Stein and Goethe walk through the Cathedral of Cologne, he called them the two greatest living Germans. Stein's work had a lasting influence on several generations. He introduced liberal and constitutional elements into the absolutist state and, by his example and influence, made participation in public life a moral postulate. He has been regarded as a political mentor of the German people well into the 20th century.

Steinmetz, Charles Proteus

One of the world's foremost electrical engineers, Charles Proteus Steinmetz developed fundamental ideas concerning alternating current systems and devised calculating methods that enabled engineers to design more efficient electrical machinery. His success in combining theory with practice made him immensely valuable to the electrical industry during its early period of growth. He led in transforming electrical engineering from a craft into a profession. Moreover, Steinmetz exemplified the engineer with a social consciousness; his political activity and efforts toward improving education, although not as well remembered as his work in electrical theory, had a widespread impact.

By courtesy of Union College, Schenectady, New York

Steinmetz.

He was born Karl August Rudolf Steinmetz on April 9, 1865, in Breslau, Germany (now Wrocław, Poland). At birth he was afflicted with a physical deformity, hunchback. As a youth he showed an unusual capability in mathematics, physics, and classical literature. On graduating from the *Gymnasium*, with honours, he went to the University of Breslau in 1882. Although a serious and hard-working student, he found time to join a student socialist club, which was banned by the government after becoming affiliated with the German Social Democrats. When some of his fellow party members were arrested, Steinmetz took over the editorship of the party newspaper, "The People's Voice." One of the articles he wrote was considered inflammatory; the police began a crackdown on the paper, and Steinmetz had to flee Breslau (1888). After a short stay in Zürich, Switzerland, he immigrated to the United States in 1889, travelling by steerage, the cheapest class at that time aboard ship. He carried with him a letter of introduction to Rudolf Eickemeyer, of Eickemeyer and Osterheld Manufacturing Company in New York, from the German editor of an electrical journal, in which he had published theoretical articles on the operation of a transformer (though until employed by Eickemeyer and Osterheld, he had never seen such a device). He soon joined the American Institute of Electrical Engineers and the New York (now American) Mathematical Society. At about the same time, Steinmetz Americanized his first name to Charles and substituted Proteus, a university nickname, for his two middle names.

Early socialist views

Under the tutelage of his employer, he became increasingly absorbed in the practical aspects of electrical engineering, and, in so doing, moved away from his theoretical interests in the mathematics of electricity. He established a small laboratory at the factory, where he did much of his scientific research. Eickemeyer, who, like Steinmetz, had been a social revolutionary in Germany, had more than 150 patents and was an important pioneer in the electrical industry. One of his inventions was a magnetic bridge, a device that Steinmetz used in his experiments on power losses in the magnetic materials used in electrical machinery and that led to his first important work, the law of hysteresis, dealing with the power loss that occurs in all electrical devices when magnetic action is converted to unusable heat. Until that time the performance of an electrically powered machine was known only after it was built. Once Steinmetz had found the law governing hysteresis loss, engineers could calculate and minimize these losses in the design of machines.

His classic work on hysteresis

In 1892 Steinmetz gave two papers before the American Institute of Electrical Engineers on this new law concerning hysteresis loss. His work was immediately recognized as a classic by the few who understood it, and the constant he calculated for this loss has remained a part of electrical engineering vocabulary. Thus, Steinmetz' reputation was assured at the age of 27.

His second contribution was a practical method for making calculations concerning alternating current circuits. This method was an example of using mathematical aids for engineering the design of machinery and power lines, so that the performance of the electrical system could be predicted in advance without the necessity of going through the expensive and uncertain process of building the system first and then testing it for its efficiency. Steinmetz' method of calculation was presented to an uncomprehending audience at the International Electrical Congress in 1893. His book *Theory and Calculation of Alternating Current Phenomena* in 1897 was read and understood by only a very few. The problem that Steinmetz faced was that electrical engineers were not taught enough mathematics to understand his new mathematical treatment of problems. To educate the electrical engineering profession, he published a book, *Engineering Mathematics*. Gradually, through his writing, lecturing, and teaching, his method of calculation was universally adopted.

In 1893 the newly formed General Electric Company purchased Eickemeyer's company, primarily for his patents, but Steinmetz was considered one of its major assets. At General Electric, Steinmetz gained an expanded opportunity for research and implementation of his ideas. He was assigned to the new calculating department, the first job of which was to work on the company's proposal for building the generators at the new Niagara Falls power station. In 1894 the General Electric Company transferred its operations to Schenectady, New York, and Steinmetz was made head of the calculating department. He at once began to indoctrinate the engineers with his method of calculating alternating current circuits and helped to establish an extension course.

He shared a house with other bachelors in Schenectady, where it was possible for him to indulge his interest in plants, such as orchids, and a menagerie of animals. One of Steinmetz' closest associates was Joseph LeRoy Hayden, a young engineer at General Electric, whom he legally adopted.

A conspicuous figure because of his deformity, his beard, and his ever-present cigar, Steinmetz won his fellow workers' esteem with his frankness and modesty. Despite his position as an executive of a giant business corporation, he expressed his political and social consciousness through his membership in the American Socialist Party. In 1911, when a Socialist was elected mayor of Schenectady, Steinmetz was appointed to the Board of Education, which then elected him president. Steinmetz ran for president of the Common Council of the city and

was elected in 1915 on the Socialist ticket. He was then successful in gaining funds for the school system. He established classes for subnormal, tubercular, and anemic children and for children with special difficulties.

Public life

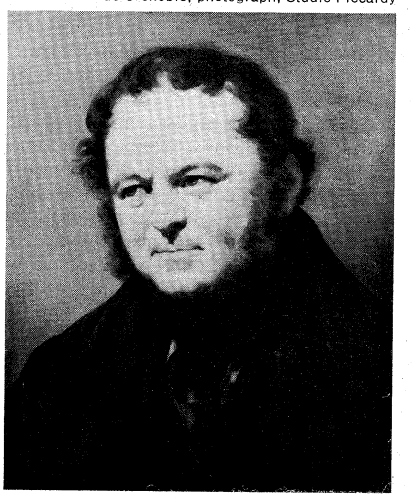
Steinmetz ran on the Socialist and Farmer-Labor ticket in New York state in 1922 for the position of state engineer and surveyor. In his campaign he proposed a plan whereby the 9,000,000-horsepower potential at Niagara Falls be realized by diverting the water from the Falls. The plan would bring the state $2,000,000,000 per year. The Falls were to be released on Sundays and holidays for sightseers. Steinmetz promised a water power survey if he were elected. He criticized the use of 54,000,000 tons of coal burned in New York state per year and wanted to substitute water power in order to bring the state into the electrical age.

In his book *America and the New Epoch* (1916) Steinmetz gave a sweeping and incisive economic analysis of history from the Roman Empire to the present era. He saw the operation of natural law in the march of economic growth from individualism to cooperation. Competition, he wrote, should not be advanced since it was as out-of-date as feudalism. The trust-busting era was the result of public antagonism to self-centred and self-satisfied industrial corporations that had failed to represent accurately their social usefulness to the public. Steinmetz saw individualism as a remnant of the past and cooperation the wave of the future. In the midst of World War I, Steinmetz wrote that America must work out its own destiny as a cooperative democratic commonwealth, after ending its racial, industrial, and political strife. The end result he favoured would be an industrial reorganization by the federal government and the emergence of cooperative industrial corporations.

In a talk on "The Future of Electricity" in 1910, Steinmetz stated his belief that the electrical engineer should promote the use of electricity by consumers in order to reduce its cost. Eventually, he thought, the cost might be reduced to one or two cents per kilowatt-hour from the high (at that time) of 20 cents per kilowatt-hour. The era of coal would end, he declared, after the supply of coal was exhausted or sooner, if the American people awakened to the viciousness of poisoning the air by burning coal. He also argued that city sewage should be carried to the outlying countryside in order to restore the fertility of the soil and stop stream pollution. The electrical production of nitrogen fertilizers, he thought, was the only way of saving the farmlands.

Steinmetz' third major scientific achievement was in the study and theory of electrical transients—that is, changes in electrical circuits of very short duration. A prime example of this phenomenon, lightning, was interesting to him as a mathematical problem; his work included the development of protective devices for transmission lines. He designed a generator that produced a discharge of 10,000 amperes and over 100,000 volts, equivalent to a power of over 1,000,000 horsepower for one-one hundred thousandth of a second. The purpose of this project, on a smaller scale than an actual stroke of lightning, was to observe and measure its destructive effects in nature. This was his last major project at the General Electric Company, where he had become head of the engineering consulting department.

Steinmetz' honours included an honorary doctorate from Union College, Schenectady, where he had taught for over ten years, the presidency of the American Institute of Electrical Engineers (1901–02), the award of the Elliott Cresson gold medal by the Franklin Institute, and memberships in the American Academy of Arts and Sciences and the American Philosophical Society. He died in Schenectady on October 26, 1923.



BIBLIOGRAPHY. JOHN WINTHROP HAMMOND, *Charles Proteus Steinmetz: A Biography* (1924), although not definitive, is the best available. See also ERNEST CALDECOTT and PHILIP L. ALGER (eds.), *Steinmetz the Philosopher* (1965), a compilation of Steinmetz' works with brief comments; SIGMUND A. LAVINE, *Steinmetz: Maker of Lightning* (1955); and JONATHAN N. LEONARD, *Loki: The Life of Charles Proteus Steinmetz* (1929), a romanticized account. Books by Steinmetz include: *America and the New Epoch* (1916); *Engineering Mathematics: A Series of Lectures Delivered at Union College*, 3rd ed. (1917); *Four Lectures on Relativity and Space* (1923); *The Future of Electricity* (1910); and *General Lectures on Electrical Engineering*, 5th ed., comp. and ed. by JOSEPH L. HAYDEN (1918).

(H.I.S.)

Stendhal

In describing the various aspects of the novelist Stendhal's character and vocation, his biographers have constantly used the word "failure": failure as a lover, failure in his military career, even failure in his vocation as a writer. Yet today almost every critic would acknowledge that he is one of the leading French writers of the 19th century, along with Balzac and Flaubert. Even more than they, he seems to speak directly to a young generation of readers, especially in France, Britain, and the United States. His writing reflects, to an unusual degree, his personality and thought, which combined countless paradoxical conflicts and desires. He claimed to write for the "happy few" who are not bound by convention, who do not find their happiness in subservience, who follow the lead of their senses and their instincts. Each hero in Stendhal's novels is presented as a man opposed to the social world in which he lives and serves. In his pursuit of happiness, Stendhal regarded the world as an enemy that must be fought in the full knowledge that it was such.

Stendhal, oil painting by Pierre-Joseph Dedreux-Dorcy (1789–1874). In the Bibliothèque Municipale de Grenoble.

Early life. "Stendhal" was the chief pseudonym of Marie-Henri Beyle, who was born in Grenoble on January 23, 1783. His father, Chérubin Beyle, was a barrister in the Grenoble parliament, and his mother, Henriette (*née* Gagnon), was the daughter of an eminent Grenoble physician. (He liked to think that, as a Gagnon, he was descended from an Italian family who had moved to Avignon with the papacy during the 14th century.)

The boy worshipped his mother, who died when he was seven; for a long time afterward, he continued to speak and write of her beauty, sensitivity, and intelligence. After his mother's death, the boy quickly grew to hate his father's ideas, manners, and love of money. He spent as much time as possible with his maternal grandfather, Henri Gagnon, whom he loved and respected and called his "real father" and who encouraged his interest in literature and the arts. At home, under the oppressive treatment (which he doubtless exaggerated) of his father, of Séraphie, his mother's sister, and of the Abbé Raillane, a private tutor, Beyle developed a nature individualistic, disrespectful, and impulsive. These three "tyrants" represented for him the bourgeoisie of Grenoble that he came to loathe. Almost until adolescence he was overly protected and isolated from most normal encounters. Extrovert activity was replaced by daydreaming and a taste for meditation that lasted throughout his life.

In his autobiography, *Vie de Henri Brulard*, Stendhal later explained his reaction against his family and education as *espagnolisme*, which he defines as a feeling of disgust for what is commonplace, a scorn for money and commerce, and a strong attraction for a willed forcefulness in man, for passionate ebullience. At the age of 17 he went to Paris, ostensibly to take the examination to enter the prestigious École Polytechnique but in reality to escape the suffocation of Grenoble. His knowledge of the world was limited to what he had read in novels (favourites included the Abbé Prevost's *Manon Lescaut* and Jean-Jacques Rousseau's *La Nouvelle Héloïse*). After only a few weeks' miserable existence, he fell ill with a stomach complaint, but a cousin of Dr. Gagnon, Noël Daru, gave the youth a room in his house. He was a stern gentleman and never fully approved of the young provincial, but he did find him a modest secretarial position with the war office.

Move to Paris

Professional career and writings. Three months later, in May 1800, Henri Beyle crossed the Alps to join the reserve army of Napoleon, who was fighting his second Italian campaign, and reached Milan the day after Napoleon's decisive victory at Marengo. Milan was a place of enchantment for him. He wrote of the magnificent music at La Scala opera house and praised the beauty of several Milanese ladies, especially that of Angela Pietragrua, who had been an intimate friend of the French painter Antoine-Jean Gros. Beyle fell in love with her. (Eleven years later he became her lover. His first sexual encounter, which took place soon after his arrival in Milan, left him with a venereal disease that he had to treat intermittently for the rest of his life.) As Beyle languished over his love for Angela—while at the same time attending performances at La Scala and gatherings at the casino—he developed a sensitivity to amorous excitement that was to be characteristic of his life. Now, at the beginning of his military career, he was also concerned with Italian lessons, fencing lessons, horseback riding, plays and operas, and infatuations with various Milanese ladies. He spent 18 months of campaign fighting without ever really being a soldier. By the end of 1801, he had made up his mind to resign from the army and return to Paris.

Literature was by this time, at the age of 20, his principal preoccupation, and drama was the aspect of literature that attracted him most. In Paris he announced that he intended to become Molière's successor. But to study he needed books, and to appear in society he needed clothes and spending money. He was often depressed by his Grenoble accent, his far from handsome physical appearance, his sense of inferiority, and his unsuccessful career as a seducer, as well as his inability to write verse drama. And yet the painful experiences he endured in Paris all helped to transform the bourgeois Henri Beyle from Grenoble into Stendhal the novelist.

He became infatuated with an actress, Mélanie Guilbert (called Louason), and in 1805 followed her to Marseille, where for a few months he became a wholesale grocer. He then returned to the war office, was present at Napoleon's entrance into Berlin in October 1806, and was stationed for two years in Brunswick (German, Braunschweig), Germany. There he continued his reading, begun earlier, of 18th-century philosophers—in particular of Destutt de Tracy and Claude-Adrien Helvétius—and cultivated a taste for Mozart. By 1809 he had returned to the active army and, as a member of the quartermaster's staff, took part in Napoleon's Russian campaign of 1812. He saw not the battles but the aftermath of the battles, the scenes of horror of the battlefield, which he described in some of his most brilliant letters. After the fall of the empire, seeing no prospect of employment under the new regime, he departed for Italy.

Military service

Milan became more than ever his favourite city. His first book, written under the pseudonym L.-A.-C. Bombet, *Vies de Haydn, de Mozart et de Métastase* (1814), raised the question of what kind of writer he should be: musicologist, art critic, or literary critic. Beyle was to use some 170 pseudonyms, but it was for the publication of *Rome, Naples et Florence en 1817* (1817) that he first used the name "M. de Stendhal," which he borrowed from the name of a small Prussian town, birthplace of J.J. Winckelmann, a famous German art critic.

When he returned to Paris, in 1821, he was 38 years old. He led there a limited social life and during the next nine years published six books: *De l'amour* (1822), "Racine et Shakespeare" (two pamphlets, 1823 and 1825), *Vie de Rossini* (1823), *Armance* (his first novel, 1827), *Promenades dans Rome* (1829), and *Le Rouge et le noir* (1830), which was to become his most famous novel.

After the July Revolution of 1830, he was named French consul at Trieste but then was sent, in April 1831, to Civitavecchia, close to Rome. He was bored by the pettiness connected with his profession and by the dullness of Civitavecchia. Nevertheless, there was plenty of opportunity to write, and during the last ten years of his life he gradually learned to love Rome as well as Milan.

For so long as he was a civil servant, Stendhal refrained from publishing. But he wrote extensively: his *Souvenirs d'égotisme* (1892), the novel *Lucien Leuwen* (1894), which he never completed, and his autobiography, *Vie de Henri Brulard* (1890), which he took only as far as his adolescence. All aspects of Rome fascinated him: the social habits, the arts, Roman chronicles and memoirs. But Stendhal had little interest in the Catholic Church and no interest in spiritual problems or mysticism. For him the Roman Catholic Church was simply an extraordinary empire, an unusually competent political system. As Stendhal grew older, he maintained a certain degree of curiosity about life, even if the desire to live diminished markedly. He dreamed of love even more than in his earlier years and indulged in memories of affairs that had been almost successful. The ghosts of innumerable feminine figures obsessed him at the time when, in the space of 52 days, he wrote *La Chartreuse de Parme* (1839) on one of his frequent visits to Paris because of poor health.

La Chartreuse de Parme

Stendhal pursued the image of happiness throughout his life, without ever trying to understand why he failed the reality. Toward the end of his life he was consoled by the conviction that posterity would honour him. Just before his death, he had the joy of reading a glowing article, written by Honoré de Balzac, on *La Chartreuse de Parme*. This praise was the first indication of what "the happy few" would eventually discover in the novels of Stendhal.

Stendhal suffered an attack of—presumably—apoplexy in March 1841. Afterward, he suffered intermittently from aphasia, an illness that resulted in spells during which he lost the power of speech. Another official leave of absence was granted, and he set out for France on October 11, 1841. Five months later Stendhal collapsed under a massive stroke and died on March 23 in his hotel room at the age of 59.

His cousin Romain Colomb and his sister Pauline were in Paris when he died. A monument with the inscription that he himself had written was placed at the grave in the cemetery at Montmartre: *Arrigo Beyle, Milanese*. Only three people, including the novelist and historian Prosper Mérimée, followed his coffin to its grave.

Emotional life. The circumstances of Stendhal's death might easily be interpreted as symbolic of the life story of a man who cherished the traditional recipes for happiness in the family and society but who never followed them—or was unable to follow them—himself. He never had a permanent address or a permanent profession; he had no home, no children, and, one might almost say, no mistress; after 1808 and the marriage of his sister Pauline (who was his confidante and to whom he wrote many letters from Marseille and from Germany), he literally had no family. Yet his nature craved intimacy. More than most men, he strove to maintain friendships. But according to all the available documents it seems that his friends showed little real sympathy for him and had no comprehension of his nature.

The fundamental life of Henri Beyle—the biography of his thoughts and fantasies and sentiments—was, therefore, lived in the novels he signed with the name "Stendhal." These books narrate basically the same story of the same young man. They are Henri Beyle's fantasies, lived out in a variety of settings and telling the story of a young

Stendhal's heroes

man who refuses to grow into adulthood. In each book a young man's charm affects the people around him: either it attracts them or else it breeds envy in them. Even though his heroes (Julien in *Le Rouge et le noir*, for example; Fabrice in *La Chartreuse de Parme*; or Octave in *Armance*) appear in different societies and become members of different communities within them, their desires, their sensitivities, and their needs are identical. They are what Stendhal himself was in his imagination, and so the novels are autobiographies in retrospect: in them he relived his own emotional life.

"Beylisme." Stendhal was so struck by his strange compulsion to write these novels, by the pleasure and the therapy they provided, that he had to invent a name for this mystery. He used his own name and not his pseudonym: *Beylisme*. The word designates both a method of writing fiction and a search for happiness.

The disciple of *Beylisme* is one of the "happy few" described above. There was nothing mystical about happiness, in Stendhal's conception of it. For him, the pursuit of happiness was comparable to a mathematical demonstration: its logic lies in following the dictates of egoism, self-interest, which Stendhal saw as the sole motivation of all man's actions. Its attainment in a complex world—which witnessed the fall of Napoleon, the restoration of the Bourbons, and the Revolution of 1830—meant calculating moves, estimating chances, practicing flattery. In many of his letters to Pauline, Beyle acknowledged a great change in himself as he began to understand the reasons for some of his defects in life and saw the ruses he would have to adopt and cultivate in order to overcome them. The Stendhal of the 1820s was very different from the young man who had spent most of his time during the early years of the century alone in his room. In *De l'amour* he analyzed his sentiments not only about love but also about himself as he was in 1821 and 1822. By that time he had begun to resemble the kind of polished gentleman he was later to portray in M. Leuwen (*Lucien Leuwen*) and Count Mosca (*La Chartreuse de Parme*). After 1830 and the publication of *Le Rouge et le noir*, he was still searching for happiness and a "method" that would permit this happiness to be attained. The philosophy from which he derived a method was that of the Idéologues, a group of 18th-century thinkers who believed in the perfectibility of the human race and whose doctrines were explained by Destutt de Tracy. *Beylisme* makes out of man's actions a fully conscious means of enjoying life to the full, materialistically and sensually.

Stendhal's epicureanism

The ways in which Stendhal trained himself to enjoy the arts, the beauty of painting and of music, reveal the epicurean side of his nature. His dreams of an existence with enough income to assure himself of the usual comforts and more—a carriage, a box at the opera, a house where he could adequately receive his friends—were the dreams of an epicurean. But the novelist's heroes were not so socially and aesthetically limited in their aims. Julien committed a crime in the name of passion, and Fabrice had in him a boldness and spirit that were not the traits of gentlemen in society. The contradictions between the epicureanism of Stendhal's own nature and the bold heroism of his fictional heroes are fused and harmonized in *Beylisme*.

Emotionally, Stendhal separated himself from his family, and intellectually he separated himself from the bourgeoisie. What Baudelaire was to call *dandysme* corresponded closely to Stendhal's attitude. It was a form of isolation on many levels: artistic, social, intellectual. The perpetual wanderings of Stendhal—from country to country, from one hotel to another—and his perpetual use of pseudonyms testify to a quest or a pilgrimage of a psychological if not a mystical nature. Subconsciously, the happiness he sought from life, which always eluded him, he found in the writing of his books and in particular of his two masterpieces, *Le Rouge et le noir* and *La Chartreuse de Parme*. These are not only novels but treatises on the ways of the world and mythical projections of the way in which Henri Beyle had learned to live, both materialistically and imaginatively, with the drama of his many selves.

MAJOR WORKS

NOVELS: *Armance, ou quelques scènes d'un salon de Paris en 1827* (1827; trans. by C.K. Scott-Moncrieff, 1928); *Le Rouge et le noir* (1830; *The Red and the Black*, 1926; *Scarlet and Black*, trans. by C.K. Scott-Moncrieff, 1927); *La Chartreuse de Parme* (1839; *The Charterhouse of Parma*, trans. by C.K. Scott-Moncrieff, 1925); *Lamiel* (unfinished, published posthumously 1889; trans. by T.W. Earp, 1952); *Lucien Leuwen* (unfinished; first published in 1855 in *Nouvelles inédites* under the title *Le Chasseur vert;* published posthumously 1894).

SHORT STORIES: *Chroniques italiennes* (1839; enlarged edition, *Nouvelles inédites*, 1855; *The Abbess of Castro, and Other Tales*, trans. by C.K. Scott-Moncrieff, 1926); *Romans et nouvelles* (1854).

AUTOBIOGRAPHY: *Vie de Henri Brulard* (1890; trans. by C.A. Phillips, 1925).

OTHER WORKS: *Vies de Haydn, de Mozart et de Métastase* (1814); *Histoire de la peinture en Italie* (1817); *Rome, Naples et Florence en 1817* (1817); *De l'amour* (1822; *On Love*, trans. by V. Holland, 1928); "Racine et Shakespeare" (two pamphlets, 1823 and 1825; published in book form as *Racine et Shakespeare, études sur le romantisme*, 1854); *Vie de Rossini* (1823); *Promenades dans Rome* (1829); *Mémoires d'un touriste* (1838); *Voyage dans le midi de la France* (1854); *Souvenirs d'égotisme* (1892; *Memoirs of an Egotist*, trans. by T.W. Earp, 1949); *Journal*, 5 vol. (1923–34; originally published in 1888 as *Journal de Stendhal*); *Vie de Napoléon* (1876, fragments; 1929, complete edition).

BIBLIOGRAPHY. V. DEL LITTO, *Bibliographie stendhalienne: 1944–46* (1948), is the fullest bibliography to date, although since 1948 there have been many studies and monographs and articles of value. The principal centre of research is the Musée Stendhal, Grenoble, which holds Stendahl's manuscripts and papers. Among individual volumes of biography and criticism, the following are useful: VICTOR BROMBERT (ed.), *Stendhal: A Collection of Critical Essays* (1962), containing studies by Erich Auerbach, Jean Prévost, Judd Hubert, Léon Blum, Jean Starobinski, Jean-Pierre Richard, and Simone de Beauvoir that are among the most penetrating essays on the work of the novelist; WALLACE FOWLIE, *Stendhal* (1969), the most recent of the introductions to the life and writings of Stendhal—the bibliography of works in English and French completes to some extent the del Litto bibliography; MATTHEW JOSEPHSON, *Stendhal: Or the Pursuit of Happiness* (1946), a moving study of the life of Stendhal and the way in which the novels reflect the life; HARRY LEVIN, *The Gates of Horn: A Study of Five French Realists* (1963), an exemplary critical estimate (section 3) that stresses *Beylisme;* and MARTIN TURNELL, *The Novel in France* (1951), a study of six aspects of Stendhal, who seems to be for this English critic the best of the French novelists.

(W.F.)

Stereotyped Response

A stereotyped response may be defined as an unlearned behavioral reaction of an organism to some environmental stimulus. It is an adaptive mechanism and may be expressed in a variety of ways. All living organisms exhibit one or more types of stereotyped response.

The capacity for unlearned behaviour is genetically determined in much the same sense as are the position, size, shape, and function of organs. Like structural features, stereotyped responses are the result of a continuing process of evolutionary modification and refinement. Those actions that most successfully aid the plant or animal in its basic drives (*e.g.*, reproduction, search for nourishment, escape from predators) are the ones most likely to be retained in succeeding generations. As environmental conditions change, inherently determined responses also become modified in order to ensure continuation of the species. Because of the fundamental differences that widely separate multicellular plants from multicellular animals, few other generalizations that apply equally to behaviour in the two groups can be made.

Problems of identification and analysis

Particular stereotyped responses in animals do not readily lend themselves to identification in highly evolved forms because learned behaviour patterns obscure the underlying unlearned behaviour; in addition, stereotyped responses provide the building blocks of instinctive behaviour, the complexity of which may obscure the integral parts (see BEHAVIOUR, ANIMAL; INSTINCT). In plants and lower animals, in which learned behaviour is absent or nil, the analysis of behavioral mechanisms is limited

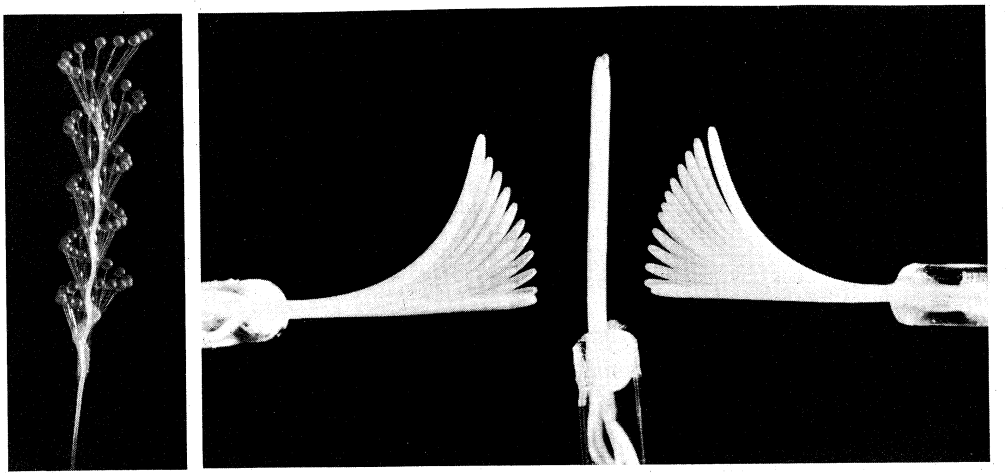

Figure 1: *Tropism.*
(Left) Phototropism shown in the multiple exposure of a fungus fruiting body. Exposures taken at a rate of one every four minutes show the sporangiophore oscillating between two light sources. (Right) Geotropism shown in the multiple exposure of oat coleoptiles. Gravitational redistribution of hormones causes the two seedlings set horizontally to grow upright like the central vertical seedling.

by the fact that many fundamental cell processes—*e.g.*, the mechanism of plant-growth hormone translocation in geotropism, which is the response to gravity in plants—are not well understood.

Animal behaviour, as a branch of psychology, represents a confluence between the disciplines of ethology and comparative psychology. Most of the pioneer work in stereotyped responses of animals was done by ethologists. During the first half of the 20th century, when much of the groundwork in experimental psychology was laid, ethologists (who were for the most part European) concerned themselves with behaviour in insects, fishes, and birds and were particularly interested in the evolution of instinct. The comparative psychologists during this formative period were mostly Americans. They studied primarily behaviour in common laboratory animals such as guinea pigs, mice, rats, and monkeys, and their interest tended to focus on environmental influences on behaviour as opposed to genetic influences. Since the 1950s, psychologists in general have recognized that both environmental and genetic factors play essential roles in any biological phenomenon. As a consequence of the separate development of ethology and comparative psychology, however, some difficulties have arisen in the use of terminology. The German-American biologist Jacques Loeb applied the term tropism to all oriented movements of organisms, and he proposed that all behaviour is composed of tropisms. Subsequently, to avoid confusion, the terms taxes (singular: taxis) and kineses were introduced by other investigators to refer to animal responses other than those of sedentary, plantlike forms. The terms also have been applied to certain plant movements.

PLANT MOVEMENTS

Although a variety of discrete stereotyped response movements occur in plants, particularly in higher forms such as flowering plants, these autonomous movements usually occur too slowly to permit detection by casual observation. That movements of plants or plant organs actually take place can be strikingly demonstrated by time-lapse photography, in which single photographs are taken at regular intervals as brief as seconds or as long as several days or more. The photographs are then compared or viewed in rapid sequence as a motion picture.

Growth movements

Growth movements, which result from cell enlargement or from an increase in the number of cells, or from both, are of three types: tropic (sometimes called tropistic) movements, nastic movements, and nutations. Tropic movements are responses to stimuli that act with greater intensity from one direction than from another. These include phototropism, response to light; geotropism, response to gravity; chemotropism, response to particular substances; hydrotropism, response to water; thigmotropism, response to mechanical stimulation; traumatotropism, response to wound lesion; and galvanotropism (or electrotropism), response to electrical stimulus.

Autonomous movements in living plants are generally classified as growth movements and turgor movements. So-called hydration movements also occur. These, however, are not necessarily associated with physiological activity and take place in dead as well as in living tissues.

Tropic movements. Most tropic movements in plants are orthotropic; *i.e.*, they are directed toward the source of the stimulus. Many instances are known, however, of movements that are oblique to the direction of stimulus (plagiotropic) or that are at right angles to it (diatropic). The oblique position of many lateral shoots of a growing plant probably results from an equilibrium between negative geotropism (movement away from gravity) and an epinasty (a more rapid growth on the upper side of an organ than on the lower side); the equilibrium is promoted by a chemical factor originating in the terminal bud of the plant. If the bud is removed, at least one of several lateral shoots curves upward. Diatropism may be observed in the growth movement of certain rhizomes (rootlike underground stems), which normally grow horizontally.

Phototropism. Phototropism occurs generally in all organs of the growing plant that are exposed to light, and it is perhaps the most easily observed of the tropic responses. The leaves of vines such as the English ivy (*Hedera helix*), which grow against a flat, vertical surface and thus receive light mostly from one direction, develop in a mosaic-like pattern, with little overlapping of the leaf blades. Similar, though less apparent, leaf mosaics occur in many other plants (*e.g.*, maple) that bear relatively large numbers of leaves. Some herbaceous, or nonwoody, plants (*e.g.*, *Silphium*, *Lactuca*) orient their blade surfaces to face east and west. At midday the flat surfaces are parallel to the direct sunlight. Because they orient in this way, such plants are commonly known as compass plants. The leaves of the mallow *Malva neglecta* turn slowly from sunrise until sunset, so that the broad surface of the leaf is constantly at a right angle to the sun.

The flowers of many plants of the family Compositae also turn with the sun, facing it from sunrise to sunset. Certain grasses (*e.g.*, Bermuda grass) are apparently negatively phototropic at high intensities of light—*i.e.*, the plant surfaces are oriented away from the light source. They lie flat under strong light and stand upright when the light is dim.

Roots normally grow in total darkness; however, when exposed to light, many roots exhibit a negatively phototropic response in that they curve away from the light.

Instances of positively phototropic roots—*i.e.*, with curvature toward the light—are rare.

Growth-rate differences

The orientation of leaves and stems toward a light source is caused by growth-rate differences between different areas of tissue and by differences in the turgor (*i.e.*, rigidity and tension resulting from the pressure of fluid contents) in cells of different tissues. The curvature of a growing leaf or stem toward a source of light is caused by the uneven growth rate between different areas of tissues. Cells on the darker side grow faster than those on the lighter side, resulting in curvature toward the light source. It may be demonstrated experimentally that such differences result from differences in the amount of auxin, a growth-stimulating hormone, present in the cells. The rapidly growing cells contain greater amounts of auxin. It has been shown that in tissue in which illumination is unilateral, auxin migrates from cells on the lighter side to cells on the darker side. It has also been postulated that auxin is destroyed by sunlight. Some investigators have shown that sunlight has an effect on plant growth independent of its influence on the distribution of auxin; the nature of this effect, however, is not yet fully understood.

The English biologist Charles Darwin demonstrated many years ago that, although bending occurs in the basal portions of a grass coleoptile (a protective sheath around the base of the terminal bud), if the tip is shaded with a cap, curvature of the unilaterally illuminated coleoptile may be prevented. Detipped coleoptiles likewise evince little or no phototropic reaction. Bending of the basal portions of the coleoptile is, therefore, subject to a controlling influence of the tip. Subsequent to Darwin's investigation, it was shown that the auxin in the tip of an oat coleoptile migrates laterally across the tip from the lighter to the shadier side. Since downward translocation of the auxin is almost strictly longitudinal, the cells on the shaded side of the coleoptile receive more auxin than those on the lighted side. The cells on the shaded side therefore elongate more than those on the illuminated side, and the coleoptile bends toward the light.

Geotropism. Typically, a plant root grows downward (toward gravity), and the stem grows upward. These are examples of positive and negative geotropism, respectively. In a horizontally oriented oat coleoptile, auxin migrates from the upper to the lower side of the tip and thence longitudinally in the usual manner. The greater concentration of auxin on the lower side than on the upper side induces greater elongation of cells in the former, and the coleoptile bends upward. In a horizontally oriented root tip, auxin also migrates from the upper to the lower side. Elongation of root cells is favoured by much lower concentrations of auxins than those that stimulate elongation of coleoptile cells, and it is retarded at concentrations higher than necessary to stimulate elongation in coleoptile cells. A relatively high auxin concentration on the lower side of the root, therefore, results in a smaller elongation of the cells on the lower as compared with the upper side; the result is a downward bending of the root.

A plant placed horizontally on a horizontally spinning wheel develops no stem or root curvature, for the force that tends to drive the plant outward (centrifugal force) serves to counteract the geotropic response. Primary, or main, roots from which the tops have been removed do not demonstrate a geotropic response. If tops are grafted upon such roots, however, the normal geotropic response is elicited.

Thigmotropism. The growth movement of a plant organ in response to contact with a solid object is known as thigmotropism. Such movements are observable in petioles (leaf stalks), stems, and especially in tendrils, which are modified stems, leaves, or leaflets. Because of inequality in growth rates in different parts of a tendril, it grows in a spiral. If a tendril encounters a solid object, the cells in immediate contact with the object shorten somewhat; those cells on the opposite side elongate. The result is that the tendril bends or creeps close to the object, thus obtaining support for the growing plant. In some species the thigmotropic reaction occurs in less than one minute, suggesting that the speed of the response results from changes in turgor rather than from a growth process. Although contact of a tendril with hard surfaces that are extremely smooth (*e.g.*, drops of mercury) does not elicit a thigmotropic response, the delicate movement of a light thread against a tendril elicits a positive response (see below *Nutation*).

Spiral growth of tendrils

Chemotropism. Unequal growth movements in plants in response to certain substances are known as chemotropisms. Seedlings of the European dodder, *Cuscata europaea,* which is parasitic on a variety of plants, respond to suitable host plants by curving toward them from as far away as ten centimetres (four inches). Cells on the side away from the stimulus grow more rapidly than do those on the near side, thus causing the seedling to "reach" toward the host plant.

Hydrotropism. The response of plant roots to unequal distribution of water is known as hydrotropism, a phenomenon that may be regarded essentially as a specific chemotropic response. Roots do not grow into soil with a moisture content so low as to induce wilting; however, they ordinarily grow into soil with a moisture content high enough to prevent wilting. A more rapid rate of growth of cells on the side of the root away from the moist areas of the soil results in curvature of the root toward the moist area.

Traumatotropism. Damage to plant tissue frequently results in the curvature of the affected organ as a result of unequal growth—a phenomenon known as traumatotropism. Injury to plant tissues probably results in changes in the distribution of auxin or interferes with the movement of food and other substances into growing tissues.

Nastic movements. Nastic movements are those in which the direction of movement is limited by the structural symmetry of the plant organ. In general, nastic movements are evoked by factors such as diffuse light (photonasty) or temperature (thermonasty), which influence the organ equally from all directions. Photonastic movement, which causes an organ to alter its shape or position when taken from the darkness and placed in diffuse light, is thus distinguished from phototropic movement, which occurs when the plant is subjected to unilateral illumination. Nastic movement occurs primarily in leaves, the structure of which largely or entirely restricts movement to specific directions.

Epinasty and hyponasty

The more rapid growth of the upper side of a plant organ is called epinasty; the more rapid growth of its lower side, hyponasty. Opening of flowers is caused by epinastic movements of the sepals or petals; closing of flowers, such as occurs in some species at night or at low temperatures, results from hyponastic movements of the floral parts.

The growing leaves of some plants (*e.g.*, the common jewelweed, *Impatiens*) droop at night, but during the day they are more or less horizontal. The growing leaves of pigweeds (*Amaranthus*) are horizontal during the day but turn upward into a vertical position at night. The movements of both *Impatiens* and *Amaranthus* are caused by differences in the growth rate between the upper and lower sides of the leaves. The movements cease after full growth is reached.

Certain flowers, such as those of *Oxalis* and the evening primrose, *Oenothera,* also demonstrate photonastic movements. Oxalis flowers are open during the day but close at night. Those of *Oenothera* open at night but are closed during the day. The flower petals of some plant species respond by movement when there are changes in temperature. A temperature increase causes the flowers of *Crocus* to open as the result of accelerated growth of the inner petal surfaces. A temperature decrease results in closure of the flower because the growth rate of cells on the outer surface of the petals exceeds that of cells on the inner surface. The daily opening or closing of floral parts and the response of leaves to environmental changes that occur with each daily cycle are sometimes called nyctinasty, or "sleep movements."

Nutation. As the growing tip of any plant organ (*e.g.*, stem, tendril, root, flower stalk, sporangiophores [spore-bearing stalks] of some fungi) elongates, it describes an

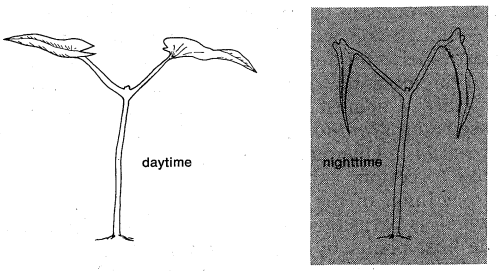

Figure 2: "Sleep movements" in bean seedlings (see text).
From F.A. Brown Jr., J.W. Hastings, and J.D. Palmer, *The Biological Clock* (1970); Academic Press, Inc.

irregular, spiral course. This results from inequality of growth rates in tissues at the periphery of the growing tip and is known as nutation. It occurs most strikingly in twining plants. In these, nutation may be caused by a thigmotropic response and, in part, by the effects of gravity and other factors. Stem tips are ordinarily slender, elongated, and lack leaves. The tip usually droops into a more or less horizontal position. More rapid growth usually occurs on the outermost and lower sides of the stem, resulting in an upward swinging motion of the growing tip. This extension results in a twisting of the stem as a consequence of the unequal rates of growth; thus, different sides of the stem are successively positioned on the lower side as the spiralling growth continues.

Turgor movements. Turgor movements may be initiated by a variety of stimuli—electrical shock, insufficient water supply, jarring physical contact, injury, exposure to certain gases, and changes from light to darkness or from darkness to light. Many turgor movements are caused by pressure changes in special cells or organs. In certain grasses, for example, rolling and folding movements of the leaves result from turgor changes in cells on the upper surface at the base of two depressions that lie parallel to the principal veins of the leaves. When in a state of high turgor, these cells maintain the leaf in a flat, expanded condition. As turgor decreases, the pressure of cells on the bottom of the leaf forces it to curl. In the sensitive plant *Mimosa pudica*, turgor movements commence within 0.075 second after the plant is stimulated. When the plant is touched—for example, at the axis of one of the secondary petioles—the leaflets move upward on each side until they meet. The stimulus may then be communicated to the leaflets of the other secondary petioles, which close (the petioles also converging), and then to the main petiole, which sinks rapidly downward toward the stem, the bending taking place at the pulvinus (swollen base of the leafstalk). The entire reaction may be completed in scarcely more than one second. Recovery of turgor in *M. pudica* occurs in from eight to 20 minutes.

Movements in the sensitive plant

Turgor movements are also responsible for the opening and closing of stomates, which are minute pores in the epidermis (a thin surface layer of cells) of plants—particularly on the lower surfaces of leaves—and through which gaseous exchange occurs between the plant and the atmosphere. The aperture size of the stomate is determined by the turgor of two kidney-shaped guard cells that lie facing each other on either side of the stomate. When the guard cells are turgid, the opening between them widens, thus increasing the quantity of gas exchange. When turgidity decreases, the aperture becomes smaller.

Guard-cell turgor is influenced by light, temperature, and by the internal water condition of the plant. The amount of light absorbed by the cells appears to be inversely related to the state of turgor. All wavelengths of the visible spectrum seem to be effective, although light at the red end of the spectrum appears to be weaker. With the cessation of light, the stomates usually close gradually. In general, the greater the quantity of light absorbed during the day, the more slowly the guard cells lose their turgor.

Each plant species has a particular temperature range at which the guard cells are least turgid; that is to say, at which the stomatal opening is smallest. In cotton and tobacco plants, for example, guard-cell turgor is greatest at 25°–30° C (77°–86° F). At both higher and lower temperatures, the size of the stomatal opening decreases. The shrinkage of total water volume in a plant usually results in a water loss in individual guard cells as the result of osmotic (*i.e.*, through the cell wall) transfer and in redistribution of water among the various tissues and organs. The resultant reduction in turgor of the guard cells causes partial-to-complete closure of the stomatal opening.

Hydration movements. Autonomous movements other than growth movements and turgor movements may occur in dead as well as in living tissues and organs of plants and are caused by changes in water content (hydration or dehydration) of cell walls. They include the splitting of seed pods and the rapid movements of sporangia (spore-bearing organs) in ferns. Such movements do not result from physiological changes.

From P. Marler and W.J. Hamilton, *Mechanisms of Animal Behavior* (1966); John Wiley & Sons, Inc.

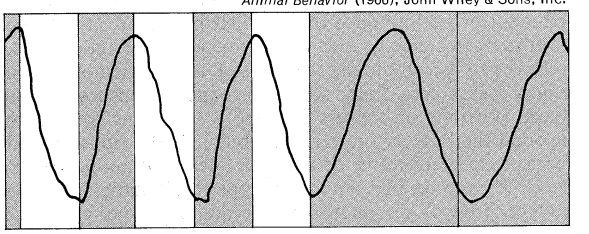

Figure 3: Circadian and tidal rhythms in *Phaseolus multiflorus* under normal day and night and continuous darkness.

Circadian rhythm in plants. Although experiments have clearly demonstrated the causal relationship between various stimuli and plant responses, it has also been shown that certain plant movements commonly associated with particular stimuli will occur in their absence.

In the laboratory, plants that move predictably according to a 24-hour cycle continue to move according to that cycle even after all extrinsic factors (*e.g.*, sunlight, temperature) known to change in a daily cyclical fashion have been stabilized or eliminated. The reason for this circadian, or daily, rhythm is not yet known (see PERIODICITY, BIOLOGICAL).

Movements in insectivorous plants. The most rapid autonomous movements in plants are probably those used in the capture of insects or other small animals by insectivorous plants. In the Venus's-flytrap (*Dionaea muscipula*), the left and right halves of the leaf blade snap together upon stimulation of hairs on the upper surface; the snapping action occurs in less than half a second, fast enough to trap even the most alert insect. The movements of the leaf probably result from a release of tautness, or tension, produced by differences in the growth rate between the upper and lower surfaces of the leaf; the mechanism by which the tension is released, however, is not yet understood. Other types of insect-eating plants respond to such stimulation even more rapidly than does the Venus's-flytrap.

Venus's-flytrap

ANIMAL MOVEMENTS

Stereotyped response in animals may be classified as unorganized or poorly organized response, reflex movements of part of an organism, reflex-like activity of an entire organism, and instinct.

Unorganized or poorly organized responses are given by early embryos or by animals (such as sponges) that lack nervous systems.

Reflex. Reflexes proper, or reflex-arc movements, include responses such as the immediate withdrawal of the hand on touching a hot surface. The basic components of the reflex arc are the receptor, or sensory-nerve cell, which senses the stimulus, and the affector, the nerve cell that directly activates the muscle. These are a theoretical minimum rather than an observed functional arrangement of cells in the body of an animal (see INSTINCT).

Reflex-like activities. Reflex-like activities of entire organisms may be unoriented or oriented. Unoriented re-

Ortho-kinesis and klinokinesis

sponses include kineses—undirected speeding or slowing of the rate of locomotion or frequency of change from rest to movement (orthokinesis) or of frequency or amount of turning of the whole animal (klinokinesis), the speed of frequency depending on the intensity of stimulation. Examples of orthokinesis are seen in lampreys, which are more active in high intensities of light, and in cockroaches, which are more active in low intensities; flatworms and many fly larvae, among other invertebrates, show orthokinesis. Klinokinesis is well demonstrated by the movements of the wood louse (*Porcellio scaber*). When wood lice are placed in dry air, they crawl about actively but without direction until they become gradually dehydrated. When the lice are placed in humid air, they move at first, but any activity they exhibited soon ceases and they become quiet. Wood lice placed in a container with dry air at one end and humid air at the other gradually congregate at the humid end. This transfer is achieved through apparently random rather than directed movements.

Oriented reflex activities of entire organisms include tropisms, taxes, and orientations at an angle. Tropisms in animals are those directed growth–curvature movements of sessile (*i.e.*, sedentary) forms that lead to equal intensities of stimulation of symmetrically placed body parts. These movements are demonstrated by hydroid animals such as *Eudendrium*.

Taxes. Taxes may be described as oriented locomotory reactions of motile organisms. They exist in purest form as oriented, forced movements; that is, as reflex actions of entire organisms. When exposed to a single source of stimulation, the body is oriented in line with the source. Movement toward the source is said to be positive; that away from it is negative.

Klinotaxis is the achievement of orientation by alternate lateral movements of part or all of a body; there appears to occur a comparison of intensities of stimulation between one position and another and a "choice" between

From J.P. Scott, *Animal Behavior*, © 1958 by the University of Chicago; all rights reserved

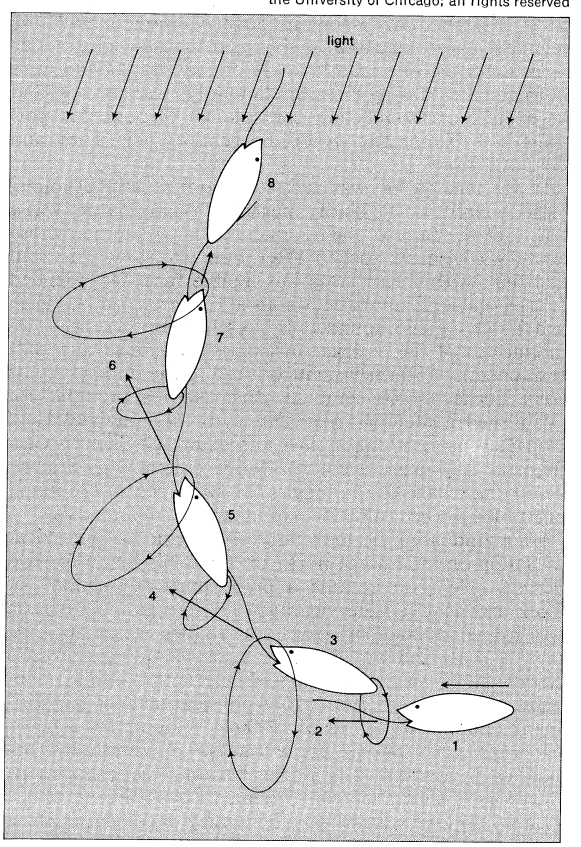

Figure 4: Klinotaxis in *Euglena*. As the animal swims in a spiral, the single eyespot at its front end swings in a circle. *Euglena* gradually orients itself so that the eyespot continues to receive even illumination.

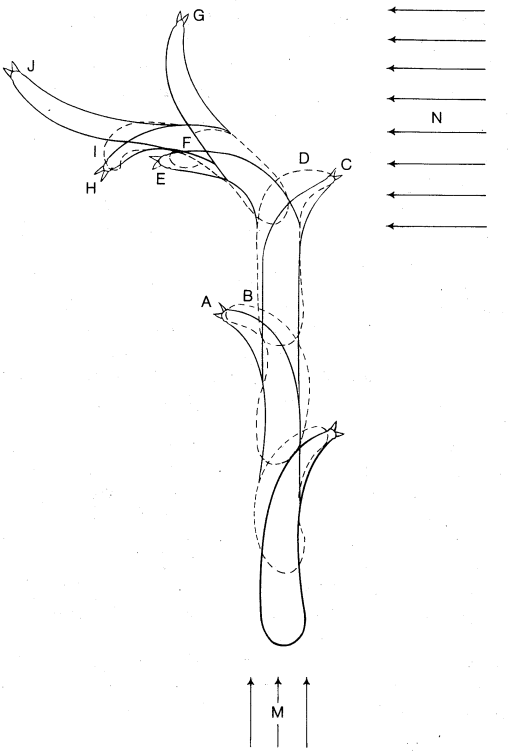

Figure 5: Klinotaxis in blow fly maggot. The maggot expands to A, contracts to B, expands to C, etc., with the light M on. At D, M is put out and N put on. The lateral movement to E is somewhat larger than A; the next one, G, increases the light falling on the receptors and is corrected by a swing over to H.
From N. Tinbergen, *The Study of Instinct;* the Clarendon Press, Oxford

them. Klinotaxis is shown by animals with a single intensity receptor such as the protozoan *Euglena*, earthworms, and fly larvae. For several days before going into the pupal (or resting) state, the blow fly maggot tends to move away from a light source. As it crawls, it swings its head alternately left and right. Presumably a light receptor is located on the maggot's head, and differences in intensity between successive light stimuli as it moves its head determine the direction in which the maggot travels. This type of response is given more commonly to chemical stimuli than to light.

Blow fly maggot response to light

In tropotaxis, attainment of orientation is direct, resulting from turning toward the less stimulated (negative) or more stimulated (positive) side as simultaneous, automatic comparisons of intensities on two sides of the body are made. No deviations (trial movements) are required. Tropotaxis is shown by animals with paired intensity receptors. If exposed to stimulation from two sources, orientation is to some intermediate point and is determined by the relative intensity of the sources. If one receptor is effectively covered, the animal moves in spirals (circus movement). Tropotaxis is shown by many arthropods, especially insects.

In telotaxis, known only for responses to light, attainment of orientation is direct and without trial movements. When between lights from two sources, the animal orients to one light, rather than to some intermediate point. The animal switches orientation from one source to the other at unpredictable intervals and consequently follows a zigzag course. The response is given to the source as though it were a goal. Bilateral balance is not necessary, and circus movements, if they occur, demonstrate that the animal is reacting tropotactically rather than telotactically. Honeybees (*Apis*) and hermit crabs (*Eupagurus*), among others, show telotaxis (see BEHAVIOUR, ANIMAL).

Orientations at an angle (transverse orientations) may or may not be accompanied by locomotion. They include the light-compass reaction (menotaxis) and dorsal (or ventral) transverse reaction. Menotaxis is shown by for-

aging insects such as ants and bees that return to a fixed nest. It has been demonstrated experimentally by covering for 2½ hours an ant returning to its nest. After being uncovered, the ant proceeds not toward the nest but at the same angle to the sun that it had been moving at the time it was hidden from the light.

In another demonstration of menotaxis, the sea slug *Elysia viridis* has been shown to move at angles of from 45° to 135° in relation to a steady source of light. No satisfactory explanation for this type of response in the sea slug is known.

Dorsal transverse action

Dorsal (or ventral) transverse reaction is demonstrated when the impact of the stimulus is kept at right angles to both longitudinal and transverse axes of the body. Locomotion need not occur. This reaction is given to light by various aquatic crustaceans—*Argulus*, the fish louse, and *Artemia*, the brine shrimp—and is given to gravity by crayfish.

Fixed-action patterns and instinct. Fixed-action patterns, commonly called FAPS, are generally sequences of uniform stereotyped responses that occur with a high degree of predictability throughout a species. Territorial behaviour in the fiddler crab (*Uca*), nest building in the three-spined stickleback fish (*Gasterosteus aculeatus*), and courtship in the green heron (*Butorides virescens*) are examples of such stereotyped response. Some fixed-action patterns, such as birdsong, although highly uniform throughout a species, often depend for normal development upon an early opportunity for a young bird to hear other birds and thus to imitate them (see BEHAVIOUR, ANIMAL).

The concept of instinct has come to refer to complex unlearned behaviour that is recognizable and predictable in at least one sex of a species (see INSTINCT).

Sterne, Laurence

An Anglican clergyman and humorist, Laurence Sterne was a great novelist and literary innovator although he produced only two novels, *Tristram Shandy* and *A Sentimental Journey*. His unconventional, nearly plotless books can be bitingly satirical, though usually the humour is tolerant and sympathetic. Thomas Jefferson called Sterne's work "the best course of morality that ever was written"; but the sexual innuendoes shocked many readers, and Sterne's own conduct with women dampened public enthusiasm. Today Sterne is recognized as the forerunner of modern psychological fiction.

Family and education

His father, Roger, though grandson of an archbishop of York, was an infantry officer of the lowest rank who fought in many battles during the War of the Spanish Succession (1701–14). In Flanders, Roger married the widow of an officer, Agnes, who was probably the daughter of a poor sutler; certainly her class was much below Roger's. When England withdrew from the war, Roger's regiment returned to Ireland, and there Laurence was born at Clonmel on November 24, 1713. Most of his early childhood was spent in poverty, moving with the regiment about England or living in the barracks of Ireland. Later Sterne spoke lovingly of the infants who were born and died during their "melancholy" wanderings, and he expressed his affection for soldiers through his portraits in *Tristram Shandy* of the gentle Uncle Toby and Corporal Trim.

At age ten, Sterne was sent to school at Hipperholme, close to Halifax. His kindly master, Nathan Sharpe, was a friend of the family, and his uncle Richard Sterne, whose estate was nearby, looked after him. He grew very tall and thin, with a long nose but likable face. He attended Jesus College, Cambridge, on an allowance from a cousin and a scholarship founded by Archbishop Sterne, once the master of the college. Instruction was dull and old-fashioned, but Sterne was introduced to the philosophy of John Locke, which came to permeate his thought. He established a lifelong friendship with the convivial John Hall-Stevenson, a minor poet and squire of Skelton Castle, near Saltburn. At college Sterne suffered his first severe hemorrhage of the lungs—"it happened in the night, and I bled the bed full." He had incurable tuberculosis.

Career as a clergyman and political journalist

After graduating he took holy orders and became vicar of Sutton-on-the-Forest, north of York, his home for two decades. He soon became a prebendary (or canon) of York and acquired the vicarage of Stillington. At first he was helped by another uncle, Dr. Jaques Sterne, precentor of York and archdeacon of Cleveland, a powerful clergyman but a mean-tempered man and a rabid politician. In 1741–42 Sterne wrote political articles supporting the administration of Sir Robert Walpole for a newspaper founded by his uncle but soon withdrew from politics in disgust. His uncle became his archenemy, thwarting his advancement whenever possible.

He fell in love with Elizabeth Lumley, a cousin to Elizabeth Montagu, the bluestocking, and married her in 1741. Elizabeth soon showed a quarrelsome disposition, and Sterne grew restless. After their arguments, he would spend nights of debauchery in York. The neighbours gos-

siped. His mother, abetted by his Uncle Jaques, made life miserable, demanding that he assign to her his wife's small fortune. Sterne refused. Once Jaques had her lodged in a prison to embarrass his nephew.

As a clergyman Sterne worked hard but erratically. One Sunday, when his dog sprang some quail, he went home for his gun, leaving the congregation in the lurch. Yet he was kind to his poor parishioners, and gave them careful religious instruction. In two ecclesiastical courts he served as commissary (judge), and his frequent sermons at York Minster were very popular, until tuberculosis injured his voice in 1762. Externally, his life was typical of the moderately successful clergy. He farmed and served as a justice of the peace. For diversion he read, painted, and "fiddled." An amusing companion, he socialized with the gentry and sometimes went to Hall-Stevenson's "Crazy Castle" to meet the Demoniacs, a club of sportsmen and amateur writers. But Elizabeth, who had several stillborn children, was unhappy. Only one child lived, Lydia.

In 1759, to support his dean in a church squabble, Sterne wrote *A Political Romance* (later called *The History of a Good Warm Watch Coat*), a Swiftian satire upon dignitaries of the spiritual courts. At the demands of embarrassed churchmen, the book was burned. Thus, Sterne lost his chances for clerical advancement but discovered his real talents. Turning over his parishes to a curate, he began *Tristram Shandy*. An initial version, probably sharply satirical, was rejected by Robert Dodsley, the London printer, just when Sterne's personal life was upset. His mother and uncle both died. His wife had a nervous breakdown and threatened suicide. Sterne continued his comic novel, but every sentence, he said, was "written under the greatest heaviness of heart." In this mood, he softened the satire and told about Tristram's opinions, his eccentric family, and ill-fated childhood with a sympathetic humour, sometimes hilarious, sometimes sweetly melancholic—a comedy skirting tragedy.

Success of *Tristram Shandy*

Sterne himself published volumes 1 and 2 at York late in 1759, but he sent half of the imprint to Dodsley to sell in London. While awaiting the outcome, he carried on a gay flirtation with Catherine Fourmantel, a concert singer. By March, when he went to London, *Tristram Shandy* was the rage, and he was famous. Dodsley's brother, James (the new proprietor), brought out a second edition. A volume of sermons followed. The witty, naughty "Tristram Shandy," as Sterne was called, or "Parson Yorick"—after his self-portrait in the book—was the most sought-after man in town. Although the timing was coincidental, Lord Fauconberg, a Yorkshire neighbour, presented him with a third parish, Coxwold.

Sterne returned north joyfully to settle at Coxwold in his beloved "Shandy Hall," a charming, odd, old house, now a museum. He began to write at Shandy Hall during the summers, going to London in the winter to publish what he had written. James Dodsley brought out two more volumes of *Tristram Shandy*; thereafter, Sterne became his own publisher. In London he enjoyed the company of many great people, but his nights were sometimes wild. In 1762, after almost dying, he fled the damp air of England into France, a journey he described as Tristram's flight from death. His illness took away his voice, which he never fully recovered. Nevertheless, this and a later trip abroad gave him much material for his later *Sentimental Journey*. Elizabeth, now recovered, followed to France, where she settled permanently. Sterne returned to England alone.

In 1767, after publishing the final volume of *Tristram Shandy*, he met Elizabeth Draper, the most important love of his life other than his wife. "Eliza," unhappily married to an official of the East India Company, was half Sterne's age, but they were drawn together by similar temperaments and interests. They carried on an open, sentimental flirtation until Daniel Draper commanded his wife to return to Bombay. After her departure, Sterne, though very weak, began the so-called "Journal to Eliza," a lachrymose narrative of heartache that he never attempted to publish. That autumn he finished *A Sentimental Journey*. He published it and collapsed.

On March 18, 1768, lying in his London lodgings, he put up his arm as though to ward off a blow, saying, "Now it is come," and died. Soon after burial at London, Sterne's body was stolen by grave robbers, taken to Cambridge, and used for an anatomy lecture. Someone recognized the body, and it was quietly returned to the grave. The story, only whispered at the time, was confirmed in 1969: the old graveyard being sold for apartment buildings, the remains were exhumed. They now rest in the churchyard at Coxwold, close to Shandy Hall.

Steroids

Steroids are a class of naturally occurring organic substances and their derivatives that are of great importance in biology, medicine, and chemistry. The steroid group includes all sex hormones, adrenal cortical hormones, bile acids, and sterols of vertebrates, the molting hormones of insects, and many other physiologically active substances of animals and plants. Among the synthetic steroids of therapeutic value are a large number of anti-inflammatory agents, anabolic (growth-stimulating) agents, and oral contraceptives. Different categories of steroids are frequently distinguished from each other by names that relate to their biological source—*e.g.*, phytosterols (found in plants), adrenal steroids, bile acids—or to some important physiological function—*e.g.*, gestogens (promoting gestation), androgens (favouring development of masculine characteristics), cardiotonic steroids (facilitating proper heart function). Because steroids of similar function and origin tend to fall into families of closely related structure, biological categorization underlies an internationally accepted systematic chemical nomenclature.

HISTORICAL BACKGROUND

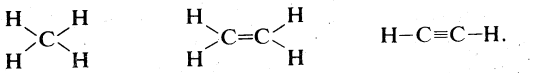
Studies of steroids commenced in the early 19th century with investigations of the unsaponifiable (*i.e.*, remaining undissolved after heating with excess of alkali) material, largely cholesterol, of animal fat and gallstones and of acids obtainabe from bile. This early work, with which many of the noted chemists of the time were associated, led to the isolation of cholesterol and some bile acids in reasonable purity and established some significant features of their chemistry. Insight into the complex polycyclic steroid structure, however, came only after the turn of the 20th century, following the consolidation of chemical theory and the development of chemical techniques by which such molecules could be broken down step by step. Arduous studies, notably by the research groups of the German chemists Adolf Windaus and Heinrich Wieland, ultimately established the structures of cholesterol; of the related sterols, stigmasterol and ergosterol; and of the bile acids. Investigation of ergosterol was stimulated by the realization that it can be converted into vitamin D. Only in the final stages of this work (1932) was the arrangement of the component rings of the nucleus clarified by results obtained by pyrolytic (heat-induced bond-breaking) dehydrogenation and X-ray crystallography.

The foundations of steroid chemistry

With the foundations of steroid chemistry firmly laid, the next decade saw the elucidation of the structures of most of the physiologically potent steroid hormones of the gonads and the adrenal cortex. Added impetus was given to steroid research when the Americans Philip S.

Hench and Edward C. Kendall announced in 1949 that the thitherto intractable symptoms of rheumatoid arthritis were dramatically alleviated by the adrenal hormone cortisone. New routes of synthesis of steroids were developed, and many novel analogues were therapeutically tested in a variety of disease states. From these beginnings there has developed a flourishing steroid pharmaceutical industry and, with it, a vastly expanded fundamental knowledge of steroid reactions that has influenced many other areas of chemistry (see, for example, CONFORMATIONAL ANALYSIS, PRINCIPLES OF).

Knowledge of the biochemistry of steroids has grown at a comparable rate, assisted by the use of radioisotopes and new analytical techniques. The metabolic pathways (sequences of chemical transformations in the body), both of synthesis and of decomposition, have become known in considerable detail for most steroids present in mammals, and much current research relates to control of these pathways and to the mechanisms by which steroid hormones exert their effects. The hormonal role of steroids in lower organisms is also of growing interest.

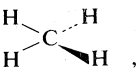


GENERAL CHEMISTRY

Organic compounds. Steroids are like many other classes of natural products in that small modifications in their molecular structures can produce remarkable differences in their biological activities. Appreciation of the relationships between structure and activity requires some familiarity with the general principles of organic chemistry; that topic is treated in detail in the article CHEMICAL COMPOUNDS, ORGANIC, and only a glimpse of it will be presented here.

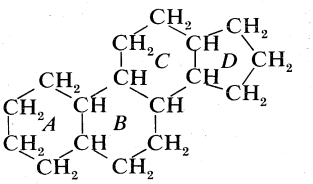
Organic chemistry, the study of compounds of carbon, traditionally has been one of the major subdivisions of the science of chemistry. The reason for setting the compounds of this one element apart from those of all the 100-odd others is that the carbon atom can form stable bonds not only with other kinds of atoms but also with other carbon atoms. This property multiplies the possibilities of compound formation because it allows the existence of molecules in which any number of carbon atoms are linked together in chains, rings, or three-dimensional networks to which atoms of other elements can be attached. The most common elements other than carbon found in organic compounds are hydrogen, oxygen, and nitrogen.

Carbon bonds



The bonds that hold carbon atoms in combination with other atoms are almost always of the type described as covalent and result from sharing of valence electrons between each pair of bonded atoms, each atom contributing one, two, or three electrons to form a single, double, or triple bond. (The other types of chemical bonds, electrovalent and metallic, are less important in organic chemistry.) Every carbon atom has four electrons that participate in formation of covalent bonds with four, three, or two other atoms, as in the compounds methane, ethylene, and acetylene. The composition of the molecules is indicated by molecular formulas: the methane (CH_4) molecule contains one atom of carbon and four of hydrogen; ethylene (C_2H_4) contains two atoms of carbon and four of hydrogen; and acetylene (C_2H_2) contains two of carbon and two of hydrogen. The arrangements of the bonds in these molecules are depicted by structural formulas in which each pair of shared electrons is represented by a line and each atom by its chemical symbol, as C for carbon and H for hydrogen:

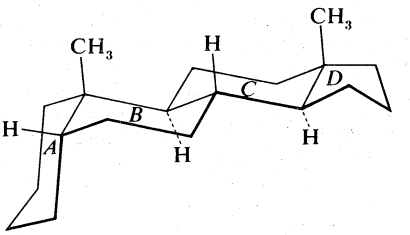
methane ethylene acetylene



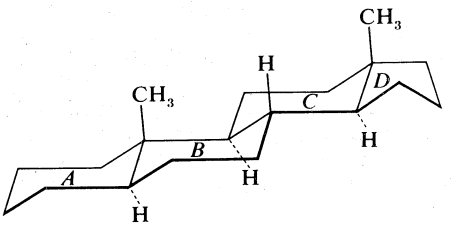
Additional important features of covalent bonds are that they are specifically directed in space and are effective only if the bonded atoms remain at characteristic distances from one another. The angles between the bonds in the acetylene molecule are 180°, so that the four atoms lie in a straight line; the angles in ethylene are close to 120°, and all six atoms lie in a plane; the angles in methane are close to 109½°, and the four hydrogen atoms lie at the corners of an imaginary tetrahedron with the carbon atom at the centre. Distortions of the characteristic bond angles or distances decrease the stability of the molecule. Methane is an example of a saturated compound, so called because the carbon atom in its molecule is bonded to the largest possible number—four—of other atoms, in contrast to ethylene and acetylene, which are unsaturated compounds.

The structural formulas shown for ethylene and acetylene adequately represent the spatial arrangements of the atoms, but a nonplanar molecule such as that of methane is difficult to illustrate by a two-dimensional drawing. When as in discussing the steroids, it is important to emphasize the orientation, or configuration, of the bonds about an atom, arbitrary conventions are used. For example in

representing methane, the full lines stand for bonds lying in the plane of the paper, the wedge stands for a bond projecting up from the page toward the viewer, and the dotted line stands for a bond projecting beneath the page away from the viewer.



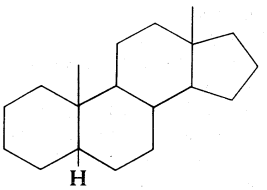
Steroid numbering system and nomenclature. All steroids are related to a characteristic molecular structure composed of 17 carbon atoms—arranged in four rings conventionally denoted by the letters *A*, *B*, *C*, and *D*—bonded to 28 hydrogen atoms. This parent structure, indicated in Diagram 1,



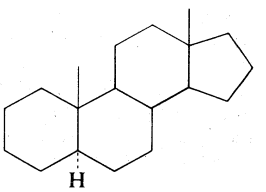
(1)

named gonane and often referred to as the steroid nucleus, may be modified in a practically unlimited number of ways by removal, replacement, or addition of a few atoms at a time; hundreds of steroids have been isolated from plants and animals, and thousands more have been prepared by chemical treatment of natural steroids or by synthesis from simpler compounds.

The steroid nucleus is a three-dimensional structure, and atoms or groups are attached to it by spatially directed bonds. Although many stereoisomers (compounds that are alike bond for bond but different in three-dimensional arrangement of atoms) of this nucleus are possible (and may be synthesized), the saturated nuclear structures of most classes of natural steroids are alike, except at the

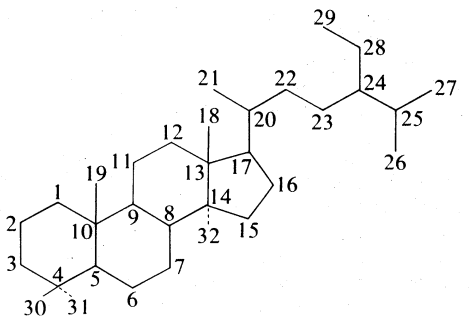


(2)



(3)

junction of rings *A* and *B*. Simplified three-dimensional diagrams may be used to illustrate stereochemical details. For example, Diagrams 2 and 3 show the alternative forms of the skeletal structure, androstane, common to a number of natural and synthetic steroids, in which the *A/B* ring fusions are called *cis-* and *trans-*, respectively. Note that at the common side of rings *A* and *B* in Diagram 2, bonds to the methyl group, CH_3, and to the hydrogen atom, H, both project upward from the general plane defined by the rest of the molecule, whereas in diagram 3, CH_3 projects up, and H projects down. Usually, however, steroid structures are represented as plane projection diagrams such as 4 and 5, which correspond to 2 and 3, respectively.



(4)

(5)

The stereochemistry of rings *A* and *B* must be specified by showing the orientation of the hydrogen atom attached at C-5 (that is, carbon atom number five; steroid numbering is explained below) as either above the plane of the diagram (designated β) or below it (α). The α-, β-symbolism is used similarly to indicate the orientation of any substituent group that is attached to a saturated (fully substituted) carbon of the steroid ring system. Groups attached to unsaturated carbons lie in the same plane as the adjacent carbons of the ring system (as in ethylene), and no orientation need be specified. When the orientation of a substituent is unknown, it is assigned the symbol ξ- (xi). Bonding of β-attached substituents is shown diagrammatically as in 4 by a full line; that of α-substituents by a broken line, as in 5, and that of ξ-substituents by a wavy line.

Each carbon atom of a steroid molecule is numbered, and the number is reserved to a particular position in the hypothetical parent skeletal structure (6) whether this position is occupied by a carbon atom or not.

(6)

Principal structural types

Steroids are named by modification of the names of skeletal root structures according to systematic rules agreed upon by the International Union of Pure and Applied Chemistry (IUPAC). By attaching prefixes and suffixes to the name of the appropriate root structure, the character of substituent groups or other structural modification is indicated. The prefixes and suffixes include numbers, called locants, indicative of the position in the carbon skeleton at which the modification occurs, and, where necessary, the orientation of a substituent is shown as α- or β-. The carbon atom at position 3, for example, is referred to as C-3; a hydroxyl group attached to C-3 is referred to as a 3-OH group or, more specifically, as a 3α-OH or 3β-OH group. In addition to differences in details of the steroid nucleus, the various classes of steroids are distinguished by variations in the size and structure of an atomic group (the side chain) attached at position 17. The derivations of the names of the more common root structures from those of naturally occurring compounds or classes of compounds of which they are most typical are indicated in Table 1.

Table 1: Names of Fundamental Structures Most Often Used in Steroid Nomenclature

	carbon atoms present (as numbered in Diagram 6)	naturally occurring general classes	examples shown in the text
Gonane	1–17	none	gonane* (1)
Estrane	1–18	estrogens	estradiol (17 f)
Androstane	1–19	androgens	androstane* (2–5); testosterone (17 c); androstanedione (17 c)
Pregnane	1–21	gestogens and adrenal steroids	progesterone (17 a); cortisol (17 b); aldosterone (17 d); batrachotoxin (14)
Cholane	1–24	bile acids	cholic acid (10 a); sodium glycocholate (10 b)
Cholestane	1–27	sterols	cholesterol (16 d); scymnol (11 a)
Ergostane	1–28	sterols	ergosterol (8); cyasterone (22)
Stigmastane	1–29	sterols	stigmasterol (7); antheridiol (12)
Lanostane	1–27, 30–32	trimethyl sterols	lanosterol (16 c); 22,25-oxido-holothurinogenin (13)
Cardanolide	1–23	cardiac glycosides	digitoxigenin (23)
Bufanolide	1–24	toad poisons	bufotoxin (24)
Spirostan	1–27	sapogenins	dioscin (25)

*Gonane and androstane themselves do not occur in nature.

For unambiguous use of the names given in Table 1, the orientation (α or β) of hydrogen at C-5 must be specified. If no other modification is indicated, the nucleus is assumed to be as shown in 2 and 3, except in the cardanolides and bufanolides: compounds of these types characteristically possess the 5β,14β configurations which, however, are specified.

For brevity in discussion and in trivial nomenclature, a number of prefixes are often attached, with locants, to the names of steroids to indicate specific modifications of the structure. In addition to the usual chemical notations for substituent groups replacing hydrogen atoms (*e.g.*, methyl-, chloro-, hydroxy-, oxo-), the following prefixes are commonly used: dehydro- (lacking two hydrogen atoms from adjacent positions); dihydro- (possessing two additional hydrogen atoms in adjacent positions); deoxy- (hydroxyl group replaced by a hydrogen atom); epi- (differing in configuration of a carbon atom bonded to two other carbon atoms); iso- (differing in configuration of a carbon atom bonded to three other carbon atoms); nor- (lacking one carbon atom); homo- (possessing one additional carbon atom); cyclo- (with a bond between two carbons that are normally not united); and seco- (with a carbon–carbon bond of the nucleus broken).

Depending upon the number and character of their functional groups, steroid molecules may show diverse reactivities. Moreover, the reactivity of a functional group varies according to its location within the molecule (*e.g.*, esters are formed readily by 3-OH groups but only with difficulty by the 11β-OH group). An important property of steroids is polarity; *i.e.*, their solubility in oxygen-containing solvents (water, alcohols) rather than hydrocarbon solvents (hexane, benzene). Hydroxyl, ketonic, or ionizable (*i.e.*, capable of dissociating to form electrically charged particles) groups in a steroid molecule increase its polarity to an extent that is strongly influenced by the spatial arrangement of the atoms within the molecule.

Polarity

Methods of isolation. Procedures for isolation of steroids differ according to the chemical nature of the steroids and the scale and purpose of the isolation. Steroids are isolated from natural sources by extraction with organic solvents, in which they usually dissolve more readily than in the aqueous tissue fluids. The source material often is treated initially with an alcoholic solvent, which dehydrates it, denatures (renders insoluble) proteins associated with the steroids, and dissolves many steroids. Saponification (treatment with aqueous alkali) either of whole tissues or of substances extracted from them by

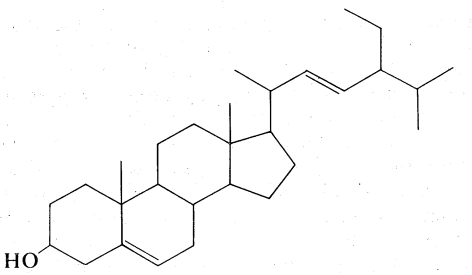
alcohol splits the molecules of sterol esters, triglycerides, and other fatty esters and permits the extraction of the sterols by means of water-immiscible solvents, such as hexane or ether, with considerable purification. Intact sterol esters or hormonal steroids and their metabolites (compounds produced by biological decomposition) that are sensitive to strong acids or alkalies, however, require essentially neutral conditions for isolation, and, although some procedures for analysis of urinary steroids employ acid treatment, milder hydrolysis, as by enzymes, is preferred. The acidity of some steroids allows them to be held in alkaline solution while nonacidic impurities are extracted with organic solvents.

Commercially, abundant steroids usually are purified by repeated crystallization from solvents. Small-scale laboratory isolations for investigative or assay purposes usually exploit differing polarities of the steroid and of its impurities, which may be separated by partition between solvents differing in polarity or by chromatography (see below). Occasionally, special reagents may selectively precipitate or otherwise sequester the desired steroid. A classical example is the precipitation of 3β-hydroxy sterols such as cholesterol by the natural steroid derivative digitonin. New steroids of great physiological interest often are isolated from tissue only with extreme difficulty because they are usually trace constituents. For example, 500 kilograms (1,100 pounds) of silkworm pupae yielded 25 milligrams of pure molting hormone, the steroid ecdysone (*i.e.*, 20×10^6-fold purification). In such cases each isolation step is followed by an assay for the relevant physiological activity to ensure that the desired material is being purified. The percentage recovery of known steroid hormones during their assay in small biological samples usually is assessed by adding a trace of the same steroid in radioactive form to the initial sample, followed by radioassay (analysis based on radioactivity) after purification is complete. The efficiency of recovery of the radioactive steroid is assumed to be the same as that of the natural substance.

Determination of structure and methods of analysis. The systematic, stepwise breakdown by chemical methods of the steroid ring systems, used in early investigations of structure, is now mainly of historical interest. The small number of different nuclear structures found in steroids often has permitted establishment of the structure of a new steroid by conversion to related compounds of known structure. Structure elucidation in the steroid field, as in all areas of organic chemistry, now depends heavily upon physical methods, particularly nuclear magnetic resonance, infrared spectroscopy, optical rotatory dispersion, mass spectrometry, and X-ray crystallography. Data obtained by these methods (which are described in CHEMICAL ANALYSIS) reinforce and often replace the classical criteria of characterization of steroids: melting point, optical rotation, elemental analysis, and ultraviolet absorption at a fixed wavelength.

Chromatography

Chromatography (*q.v.*) is a crucial technique in steroid chemistry. The behaviour of a steroid in selected chromatographic systems often identifies it with a high degree of probability. The identification may be made virtually certain by the conversion of the material to derivatives that in turn are examined chromatographically. Abundant data for the behaviour of steroids in paper chromatography, thin-layer chromatography, and gas-liquid chromatography show that individual features of molecular structure determine the chromatographic properties of steroids in a predictable manner. Because gas–liquid chromatography is the most precisely controllable technique, it provides the most valuable data for structural identification. The gas–liquid chromatograph linked directly to the mass spectrometer permits characteristic mass-spectral fragmentation patterns and critical gas–liquid chromatographic data to be obtained simultaneously, using a sample containing less than a microgram of a steroid. This powerful technique is of growing importance in the structural analysis of steroids in extracts of such body fluids as blood and urine.



Synthesis of steroids. *Total synthesis.* The total synthesis of any steroid (*i.e.*, synthesis from simple organic chemicals by reactions that follow known pathways) is formally the final proof of its chemical structure. To reproduce all stereochemical details of the naturally occurring material, however, is an exacting intellectual and technical challenge that has been met with extraordinary ingenuity and originality by several chemists.

In most total syntheses of steroids, a monocyclic starting material such as a quinone provides one ring upon which the other rings of the nucleus are elaborated, step by step, by condensation reactions with smaller molecules to give the desired stereochemistry in successive ring fusions. Each new ring closure must also provide functional groups that can be used in building up the next ring. In a quite different approach, stereochemical control of ring fusions is achieved by using the fact that, under acidic conditions, open-chain molecules containing suitably located double bonds cyclize to multi-ring structures that have the necessary stereochemistry and that can be relatively easily converted to steroids. From its analogy with the cyclization of squalene 2,3-oxide to lanosterol in the biosynthesis of cholesterol (see below), this method is said to involve "biogenetic-type cyclization."

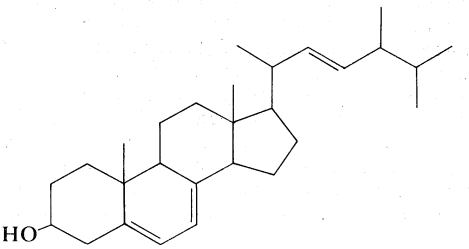
Partial synthesis. Although total synthesis of steroids has proved commercially feasible, it is often more practical to prepare them by partial synthesis; that is, by modification of other steroids that are naturally abundant. To be useful as a starting material for partial synthesis, the naturally occurring steroid must possess a molecular structure that can be easily converted to that of the desired product. For the synthesis of cortisol, cortisone, and their analogues, which carry an oxygen function at C-11, a pre-existing oxygen function at this position or at the adjacent C-12 is highly desirable. Indeed, prior to the advent of methods for microbiological oxidation, this was a crucial requirement, since the introduction of any functional group at C-11 of most steroids was extremely difficult.

Commercial synthesis

In the early commercial synthesis of androgenic steroids, cholesterol was the main starting material. Cholic acid and deoxycholic acid, inexpensive by-products from slaughterhouses, were starting materials for production of cortisone. The bulk of steroid drugs now is manufactured from the abundant steroids of plant origin, notably the sapogenins. Diosgenin, obtainable from several varieties of *Dioscorea*, a Mexican yam, is used in the commercial manufacture of progesterone, which can be converted to androgenic and estrogenic hormones and to the more complex adrenal steroid hormones, such as cortisone and cortisol. A most important advance in this field was the discovery that micro-organisms such as *Rhizopus nigricans* introduce hydroxyl groups into a variety of steroids at C-11 and elsewhere: they are used in the commercial synthesis of a large number of steroid hormone analogues. A sapogenin, hecogenin, obtainable in quantity from the waste of sisal plants, is used for synthesis of cortisol. Stigmasterol, which is readily obtainable from soybean oil, can be transformed easily to progesterone and to other hormones, and commercial processes based on this sterol have been developed.

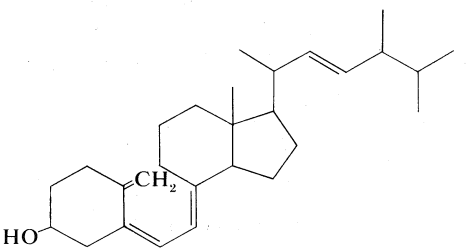
stigmasterol (7)

NATURAL DISTRIBUTION AND FUNCTIONS



Sterols and bile acids. The most generally abundant steroids are sterols, which occur in all tissues of animals, green plants, fungi, and yeasts. Evidence for the presence of steroids in bacteria and in primitive blue-green algae is

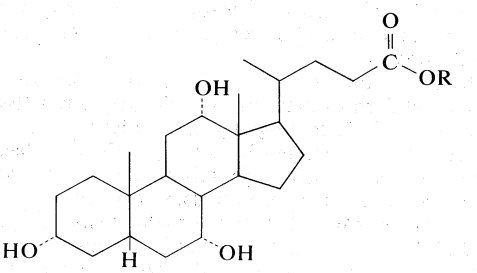
Table 2: Some Important Sterols and Their Sources



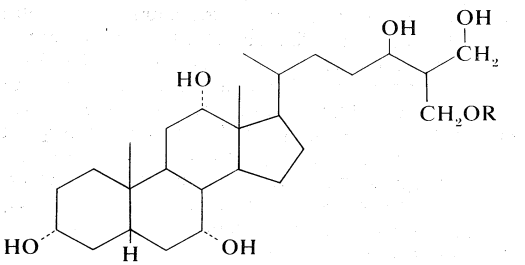
common name	systematic name	occurrence
Cholesterol	5-cholesten-3β-ol	principal sterol of most animals and all vertebrate tissues
Coprostanol	5β-cholestan-3α-ol	feces of vertebrates
Cholestanol	5α-cholestan-3β-ol	minor vertebrate sterol: guinea pig and rabbit adrenal
Lathosterol	5α-cholest-7-en-3β-ol	vertebrate skin, intestine
7-Dehydrocholesterol	5,7-cholestadien-3β-ol	mammalian skin, intestine
Desmosterol	5,24-cholestadien-3β-ol	chick embryo, barnacle (*Balanus glandula*)
Zymosterol	5α-cholesta-8,24-dien-3β-ol	minor sterol of yeasts
Ergosterol	5,7,22-ergostatrien-3β-ol	principal sterol of yeasts, ergot (*Claviceps purpurea*), and other fungi
Stigmasterol	5,22-stigmastadien-3β-ol	most green plants, soy beans
Sitosterol	5-stigmasten-3β-ol	most green plants, wheat germ
Fucosterol	5,24(28)-stigmastadien-3β-ol	principal sterol of marine brown algae (*Fucus* species)
Lanosterol	8,24-lanostadien-3β-ol	skin, sheep wool fat, yeasts
Lophenol	4α-methyl-5α-cholest-7-en-3β-ol	skin, intestine, feces, cactus (*Lophocerus schotti*)
Cycloartenol	9,19-cyclo-24-lanosten-3β-ol	generally minor sterol of green plants (*Artocarpus* species)

conflicting. The major sterols (Table 2) of most tissues are accompanied by traces of their precursors—lanosterol in animals and cycloartenol in plants—and of intermediates between these compounds and their major sterol products. In mammalian skin, one precursor of cholesterol, 7-dehydrocholesterol, is converted by solar ultraviolet light to cholecalciferol, vitamin D_3, which controls calcification of bone by regulating intestinal absorption of calcium. The disease rickets, which results from lack of exposure to sunlight, can be treated by administration of the vitamin or of the corresponding derivative of ergosterol, ergocalciferol (vitamin D_2).

Rickets and atherosclerosis



ergosterol (8)



ergocalciferol (9)

Sterols are present in tissues in both the non-esterified (free) form and as esters of aliphatic fatty acids. In the disease atherosclerosis, fatty materials containing cholesterol form deposits (plaques), especially in the walls of the major blood vessels, and vascular function may be fatally impaired. The disease has many contributory factors but typically is associated with elevated concentrations of cholesterol in the blood plasma. One aim of medical treatment is to lower the plasma cholesterol level.

Free sterols appear to stabilize the structures of cellular and intracellular membranes. Because the sheath of nerve fibres is a deposit of many layers of the membranes of neighbouring cells, mature mammalian nerve tissue (*e.g.*, beef brain) is the richest source of cholesterol. Cholesterol also is converted in animals to steroids that have a variety of essential functions, and in plants to steroids the functions of which are less clearly understood. The bile acids (cholanoic acids, earlier called cholanic acids) of higher vertebrates form conjugates with the amino acids taurine and glycine, and the bile alcohols (cholane derivatives) of lower animals form esters with sulfuric acid (sulfates; Table 3). These conjugates and sulfates enter the intestine as sodium salts and assist in the emulsification and absorption of dietary fat, processes that may be

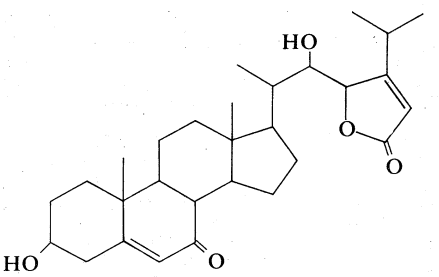
cholic acid (10a; R = H) and sodium glycocholate (10b; R = $NHCH_2COO^-Na^+$)

scymnol (11a; R = H) and sodium scymnol sulfate (11b; R = $SO_3^-Na^+$)

Table 3: Evolutionary Relationships of Bile Alcohols and Bile Acids

species	bile alcohol or bile acid (trivial name)
Elasmobranch fish	
Myxine glutinosa (hagfish)	5α-cholestane-3β,7α,16α,26-tetrol (myxinol)
Mustelus manazo (dogfish)	5β-cholestane-3α,7α,12α,24,26,27-hexol (scymnol)
Teleostian fish	
Latimeria chalumnae (coelacanth)	5α-cholestane-3β,7α,12α,26,27-pentol (latimerol)
Cyprinus carpio (carp)	5α-cholestane-3α,7α,12α,26,27-pentol (5α-cyprinol)
Amphibians	
Rana temporaria (frog)	5α,27-norcholestane-3α,7α,12α,24,26-pentol (5α-ranol)
Bufo vulgaris japonica (toad)	5β-cholestane-3α,7α,12α,25,26-pentol (5β-bufol)
Reptiles	
Alligator mississippiensis (alligator)	3α,7α,12α-trihydroxy-5β-cholestan-27-oic acid (trihydroxycoprostanoic acid)
Bitis arietans (puff adder)	3α,12α,23-trihydroxy-5α-cholanoic acid (bitocholic acid)
Bird	
Anser domesticus (goose)	3α,7α-dihydroxy-5β-cholanoic acid (chenodeoxycholic acid)
Mammals	
Man and most (but not all) species	3α,7α,12α-trihydroxy-5β-cholanoic acid (cholic acid) 3α,12α-dihydroxy-5β-cholanoic acid (deoxycholic acid) 3α-hydroxy-5β-cholanoic acid (lithocholic acid)

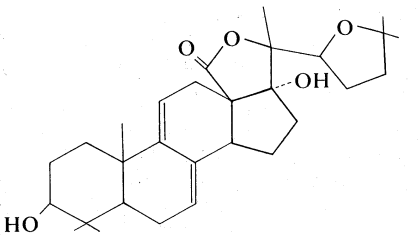
impaired when bile acid secretion is reduced, as in some liver diseases and in obstructive jaundice. The mixture of bile acids found in feces reflects the actions of intestinal micro-organisms upon the primary bile acid secretory products (*e.g.*, deoxycholic acid arises by bacterial transformation of cholic acid).



Sex hormones. Steroids that have a phenolic ring *A* (that is, those in which ring *A* is aromatic and bears a hydroxyl group) are ubiquitous products of the ovary of vertebrate animals. These are the estrogens, of which estradiol is the most potent. They maintain the female reproductive tissues in a fully functional condition, promote the estrous state of preparedness for mating, and stimulate development of the mammary glands and of other feminine characteristics. Estrogenic steroids have been isolated from urines of pregnant female mammals of many species including man, from placental and adrenal tissues, and, unexpectedly, from the testes and urines of stallions.

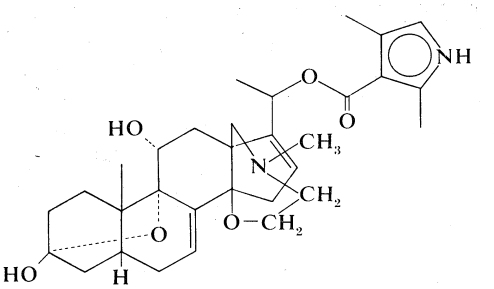
Estrogens and androgens

The corpus luteum, a modification of vertebrate ovarian tissue that forms following ovulation, produces the gestogens, which include progesterone and its derivatives. Gestogens also are secreted by the adrenals and placenta in some species. These compounds, in combination with the estrogens, regulate the metabolism of the uterus to permit implantation and subsequent development of the fertilized ovum in mammals. In birds, estrogens and gestogens stimulate the development of the oviduct and its secretion of albumin. Estrogens and gestogens suppress ovulation (release of the mature egg cell from the ovary); this fact is the basis of action of steroid anti-fertility drugs (see below). Estrogens and gestogens occur in primitive invertebrates, but their functions in those animals are obscure.



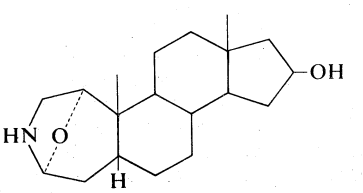
In male vertebrates, the androgens—steroids secreted by the testes—maintain spermatogenesis and the tissues of the reproductive tract. They promote male sexual behaviour and aggressiveness, muscular development, and, in man, the growth of facial and body hair and deepening of the voice. Testosterone and androstenedione are the principal androgens of the testes. Testosterone is more potent than androstenedione, but in the sexual tissues it appears to be converted to 5α-dihydrotestosterone, an even more potent androgen.

Adrenal hormones. The adrenal cortex of vertebrates synthesizes oxygenated progesterone derivatives. These compounds are hormones that are vital to survival and are classified according to their biological activity. The glucocorticoids promote deposition of glycogen in the liver and the breakdown of body proteins. Mineralocorticoids stimulate retention of sodium in the extracellular body fluids. Cortisol is the principal glucocorticoid in many species including man; in most rodents, this role is filled by corticosterone. The most potent mineralocorticoid of all species is aldosterone. Aldosterone has about 20 percent of the glucocorticoid activity of cortisol, which, conversely, has about 0.1 percent of the mineralocorticoid activity of aldosterone. Either steroid can maintain life in an animal from which the adrenal glands have been removed. The secretion of glucocorticoids is exquisitely responsive to injury and fear in animals and is primarily responsible for metabolic adaptation to stressful conditions. Failure of the adrenal cortex in man gives rise to Addison's disease, a formerly fatal condition that can now be successfully treated with synthetic adrenal steroids.



antheridiol (12)

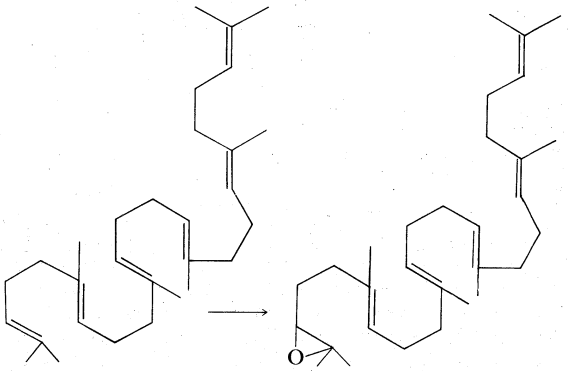
Steroids of lower organisms. An area of increasing interest is the role of steroids in the reproduction, development, and self-defense of lower organisms. In an aquatic fungus, *Achlya bisexualis*, the steroid antheridiol (12) of the female stimulates male gamete formation. Insects and crustaceans produce the ecdysones, steroid hormones that promote molting and the development of adult characteristics (Table 4). Many plants, especially ferns and conifers, contain steroids that may protect them against some predatory insects, although this function is not established. Progesterone, 11-deoxycorticosterone, and related steroids with no known endocrine function in insects are released into the water by several species of water beetles to repel predatory fish, and the sea cucumbers (Holothuroideae) produce the holothurinogenins, a group of lanosterol derivatives toxic to nervous tissue.



22,25-oxidoholothurinogenin (13)

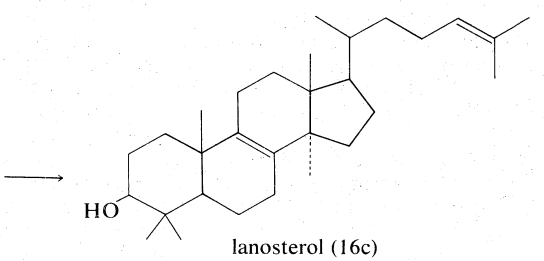
Cardanolide and bufanolide derivatives, found in many plants and in the skin of toads, cause vomiting, visual disturbances, and slowing of the heart in vertebrates and are strong deterrents to predators. Birds and other predators avoid certain grasshoppers and butterflies that store cardenolides of the plants upon which they feed. The skin of the Colombian frog, *Phyllobates aurotaenia*, produces a deadly alkaloid, batrachotoxin, which is used by tribal peoples as an arrow poison. The skin of salamanders secretes a comparably poisonous alkaloid—samandarin.

batrachotoxin (14)



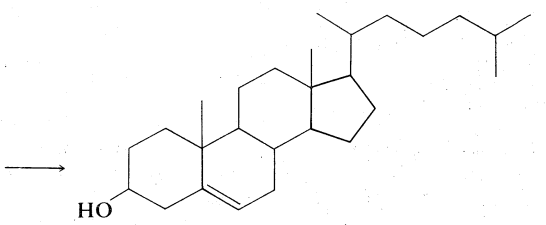
samandarin (15)

Many steroid alkaloids occur in plants, but their functions, like those of the steroid saponins, are unknown. It is possible that the taste of many of these compounds deters grazing animals or that they attract certain insect species to the plant.



BIOSYNTHESIS AND METABOLISM OF STEROIDS

Cholesterol. Steroids are probably synthesized in all vertebrates and in many invertebrates by the same pathway, which includes cholesterol. Biosynthesis (formation in intact organisms) of cholesterol is especially vigorous in the liver of vertebrates but also occurs in the intestine, gonads, skin, and immature brain. It is barely detectable in the adult brain. The insects, certain mollusks, annelids, and some protozoa do not synthesize cholesterol but must obtain it, or a related sterol, in their diet.



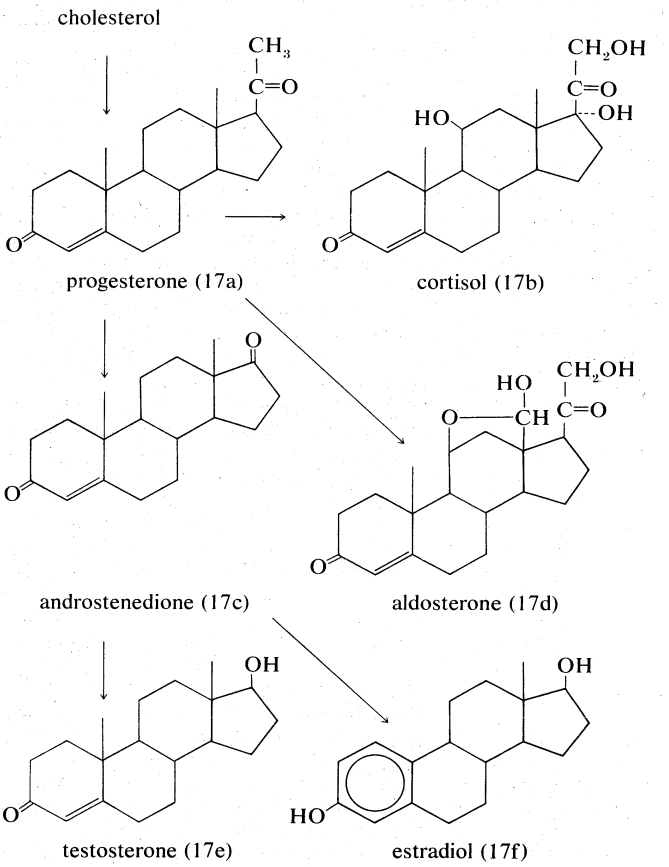
Cholesterol and other steroids are biosynthesized by extension of the enzyme pathway by which terpenoids are synthesized (see ISOPRENOIDS).

squalene (16a) squalene 2,3-oxide (16b)

lanosterol (16c)

cholesterol (16d)

biogenesis of cholesterol



Squalene and lanosterol

Acetate fragments derived from common nutrient materials are converted into mevalonic acid, from which the terpenoid hydrocarbon squalene is formed. One end of the squalene molecule is then oxidized, giving squalene 2,3-oxide, which, by an intramolecular reaction (cyclization) and structural rearrangement, yields the steroid lanosterol. This enzyme-controlled reaction may be initiated by introduction of a positive charge into the oxide ring because it is remarkably similar to the nonenzymic, acid-catalyzed cyclizations of certain unsaturated hydrocarbons similar in structure to squalene. Cholesterol is formed from lanosterol by further structural changes.

The principal forms in which cholesterol is excreted by vertebrates are the bile acids, which are synthesized in the liver. Their formation involves specific modifications of the steroid nucleus and formation of a carboxylic acid group that is linked to the amino acids taurine or glycine to give the forms in which the bile acids are secreted into the bile. The biosynthesis of cholesterol is influenced by feedback mechanisms that suppress the formation of mevalonic acid and, consequently, of cholesterol when levels of cholesterol and bile acids in the tissues are elevated.

Steroid hormones. In vertebrates, cholesterol is the central precursor of all steroid hormones secreted by the testes of the male, the ovaries of the female, and the adrenals of both sexes. These tissues share an embryonic tissue of origin and, in consequence, many enzymes for the transformation of cholesterol. A major (though not exclusive) common pathway involves conversion to progesterone. Progesterone is secreted by the corpus luteum of the ovary, but in the adrenal cortex it is further metabolized to steroid hormones (corticosteroids) such as cortisol and aldosterone. In both ovary and testis, progesterone is transformed further to the androgenic steroid androstenedione, which, together with its derivative testosterone, is secreted by the testis. In the ovary, androstenedione is modified to the estrogen estradiol. Normally, each organ secretes its own characteristic pattern of hormones, but in some disease states (*e.g.*, genetic defects and some tumours of these endocrine glands) these patterns may be profoundly distorted.

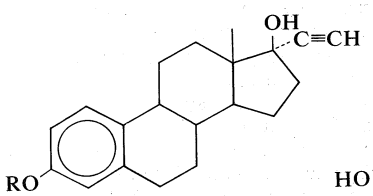
Progesterone

biogenetic relationships of principal vertebrate steroid hormones

Many tissues, but mainly the liver, metabolize the steroid hormones to physiologically inactive products that are voided mainly in the urine, though some are also eliminated via the bile and, ultimately, the feces. Diagnosis of endocrine abnormalities may be assisted by analysis of urinary steroids. Urinary 17-ketosteroids (androstane derivatives with a $>C=O$ function at C-17) arise principally through oxidation of adrenal steroid hormones in the liver and thus gauge secretion by the adrenal rather than by the testis. In pregnancy, the urinary excretion of pregnanediol, the principal metabolite of progesterone, measures placental progesterone output. Its decline before term may forewarn of abortion, which may be averted by administration of progestational hormones.

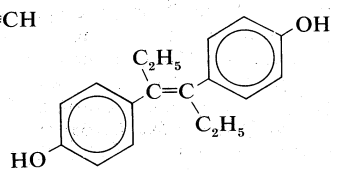
Steroid metabolism in plants. The early steps in the biosynthesis of steroids of both plants and animals are the same, except that in plants lanosterol is replaced by the related compound cycloartenol, which contains a three-membered ring (C-9, C-10, C-19) in lieu of the nuclear double bond of lanosterol. The side chains of the phytosterols, such as stigmasterol, and of the sterol ergosterol of yeasts and fungi contain extra carbon atoms that are incorporated in reactions involving *S*-adenosylmethionine, which donates methyl (CH_3) groups in numerous biological processes. Although most plant tissues contain only traces of cholesterol, this sterol is the biogenetic precursor of such important plant steroids as the sapo-

genins, cardiac glycosides, and steroid alkaloids. Because pregnane derivatives are intermediates in some of these transformations, plants and animals appear to have important features of steroid metabolism in common.



STRUCTURAL RELATIONSHIPS OF THE PRINCIPAL CATEGORIES OF STEROIDS

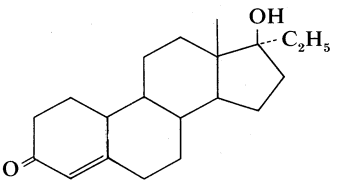
Sterols. A large group, the sterols, comprises the common 3-monohydroxy steroids of the cholestane, ergostane, and stigmastane series and their "methyl sterol" biogenetic precursors: lanosterol, cycloartenol, and certain derivatives of these sterols, such as lophenol (Table 2). Most sterols have a 3β-hydroxyl group, and many (though not the 4-methyl sterols) have a double bond between carbon atoms 5 and 6. Various sterols have double bonds at other positions in the nucleus corresponding to stages in the biosynthesis of cholesterol and other steroids that resemble it in the structure of ring *A*. Animal sterols, especially in embryonic tissues and skin, and phytosterols (*e.g.*, stigmasterol) also may have a double bond in the side chain. Sterols of feces (*e.g.*, coprostanol) have a 3α-hydroxyl group and *cis*- (5β) linked rings *A* and *B;* they are formed by metabolism of other sterols by intestinal bacteria. Certain sterols are transformed to calciferols (D vitamins) by ultraviolet light; this process occurs naturally in the skin and is used commercially in the manufacture of vitamin D_2 (ergocalciferol) from ergosterol and of vitamin D_3 (cholecalciferol) from synthetic 7-dehydrocholesterol.



Bile acids and alcohols. The molecular structures of metabolites of cholesterol form an evolutionary series from the bile alcohols, such as myxinol and scymnol of the elasmobranch fishes and the related alcohols of some bony fishes and frogs, through the 5β-cholestanoic acids of crocodiles and alligators, to the 5β-cholanoic acids of the birds and mammals. This evolutionary trend is illustrated by the selected compounds in Table 3. They are not exclusively confined to the species indicated; for example, chenodeoxycholic acid is a major bile acid in man and many other mammals, and cholic acid is found in many nonmammalian species, together with primitive bile acids or alcohols that are not found in the mammals.

Estrogens. The estrogens of the ovary of vertebrates are steroids that are abundant in the urines of pregnant mares and of stallions. The most potent natural estrogen is estradiol; the less potent estrogens—estrone, estriol, and other oxygenated phenolic steroids—are metabolites of estradiol. Some species, notably the Equidae, secrete the less active estrogen equilenin. Estrone, synthesized from diosgenin, has been used as a starting material for synthesis of androgenic and progestational steroids lacking a C-19 methyl group (19-nor steroids). Synthetic estrogens, as estranol or mestranol, commonly used in oral contraceptives and for other therapeutic purposes, have acetylenic (containing triple bonds between carbon atoms) substituents. Non-steroidal synthetic estrogens—*e.g.*, diethylstilbestrol and related compounds—are used clinically and also in animal husbandry to promote fattening of livestock and poultry and to improve the quality of their meat.

Estradiol



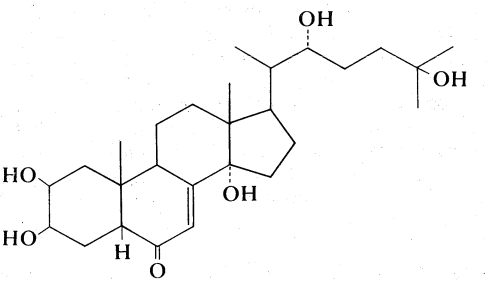
estranol (18a; R = H) and mestranol (18b; R = CH_3)

diethylstilbestrol (19)

Progestational steroids (gestogens, progestins). Three naturally occurring steroids of the corpus luteum and placenta have progestational action; these are progesterone and two of its metabolites. All possess an unsaturated ketonic structure in ring *A*. Pregnanediol, the main metabolite of progesterone, lacks both this structural feature and progestational activity.

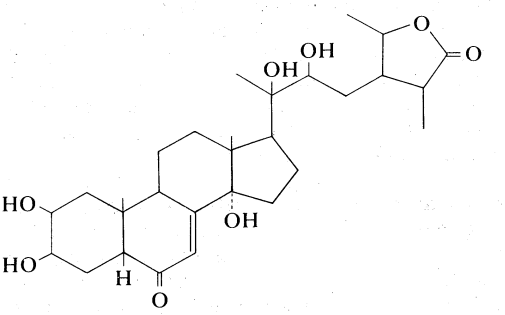
Synthetic progestational steroids that are used in oral contraceptives and for other therapeutic purposes (see below) are derivatives of progesterone or of 19-nortestosterone. Among the latter is norethandrolone.

norethandrolone (20)



Androgens. Testosterone and androstenedione are the major testicular androgens. Several other less active androgens occur naturally. Major metabolites of testosterone are androsterone and etiocholanolone. The latter compound is androgenically inactive, but it is a pyrogen (*e.g.*, a fever-producing agent) that has been associated clinically with some febrile conditions. Various carboxylic acid esters and a number of synthetic analogues of testosterone are used therapeutically (see below).

Adrenal cortical hormones. The steroids of the adrenal cortex are progesterone derivatives that bear hydroxyl groups at positions 11, 17α, or 21. The potent mineralocortoid aldosterone carries an aldehyde function in place of the more usual C-18 methyl group. Glucocorticoid potency is higher in the trihydroxy derivative cortisol of man, monkeys, and dogs than in the dihydroxy steroid corticosterone of rats and mice. Every adrenal steroid hormone has a ketone group at C-3 and a double bond between C-4 and C-5. In the liver their physiological activities are lost when ring *A* is reduced, and they are partially inactivated when the 11β-hydroxyl is oxidized to a ketone group (as in cortisone and 11-dehydrocorticosterone). The adrenal corticoids are among the most chemically reactive of the steroid hormones; they are sensitive to strong acids and alkalies and to elevated temperatures.



In many synthetic analogues of cortisol and cortisone, physiological activity is modified. Derivatives with enhanced anti-inflammatory activity are especially valuable therapeutically and are discussed below.

Ecdysones. The molting hormones (zooecdysones) of insects and crustaceans are generally derivatives of cholestane (Table 4). All possess a ketone group at position 6, a double bond between positions 7 and 8, and 2β, 3β, and 14α-hydroxyl groups. The side chain is hydroxylat-

C_{28} steroids		
Callinecdysone B	20-hydroxy-, 24-methyl-	*Callinectes sapidus* (post-molting)
Makisterone B	20, 26-dihydroxy-, 24-methyl-25-deoxy-	*Podocarpus macrophyllus*
C_{29} steroids		
Makisterone C	20-hydroxy-, 24-ethyl-	*Podocarpus macrophyllus*
Cyasterone	20, 22-dihydroxystigmasteno-26, 28-lactone side chain	*Cyathula capitata* and several *Ajuga* species

ed at C-22 and variously at C-20, C-25, and C-26. Some of these compounds occur in plants, many of which also contain potent ecdysone analogues (phytoecdysones) with ergostane and stigmastane side chains.

The ecdysones show cross-species activity—that is, the ecdysone of one species induces molting in another species. The preponderance of ecdysones related to cholestane even in phytophagous insects probably reflects their capacity to convert dietary phytosterols to cholestane derivatives.

Cardiac glycosides and aglycones. Many species of plants contain toxic (specifically, heart-arresting) steroids of the cardanolide type as glycosides (compounds that contain structural groups derived from sugars) of up to four sugar residues, which may include glucose, rhamnose, and ten other sugars peculiar to this group of natural products. Typically, these compounds (Table 5) are 5β-steroids and have 3β- and 14β-hydroxyl groups, but hydroxyl groups may occur in many other positions. In all cases, the aglycone (the steroid that results when the sugar groups are removed) is less active than its glycosides, but generally, activity declines with increasing numbers of sugar residues after the first. The structures of the sugars have important but not predictable effects on activity.

The most important cardiac glycosides, medicinally, are those occurring in foxglove (*Digitalis*): digitoxin, gitoxin, and digoxin. Each of these contains a specific aglycone (*e.g.*, digitoxigenin is the aglycone of digitoxin)

digitoxigenin (23)

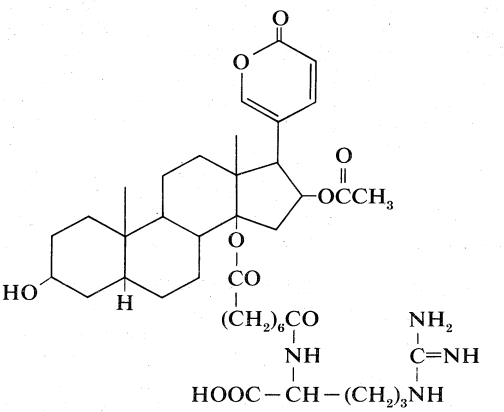

Table 5: Some Cardiac Glycosides and Their Cardenolide Aglycones

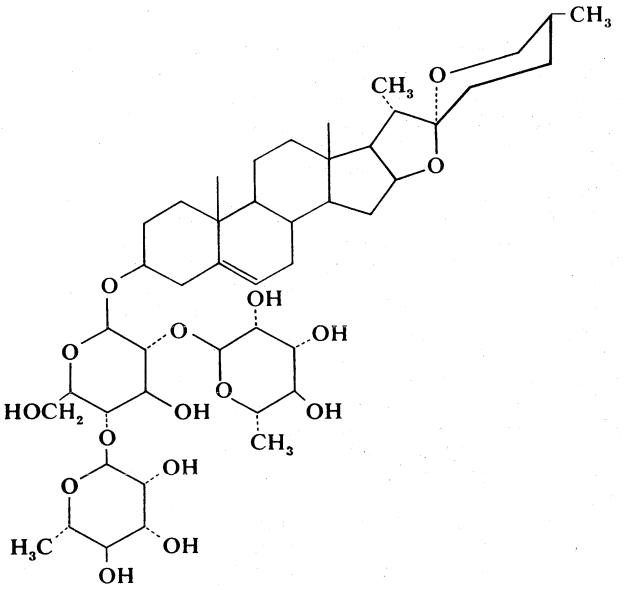
glycoside	aglycone	systematic name of aglycone
Digitoxin	digitoxigenin	3β,14β-dihydroxy-5β-card-20(22)-enolide
Gitoxin	gitoxigenin	3β,14β,16β-trihydroxy-5β-card-20(22)-enolide
Digoxin	digoxigenin	3β,12β,14β-trihydroxy-5β-card-20(22)-enolide
Periplocin	periplogenin	3β,5β,14β-trihydroxy-5β-card-20(22)-enolide
Sarmentocymarin	sarmentogenin	3β,11α,14β-trihydroxy-5β-card-20(22)-enolide
k-Strophanthin	strophanthidin	3β,5β,14β-trihydroxy-19-oxo-5β-card-20(22)-enolide
Ouabain	ouabagenin	1β,3β,5β,11α,14β,19-hexahydroxycard-20(22)-enolide

linked to three molecules of the sugar digitoxose and is derived from a more complex glycoside (digilanides A, B, and C, respectively) from which glucose and acetic acid are removed during the isolation procedures.

The squill, or sea onion, *Scilla maritima*, a seashore plant, contains several toxic glycosides of which the aglycones are bufadienolides more typical of the toad poisons than of plant products. (In a bufadienolide, two double bonds are present in the bufanolide side chain.) A white form of the squill produces the glycoside scillaren A, which contains the aglycone scillarenin, while a red form produces scilliroside, which is specifically toxic to rodents and has long been used as a rat poison. The contribution of the side chain to cardiac activity differs little between the bufanolides and the cardanolides.

Toad poisons. Defensive venoms secreted by skin glands (principally the parotid glands) of the toad owe their high toxicity to bufadienolides that occur both free (bufogenins) and combined (bufotoxins). These compounds have digitalis-like properties and have been used medicinally in a traditional Chinese preparation, Ch'an Su. The best characterized is bufotoxin, from the European toad *Bufo vulgaris* and the Oriental toad *Bufo gargarizans*, of which the bufogenin is bufotalin, a close structural relative of gitoxin.

bufotoxin (24)



Sapogenins and saponins. Sapogenins are steroids of the spirostan type that occur widely and in great variety in plants. They are linked to sugars as glycosides, usually through a 3β-hydroxyl group. The glycosides are saponins, so called because they form soapy solutions and have other surface active (*e.g.*, hemolytic) properties. Since saponins are difficult to purify, the complete structures of only a few are known. Among these is dioscin (from certain yams, *Dioscorea* species, and yuccas, *Trillium* species); the steroid portion of this saponin is diosgenin.

The nature and number of sugar residues per molecule are known for many saponins. These include the common sugars glucose, xylose, galactose, rhamnose, and arabi-

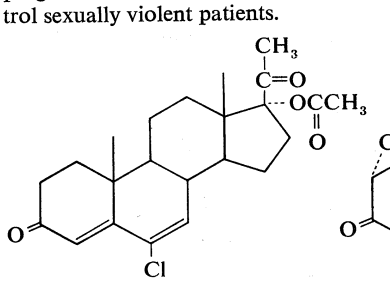
dioscin (25), a saponin of diosgenin

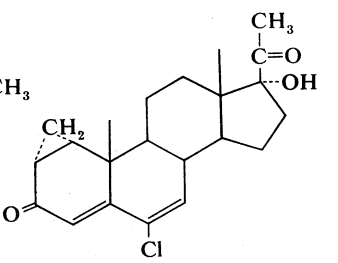
nose. In most cases, however, only the structure of the sapogenin, which can be released from the saponin by acid hydrolysis, is known with certainty. Linkage of rings *A* and *B* may be *cis*- (5β) or *trans*- (5α) or may involve unsaturation at C-5. A hydroxyl group is nearly always present at position 3, and hydroxyl or ketonic groups may be present at positions 1, 2, 4, 5, 6, 11, 12, or 15. Many pairs of natural sapogenins differ only in configuration at C-25. Their structural features and abundance make diosgenin and hecogenin useful as starting materials for steroid hormone manufacture.

PHARMACOLOGICAL ACTIONS OF STEROIDS



Side effects

Aside from their principal physiological effects, all steroid hormones have generalized influences upon metabolic systems throughout the body. These are sometimes seen as powerful pharmacological side effects when, either during hormone therapy or through some endocrine abnormality, the body is exposed to excessive amounts of a naturally occurring steroid hormone. In some synthetic analogues of the natural hormones, a desired activity is accentuated while others are minimized. Furthermore, just as naturally occurring steroid hormones of differing biological activity (estrogens, androgens, glucocorticoids, mineralocorticoids) often act antagonistically, the many steroid analogues include a number of inhibitors of the natural hormones. Details of the effects of steroids upon living organisms, including pharmacological applications, are more fully covered in other articles (see HORMONE; ENDOCRINE SYSTEM, HUMAN; ENDOCRINE SYSTEM DISEASES AND DISORDERS).



Androgens and anabolic steroids. Androgens secreted or administered in abnormally large amounts can cause development of male characteristics in the female and precocious sexual development in the male. Conversely, hypogonadism of the male (inadequate testicular function) leads to retarded sexual development and retention of feminine bodily characteristics (eunuchoidism), which can sometimes be remedied by administration of androgenic steroids. Several esters of testosterone are commonly used by injection for this purpose. Many orally active analogues of testosterone are also available (Table 6) in which activity is greatly enhanced, and often the ratio of androgenic activity to anabolic activity is shifted markedly in favour of the latter. This ratio primarily determines the therapeutic value of these compounds as anabolic agents. They are used together with growth hormone to promote growth in children in whom growth is retarded. They are also used to promote physical recovery from debilitating diseases. Their alleged use by some athletic competitors in sports has been decried.

The psychic effects of androgens have been exploited in their use to correct frigidity in women and lack of self-esteem in adolescents. Androgens are also used in the treatment of estrogen-dependent tumours, such as breast cancer in women.

Anti-androgens. The estrogens and a number of the synthetic gestogens, such as medroxyprogesterone acetate and chlormadinone acetate (Table 7), have anti-androgenic properties that are the basis for their use against benign or malignant hyperplasia of androgen-dependent tissues such as the prostate. Other anti-androgens are A-nortestosterone and A-norprogesterone and their derivatives. The anti-androgens cyproterone and medroxyprogesterone acetate have been used successfully to control sexually violent patients.

chlormadinone acetate (26)

cyproterone (27)

Synthetic estrogens and gestogens: steroid contraceptives. The most effective currently available method of contraception uses combinations of synthetic estrogens and gestogens that prevent ovulation and render the uterine environment inimical to conception and to the development of the ovum. Unlike the natural hormones, these synthetic steroids are highly active when taken orally, as tablets, and as contraceptives they are popularly referred to as the Pill. Ovulation is suppressed because release of the pituitary hormone that stimulates it is inhibited, primarily by the estrogenic component. The gestogens are also anti-ovulatory, but their principal function in oral contraceptives is to control the uterine bleeding (menstruation) that follows withdrawal of the estrogen. The tablets are taken according to schedules

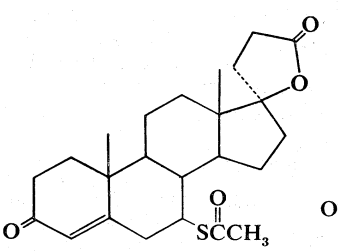
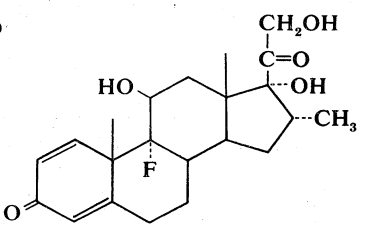
that simulate a 28-day menstrual cycle. Most frequently, a combination of the two types of steroid is taken daily during 21 or 22 days and is then interrupted for the remainder of the 28-day period. During the nonmedication days, the menstrual flow occurs. An alternative sequential schedule aims to approximate more closely to the endocrine events of the normal menstrual cycle by the use of tablets of estrogen alone for 14–15 days followed by tablets of combined estrogen and gestogen for 5–7 days prior to interruption to permit menstruation. The combination method is somewhat more reliable, probably because the gestogens in the combination regime influence the uterine environment to prevent implantation of the ovum in those few cycles in which ovulation is not inhibited. Other regimes of administration in the investigative stage in the early 1970s are a "once-a-month pill," utilizing the long-acting estrogen quinestrol, and a postcoital ("morning-after") pill.



The contraceptive steroids, which were brought into popular use in the early 1960s, have proved remarkably safe. Their discontinuance is usually followed by a prompt return of fertility. Some individuals suffer unpleasant symptoms (nausea, water retention, tiredness) in the use of certain preparations, but a variety of alternative types have become available (Table 7), among which a satisfactory one usually may be found. In oral contraceptives available in the early 1970s, only two estrogens were used: estranol, which has about the same potency as estradiol, and mestranol, which is less potent. The main differences between preparations are the character of the gestogens and the quantities and ratios of the steroids that they contain.

Other uses of estrogens and gestogens



Besides their use in birth control, the contraceptive steroid preparations and synthetic gestogens are used to correct irregularities of the menstrual cycle and its frequent physical and psychological symptoms. The gestogens are used to maintain pregnancy in cases of threatened abortion, some as anti-androgens, and others as anti-estrogens. Contraceptive steroid preparations are also used for control of breeding cycles and synchronization of estrus in farm animals. The synthetic estrogens are used to alleviate the unpleasant physical and psychic symptoms of the menopause in women and for the treatment of some cancers of the prostate in men and of the breast in women. They are also used in some cases to suppress the plasma cholesterol concentrations in sufferers from advanced atherosclerosis, a disease that is markedly more prevalent in men and postmenopausal women than in younger women with intact ovaries.

Anti-estrogens. Androgenic steroids are anti-estrogenic and are often used to suppress the growth of estrogen-dependent cancers. Methyltestosterone and fluoxymesterone (Table 6), and norethindrone (norethisterone) and norgestrel (Table 7) are anti-estrogens. Since estrogens block the release of the pituitary hormone responsible for ovulation, a potent anti-estrogen can stimulate ovulation by inhibiting this action of estrogens.

Adrenal hormones. The anti-inflammatory and glucocorticoid activities of cortisol are enhanced, in some cases with relative reduction of its mineralocorticoid activity, by various structural modifications (Table 8). A 9α-fluorine atom enhances the glucocorticoid activity of cortisol about 10-fold, but its salt-retaining activity about 50-fold. On the other hand, unsaturation at C-1 increases glucocorticoid, but not mineralocorticoid, activity, and 6α-fluorine or methyl and 16-methyl or hydroxyl groups (and especially 16α,17α-acetonides—*i.e.*, compounds formed from 16α,17α-dihydroxy compounds and acetone) enhance anti-inflammatory activity while reducing salt activity. These groupings, therefore, appear in various combinations in anti-inflammatory steroids, many of which, however, lack the salt-retaining activity necessary for total adrenal replacement therapy. Cortisol analogues, such as dexamethasone, are used to treat many inflammatory and rheumatic diseases, to suppress the immune response in allergies and in organ transplantation, and to delay the progress of leukemia. They are also widely used for the treatment of local inflammatory reactions. A synthetic steroid of a quite different type, spironolactone (Aldactone A),

spironolactone (28)

dexamethasone (29)

is used as an antagonist to the action of aldosterone in certain cases of hypertension.

Cardiotonic steroids. Preparations in which cardiotonic steroids of both vegetable and animal origin are the active principles have been used as emetics, diuretics, and arrow poisons since ancient times. The use of digitalis, ouabain, and strophanthin glycosides to slow the rate and strengthen the contractility of the failing heart is one of the most important methods of treatment of this condition. Of these agents, the digitalis glycosides are the most widely used. The therapeutic effects of these agents are related to their influence upon muscle cells, but knowledge of their mechanism of action is incomplete and their use in medicine remains essentially empirical.

Conclusion: The general biological significance of steroids. That such diverse physiological functions and effects should be shown by steroids, all of which are synthesized by essentially the same central biosynthetic pathway, is a remarkable example of biological economy. Most of these functions, especially those of a hormonal type, involve the transmission of biologically essential in-

Table 8: Approximate Relative Anti-inflammatory Potency of Some Analogs of Cortisol

formation. The specific information content of the steroid resides in the character and arrangement of its substituent groups and in other subtle structural modifications. The mechanism of action of no steroid hormone at the molecular level is as yet known, nor is it known why the steroid nucleus is so highly appropriate as a carrier of informational signals in systems of biological control. But that it is, is beyond doubt, and it seems reasonable to expect that many further regulatory functions of steroids, especially in lower life forms, remain to be discovered.

BIBLIOGRAPHY. The chemistry of steroids is comprehensively treated in L.F. and M. FIESER, *Steroids* (1959); more recent information appears in several chapters in S. COFFEY (ed.), *Rodd's Chemistry of Carbon Compounds*, 2nd ed., vol. 2, *Steroids*, 2 pt. (1970–71); for biochemical aspects, see M. FLORKIN and E.H. STOTZ (eds.), *Sterols, Bile Acids and Steroids* (1963); or D.M. GREENBERG, *Metabolic Pathways*, vol. 2 (1968); for comprehensive coverage of the biology and chemistry of the Pill, see D. LEDNICER (ed.), *Contraception: The Chemical Control of Fertility* (1969).

(R.B.C.)

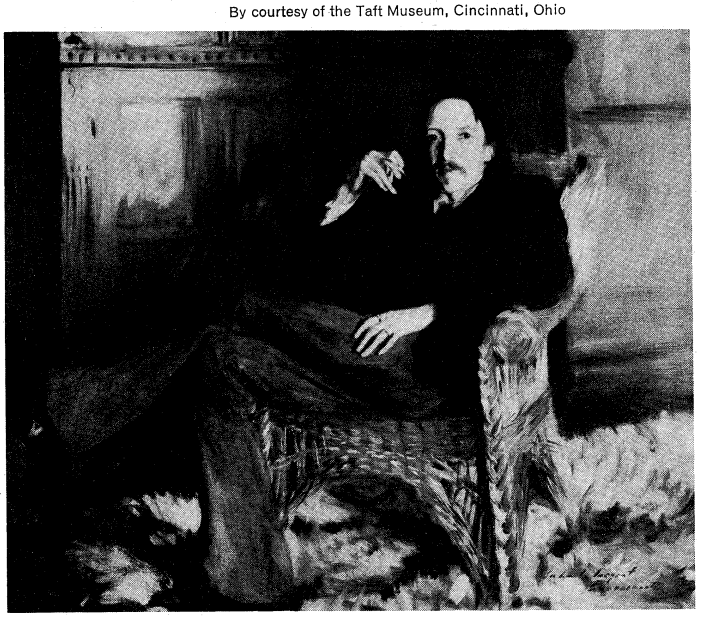
Stevenson, Robert Louis

Though he was best known in his lifetime, and is still popular, as an author of adventure stories and as a personal essayist in the Romantic tradition, Robert Louis Stevenson is a writer of greater variety and subtlety than this would suggest, and his mature fiction includes work of great originality and power.

Early life. Born at Edinburgh on November 13, 1850, Stevenson was the only son of Thomas Stevenson, a prosperous civil engineer, and his wife, Margaret Isabella Balfour. His poor health made regular schooling difficult, but he attended Edinburgh Academy and other schools before, at 17, entering Edinburgh University, where he was expected to prepare himself for the family profession of lighthouse engineering. But Stevenson had no desire to be an engineer, and he eventually agreed with his father, as a compromise, to prepare instead for the Scottish bar.

He had shown a desire to write early in life, and once in his teens he had deliberately set out to learn the writer's craft by imitating a great variety of models in prose and verse. His youthful enthusiasm for the Covenanters (*i.e.*, those Scotsmen who banded together to defend their version of Presbyterianism in the 17th century) led to his writing *The Pentland Rising*, his first printed work. During his years at the university he rebelled against his parents' religion and set himself up as a liberal Bohemian who abhorred the alleged cruelties and hypocrisies of bourgeois respectability.

Friendship with Fanny Sitwell



In 1873, in the midst of painful differences with his father, he visited a married cousin in Suffolk, where he met Sidney Colvin, the English scholar, who became a lifelong friend, and Mrs. Fanny Sitwell (who later married Colvin). Mrs. Sitwell, an older woman of charm and talent, drew the young man out and won his confidence. Soon Stevenson was deeply in love, and on his return to Edinburgh he wrote her a series of letters in which he played the part first of lover, then of worshipper, then of son. One of the several names by which Stevenson addressed her in these letters was "Claire," a fact that many years after his death was to give rise to the erroneous notion that Stevenson had had an affair with a humbly born Edinburgh girl of that name. Eventually the passion turned into a lasting friendship.

Later in 1873 Stevenson suffered severe respiratory illness and was sent to the French Riviera, where Colvin later joined him. He returned home the following spring. In July 1875 he was called to the Scottish bar, but he never practiced. Stevenson was frequently abroad, most often in France. Two of his journeys produced *An Inland Voyage* (1878) and *Travels with a Donkey in the Cévennes* (1879). His career as a writer developed slowly. His essay "Roads" appeared in the *Portfolio* in 1873, and in 1874 "Ordered South" appeared in *Macmillan's Magazine*, a review of Lord Lytton's *Fables in Song* appeared in the *Fortnightly*, and his first contribution (on Victor Hugo) appeared in *The Cornhill Magazine*, then edited by Leslie Stephen, a critic and biographer. It was these early essays, carefully wrought, quizzically meditative in tone, and unusual in sensibility, that first drew attention to Stevenson as a writer.

Stephen brought Stevenson into contact with Edmund Gosse, the poet and critic, who become a good friend. Later, when in Edinburgh, Stephen introduced Stevenson to the writer W.E. Henley. The two became warm friends, and were to remain so until 1888, when a letter from Henley to Stevenson containing a deliberately implied accusation of dishonesty against the latter's wife precipitated a quarrel that Henley, jealous and embittered, perpetuated after his friend's death in a venomous review of a biography of Stevenson.

In 1876 Stevenson met Fanny Vandegrift Osbourne, an American lady separated from her husband, and the two fell in love. Stevenson's parents' horror at their son's involvement with a married woman subsided somewhat when Mrs. Osbourne returned to California in 1878, but it revived with greater force when Stevenson decided to join

her in August 1879. Stevenson reached California ill and penniless (the record of his arduous journey appeared later in *The Amateur Emigrant*, 1895, and *Across the Plains*, 1892). His adventures, which included coming very near death and eking out a precarious living in Monterey and San Francisco, culminated in marriage to Fanny Osbourne (who was by then divorced from her first husband) early in 1880. About the same time a telegram from his relenting father offered much-needed financial support, and after a honeymoon by an abandoned silver mine (recorded in *The Silverado Squatters*, 1883) the couple sailed for Scotland to achieve reconcilation with the Thomas Stevensons.

Marriage

Romantic novels. Soon after his return, Stevenson, accompanied by his wife and his stepson, Lloyd Osbourne, went, on medical advice (he had tuberculosis), to Davos, Switzerland. The family left there in April 1881 and spent the summer in Pitlochry and then in Braemar, Scotland. There, in spite of bouts of illness, Stevenson embarked on *Treasure Island* (begun as a game with Lloyd), which started as a serial in *Young Folks*, under the title *The Sea-Cook*, in October 1881. Stevenson finished the story in Davos, to which he had returned in the autumn, and then started on *Prince Otto* (1885), a more complex but less successful work. *Treasure Island* is an adventure presented with consummate skill, with atmosphere, character, and action superbly geared to one another. The book is at once a gripping adventure tale for boys and a wry comment on the ambiguity of human motives.

In 1881 Stevenson published *Virginibus Puerisque*, his first collection of essays, most of which had appeared in *The Cornhill*. The winter of 1881 he spent at a chalet in Davos. In April 1882, he left Davos; but a stay in the Scottish Highlands, while it resulted in two of his finest short stories, "Thrawn Janet" and "The Merry Men," produced lung hemorrhages, and in September he went to the south of France. There the Stevensons finally settled at a house in Hyères, where, in spite of intermittent illness, Stevenson was happy and worked well. He revised *Prince Otto*, worked on *A Child's Garden of Verses* (first called *Penny Whistles*), and began *The Black Arrow: A Tale of the Two Roses* (1888), a historical adventure tale deliberately written in anachronistic language. The threat of a cholera epidemic drove the Stevensons from Hyères back to England. They lived at Bournemouth from September 1884 until July 1887, but his frequent bouts of dangerous illness proved conclusively that the British climate, even in the south of England, was not for him. The Bournemouth years were fruitful, however. There he got to know and love Henry James. There he revised *A Child's Garden* (first published in 1885) and wrote "Markheim," *Kidnapped* (1886), and *The Strange Case of Dr. Jekyll and Mr. Hyde* (1886). The poems in *A Child's Garden* represent with extraordinary fidelity an adult's recapturing of the emotions and sensations of childhood; there is nothing quite like them in English literature. In *Kidnapped* the fruit of his researches into 18th-century Scottish history and of his feeling for Scottish landscape, history, character, and local atmosphere mutually illuminate one another. But it was *Dr. Jekyll* —both moral allegory and thriller—that established his reputation with the ordinary reader.

American sojourn

In August 1887, still in search of health, Stevenson set out for America with his wife, mother, and stepson. On arriving in New York, he found himself famous, with editors and publishers offering lucrative contracts. He stayed for a while in the Adirondack Mountains, where he wrote essays for *Scribner's* and began *The Master of Ballantrae* (1889). This novel, another exploration of moral ambiguities, contains some of his most impressive writing, although marred by its contrived conclusion.

Life in the South Seas. In June 1888 Stevenson, accompanied by his family, sailed from San Francisco in the schooner yacht "Casco," which he had chartered, on what was intended to be an excursion for health and pleasure. In fact, he was to spend the rest of his life in the South Seas. They went first to the Marquesas Islands, then to Fakarava Atoll, then to Tahiti, then to Honolulu, where they stayed nearly six months, leaving in June 1889 for the Gilbert Islands, and then to Samoa, where he spent six weeks.

Journalist in the South Pacific

During his months of wandering around the South Sea islands, Stevenson made intensive efforts to understand the local scene and the inhabitants. As a result, his writings on the South Seas (*In the South Seas*, 1896; *A Footnote to History*, 1892) are admirably pungent and perceptive. He was writing first-rate journalism, deepened by the awareness of landscape and atmosphere, such as that so notably rendered in his description of the first landfall at Nuku Hiva in the Marquesas.

In October 1890 he returned to Samoa from a voyage to Sydney and established himself and his family in patriarchal status at Vailima, his house in Samoa. The climate suited him; he led an industrious and active life; and when he died suddenly on December 3, 1894, it was of a cerebral hemorrhage, not of the long-feared tuberculosis. His work during those years was moving toward a new maturity. While *Catriona* (U.S. title, *David Balfour*, 1893) marked no advance in technique or imaginative scope on *Kidnapped*, to which it is a sequel, *The Ebb-Tide* (1894), a grim and powerful tale written in a dispassionate style (it was a complete reworking of a first draft by Lloyd Osbourne), showed that Stevenson had reached an important transition in his literary career. The next phase was demonstrated triumphantly in *Weir of Hermiston* (1896), the unfinished masterpiece on which he was working on the day of his death. "The Beach of Falesá" (first published 1892; included in *Island Night's Entertainments*, 1893), a story with a finely wrought tragic texture, as well as the first part of *The Master of Ballantrae*, pointed in this direction, but neither approaches *Weir*. Stevenson achieved in this work a remarkable richness of tragic texture in a style stripped of all superfluities. The dialogue contains some of the best Scots prose in modern literature. Fragment though it is, *Weir of Hermiston* stands as a great work and Stevenson's masterpiece.

Assessment. Stevenson was an indefatigable letter writer, and his letters (edited by Sidney Colvin in 1899) provide a lively and enchanting picture of the man and his life. But Colvin omitted many of the most interesting letters and compressed and dovetailed others, with the result that many important facts about Stevenson's emotional life remained unknown until the true text of all the letters was available. Colvin presented Stevenson's letters to Mrs. Sitwell to what is now the National Library of Scotland with the proviso that they were not to be opened until 1949; the revealing and often fascinating letters to Charles Baxter, a friend, are deposited in the Yale University Library. Stevenson's biography suffered from his being early canonized; later writers built up a counterpicture of an immoral swaggerer restrained into reluctant respectability by a jealous wife. Access to the crucial letters yielded a picture of a Stevenson who was neither the "seraph in chocolate" against whom Henley protested nor a low-living rake nor an optimistic escapist nor the happy invalid but a sensitive and intelligent writer who had no illusions about life and wryly made the best of a world to which he did not profess to have the key.

Literary reputation

His literary reputation has also fluctuated. The reaction against him set in soon after his death: he was considered a mannered and imitative essayist or only a writer of children's books. But eventually the pendulum began to swing the other way, and by the 1950s his reputation was established among the more discerning as a writer of originality and power; whose essays at their best are cogent and perceptive renderings of aspects of the human condition; whose novels are either brilliant adventure stories with subtle moral overtones or original and impressive presentations of human action in terms of history and topography as well as psychology; whose short stories produce some new and effective permutations in the relation between romance and irony or manage to combine horror and suspense with moral diagnosis; whose poems, though not showing the highest poetic genius, are often skillful, occasionally (in his use of Scots, for example) interesting and original, and sometimes (in *A Child's Garden*) valuable for their exhibition of a special kind of sensibility.

MAJOR WORKS

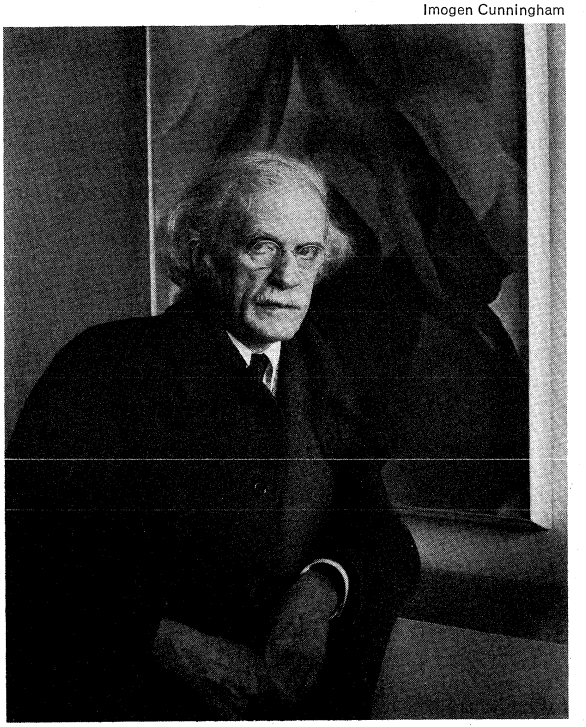
TALES AND NOVELS: *New Arabian Nights*, 2 vol. (1882; the stories in vol. 1 appeared as *Latter-Day Arabian Nights*, 1878; those in vol. 2 had appeared in *The Cornhill* and other magazines); *Treasure Island* (1883; serialized in a slightly different form in *Young Folks*, 1881–82); *More New Arabian Nights*, with Fanny Van de Grift Stevenson (1885); *Prince Otto* (1885); *Strange Case of Dr. Jekyll and Mr. Hyde* (1886); *Kidnapped* (1886; in *Young Folks*, 1886); *The Merry Men and Other Tales and Fables* (1887), including "Thrawn Janet" and "Olalla"; *The Black Arrow: A Tale of the Two Roses* (1888; in *Young Folks*, 1883); *The Master of Ballantrae* (1889; serialized in *Scribner's Magazine*, 1888–89); *Catriona*, (1893), a sequel to *Kidnapped; The Ebb-Tide*, with Lloyd Osbourne (1894; serialized in *To-Day*, 1893–94); *Weir of Hermiston* (unfinished 1896); *St. Ives*, completed by Sir Arthur Quiller-Couch, pseudonym "Q" (1897).

ESSAYS AND MISCELLANEOUS: *An Inland Voyage* (1878); *Travels with a Donkey in the Cévennes* (1879); *Virginibus Puerisque* (1881), collected essays, mainly from *The Cornhill Magazine; Familiar Studies of Men and Books* (1882); *Memories and Portraits* (1887), 16 essays; *Across the Plains* (1892), 12 essays; *Vailima Letters*, to Sidney Colvin (1895); *From Scotland to Silverado*, ed. by J.D. Hart (1966), brings together all Stevenson's previously published and unpublished writings about his trip to California in 1879–80.

POETRY: *A Child's Garden of Verses* (1885); *Underwoods* (1887), 38 poems in English, 16 in Scots; *Ballads* (1890); *Songs of Travel and Other Verses* (1896). *Collected Poems*, ed. by J. Adam Smith, 2nd ed. (1971), is the standard edition of Stevenson's poetry.

BIBLIOGRAPHY. There is a bibliography of works by and about Stevenson in *The New Cambridge Bibliography of English Literature*, vol. 3 (1969). See also WILLIAM F. PRIDEAUX, *A Bibliography of the Works of Robert Louis Stevenson*, rev. by F.V. LIVINGSTON (1917); and GEORGE L. MCKAY (comp.), *A Stevenson Library . . . , Formed by Edwin J. Beinecke*, 6 vol. (1951–64). Of the many collected editions of Stevenson's works the following are notable: Pentland edition, ed. by EDMUND GOSSE, 20 vol. (1906–07); Swanston edition, 25 vol. (1911–12); Vailima edition, ed. by LLOYD OSBOURNE, with prefatory notes by FANNY VAN DE GRIFT STEVENSON, 26 vol. (1922–23); Skerryvore edition, 30 vol. (1924–26); Tusitala edition, 35 vol. (1923–24); South Seas edition, 32 vol. (1925), JAMES D. HART (ed.), *From Scotland to Silverado* (1966), brings together all of Stevenson's previously published and unpublished writings about his trip to California in 1879–80, with a biographical introduction. *The Letters of Robert Louis Stevenson to His Family and Friends* were edited by SIDNEY COLVIN (2 vol., 1899; 4 vol., 1911), but these are far from complete, and the text has sometimes been tampered with. Stevenson's lively and important correspondence with his lifelong friend Charles Baxter, *RLS: Stevenson's Letters to Charles Baxter*, was edited by DE LANCEY FERGUSON and MARSHALL WAINGROW (1956).

The official biography of Stevenson is by his cousin GRAHAM BALFOUR, *The Life of Robert Louis Stevenson*, 2 vol. (1901, reprinted 1968). This is valuable, but there are serious omissions and evasions. The standard modern biography is JOSEPH C. FURNAS, *Voyage to Windward: The Life of Robert Louis Stevenson* (1951); MALCOLM ELWIN, *The Strange Case of Robert Louis Stevenson* (1950, reprinted 1971); and RICHARD ALDINGTON, *Portrait of a Rebel* (1957), are lively retellings of the life. *Henry James and Robert Louis Stevenson: A Record of Friendship and Criticism*, ed. by J. ADAM SMITH (1948), gives an account of the relationship between the two writers and prints both their criticisms of each other's work and their letters to each other. Modern critical works on Stevenson are DAVID DAICHES, *Robert Louis Stevenson* (1946); LETTICE COOPER, *Robert Louis Stevenson* (1947); ROBERT KIELY, *Robert Louis Stevenson and the Fiction of Adventure* (1964); and EDWIN M. EIGNER, *Robert Louis Stevenson and Romantic Tradition* (1966).



(D.Da.)

Stieglitz, Alfred

Often called the father of modern photography, Alfred Stieglitz was a slight, wiry man of intense passion, incredible energies, and ardent convictions. He devoted his life first to achieving the recognition of photography as an art and then to the introduction of modern art to the United States. As a renowned photographer, Stieglitz himself broke down the barriers against photography in American art museums. His prints were the first photographs accepted as art and received as such by major museums in Boston, New York, and Washington. In those museums his photographs were hung and exhibited in the same manner as other notable achievements in the graphic arts.

A born leader, Stieglitz had an infallible eye, a flexible and inquiring mind, and a temperament conducive to battling for his revolutionary beliefs. Almost single-handedly, he launched his country into the 20th-century art world, not only in the field of photography but in painting and sculpture as well. He awakened the public by exposing it, for the first time, to the best of modern art. With camera and pen, with fiery harangues in his own galleries, he goaded Americans away from their complacent artistic tradition, which largely had been confined to the imitation of European academicians since the 19th century, and worked for the recognition of the contemporary artist in the United States as a force in the international art world.

Imogen Cunningham

Stieglitz at his gallery "291" in 1934. Behind him is a painting by his wife, Georgia O'Keeffe.

Early years in America and Europe

Born in Hoboken, New Jersey, on January 1, 1864, Stieglitz was the oldest son of Edward Stieglitz, a retired woollen merchant. After his early schooling in New York, the Stieglitz family moved to Europe in 1881 to further their children's education. Stieglitz eventually registered for studies in mechanical engineering at the Berlin Polytechnic in 1883. A few months later, the purchase of a small camera led him to abandon engineering for photochemistry and to begin his photographic career.

While still a student at Berlin, where many of his friends were painters, Stieglitz decided to fight for the recognition of photography as a creative art medium equal to that of painting. The best way to gain this acceptance, he innocently believed, was to become a photographic authority, and to become such an authority, he believed he had only to set the highest standards for his own prints and to win all possible prizes and medals.

Both in Europe and the United States, where he returned to live in 1890, his early work (*c.* 1883–1910) reflects these aims. It was characterized by constant technical innovations, which at the time were believed impossible to achieve. Before the turn of the century, for example, Stieglitz had made the first successful photographs in snow, in rain, and at night and had undertaken the first serious use of a small, hand-held camera. By 1910 these photographs had won more than 150 important prizes.

The Photo-Secession group of photographers

Realizing that his own early fame could not alone bring about the recognition of photography as an art, Stieglitz believed that the work of a group might be more effective than that of an individual. After several ventures with established photographic organizations, in which Stieglitz usually led dissident factions, in 1902 he founded a new group of his own, the Photo-Secession, a title adapted from the German Secessionist painters who at that time also were in revolt against the traditional art world. As its leader, Stieglitz gathered around him a group of talented American photographers dedicated to his ideals.

Until 1905, however, the Photo-Secession had not had a centre to exhibit its work in. That year, largely at the urging of Edward Steichen, a close friend and associate, Stieglitz finally agreed that the group should have its own space. Initially called the Little Galleries of the Photo-Secession, located in New York City, the group soon became known by the gallery's street number ("291"); and Stieglitz himself was so closely identified with its work that he often signed his personal correspondence "291."

Soon after its establishment Stieglitz turned his energies to the cause of modern art. At first he did not claim to understand the modern movements, but he did consider them to be fascinating new ways of expressing reality.

The famous Armory Show of 1913 is often considered to have introduced modern art to the United States. Stieglitz in 1908, however, had already held the first showings of work by the sculptor Auguste Rodin and the painter Henri Matisse, and he continued to hold exhibitions of the painters Toulouse-Lautrec, Henri Rousseau, Paul Cézanne, and Pablo Picasso during the five years before the Armory Show. Even more revolutionary was Stieglitz' fervent belief that living American artists were of equal importance and could create significant works of art in their own lifetime. Thus, during the same years that he was bringing modern European art to the United States, he also was holding exhibitions of the work of American painters John Marin, Marsden Hartley, Arthur Dove, Alfred Maurer, and Max Weber. By the time "291" closed in 1917, Stieglitz also had given Americans their first shows of works by the sculptors Constantin Brancusi and Elie Nadelman and the painters Francis Picabia, Gino Severini, Stanton Macdonald-Wright, and Georgia O'Keeffe, who was to become his wife in 1924. For the most part these exhibitions were viewed by a hostile and derisive public. The history of these stormy years is documented in *Camera Work* (1903–17), the radical and beautiful magazine edited and published by Stieglitz.

Neither "291" nor *Camera Work* survived the difficulties of the World War I years, both coming to an end in 1917. With the closing of the gallery, Stieglitz once more had time for his own photography, neglected during the years of "291." His interests turned from his youthful preoccupation with technique and a wide subject matter to an intense preoccupation with what he saw and lived with daily—either at his summer home in Lake George, New York, or at his New York City residence. Two series of this period (1917–37), each consisting of more than 400 prints, are often considered his greatest photographs: the portraits of Georgia O'Keeffe, and the equivalents—photographs of abstract cloud shapes corresponding to all possible emotional experiences. In both he continued to extend the frontiers of photography.

The equivalents and the portraits

Stieglitz' preoccupation with his photography did not deter him from continuing to hold shows of American painters, thus helping to provide them a living and the freedom to work as they wished. Since by that time the once-ridiculed European artists had become a commercial success, he ceased working for them. (He was not a dealer and never profited financially from his activities for artists.) Fanatic until the end in his belief that significant art existed in the United States, his steadfast interest encouraged a group of American artists (principally Charles Demuth, Dove, Hartley, Marin, and O'Keeffe) to achieve this vision. His faith was demonstrated in more than 175 exhibitions held in his three galleries (1905–46), first at "291" (1905–17), then at the Intimate Gallery (1925–29), and finally at An American Place (1929–46). By the end of his life he had changed the climate for all American painting, gaining for it a truly independent status and acceptance.

Shortly after the end of the 1946 season at An American Place, Stieglitz, preparing for his yearly summer trip to Lake George, suffered a stroke and died on July 13, 1946, in New York.

BIBLIOGRAPHY. The most complete set of Stieglitz photographs is held by the National Gallery of Art, Washington, D.C. Other important collections are those of the Metropolitan Museum of Art and the Museum of Modern Art in New York; the Museum of Fine Arts, Boston; the Art Institute of Chicago; and the San Francisco Museum of Art. The main portions of the Alfred Stieglitz collection of paintings are at the Metropolitan Museum of Art and the Art Institute of Chicago. Works on Stieglitz include: DORIS BRY, *Alfred Stieglitz: Photographer* (1965); FRANK WALDO *et al.* (eds.), *America and Alfred Stieglitz: A Collective Portrait* (1934); DOROTHY NORMAN, *Alfred Stieglitz* (1960); and HERBERT J. SELIGMANN, *Alfred Stieglitz Talking* (1966).

(D.Br.)

Stilicho

Perhaps the most energetic, ambitious, and competent of military rulers as the Roman Empire ended in the West was Flavius Stilicho—half-Roman, half-Vandal by birth—who was regent in the West for the young and weak-willed Honorius, son of the emperor Theodosius I. Stilicho effectively ruled the Western empire from AD 395 until his death in 408 and was able to halt the advance of the Visigoth invaders. His rivalry with Flavius Rufinus, his counterpart in the East, to which Theodosius' son Arcadius had succeeded, signalled the complete and formal division of the empire into its eastern and western halves.

Alinari

Stilicho with wife and son, ebony diptych, *c.* 400. In the Cathedral Treasury, Monza, Italy.

Stilicho was born *c.* AD 365, the son of a mercenary captain. Making the army his career, in 383 he served on an embassy to the Persian king Shāpūr III, afterward marrying Serena, the favourite niece of Theodosius. He was appointed count of the domestics (commanding the Emperor's household troops) *c.* 385 and then, in or before 393, master of both services (*i.e.*, commander in chief of the army), an office he held until his death.

Little is known of Stilicho's military exploits before 395. He became the enemy of Rufinus because of a difference of opinion about the treatment of some barbarian invaders in 389. Before his death Theodosius appointed Stilicho and Rufinus to be the guardians of his sons. Stilicho had a great military advantage over his rival, for the army Theodosius had assembled to crush the usurper Eugenius was still concentrated in the West under Stilicho's command when Theodosius died.

Before either Stilicho or Rufinus could attack the other,

the Visigoths, a Germanic tribe living in Lower Moesia who had suffered severe losses in the campaign against Eugenius, rebelled under the leadership of their chieftain Alaric and began to devastate Thrace and Macedonia. Stilicho, who claimed for the Western government the prefecture of Illyricum, which was disputed between the emperors, went with his army to Thessaly. About to engage Alaric there, however, he was ordered by Arcadius, acting on Rufinus' advice, to send a number of his troops to Constantinople. Stilicho obeyed and thus enabled Alaric to penetrate into Greece; but the troops sent to Constantinople murdered Rufinus there on November 27, 395. The gifted poet Claudian began to publish his poems in praise of Stilicho, an important source of information about the politics of the time until 404, when the poet apparently died.

Conflict with Rufinus

In 397 Stilicho took another army to Greece but failed again to bring Alaric to battle and withdrew to Italy. In that same year, Gildo, the count of Africa, rebelled against the Roman government and refused to allow African grain ships to sail to Rome. Stilicho promptly imported grain from Gaul and Spain. In the following year he sent Gildo's brother, Mascezel, to Africa with an army and he easily overthrew Gildo and put him to death; but Mascezel died soon afterward and Stilicho was suspected of having had him murdered so that he might not become a rival. In 398 Stilicho's daughter Maria was married to the emperor Honorius, and Stilicho himself became consul in 400.

The Visigothic invasion

In 401 when Alaric and the Visigoths invaded Italy and threatened Milan, where Honorius was living, Stilicho summoned troops from the Rhine frontier and from Britain to strengthen his army; and in 402 he engaged the Goths at Pollentia (Pollenzo, near modern Bra). The battle, fought on Easter Sunday, April 6, resulted in an incomplete victory for Stilicho, but he captured the Gothic camp. Alaric then marched toward Etruria, but after negotiations he agreed to withdraw from Italy. In 403, however, he re-entered Italy and attacked Verona. Stilicho once more engaged him successfully and pursued him northward. Again an understanding was reached, and Alaric, though his army was in bad condition, was allowed to escape.

Late in 405 Italy was menaced by new invaders, a vast host of Germans, mainly Ostrogoths, led by a pagan called Radagaisus. Contemporary accounts numbered them in hundreds of thousands, though any such figure is impossible. They attacked Florence, but Stilicho compelled their withdrawal to Fiesole, where he cut off their supplies and massacred them. Radagaisus was executed on August 23, 406, and, in celebration, a triumphal arch was erected at Rome.

Attempt to gain Illyricum

Stilicho had never abandoned his plans to annex Illyricum, and in 407 he put them into operation. He closed the ports of Italy to all Eastern ships, instructed Alaric to hold Epirus for Honorius, and himself prepared to cross the Adriatic. But a false report reached him that Alaric was dead, and then he heard of the revolt of Constantine in Britain. Once more his plans had to be abandoned. Alaric then marched to the province of Noricum (roughly central Austria) and demanded compensation for the trouble he had been put to. His price was high—4,000 pounds (in weight) of gold—but despite considerable opposition Stilicho persuaded the Roman Senate to pay it.

By this time the empress Maria had died, but early in 408 Honorius married another daughter of Stilicho, Thermantia. Stilicho's influence, however, had declined. It was rumoured that he wished to have his son Eucherius elevated to the throne. Reports reached him early in 408 that his army was disaffected. Then came news of the death of the Eastern emperor, Arcadius, and Stilicho proposed to go to Constantinople. A certain Olympius, a palace official, spread the rumour that Stilicho was preparing to put his own son on the Eastern throne, and so the troops in Tictinum (Pavia) killed nearly all of the officials present on August 13. Stilicho went to Ravenna but was imprisoned by Honorius' orders. He was beheaded on August 22; Eucherius was put to death shortly thereafter.

BIBLIOGRAPHY. There is no recent biography of Stilicho; however, for information about him, J.B. BURY, *A History of the Later Roman Empire*, vol. 1 (1923), is adequate. The most important ancient source is the poet Claudian; ALAN CAMERON, *Claudian: Poetry and Propaganda at the Court of Honorius* (1970), is fundamental on Stilicho as well as Claudian.

(E.A.T.)

Stimulant

In general terms, a stimulant may be defined as a drug that excites some bodily function. Defined in this way, however, stimulants include half of all known drugs, ranging from cathartics, which stimulate the churnings of the large intestine; to psychedelics, which stimulate self-awareness; and hormones, such as insulin which stimulates the entry of glucose into cells. A more restricted but generally accepted definition refers to stimulants as agents that excite the central nervous system. Stimulation of the central nervous system frequently is defined as a mental state associated with heightened alertness and elevation of mood. Although this article is mainly concerned with stimulants of the central nervous system, drugs that stimulate functions of the peripheral nervous system also are considered briefly. Central nervous system stimulants may be classified as one of two types. Stimulants of one type affect alertness and have only secondary actions on emotions; stimulants of the second type, commonly called antidepressants, affect the emotions. Minor tranquillizers and stimulants (*e.g.*, amphetamine) are among the most commonly prescribed drugs. Methylxanthines, the major stimulant ingredients in coffee, tea, cocoa, and cola beverages, may be the most widely consumed drugs.

General features. *Nerve functions affected by stimulants.* In order to understand the mechanism of stimulant action, it is necessary to know the brain functions that are affected by stimulants. Information processing throughout the nervous system is primarily the function of the specialized nerve cells called neurons. A neuron has a long cell projection called an axon, which terminates in a nerve ending. Nervous function depends on the ability of a neuron to send an electrochemical current in one direction along its axon to the nerve ending. The nerve ending is in contact with other neurons either at the cell body or at dendrites originating at the cell body. A large number of nerve endings that may contact other neurons leave each axon, and cell bodies and dendrites are in contact with nerve endings from many different neurons. Thus the brain is a vast network of neuronal connections, and an almost infinite number of interactions among different neurons is possible. The purpose of nerve function is to convey information from the nerve ending of one neuron across a gap to the cell body or dendrites of another neuron. The gap is called a synaptic cleft, and the junction between two neurons is called a synapse.

Action of neurotransmitters

At most synapses the electrically excited state of a nerve ending stimulates the release of a chemical or neurotransmitter that diffuses across the synaptic cleft to another neuron. Different systems of neurons in the brain utilize different neurotransmitters. The chemical compositions of about five brain neurotransmitters are known; there may be others in addition to these.

Nervous function in the peripheral nervous system is essentially the same as that in the central nervous system (*i.e.*, brain and spinal cord). The peripheral nervous system includes nerves that innervate voluntary muscles (*e.g.*, those that move arms and legs) and those that innervate involuntary muscles (*e.g.*, the heart) and glands. In contrast to the central nervous system, in which at least five neurotransmitter substances are known, only two, the chemicals acetylcholine and norepinephrine, are known in the peripheral nervous system. Acetylcholine is a neurotransmitter both at the junctions of nerves with voluntary muscles and also at the junctions of some involuntary or autonomic nerves. The autonomic nerve endings that release acetylcholine are concerned with body functions associated with a calm state; *e.g.*,

acid secretion in the stomach, decrease in the heart rate, bowel function, constriction of the pupils of the eyes, dilation of blood vessels, and urination. These nerves are called collectively the parasympathetic nervous system. Norepinephrine, on the other hand, is the neurotransmitter for autonomic nerves whose stimulation produces a state of alarm; *e.g.*, increase in heart rate, constriction of blood vessels with an increase in blood pressure, dilation of the pupils and the bronchioles in the lung, and inhibition of bowel and urinary bladder function. These nerves are called collectively the sympathetic nervous system.

Mode of stimulant action. Drugs that either facilitate or antagonize the actions of acetylcholine and norepinephrine in parasympathetic and sympathetic nerves are widely used in medicine. The norepinephrine released by the stimulation of sympathetic nerves dilates the bronchioles in the lungs; therefore, drugs similar in structure to and capable of mimicking or facilitating the action of norepinephrine are valuable for treating bronchial asthma, a condition in which the bronchioles are constricted. Among the drugs used for this purpose are epinephrine, ephedrine, pseudoephedrine (Sudafed), and isoproterenol. Norepinephrine itself is one of the best known treatments for shock, the symptoms of which are vascular collapse accompaned by very low blood pressure; norepinephrine-like drugs used in treating shock include metaraminol and ephedrine.

Drugs may also block the actions of neurotransmitters; atropine, for example, antagonizes acetylcholine at parasympathetic nerve endings. The effects of atropine include dilation of the pupils, inhibition of acid secretion in the stomach, delayed urination, and constipation. Atropine and related compounds (*e.g.*, tincture of belladonna, scopolamine, banthine, and pro-banthine), therefore, are used to relieve symptoms of peptic ulcer and diarrhea.

After their release, neurotransmitter substances are normally inactivated so that the muscle, the gland, or the neuron can recover and receive another stimulation. A drug may act to enhance neurotransmitter effects by blocking neurotransmitter inactivation; acetylcholine, for example, is inactivated by enzymatic breakdown catalyzed by acetylcholinesterase. Drugs that inhibit acetylcholinesterase (*e.g.*, edrophonium chloride, physostigmine, and neostigmine) enhance the effects of acetylcholine at voluntary muscles and are used to treat diseases involving muscular weakness (*e.g.*, myasthenia gravis).

Effects on emotions

In the brain, norepinephrine is localized in neuronal systems concerned with emotional behaviour. Stimulation of these systems produces effects (alertness and euphoria, a feeling of intense well-being) analogous to the alarm effects associated with norepinephrine release in the sympathetic nervous system. In contrast to the enzymatic inactivation of acetylcholine, norepinephrine, after its release from a nerve ending, is inactivated by being pumped back into the same nerve ending by a specialized transport system. Drugs that inhibit this pumping process potentiate the effects (alertness and euphoria) of norepinephrine and are called euphoriants or stimulants. Both amphetamine and the so-called tricyclic class of antidepressant drugs inhibit the norepinephrine pumping process, thus potentiating its effects after it is released from nerve endings.

Although norepinephrine can be broken down by at least two enzymes, it is not likely that enzymatic breakdown plays a major role in synaptic inactivation. But if the activity of these enzymes is inhibited, the concentration of norepinephrine at nerve endings increases; thus, a drug that inhibits the enzymatic breakdown of norepinephrine stimulates the central nervous system. The enzyme monoamine oxidase, for example, found in nerve endings containing norepinephrine and in many other sites in the body (*e.g.*, the liver), catalyzes a reaction in which the synaptic activity of norepinephrine is lost. Drugs that inhibit the action of monoamine oxidase also inhibit the breakdown of norepinephrine, resulting in its accumulation at nerve endings; such drugs may be used as antidepressants.

Drugs also stimulate the central nervous system by releasing norepinephrine directly from nerve endings or by mimicking the action of norepinephrine at receptor sites. Amphetamine, for example, releases norepinephrine and may also mimic it at receptors. Amphetamine may stimulate the central nervous system in one of three ways: by inhibiting the pumping process that inactivates norepinephrine, by causing direct release of norepinephrine at nerve endings, or by activating norepinephrine receptors.

Absorption, metabolism, and excretion. Monoamine-oxidase inhibitors are readily absorbed when given by mouth. Although present in the body only a short time, the drugs have long-lasting effects because they irreversibly inactivate monoamine oxidase. Termination of an inhibitor drug's effects occurs after several weeks, when the enzyme again is formed. Amphetamine and its derivatives are effective when given by mouth, may act for long periods, and may be found in high concentrations in the brain and in cerebrospinal fluid. Since many of these drugs are resistant to inactivation by liver enzymes, substantial amounts are excreted unchanged in the urine. Methylxanthines are absorbed readily after administration orally, rectally, or by injection. The rate of absorption depends on the specific compound—caffeine, theophylline, or theobromine—and the kind of administration used. The methylxanthines, which may be partially metabolized in the body, are excreted largely as methyluric acids or methylxanthines (about 10 percent).

Antidepressant drugs. Since their introduction about 1957, antidepressant drugs, also called psychic energizers, have had a significant influence in the treatment of depressed patients. There are two types: monoamine-oxidase inhibitor drugs and tricyclic antidepressant drugs. An important feature of antidepressant drugs is the delay (up to four weeks) in the onset of their action in patients receiving them.

Monoamine-oxidase inhibitor drugs. Discovered by accident, the first monoamine-oxidase inhibitor drug, iproniazid (Marsilid), was introduced as a drug similar in function to the antituberculotic drug isoniazid (see CHEMOTHERAPEUTIC DRUGS). The moods of patients receiving the drug were elevated more than their infections were relieved, and within a year, iproniazid was being used to elevate the mood of depressed patients. After the discovery that iproniazid could inhibit monoamine-oxidase activity, other inhibitor drugs with a wide range of chemical structures were developed; some of them resemble norepinephrine while others do not, but all manifest some degree of antidepressant activity. Five monoamine-oxidase inhibitor drugs are commonly used; these include isocarboxazid (Marplan), nialamide, phenelzine, tranylcypromine (Parnate), and pargyline (Eutonyl).

Since they are absorbed readily from the stomach, monoamine-oxidase inhibitor drugs are given orally. Although they remain in the body for only a short time, these drugs may inhibit the activity of monoamine oxidase for one to two weeks or until new monoamine-oxidase enzyme molecules are formed.

Toxic effects

Some persons receiving monoamine-oxidase inhibitor drugs suddenly develop very high blood pressure, sometimes with fatal consequences, after ingestion of certain foods containing large amounts of amines (*e.g.*, tyramine) that act as powerful blood-pressure-elevating agents. These amines, normally broken down by monoamine oxidase in the liver, circulate in the blood stream of patients receiving inhibitor drugs and cause an increase in blood pressure. Paradoxically, the most common side effect of monoamine-oxidase inhibitor drugs in patients on amine-free diets is low blood pressure; in fact, one monoamine-oxidase inhibitor drug, pargyline, is used primarily to lower blood pressure. The most severe side effect caused by the monoamine-oxidase inhibitor drugs is liver damage; for this reason, iproniazid is no longer used.

Tricyclic antidepressant drugs. The antidepressant properties of tricyclic antidepressant drugs were discovered by accident after they were introduced as drugs similar in chemical structure and function to phenothiazine drugs (antischizophrenic tranquillizers). Imipramine (Tofranil), the first tricyclic antidepressant drug,

soon was used to treat depressed patients, and the tricyclic drugs now are among the most effective antidepressant drugs known. In addition to imipramine, amitriptyline, desmethylimipramine, and nortriptyline (Aventyl) are used.

Tricyclic drugs may inhibit the inactivation of the norepinephrine-pumping process, thus potentiating the effects of norepinephrine. In persons not suffering from depression, the tricyclic antidepressant drugs cause lethargy and sedation, effects probably related to a tranquillizing action of the drugs. In treating depression the tricyclic antidepressant drugs relieve symptoms in a high proportion (about 70 percent) of patients, produce few side effects, and do not require the avoidance of specific foodstuffs; they generally are preferred to monoamine-oxidase inhibitor drugs. As with the monoamine-oxidase inhibitor drugs, the antidepressant action of tricyclic antidepressant drugs may not become apparent until two to four weeks after treatment is begun. The possible side effects of tricyclic antidepressant drugs include dry mouth, blurred vision, constipation, dizziness, and difficulty in urination.

Amphetamine and related stimulant drugs. Unlike the monoamine-oxidase inhibitor drugs and the tricyclic antidepressant drugs, amphetamine was produced intentionally as a drug with norepinephrine-like effects; unexpectedly, however, amphetamine proved to affect the central nervous system more than the peripheral nerves. Amphetamine was introduced in 1935 as a treatment for narcolepsy, a condition in which patients spontaneously fall asleep; eventually it also was used to overcome fatigue in soldiers and to treat obesity. In recent years, use of amphetamines and related drugs as euphoriants has been abused.

Amphetamine appears to exert its actions by potentiating norepinephrine released in the brain, as do the antidepressant drugs. Unlike antidepressant drugs, amphetamine can potentiate norepinephrine in more than one way, but stimulation of the direct release of norepinephrine from nerve endings is probably its major mode of action. Although amphetamine potentiates norepinephrine, it is not used as an antidepressant drug; in most cases, its use results in a deterioration of the condition of a psychotically depressed patient. The interactions of amphetamine with norepinephrine differ in subtle ways from those of the antidepressant drugs. One difference may be that antidepressant drugs potentiate norepinephrine normally released by nerve endings, while amphetamine causes release of norepinephrine.

Amphetamine derivatives

The amphetamine molecule is chemically asymmetric; *i.e.*, there are two different forms of amphetamine, one the mirror image of the other. Although each form has the same effect on blood pressure (small doses cause a slight increase), one of them, dextroamphetamine (Dexedrine), has much greater stimulant activity on the central nervous system than the other. Several drugs similar in structure and function to amphetamine are used primarily as dieting aids because they decrease the appetite; these include methamphetamine hydrochloride (Methedrine), benzphetamine (Didrex), phentermine (Ionamin), diethylpropion hydrochloride (Tenuate), phenmetrazine (Preludin), and phendimetrazine (Plegine).

In contrast to the lag in onset of action with the antidepressant drugs, the principal psychological effects of amphetamine occur within minutes after the drug is taken. Effects of amphetamine include increased alertness; decreased fatigue; elevation of mood; and increased initiative, confidence and ability to concentrate. Speech and activity also increase. Although intellectual sharpness is not increased by amphetamine or drugs related to it, physical performance is enhanced, presumably because the drugs decrease fatigue. Amphetamine and its derivatives now are used by soldiers, pilots, and astronauts on long-term missions; the apparent beneficial effects of amphetamine drugs (particularly dextroamphetamine and methamphetamine), however, have resulted in their use by many individuals who want pep pills. Although amphetamine's stimulation of the central nervous system and its appetite-decreasing effect were once thought to be closely linked, there is an amphetamine derivative, fenfluramine, that is a potent appetite suppressant but does not affect the central nervous system.

Disadvantages of amphetamine usage

The initial enthusiasm for amphetamine and related stimulant drugs was based largely on studies with single doses or short-term use by emotionally stable individuals. Only after these drugs were consumed extensively by many people did disadvantages become apparent. Tolerance to these stimulant drugs develops rapidly, so that progressively larger doses must be consumed. The letdown effect that occurs after stimulant effects have abated is most pronounced when a chronic user of a stimulant drug stops taking it; this effect also occurs, however, after a single dose of the drug has worn off. The letdown effect in chronic users often is a deep mental depression. In the 1960s, a pattern of stimulant-drug abuse developed. Intravenous injection—especially of the amphetamine derivative methamphetamine (Methedrine)—informally called speed, crystal, or meth—resulted in rapid development of tolerance, so that addicts soon required extremely large doses (500 milligrams compared with the usual medical dose of 5 to 10 milligrams).

After injection, methamphetamine produces a short-lasting feeling of euphoria, which is followed by a profound and long-lasting (up to several days) depression. The most severe aftereffect of large doses of amphetamine, administered either intravenously or orally, is amphetamine psychosis. Psychotic reactions, which may occur after drug withdrawal or during its usage, resemble those of paranoid schizophrenia. Amphetamine addiction is more common than can be accounted for by the relatively few cases of intravenous users called speed freaks. Patients who use amphetamine derivatives for dieting usually increase dosage as tolerance develops and then may require barbiturates to overcome the resultant insomnia. In these cases the danger of amphetamine psychosis is added to the threat of overdoses of either drug (see also DRUG PROBLEMS).

Amphetamines and hyperactive children

Amphetamine and its derivatives have had a major role in the management of hyperactive children. The hyperactivity syndrome apparently is a true disease that results from a delayed maturation of brain function. Children with this condition may have normal or superior intelligence but are unable to sit quietly or to concentrate. Amphetamine derivatives calm such children and enable them to concentrate, usually within a day after treatment is begun. Children with the syndrome can tolerate large doses, up to 40 milligrams of dextroamphetamine or methylphenidate (Ritalin), with few ill effects; such large doses make adults or nonhyperactive children jittery, sleepless, and unable to eat. There is no evidence thus far that amphetamine treatment of hyperactive children affects them adversely as they mature. Dextroamphetamine has been used in the treatment of narcolepsy and Parkinson's disease. Amphetamine and its derivatives, as previously noted, also are used in weight-reducing programs because they effectively decrease the appetite.

Methylxanthine stimulants: caffeine, theophylline, and theobromine. Methylxanthines are the active ingredients of coffee, tea, cocoa, and cola beverages that stimulate the central nervous system. Since billions of pounds of coffee, tea, and cocoa are consumed each year, caffeine, theophylline, and theobromine probably are the most widely used drugs.

The chemical structure of methylxanthines is similar to that of the purine bases adenine and guanine, which are components of nucleic acids (DNA and RNA) and uric acid, whose overproduction and precipitation into nodules accounts for the symptoms of gout. The three methylxanthines in foodstuffs, caffeine, theophylline, and theobromine, are derivatives of the purine base xanthine; caffeine has three methyl groups (carbon and three hydrogens), and theophylline and theobromine have two.

Stimulant content in various beverages

The principal methylxanthine in coffee and cola beverages is caffeine; tea contains theophylline and caffeine, and cocoa contains caffeine and considerable amounts of theobromine. Caffeine is the most potent methylxanthine stimulant. One cup of coffee or tea each contains the same amount of caffeine, about 100–150 milligrams.

Assuming that caffeine is the major stimulant ingredient in these beverages, coffee and tea should be equally active; tea, however, has a greater stimulant effect since it also contains theophylline, a weaker central nervous system stimulant. The major methylxanthine in cocoa (theobromine) has very little stimulant activity on the central nervous system, but an average cup of cocoa also contains 50 milligrams of caffeine. There are about 50 milligrams of caffeine in a 12-ounce glass of cola beverage.

The popularity of beverages containing methylxanthines appears to be related to their stimulant properties. In addition to allowing sustained intellectual effort and association of ideas, caffeine enhances discrimination of sensory stimuli, quickens reaction time, and decreases drowsiness and fatigue. The methylxanthines also are used in medicine. Caffeine has the most potent action, which is manifested in all parts of the brain, including centres that regulate respiration; therefore, caffeine is a valuable antidote to respiratory depression induced by drug overdose (*e.g.*, from morphine or barbiturates). The methylxanthines also facilitate breathing by relaxing the bronchioles in the lungs. Theophylline, the most active agent in producing these effects, is valuable for the management of severe asthma. The methylxanthines also enhance the production of urine by the kidneys and acid secretion by the stomach. The rate of the heartbeat and the total output of blood by the heart are stimulated by the methylxanthines, especially theophylline, which is used to treat congestive heart failure. Although the methylxanthines dilate most blood vessels, they constrict those of the brain; thus methylxanthines, especially caffeine, are useful in treating headaches caused by dilatation of blood vessels in the brain. Caffeine is a constituent of many nonprescription headache pills, which probably account for its most widespread medical use.

SNYDER, "New Developments in Brain Chemistry: Catecholamine Metabolism and the Action of Psychotropic Drugs," *Amer. J. Orthopsychiat.*, 37:864–879 (1967), a lucid review article, understandable to the layman, concerning ways in which drugs affect mental functioning by neurochemical interactions with neurotransmitters.

(S.H.S.)

Stockholm

Stockholm, the capital and largest city in Sweden, is situated at the outlet of Mälaren (Lake Mälar) on the Baltic. The city is built upon 22 islands as well as the mainland of Uppland and Södermanland. Stockholm is by virtue of its position regarded as one of the most beautiful capital cities in the world. The name means "the island at Stocksund." Stocksund was the old name for Norrström (North Stream)—the expanse of water by which Lake Mälar is connected with the Baltic.

The city, which was founded in the middle of the 13th century, came to be officially regarded as the capital in 1436. The Stockholm of today is the second largest city in Scandinavia (Copenhagen is the largest) and has a population of 746,560 (1970). A shortage of land reserves has resulted in a slow decrease in population in the city itself. Greater Stockholm, however, is rapidly expanding and in the early 1970s contained over 1,343,000 inhabitants. As a result of fortuitous developments in the last 100 years, Stockholm has no slum areas. The emblem of Stockholm is a picture of St. Erik, first recorded in 1376.

Layout and boundaries. The layout of the city is characterized to the north by the Stockholm Ridge, comprising Observatory Hill, Brunkeberg Ridge, and the higher areas of Stadsholmen (City Island). To the south there is a steeply sloping fault scarp: the Skinnarvik Hills and the Southern Hills. Stadsholmen, the oldest part of Stockholm, is surrounded to the north by the North Stream, to the south by the South Stream, to the west by Lake Mälar, and to the east by the Baltic.

The Old Town

The original nucleus of the city is the "city between the bridges"—Gamla Stan (Old Town), consisting of Stadsholmen, Helgeandsholmen (Island of the Holy Spirit), and Riddarholmen (Nobles' Island). The buildings in this area are primarily from the 16th and 17th centuries. The well-preserved medieval city nucleus, with the original old network of streets from the Middle Ages as well as a large portion of the buildings, is of great antiquarian and historical interest and is legally protected from change. Stadsholmen contains the Royal Palace, Storkyrkan, also known as the Cathedral or Church of St. Nicolas, the German Church, the House of Lords, the government offices, the Stock Exchange, and a number of other notable buildings. Riddarholmen is dominated by the Riddarholm Church. The House of Parliament and the National Bank are situated on Helgeandsholmen. The area of lower Norrmalm contains the Opera, the Concert House, the Foreign Ministry (the Palace of the Prince Royal), the Central Station, and the Central Post Office. The Blasieholm Peninsula is dominated by the National Museum and the Grand Hotel. Skeppsholmen (Ship Island), a naval base from the 17th century until 1960, now houses the Modern Museum and the East Asian Museum in the old naval buildings. Just to the east lies Kastelholmen, with its citadel and its salute battery.

The Vasa district (Vasastaden) contains a university area around the Observatory Hill (including buildings of the University of Stockholm, the Stockholm School of Commerce, and the City Library). Most foreign embassies are to be found in the Östermalm district. This district also contains the Ministry of Defense and other military administrative units. In the 1930s, blocks of modern apartment buildings were constructed in the district of Ladugårdsgärdet, or Gärdet, for many years a parade ground. Northern Djurgården contains the studios and offices of the Swedish Broadcasting Corporation as well as the TV tower (Kaknästornet), one of the tallest buildings in Scandinavia. South Djurgården, which takes the form mainly of a natural park, contains Skansen and the Nordic Museum, Liljevalchs Art Hall, Waldermarsudde, the Thielska Gallery, and Gröna Lund ("green arbour") with its amusement park, Tivoli. The oldest of the western districts of the city is Kungsholmen, with its famous City Hall, the Serafimer Hospital, the Central Police Station, and the City Court. The offices of two major newspapers are to be found in Marieberg. Södermalm (South Malm) is noted for its steep cliff facing the north.

The area between the southern parts of the original city island and Södermalm is called Slussen (the Sluice) because of the sluice in the South Stream here, which is used to regulate the outflow of Lake Mälar into the Baltic. This part of the city has well-preserved blocks of houses from the 17th and 18th centuries. Traffic is very heavy around Slussen, and the centre of the area consists of an internationally famous network of overpasses. Västerbron (Western Bridge), which connects Kungsholmen with the south, passes over Långholmen (well-known for its prison). The west, northwest, and the south all contain large complexes of houses and multistory apartment buildings. These areas have their own shopping centres, such as Appelviken, Vällingby, and Skärholmen. The outer suburbs also contain large office blocks for state enterprises, such as the Swedish Board of Telecommunications in Farsta and the National Power Administration in Råcksta.

Reconstruction of the city centre

The central parts of the city are undergoing reconstruction, and this contributes to the decrease in population of this area. Sergels Torg (Sergel Square) at lower Norrmalm will be the new city centre, containing a large complex of buildings for cultural purposes. The Sergel area also contains the largest concentration of department

Gamla Stan (Old Town), in central Stockholm, as seen from atop the City Hall. The openwork spire of the Riddarholm Church is on Riddarholmen (Nobles' Island) in the foreground. At the upper left are the Royal Palace and Storkyrkan, Stockholm's cathedral.
Refot—Rapho Guillumette

stores in Sweden as well as a number of new central bank "palaces." Stockholm proper, which includes the incorporated parishes of Bromma, Brännkyrka, and Spånga, also shows a general tendency toward a reduction in population. This is counterbalanced, however, by increases in Greater Stockholm; that is, the city together with the 17 other communities in the inner suburbs.

The environs of Stockholm, both toward Lake Mälar and toward the Baltic, are famous for their beauty. The Stockholm Archipelago, consisting of 10,000 islands of varying size, most of which are uninhabited, is especially worthy of note in this respect. The land area of Stockholm is 72 square miles (186 square kilometres). The area of Greater Stockholm amounts to 640,000 acres, with 224,000 acres of forest and 100,000 acres of arable land. An uncommon geographical feature of Stockholm is the blending of the city buildings with a natural landscape, which not even the city centre can entirely smother. Water, crags, and forest areas provide Greater Stockholm with a beautiful environment. No other city of comparable dimensions is dispersed over so wide an area as Greater Stockholm.

History. Lake Mälar has been the determining factor in the development of Stockholm. Its waters have been used since antiquity for communications and trade. Lillön (Little Island), also known as Helgö (Saints' Island), in Lake Mälar was inhabited as early as the first centuries AD. A township existed here for many centuries and had extensive international contacts. About 800, Birka on Björkö was founded—the first real town in Sweden. Birka, probably initially created by the indigenous royal family, developed gradually into an important trading centre with connections with both western Europe and Russia as well as with the Byzantine Empire. The first Christian town in Sweden was Sigtuna, which assumed Birka's previous role at the beginning of the 11th century. The German colonization of the coastal area from Holstein to the Weichsel resulted in a rapid expansion of trade in the Baltic.

The medieval period

According to the medieval Erik's chronicle, which was begun in about 1320, Birger Jarl was responsible for the building of the city, and this appears to be reliable. The name is first recorded in documents in 1252, at which time Stockholm seems to have existed as a town for only a short period; archaeological studies suggest that the first buildings on the island were scarcely of earlier origin than the latter part of the 13th century. There were, however, villages and farms nearby as early as Viking times.

The founding of Stockholm was in all probability one of the measures taken by the royal family in its attempts to maintain control over the whole country during a phase of opposition from the Separatists of Uppland, immediately to the north of the future city. It is clear that the rapid growth of the city was connected with a trade agreement made in about 1250 between Birger Jarl and the ambitious people of the German city of Lübeck. This agreement ensured the people of Lübeck freedom from customs charges for their trade in Sweden as well as the right to settle there. Political and military events centred upon Stockholm during the latter part of the Middle Ages, and the town fortifications were developed, especially by Gustav I. The town retained its medieval character until the first half of the 17th century. The old medieval castle was rebuilt during the later period of the Vasa dynasty (1521-1654) in order to serve as a centre for the government of the country. The tower was raised and was provided with a spire with three crowns.

Sweden's period as a great power in the 17th century resulted in a considerable increase in prestige for Stockholm. The first organized construction in the so-called malm areas immediately to the north and south of the original Stadsholmen took place during this period. Norrmalm was a town in its own right between 1602 and 1636. The Ladugård area was finally incorporated into Stockholm in 1682. Kungsholmen (until 1672, Munkläget) was donated by Queen Christina to the town.

A trade agreement of 1636 prohibited all towns north of Stockholm and Åbo from trading with foreign countries, so that trade might be concentrated in the capital. In 1634 Stockholm became an independent administrative unit governed by a lord mayor. The first incumbent of the office, Claes Fleming, initiated extensive rebuilding of the city; new town plans were developed and carried out in the Renaissance style.

When the medieval royal castle burned down in 1697, plans for a new palace were begun by the architect Nicodemus Tessin the Younger. Work was in progress for the greater part of the 18th century. The city changed little during the period from the death of Charles XII in 1718

until the coronation of Gustav III in 1772. Devastating fires, which struck the Klara district in 1751 and Södermalm in 1773 and 1759, accentuated the need for more careful regulations with respect to building activities. In commercial terms this period was extremely active for Stockholm. The large merchants financed the ironworks in Bergslagen and distributed their products to the European market. During the Gustavian period, from 1772–1809, Stockholm's position as the cultural centre of the country was clearly underlined. A number of architecturally excellent buildings and city areas were built during this period.

City improvements in the 19th century

Stockholm had earned a very bad reputation for poor hygiene during the first half of the 19th century. But the introduction of municipally organized cleaning (1859) and sanitation (1861) and other sanitary arrangements during the latter half of the 19th century radically changed the situation and contributed to a rapid increase in population. The city began to be redesigned according to the French and German pattern, on the basis of a general outline proposed in the Lindhagen city plan (after the legal administrator and town planner Albert Lindhagen).

In 1860 Stockholm received its first railway connection with the south and west of Sweden and thereby also with the rest of Europe, which countered the previous provincialism. The Central Station was completed in the city centre in 1871, and the railway lines to the north and south of Stockholm could then be linked up. The last three decades of the 19th century saw further innovations, such as street cars, telephones, gas, and electricity.

The prominent ridge of Brunkeberg, which runs in a north–south direction through Norrmalm, for many years prevented a consistent application of town planning and impeded communications through the centre in an east–west direction. It was not until 1911 that the first broad street was excavated through the ridge; this was Stockholm's famous Kungsgatan, which in the 1970s was a centre for wholesale and retail trade. The first skyscraper in Sweden and Europe was built here in 1923—Northern Kungstornet.

Population. It is impossible to make an exact computation of the population of the city during the Middle Ages and the 16th century. It has been estimated that the population at the beginning of the 16th century was about 7,000. The number would appear to have increased to about 15,000 a century later. The population increased very rapidly during the 17th century, culminating in about 1675 at a level of 50,000-55,000. Population growth was directly related to the commercial revolution during the 17th and 18th centuries.

Until the 1860s the number of deaths was greater than that of births, so that population increases could come only from other areas. Infant mortality in Stockholm was considerably higher than in the rest of the country. Thirty-five percent of all children died before their first birthday in the first decade of the 19th century, and the figure was still more than 25 percent as late as 1880. It was not until the 1920s that the figure for Stockholm was reduced to the level for the country as a whole. In 1900 the city had 300,000 inhabitants, and in 1922 the half-million mark was passed. Stockholm attained its largest population of 808,000 in 1961. This population has been decreasing by 5,000 to 10,000 annually in recent years, and this reduction is expected to continue. Vacant lots for building purposes are very limited. The city centre has decreased in population since the end of the 1930s.

Principal manufactures

Economic life. Stockholm is Sweden's leading industrial area, although it is not normally regarded as an industrial city. Industries of special importance are metal and machine manufacturing, paper and printing, foodstuffs, and chemicals. Stockholm also possesses the country's largest wholesale stores, and the city accounts for about 20 percent of the total retail trade in Sweden. Banks and insurance companies are also concentrated around Stockholm. In addition, many large industrial concerns are situated in neighbouring administrative districts.

Stockholm is the second largest port in Sweden, Göteborg being the first. The total length of quays is about 12 miles. The most important harbours are Skeppsbron, which handles traffic to Finland; Stadsgårdskajen; Värta Harbour; the Free Harbour and Oil Harbour at Loudden in Lilla Värtan; and the Hammarby Harbour to the south.

Transport. Public transport is provided by a large number of bus lines and a well-developed underground system. The underground network consists of 39.3 miles, of which 14 miles are actually underground. Traffic to the more peripheral outer areas is handled primarily by means of modern commuter trains. Stockholm is also the starting point for four main railway lines: Stockholm-Malmö, Stockholm-Göteborg, Stockholm-Ånge, and the Västerås line.

A number of impressive bridges and motorways have been constructed to ease the complicated traffic conditions that result from Stockholm's unusual position on a large number of islands. The Essinge Motorway (Essingeleden) brings automobile traffic from the west of Kungsholmen at Fredhäll by means of two bridges over Lake Mälar at Essingen to Nyboda and Brännkyrka, where it links up with European Highway No. 4. The Huvudsta Motorway provides facilities for traffic toward the north and west. Bridges to the south are at Skanstull, Danvikstull, and Liljeholmen, with Årsta Bridge being reserved for railway traffic. The city centre is connected with the western districts of the city by the Traneberg Bridge.

Stockholm's airport Arlanda, near Märsta in Uppland, has a worldwide network of connections. Domestic and charter flights as well as private flights have Bromma Airport as their base. Stockholm's radio and television transmitters are situated in Nacka to the west of the city.

Administration and cultural life. *Local government.* Stockholm is administratively incorporated in Stockholm County. The city courts in Stockholm are lower courts. The courts have 24 departments and consist of the mayor, 79 magistrates, and a number of extra magistrates and judges, together with 1,000 jurors appointed by the City Council.

Municipal decision making is conducted by the City Council's 100 members. The administration is run by the Central Board of Administration (12 members), which is divided into nine sections, each under the supervision of a commissioner. The head of the financial section, the economic commissioner, is chairman of the Commissioners' council, which prepares matters to be dealt with in the City Council and attempts to achieve uniform principles in the administration. A number of councils, boards, and administrative units are responsible for day-to-day administration.

Stockholm County consists not only of Stockholm but also of 50 communities surrounding the capital. The county is administered by a County Council of 149 elected members. The Council is responsible for matters concerning regional policy, medical services, collective traffic, and housing. The state is represented in the county by means of a county governor whose residence is in Stockholm.

Religion. In addition to the Evangelical Lutheran State Church, there are a number of other churches and denominations to be found in Stockholm, such as Protestant free churches, Roman Catholic and Greek Orthodox churches, and Jewish rites. The vast majority of Stockholmers are members of the official state church.

Education. Stockholm is the largest educational centre in Sweden. In addition to the University of Stockholm, the city's colleges and universities include the College of Gymnastics and Sports, Stockholm School of Commerce, Caroline Medical Institute, an art college, a teachers' training college, a college of music, a school of forestry, a college of dentistry, Institute of Technology, and a veterinary college. The university is gradually being moved to Freskati, a campus 2½ miles to the north of the city. The transfer is expected to be completed by the end of the 1970s.

There are a number of learned academies and scientific institutions based in Stockholm. The most important are

the Royal Academy of Sciences, founded in 1739; the Royal Academy of Letters, History and Antiquities; and the Swedish Academy, founded in 1786.

Newspapers. Several newspapers are published in Stockholm. They include *Dagens Nyheter*, the largest morning paper in the country, and the evening paper *Expressen*, which is the largest in Scandinavia.

Music and theatre. The musical life of Stockholm is dominated by the Royal Theatre (the opera), the Concert Association (Stockholm Philharmonic Orchestra), and the Swedish Broadcasting Corporation, which has its own symphony orchestra. The leading theatres are the Royal Dramatic Theatre and the City Theatre. Regular opera performances are given during the summer in the Drottningholm Theatre, situated by the Royal Palace of Drottningholm to the west of the city. This theatre, which has been preserved intact since the 1760s, is unique in Europe by virtue of its original decorations.

BIBLIOGRAPHY. The extensive literature on Stockholm is mainly in Swedish. A number of more recent scholastic works have, however, been provided with English or German summaries. In English, see ELSPETH HARLEY SCHUBERT, *Brief Encounter with Stockholm* (1965); and TORD OLSSON NORDBERG, *Buildings and Monuments in Stockholm: A Short History and 8 Excursions* (1949). The latter provides a good account of the historical development of the city and a detailed description of important areas of the city and of its buildings.

(H.S.A.)

Stoicism

Stoicism, a school of thought that flourished in Greek and Roman antiquity, was one of the loftiest and most sublime philosophies in the record of Western civilization. In urging participation in the affairs of man, Stoics have always believed that the goal of all inquiry is to provide man with a mode of conduct characterized by tranquillity of mind and certainty of moral worth.

NATURE AND SCOPE OF STOICISM

For the early Stoic philosopher, as for all the post-Aristotelian schools, knowledge and its pursuit are no longer held to be ends in themselves. The Hellenistic Age was a time of transition, and the Stoic philosopher was perhaps its most influential spokesman. A new culture was in the making. The heritage of an earlier period, with Athens as its intellectual leader, was to continue, but to undergo many changes. If, with Socrates, to know is to know oneself, rationality as the sole means by which something outside of the self might be achieved may be said to be the hallmark of Stoic belief. As a Hellenistic philosophy, Stoicism presented an *ars vitae*, a way of accommodation for people to whom the human condition no longer appeared as the mirror of a universal, calm, and ordered existence. Reason alone could reveal the constancy of cosmic order and the originative source of unyielding value; thus, reason became the true model for human existence. To the Stoic, virtue is an inherent feature of the world, no less inexorable in relation to man than are the laws of nature.

Fundamental tenets

The Stoics believed that perception is the basis of true knowledge. In logic, their comprehensive presentation of the topic is derived from perception, yielding not only the judgment that knowledge is possible but also that *certain* knowledge is possible, on the analogy of the incorrigibility of perceptual experience. To them, the world is composed of material things, with some few exceptions (*e.g.*, meaning), and the irreducible element in all things is right reason, which pervades the world as divine fire. Things, such as material, or corporeal, bodies, are governed by this reason or fate, in which virtue is inherent. The world in its awesome entirety is so ruled as to exhibit a grandeur of orderly arrangement that can only serve as a standard for mankind in the regulation and ordering of his life. Thus, the goal of man is to live according to nature, in agreement with the world design. Stoic moral theory is also based on the view that the world, as one great city, is a unity. Man, as a world citizen, has an obligation and loyalty to all things in that city. He must play an active role in world affairs, remembering that the world exemplifies virtue and right action. Thus, moral worth, duty, and justice are singularly Stoic emphases, together with a certain sternness of mind. For the moral man is neither merciful nor shows pity, because each suggests a deviation from duty and from the fated necessity that rules the world. Nonetheless—with its loftiness of spirit and its emphasis on man's essential worth—the themes of universal brotherhood and the benevolence of divine nature make Stoicism one of the most appealing of philosophies.

Rival schools in antiquity

Its chief competitors in antiquity were: (1) Epicureanism, with its doctrine of a life of withdrawal in contemplation and escape from worldly affairs and its belief that pleasure, as the absence of pain, is the goal of man; (2) Skepticism, which rejected certain knowledge in favour of local beliefs and customs, in the expectation that these guides would provide man with the quietude and serenity that the dogmatic philosopher (*e.g.*, the Stoic) could not hope to achieve; and (3) Christianity, with its hope of personal salvation provided by an appeal to faith as an immanent aid to human understanding and by the beneficent intervention of a merciful God.

Along with its rivals, Stoicism enabled the individual to better order his own life and to avoid the excesses of human nature that promote disquietude and anxiety. It was easily the most influential of the schools from the time of its founding through the first two centuries AD, and it continued to have a marked effect on later thought. During the late Roman and medieval periods, elements of Stoic moral theory were known and used in the formulation of Christian, Jewish, and Muslim theories of man and nature, of the state and society, and of law and sanctions—*e.g.*, in the works of Marcus Cicero, Roman statesman and orator; in Lactantius, often called the "Christian Cicero"; and in A.M.S. Boethius, a scholar transitional to the Middle Ages. In the Renaissance, Stoic political and moral theory became more popular to theorists of natural law and politcal authority and of educational reform—*e.g.*, in Hugo Grotius, a Dutch jurist and statesman, and in Philipp Melanchthon, a major Reformation scholar. More recently, Stoicism has become popular again for its insistence on the value of the individual and the place of value in a world of strife and uncertainty —*e.g.*, in Existentialism and in Neo-orthodox Protestant theology. Stoicism also plays an important role in reassessments of the history of logic—*e.g.*, in Jan Łukasiewicz, a Polish logician, and in William and Martha Kneale, mid-20th-century British logicians.

ANCIENT STOICISM

Historical and philosophical setting

Early Greek Stoicism. With the death of Aristotle (322 BC) and that of Alexander the Great (323 BC), the greatness of the life and thought of the Greek city-state (polis) ended. With Athens no longer the centre of worldly attraction, its claim to urbanity and cultural prominence passed on to other cities—to Rome, to Alexandria, and to Pergamum. The Greek polis gave way to larger political units; local rule was replaced by that of distant governors. The earlier distinction between Greek and barbarian was destroyed; provincial and tribal loyalties were broken apart, first by Alexander and then by Roman legions. The loss of freedom by subject peoples further encouraged a deterioration of the concept of the freeman and resulted in the rendering of obligation and service to a ruler whose moral force held little meaning. The earlier intimacy of order, cosmic and civic, was now replaced by social and political disorder; and traditional mores gave way to uncertain and transient values.

Stoicism had its beginnings in a changing world, in which earlier codes of conduct and ways of understanding proved no longer suitable. But it was also influenced by tenets of the older schools. The earliest Greek philosophers, the Milesians, had called attention to cosmic order and the beauty of nature. Later, the monist Parmenides of Elea stressed the power of reason and thought, whereas Heracleitus of Ephesus, precursor of the philosophy of becoming, had alluded to the constancy of change and the omnipresence of divine fire, which illumined all things. A deeper understanding of man himself came with Socrates,

symbol of the philosophic man, who personified *sophia* and *sapientia* (Greek and Latin: "wisdom"). Of the several schools of philosophy stemming from Socrates, the Cynic and Megarian schools were influential in the early development of Stoic doctrine: the Cynics for their emphasis on the simple life, unadorned and free of emotional involvement; and the Megarians for their study of dialectic, logical form, and paradoxes.

The Early Stoa

Stoicism takes its name from the place where its founder, Zeno of Citium (Cyprus), customarily lectured—the Stoa Poikile (Painted Colonnade). Zeno, who flourished in the early 3rd century BC, showed in his own doctrines the influence of earlier Greek attitudes, particularly those mentioned above. He was apparently well versed in Platonic thought, for he had studied at Plato's Academy both with Xenocrates of Chalcedon and with Polemon of Athens, successive heads of the Academy. Zeno was responsible for the division of philosophy into three parts: logic, physics, and ethics. He also established the central Stoic doctrines in each part, so that later Stoics were to expand rather than to change radically the views of the founder. With some exceptions (in the field of logic), Zeno thus provided the following themes as the essential framework of Stoic philosophy: logic as an instrument and not as an end in itself; human happiness as a product of life according to nature; physical theory as providing the means by which right actions are to be determined; perception as the basis of certain knowledge; the wise man as the model of human excellence; Platonic Ideas—or the abstract Forms that things of the same genus share—as being unreal; true knowledge as always accompanied by assent; the fundamental substance of all existing things as being a divine fire, the universal principles of which are (1) passive (matter) and (2) active (reason inherent in matter); belief in a world conflagration and renewal; belief in the corporeality of all things; belief in the fated causality that necessarily binds all things; cosmopolitanism, or cultural outlook transcending narrower loyalties; and man's obligation, or duty, to choose only those acts that are in accord with nature, all other acts being a matter of indifference.

Cleanthes of Assos, who succeeded Zeno as head of the school, is best known for his *Hymn to Zeus*, which movingly describes Stoic reverence for the cosmic order and the power of universal reason and law. The third head of the school, Chrysippus of Soli, who lived to the end of the 3rd century, was perhaps the greatest and certainly the most productive of the early Stoics. He devoted his considerable energies to the almost complete development of the Zenonian themes in logic, physics, and ethics. In logic particularly, he defended against the Megarian logicians and the Skeptics such concepts as certain knowledge, comprehensive presentation, proposition and argument, truth and its criterion, and assent. His work in propositional logic, in which unanalyzed propositions joined by connectives are studied, made important contributions to the history of ancient logic and is of particular relevance to more recent developments in logic.

In physics, Chrysippus was responsible for the attempt to show that fate and free will are not mutually exclusive conceptual features of Stoic doctrine. He further distinguished between "whole" and "all," or "universe," arguing that the whole is the world, while the all is the external void together with the world. Zeno's view of the origin of man as providentially generated by "fiery reason" out of matter was expanded by Chrysippus to include the concept of self-preservation, which governs all living things. Another earlier view (Zeno's), that of nature as a model for life, was amplified first by Cleanthes and then by Chrysippus. The Zenonian appeal to life "according to nature" had evidently been left vague, because to Cleanthes it seemed necessary to speak of life in accord with nature conceived as the world at large (the cosmos), whereas Chrysippus distinguished between world nature and human nature. Thus, to do good is to act in accord with both human and universal nature. Chrysippus also expanded the Stoic view that seminal reasons were the impetus for animate motion.

He established firmly that logic and (especially) physics are necessary and are means for the differentiation of goods and evils. Thus, a knowledge of physics (or theology) is required before an ethics can be formulated. Indeed, physics and logic find their value chiefly in this very purpose. Chrysippus covered almost every feature of Stoic doctrine and treated each so thoroughly that the essential features of the school were to change relatively little after his time.

The Middle Stoa

Later Roman Stoicism. The Middle Stoa, which flourished in the 2nd and early 1st centuries BC, was dominated chiefly by two men of Rhodes: Panaetius, its founder, and his disciple Poseidonius. Panaetius organized a Stoic school in Rome before returning to Athens, and Poseidonius was largely responsible for an emphasis on the religious features of the doctrine. Both were antagonistic to the ethical doctrines of Chrysippus, who, they believed, had strayed too far from the Platonic and Aristotelian roots of Stoicism. It may have been because of the considerable time that Panaetius and Poseidonius lived in Rome that the Stoa there turned so much of its emphasis to the moral and religious themes within the Stoic doctrine. Panaetius was highly regarded by Cicero, who used him as a model for his own work. Poseidonius, who had been a disciple of Panaetius in Athens, taught Cicero at his school at Rhodes and later went to Rome and remained there for a time with Cicero. If Poseidonius admired Plato and Aristotle, he was particularly interested—unlike most of his school—in the study of natural and providential phenomena. In presenting the Stoic system in the second book of *De natura deorum* (45 BC), Cicero most probably followed Poseidonius. Because his master, Panaetius, was chiefly concerned with concepts of duty and obligation, it was his studies that served as a model for the *De officiis* (44 BC) of Cicero. Hecaton, another of Panaetius' students and an active Stoic philosopher, also stressed similar ethical themes.

If Chrysippus is to be commended for his diligence in defending Stoic logic and epistemology against the Skepticism of the New Academy (3rd–2nd century BC), it was chiefly Panaetius and Poseidonius who were responsible for the widespread popularity of Stoicism in Rome. It was precisely their turning of doctrine to themes in moral philosophy and natural science that appealed to the intensely practical Romans. The times perhaps demanded such interests, and with them Stoicism was to become predominantly a philosophy for the individual, showing how—given the vicissitudes of life—one might be stoical. Law, world citizenship, nature, and the benevolent workings of Providence and the divine reason were the principal areas of interest of Stoicism at this time.

The Late Stoa

These tendencies toward practicality are also well illustrated in the later period of the school (in the first two centuries AD) in the writings of Lucius Seneca, a Roman statesman; of Epictetus, a slave freed by Nero; and of Marcus Aurelius, a Roman emperor. Both style and content in the *Libri morales* (Eng. trans., *Moral Essays*) and *Epistulae morales* (*Moral Letters*) of Seneca reinforce the new direction in Stoic thought. The *Encheiridion* (*Manual*) of Epictetus and the *Meditations* of Marcus Aurelius furthered the sublime and yet personal consolation of the Stoic message and increasingly showed the strength of its rivalry to the burgeoning power of the new Christianity. The mark of a guide, of the religious teacher, is pre-eminent in these writings. It is difficult to establish with any precision, however, the extent of Stoic influence by the time of the first half of the 2nd century AD. So popular had these ideas become that many specifically Stoic terms (viz., right reason, comprehension, assent, indifference, *logos*, natural law, and the notion of the wise man) commonly were used in debate and intellectual disputes.

Stoic elements in Pauline and patristic thought. There is much disagreement as to the measure of Stoic influence on the writings of St. Paul, the Apostle of Christ. At Tarsus, Paul certainly had opportunities for hearing Stoic lectures on philosophy. And it may be that his discussion of nature and the teaching of it (I Cor. 11:14) is Stoic in origin, for it has a parallel in the *Manual* of Epictetus 1.16, 10. Although not a Stoic technical term, *syneidēsis*,

which Paul used as "conscience," was generally employed by Stoic philosophers. In I Cor. 13 and in the report of Paul's speech at Athens (Acts 17), there is much that is Hellenistic, more than a little tinged by Stoic elements—*e.g.*, the arguments concerning man's natural belief in God and the belief that man's existence is in God.

The assimilation of Stoic elements by the Church Fathers was generally better understood by the 4th century. Stoic influence can be seen, for example, in the relation between reason and the passions in the works of St. Ambrose, one of the great scholars of the church, and of Marcus Minucius Felix, a Christian Apologist. Each took a wealth of ideas from Stoic morality as Cicero had interpreted it in *De officiis*. In general, whereas the emerging Christian morality affirmed its originality, it also assimilated much of the pagan literature, the more congenial elements of which were essentially Stoic.

Stoic concepts in Tertullian and Origen

Earlier, in the 3rd century, Quintus Tertullian, often called the father of Latin Christian literature, seems to have been versed in Stoic philosophy; *e.g.*, in his theory of the agreement between the supernatural and the human soul, in his use of the Stoic tenet that from a truth there follow truths, and in his employment of the idea of universal consent. Even in his polemical writings, which reveal an unrelenting hostility to pagan philosophy, Tertullian showed a fundamental grasp and appreciation of such Stoic themes as the world *logos* and the relation of body to soul. This is well illustrated in his argument against the Stoics, particularly on their theme that God is corporeal being and identified with reason as inherent in matter—also to be found in his polemics against Marcion, father of a heretical Christian sect, and against Hermogenes of Tarsus, author of an important digest of rhetoric. Yet in his doctrine of the Word, he appealed directly to Zeno and Cleanthes of the Early Stoa. Another important polemic against the Stoics is found in the treatise *Contra Celsum*, by Origen, the most influential Greek theologian of the 3rd century, in which he argued at some length against Stoic doctrines linking God to matter.

Also, St. Cyprian, bishop of Carthage in the 3rd century, revealed the currency of Stoic views; *e.g.*, in his *Ad Demetrianum*, a denunciation of an enemy to Christianity, in which Cyprian castigates the ill treatment of slaves, who, no less than their masters, are formed of the same matter and endowed with the same soul and live according to the same law. The beliefs in the brotherhood of man and in the world as a great city, commonly found in early Christian literature, were current Stoic themes. The Christian attitude appears in what St. Paul said of Baptism: "You are all sons of God through Faith. For as many of you as were baptized into Christ have put on Christ" (Gal. 3:26–27).

STOICISM IN MEDIEVAL AND MODERN PHILOSOPHY

Stoic undercurrents in medieval thought. During the period when Christian institutions and doctrines were developing (AD 230–1450), Stoicism continued to play a popular role. The *De consolatione philosophiae* (524) of Boethius (died AD 524/525) was widely known and appreciated as a discourse on the mysterious questions of the nature of good and evil, of fortune, chance, or freedom, and of divine foreknowledge. If the plan of Boethius was to serve as an interpreter of Plato and Aristotle, he succeeded only in working through some logical theories of Aristotle, together with several commentaries on those theories. In the *Consolatione*, however, the themes are quite different; in the fifth book, for example, he attempted to resolve the apparent difficulty of reconciling human freedom with the divine foreknowledge, a problem that among Stoic thinkers—though by no means uniquely among them—had been in general currency for a long time. This work of emancipation from worldly travail through the glories of reason and philosophy, which included Stoic doctrines as found in the writings of Cicero and Seneca, was much more influential for later medieval thought than that of Lactantius, of the late 3rd to early 4th century, who was largely concerned with the writing of a history of religion—a summary statement of Christian doctrine and life from earliest times. Lactantius also wrote a not unimportant work, *De ira Dei* (313), on the possibility of anger in God. It poses a problem of how to deal with the essentially Greek, or philosophic, view that God cannot feel anger because he is not subject to passions and that *apatheia* ("apathy," or "imperturbableness") is not merely the mark of the wise man but is also a divine attribute. This view, which had been most thoroughly developed among Stoic thinkers and particularly by Epictetus, raised a peculiarly Christian problem, the concern of the power of God to reward the righteous and punish the transgressor; thus, it challenged the very idea of Providence. Other manifestations of anthropopathism, the attributing of human feelings to God, had also been charged against the early Christian religionists; and the writers of the time—Lactantius and Tertullian among them—took great pains to refute the largely Stoic formulations of these charges. Although the refutations took the form—in St. Augustine, for example—of denying that the wrath of God is a perturbation of the soul and of holding that it is rather a judgment, the concept of the divine essence excludes all passions. Within the monastic tradition, there remained more than a residue of concern over apathy as a divine attribute and as a model for the truly religious.

Stoicism in legal and political theory

Other significant Stoic influences appeared in medieval discussions of the popular origin of political authority, *res publica* and *res populi*, and on the distinctions made in law between *jus naturale, jus gentium, jus civile*—doctrines of Stoic origin—found in 3rd-century Roman juridical texts gathered together by Isidore of Seville (died AD 636), a Spanish encyclopaedist and theologian. The Stoic belief—as against Aristotle—that men are by nature equal was an integral part of the knowledge that certain rules of law are universally recognized, laws that all people might naturally follow. In this way, the Romans—whose genius lay in organization and in law—fostered the conception of natural, or common, law, which reason was supposed to make evident to all men. Thus, in the second half of the 11th century, the Stoic texts of Cicero and Seneca became important doctrinal sources for the initial discussions of social and political philosophy. These early theories of law, of the natural equality of men, and of the rights of prince and populace were to become the basis for 13th-century systems of social and political privilege and obligation.

In the 12th century, John of Salisbury, an English critical scholar, produced, in his *Policraticus* (1159), the first complete attempt at a philosophy of the state since Classical times. Stoic doctrines of natural law, society, state, and Providence were important elements in his effort to construct a social philosophy on ethical and metaphysical principles. The impact of these doctrines and the lengthy history of their use in the earlier Middle Ages can also be found in the views of Thomas Aquinas on the philosophy of the state and of man.

Renascence of Stoicism in modern times. If the influence of Stoic doctrines during the Middle Ages was largely restricted to the resolution of problems of social and political significance, it remained for the Renaissance, in its passion for the rediscovery of Greek and Roman antiquity, to provide a basis for the rebirth of Stoic views in logic, epistemology, and metaphysics, as well as the documentation of the more familiar Stoic doctrines in ethics and politics. Late in the 16th century, Justus Lipsius, a Flemish scholar and Latin Humanist, was responsible for the first restatement of Stoicism as a defensible and thoroughgoing (Christian) philosophy of man. His treatises *De constantia* (1584) and *Politicorum sive civilis doctrinae libri V* (1589) were widely known in many editions and translations. His defense of Stoic doctrine in *Manuductio ad Stoicam Philosophiam* (1604) and *Physiologia Stoicorum* (1604) provided the basis for the considerable Stoic influence during the Renaissance. Around the turn of the 17th century, Guillaume du Vair, a French lawyer and Christian philosopher, made Stoic moral philosophy popular, while Pierre Charron, a French theologian and Skeptic, utilized Stoic themes in *De la sagesse* (1601; Eng. trans., *Of Wisdome*, 1608), as did the Skep-

Stoic concepts in Lipsius and certain Skeptics

tic Michel de Montaigne in his *Essais* (1580; Eng. trans., 1603). Through the work of Lipsius, Stoic doctrines were to influence the thought of Francis Bacon, a precursor of modern philosophy of science, and, later, the *De l'esprit des lois* (1748; Eng. trans., *The Spirit of Laws*, 1750), by the political theorist Charles-Louis, baron de Montesquieu. In the continuing and relentless war against the Aristotelianism of the later Middle Ages, the doctrines of Stoicism influenced many prominent figures of the Renaissance and Reformation periods.

Pietro Pomponazzi, an Aristotelian of early-16th-century Italy, in defending an anti-Scholastic Aristotelianism against the Averroists, who viewed the world as a strictly necessitarian and fated order, adopted the Stoic view of Providence and human liberty. The 15th-century Humanist Leonardo Bruni absorbed Stoic views on reason, fate, and free will. Pantheism, the view that God and nature are unitary in the sense that God is an impersonal being, and naturalism, the view that nothing is supernatural, both of which identify God with the cosmos and ascribe to it a life process of which the world soul is the principle, were widely held Renaissance notions. Such a pantheistic naturalism was advocated—though from diverse standpoints—by Francesco Patrizi, a versatile Platonist, and by Giordano Bruno, defender of an infinite cosmos; and in both authors the inspiration and source were fundamentally Stoic. In the development of a philosophy of public law based upon a study of man, Stoic elements are found in the *Utopia* (1516; Eng. trans., 1551), by Thomas More, and the *De Jure Belli ac Pacis* (1625; Eng. trans., 1682), by Hugo Grotius. This latter work is one of the most famous Renaissance treatises on the theory of natural and social rights.

The foremost Swiss reformer of the early 16th century, Huldrych Zwingli, who regarded justification by subjective belief as the foundation of the new Christianity, utilized Stoic views on the autonomy of the will, on the absolute predestination of the good and evil man, and on moral determinism.

Another Stoic influence of considerable importance in the tradition of Christian Humanism was the view that all religions have a common basis of truths concerning God —a universal Deism. Among those who favoured such a view were Zwingli and Desiderius Erasmus, the great Renaissance Humanist and scholar. More and Grotius also laid special stress on this view, and its influence was felt in the moral, social, and even the artistic life of the 16th century. Later, Herbert of Cherbury, often called the father of Deism, further developed the idea of religious peace and the reduction of opposing religious views to common elements. This view became one of the most popular ideas of the 17th century.

Philipp Melanchthon also cultivated Humanism and the philosophy of antiquity as a basis for a reborn Christianity. Although Aristotle was his chief inspiration, Melanchthon made telling use of the Stoic theory of knowledge, with its notions of innate principles and the natural light of reason, which teach man the great truths of metaphysical and moral order. Stoicism thus became the basis for the natural-law theory, which holds that the state is of immediately divine origin and independent of the church —a Protestant view opposed by Catholic writers.

Stoic concepts in Cartesian and Spinozistic thought

The Cartesian revolution in thought in the 17th century brought forward several Stoic notions: that morality consists of obedience to the law of reason, which God has deposited within man; that ethics presupposes a knowledge of nature, because man must learn to know his place in the world, for only then may he act rightly; that self-examination is the foundation of ethics; and that the innateness and commonality of truths bespeak the view that only thoughts and the will belong properly to man, for the body is a part of the material world. Such views were particularly developed by René Descartes, often hailed as the father of modern philosophy, in his dualism of mind (or soul) and body.

Benedict de Spinoza, a freethinking Jewish Rationalist, made similar use of Stoic views on the nature of man and the world. That aspect of Spinoza's thought that is debatably labelled pantheist is essentially Stoic in character. Together with the Cartesians, Spinoza insisted upon the importance of internal and right reason as the sole means by which to attain to indubitable truths and to the possibility of human freedom.

Blaise Pascal, a French scientist and religious writer, also was sympathetic to Cartesian conceptions of man and nature. Though he turned his back on philosophy, his religious thought retained the Cartesian and Stoic insistence on the independence of human reason, holding that man is fundamentally a thinking being, innately capable of making right decisions. There is an important and crucial difference and conflict between Pascal's views and those of Spinoza and the Cartesians: for Pascal, though the use of (the Stoic) right reason might result in proofs and demonstrations that lead to the God of truth, it would never lead to the God of love, the one true God. Thus, the Stoic exaltation of reason to an entity in its own right—indeed, to a divine entity—as exemplified among the Cartesians and in the thought of Spinoza, was rejected by Pascal in the Jansenist Christianity that he finally adopted—a rejection that, because it also repudiated free will, distinguishes Pascal from those who held Stoic as well as alternative conceptions of human freedom and responsibility.

Stoic concepts in Christianity and modern philosophical thought

Christianity in general, in spite of striking contrasts with Stoicism, has found elements within it that parallel its own position. As the Stoic, for example, feels safe and protected in the rational care of some immanent Providence, so the Christian senses that a transcendent though incarnate and loving God is looking after him. And in general, Stoicism has played a great part throughout the ages in the theological formulation of Christian thought as well as in the actual realization of the Christian ideals.

Contemporary philosophy has borrowed from Stoicism, at least in part, its conviction that man must be conceived as being closely and essentially connected with the whole universe. And contemporary Humanism still contains some obviously Stoic elements, such as its belief in the solidarity of all peoples based upon their common nature, and in the primacy of reason. It is perhaps just because Stoicism has never become a full-fledged philosophic system that, many centuries after the dissolution of the Stoic school, fundamental themes of its philosophy have emerged again and again, and many have become incorporated into modern thinking.

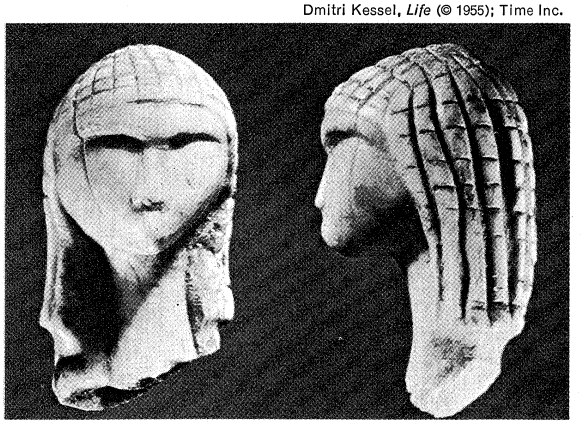
Stone Age European Peoples, Arts of



The earliest known example of something definable as art dates from the appearance of Cro-Magnon man (*Homo sapiens*) in the last glacial and post-glacial phases of the Paleolithic period (32,000–10,000 BC). Subsequent phases of the arts of the Stone Age peoples include the Mesolithic, which began around 10,000 BC, and the Neolithic, which began around 6,500 BC in the eastern Mediterranean area and around 3,000 BC in Spain and northern Europe. Although other peoples passed through similar phases of Stone Age culture, this article includes coverage only of the arts of Stone Age European peoples. Arts of Stone Age Asian peoples are treated in history articles and in SOUTHEAST ASIAN PEOPLES, ARTS OF; SOUTH ASIAN PEOPLES, ARTS OF; and CENTRAL ASIAN PEOPLES, ARTS OF. The arts of the Stone Age American Indian, African, and Oceanic peoples are dealt with in AMERICAN INDIAN, ARTS OF; AFRICAN PEOPLES, ARTS OF; OCEANIC PEOPLES, ARTS OF.

UPPER PALEOLITHIC AND MESOLITHIC AGES

Although throughout the Paleolithic period (from about 600,000 or 700,000 years ago until about 10,000 BC) man lived by fishing, gathering plant food, and hunting, he made great cultural progress during the Upper Paleolithic period. The hand axes and flake tools of the earlier assemblages were replaced by diversified and specialized tools made on blades struck from specially prepared cores. Many important inventions appeared, such as needles and thread, skin clothing, stone and bone tools provided with handles, the harpoon, the spear-thrower, and special fishing equipment. Bone, ivory, and antler, in addition to flint, were used extensively. The earliest man-made dwellings, consisting of semi-subterranean pit houses, are found in this period. Of prime importance and interest is the beginning of the basic techniques of drawing, modelling, sculpting, and painting, as well as the earliest manifestations of dancing, music, the use of masks, ceremonies, and the organization of society into patterns that were apparently fairly complex. Indeed, the location of certain settlements suggests a fairly complex social life, perhaps including collective hunting. There is evidence for fertility magic, private property, and possible social stratification. Furthermore, primitive types of early man disappeared, and the remains of men of modern type (*Homo sapiens*) alone are found in Upper Paleolithic sites.

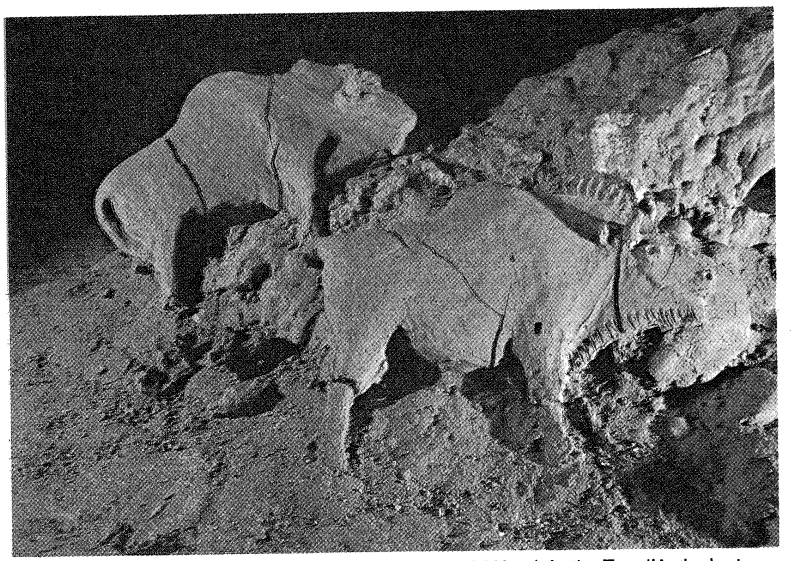
Beginning of art

Dmitri Kessel, *Life* (© 1955); Time Inc.

Views of an ivory female head (fragment of a "Venus" figurine), Aurignacian-Gravettian (c. 22,000 BC). From the Grotte du Pape, Brassempouy, Landes, France. In the Musée des Antiquités Nationales, Saint-Gérmain-en-Laye, France. Height 3.5 cm.

The chronology of this interval in Europe shows a succession of cultures known as Lower Perigordian (*c.* 32,000–*c.* 28,000 BC), Aurignacian (*c.* 28,000–*c.* 22,000 BC), from which the oldest known art is dated, Upper Perigordian (*c.* 22,000–*c.* 18,000 BC), Solutrean (*c.* 18,000–*c.* 15,000 BC), and Magdalenian (*c.* 15,000–*c.* 10,000 BC), each characterized by its distinctive types of artifacts along with gravers (or burins), end scrapers, points, and so on, which are common to all levels. The graver itself is an important tool, the invention of which made possible the extensive working of bone and facilitated the development of art. The climate of the Upper Paleolithic varied from cold steppe or even Arctic tundra to north temperate (taiga), similar to parts of Siberia and Canada of the present day.

Mesolithic Age

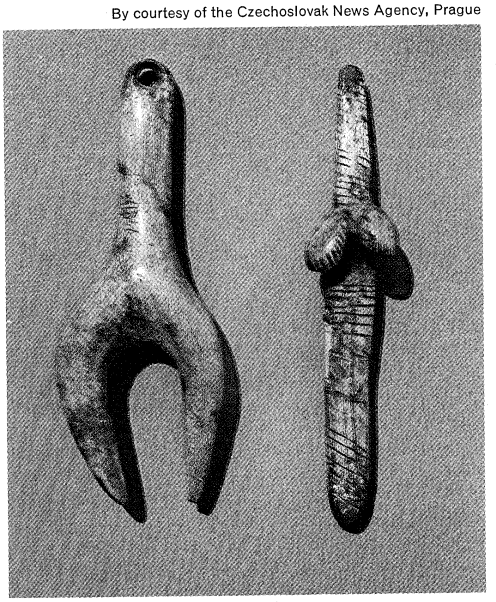


The retreat of the ice sheet resulted in radical changes of climate, fauna, and flora and gave rise to a tundra-like vegetation that was later replaced by temperate forest land. The first human cultures of the Mesolithic period appear to have been degeneracies of the Upper Paleolithic cultures; adaptation to the new environment proved difficult. Consequently the equipment of the Azilians of France, Switzerland, and southern Germany (descendants of the Magdalenians) was relatively poor; their antler harpoons were large and clumsy, their flint implements, known as microliths, became extremely small, and Magdalenian cave art degenerated into conventionalized designs painted on pebbles. Full adaptation to the environment was not achieved until the Boreal period. The many local cultures that flourished at that time (6,800–5,000 BC) are collectively referred to as Tardenoisian, known largely from their carefully trimmed microliths. They lived mainly on unforested sandy ground and left some of the earliest traces of habitations—skin or birch-bark tents in the summer and half-subterranean timber-framed shelters in the winter.

At the same time in northern Europe, communities living in a forest environment developed elaborate hunting and fishing equipment. These Maglemosians were among the first people to build canoes and to tame a domestic animal, the dog. Toward the end of the Mesolithic period in western Europe (*c.* 4,000 BC), they could grind stone and make rudimentary pottery, techniques probably derived from the advanced civilizations of the Near East. After the retreat of the glacier, the cultures of eastern Europe became more differentiated. In the south and to some extent in the central wooded belt, Stone Age cultures resembled those of Western Europe (microlithic stone industries), while their northern neighbours were more like the Mesolithic Scandinavians (heavy stone tools, bone points, and so on).

The northern peoples may have developed further in what can be termed the Epi-Mesolithic period. They already had acquired some cultural traits characteristic of the Neolithic (mainly pottery of the pitted-ware type and ground stone axes) but were ignorant of agriculture and the breeding of domesticated animals. The origin and chronology of their cultures has not yet been fully cleared up; it is believed, however, that they survived very late and were contemporary with the central and west European Bronze Age. (Ed.)

Venus figures



Paleolithic art: carved and incised objects. Although human beings are rarely represented in the cave art of western Europe, the earliest plastic figures represent mature, large-buttocked females with pendulant breasts. These figurines, which show remarkable consistency in style over their total distribution from France to southern U.S.S.R., are carved in bone or schist, once coloured, and

Two bison modelled in clay, Magdalenian (c. 15,000–c. 10,000 BC). In the Tuc d'Audoubert cave, Ariège, France. Length of bison at right 61 cm.
J. Vertut—Ziolo

are known now as "Venuses." The earliest examples come from middle Aurignacian contexts; those from the later Aurignacian–Perigordian period are of higher quality. About 130 examples are known, many from encampment sites of mammoth hunters at Gagarino, Ukraine, U.S.S.R., where special niches to house them were built into the hut walls. One of the most noted examples is from Willendorf, Austria (Naturhistorisches Museum, Vienna); and another, the head of such a figure with retted hair and beautifully marked facial features, is a famous Venus from Brassempouy, Landes, France (Musée les Antiquités nationales, Saint-Germain-en Laye). In the Ukraine and in Moravia, Czechoslovakia, these figurines became highly schematized, reduced often to pegs of ivory or bone with highly developed buttocks and breasts. Few bodily features are marked, although some examples have extremely thin arms folded over the chest. Moravian examples have incised geometric spiral designs on the back and buttocks that might represent tattooing. Male statuettes are much rarer and are artistically inferior, but a male head from Dolní Věstonice in Moravia (Moravian Museum, Brno) has realistically carved features.

Stylized "Venus" figurines carved in ivory, Aurignacian-Gravettian (c. 24,800 BC). From Dolní Věstonice, Mikulov, Moravia, Czechoslovakia. In the Moravian Museum, Brno, Czechoslovakia. Height (left) 8.3 cm and (right) 8.6 cm.

Larger scale sculpture is almost entirely confined to France and probably evolved from natural rock forms of suggestive shape. A parallel to the Aurignacian Venus figurines is a low relief from Laussel, Dordogne, of a large-buttocked female figure holding a "cornucopia." (Musée de L'Homme, Paris). Similar Perigordian reliefs were carved in partly exposed rock shelters at Cap Blanc, Dordogne, and some of ibex and wild boar have been found on the Roc-de-Sers, Charente. High-relief animal sculptures at Angles-sur-l'Anglin, Vienne, are Magdalenian. The only piece of sculpture in the round is a head of a musk ox from Laugerie-Haute, Dordogne, nine inches high (Musée des Antiquités Nationales, Saint-Germain-en-Laye); but Magdalenian clay sculptures of a bear from the Montespan cave, Garonne, and copulating bison from the Tuc d'Audoubert, Ariège, approach the roundness of sculpture. Some of the stone reliefs are the only art attributable to the ill-defined Solutrean period.

Miniature carving of animals

In the Magdalenian period, miniature carving of animals predominated, particularly in western Europe. Archaeologically stratified ivory carvings have come from Stetten ob Lontal, Baden-Württemberg, Germany (wild horse, panther, mammoth; Institut für Vor- und Frühgeschichte, Tübingen), and from late Aurignacian mammoth-hunting stations in Moravia, where clay models accompanied ivory (mammoth, bear, wild horse, reindeer, owl). In French sites, miniature sculpture comes mostly from Magdalenian strata. These pieces, particularly those of horse and bison heads, surpass anything in eastern Europe. Particularly fine are a horse's head carved of reindeer antler from Le Mas d'Azil, Ariège, and a standing horse in ivory from Lourdes (both Musée des Antiquités Nationales). Some have harpoons engraved upon them and must have been used as hunting talismans; some of the best examples are carved on throwing sticks and other hunting implements.

In this category are carved finials of spear-throwers of Le Mas d'Azil in the form of a chamois (small, goatlike antelope; Péquart Collection, Saint Brieuc) or a black cock (Musée des Antiquités Nationales), handles such as one carved in the form of two crouching deer from Bruniquel, Tarn-et-Garonne (British Museum), and another in the form of a single reindeer from Laugerie-Basse. Perforated staves of ivory are sometimes carved with animal terminals; although known as *bâtons de commandement*, they were probably used as arrow straighteners. They are often covered with designs of deer, horses, birds, and fish.

The vast majority of Magdalenian finds are isolated engravings on bone, flat tines (pointed branches) of antler, small slabs of stone, or flat pebbles, executed some-

Head of an ibex, engraving on a bone staff, Magdalenian (*c.* 15,000–*c.* 10,000 BC). From Isturits, Basses-Pyrénées, France. In the Sainte-Périer Collection, Morigny, France. Height 13 cm.
J. Vertut—Ziolo

times with surety, sometimes as though they were practice pieces. Notable are Dordogne examples of hairy bisons' heads from Limeuil and Laugerie-Basse on bone and small limestone blocks. Unusual perspective and impressionistic effects were sometimes achieved by the Magdalenian artists. From Teyjat are experiments in group drawing: a herd of reindeer with only the outer animals drawn in detail, the herd effect achieved by central multiplications of legs and antlers. A herd of galloping horses is treated less summarily. A more detailed style is seen in antler engravings from Lorthet in the Pyrenees where, on a spear-thrower, reindeer are shown swimming. The hooves and body hairs are drawn with precision, as are details of salmon swimming between the beasts' feet. It is typical of a group of Upper Magdalenian miniatures in which the patterning of hair, skin, and fur forms a significant element.

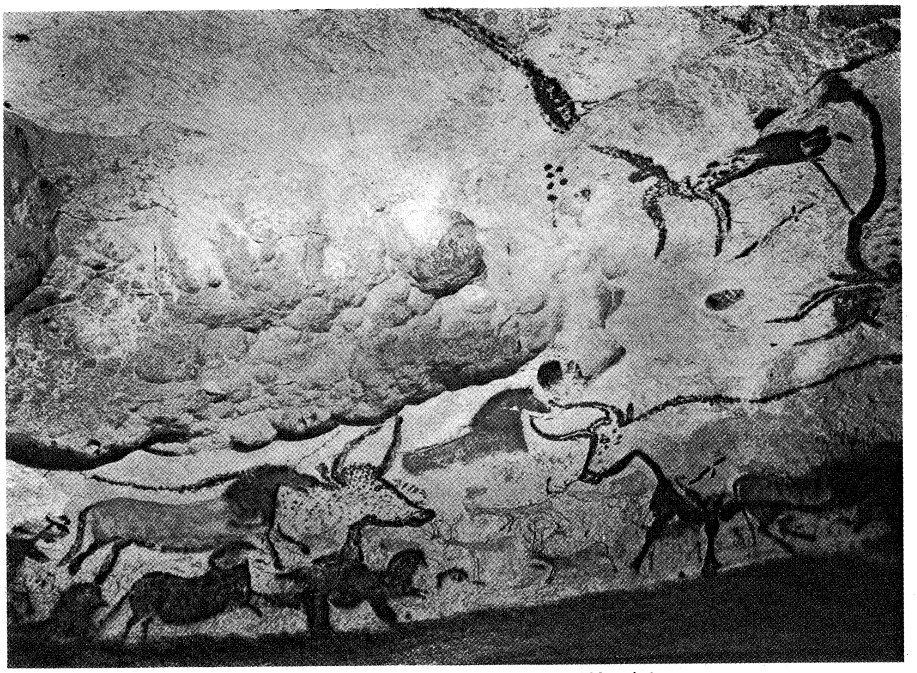
Bone engravings of Pyrenean quality are not common elsewhere in Europe, but from the Pekárna cave in Moravia comes a masterly representation of bison in combat (Moravian Museum, Brno). Here too were found perforated staves parallel to the French type and bone pieces engraved with horse, bison, and chamois. Outline engravings of mammoths have been found at Kostienki I and Maltà, near Lake Baykal, Siberia. In these minor and applied arts of the Magdalenian period no interest is shown in scenic background or the human figure; the few examples of what appear to be human beings, including an engraved bone from La Colombière, France (Université de Lyons), are badly executed and difficult to discern. These minor pieces, though scarcely surpassed in treatment and skill, are greatly surpassed in scale by engravings and paintings in caves.

Paleolithic art: cave engravings and paintings. Geographical limitations confine cave art largely to southwestern France and northeastern Spain, the so-called Franco-Cantabrian province, but isolated finds come from southern Italy, southern Germany, and southern U.S.S.R. In the absence of firm chronology, it is difficult to reconstruct stylistic development, even in France.

Franco-Cantabrian cave art

Cave decoration was made either with stone gravers or with masses of liquid paint. While massive sculpture was usually placed in open rock shelters, paintings and engravings were usually hidden in deep recesses of caves where clay modelling was also practiced.

Cave art evolved from simple Aurignacian line engraving to late Magdalenian polychrome painting. Incised on hard rock surfaces, painted, or drawn in wet clay with a finger, the lines were originally of uniform thickness, later revised and modulated. Detailed drawing of pelt, muscles, and other anatomy tends to be zonal.



Painting and engraving often appear together in caves and probably came into use simultaneously. Distinctions in style suggest that painters and engravers practiced separate crafts. Only one known cave is decorated exclusively with engraved designs: Les Combarelles, Dordogne, has thousands of superimposed engravings from late Aurignacian through middle Magdalenian, suggesting that this cave was the centre of a hunting cult. Bison and reindeer are the main repertoire, but there are also grotesque part human, part animal figures, which are perhaps decoys or hunting magicians. Some of the engraved animals are lively, others stiff; chronological distinctions between the styles cannot be accurately made. From stratified caves, however, it would appear that Aurignacian style was close contoured and stiff and lacked the three-dimensional qualities of the later period. At Altamira, Teyjat (Dordogne), and Font-de-Gaume, engravings accompany Magdalenian wall paintings; it is possible to appreciate the plastic qualities of Magdalenian engraving and efforts to represent dimension, although the position of feet (often completely omitted) is embarrassing. Action is depicted at Font-de-Gaume, where a pregnant lioness is engraved ready to spring and horses canter in file. At Altamira leaping hinds and baying stags have lifelike qualities, antlers drawn in fine perspective. These epitomize the extremely flowing style of Magdalenian engraving, seen in plodding mammoths at Font-de-Gaume and some bears depicted at Les Combarelles.

Lascaux and Pech-Merle caves

At Lascaux, in a cave with passages and chambers on various levels, the best preserved traditions of later Aurignacian art survive; the Pech-Merle cave, Cabrerets, should be associated with it. Paintings in both caves are executed in thick black outline little refined. The bodies of some of the animals are washed in with red or brown paint, shading off toward the underparts. Most horses are painted in solid-black silhouette, but some horses, bison, and aurochs (extinct long-horned wild ox) in both caves are painted with an overall dot pattern. Friezes of horses and bulls traverse the lower edge of the arched roof, while the upper portions are left for depicting larger animals. Although the paintings are superimposed, at Lascaux there seems to have been a consistent attempt to decorate the roof in an orderly fashion. In other caves, animals are painted without significant relationships.

Altamira Cave remains pre-eminent in Magdalenian style. Natural bulges of the seven-foot- (two-metre-) high rock roof were painted with standing and squatting bison, thickly outlined in black and filled in with red, producing an effect of unparalleled beauty and realism. About 20 of them cover a distance of about 15 yards (14 metres). The rock formation was used to give a round effect in the body; the legs were painted from underneath (the alternative in the visual dilemma was to paint the legs from the side), giving the animals a slightly concave appearance countered by the rock surface. Font-de-Gaume Cave closely parallels the painted-in technique of Altamira and indeed, in parts, probably represents an earlier late Aurignacian style, but unfortunately it is badly preserved. The Niaux caves, Ariège, belong to the same black-outline tradition but do not have painted fillings. The outlines, however, are painted with thick strokes and adjusted with thin and are more carefully drawn than elsewhere; and the perspective of the feet of bison and wild horse is more successfully achieved.

Besides introducing painting as a pictorial technique, the primitive art of the Paleolithic begins an expressional and magical use of colour. Black, red, brown, and a dull yellow were chiefly used. Besides animals and anthropoid figures, areas and brush marks of colour and curiously shaped tectiforms (wedge-shaped markings perhaps representing huts) were sometimes painted in, as were colour-blotched outlines of stumpy human hands. Among the pigments at Altamira and Lascaux, natural oxides of iron and manganese supplied red and black; iron carbon-

ate gave yellow; at Lascaux blue-black and dark-brown manganese oxides were found; other blacks came from soot. When finely ground, these pigments were mixed with water rather than a fatty base, allowing quick application to damp rock. Pigments were stored in such hollow receptacles as bones, stones, and skulls, as at Les Cottés, Vannes. Bone mortars and pestles for grinding paints and stone lamps for lighting dark recesses have been found. Fingertips, brushes, and daubing pads were used to apply the colour.

Function of the cave art

The purpose of this art is not clear. Executed far from normal gaze, the work was apparently done in great discomfort. That it was directed at the magical possession of favourable hunting conditions is occasionally indicated. An outline-painted mammoth in the Pindal cave, Asturias, Spain, has a red blotch indicating the position of the heart and a batch of arrows painted in front of it. Outlined bison in the Niaux cave, Pyrenees, have superimposed painted barbs pointing at the heart and midrib and blotches of red (blood?) on the body. Patchwork squares painted in front of such naturally curious animals as oxen and goats at Lascaux might represent pitfalls covered with sheets of skins. In the same cave is a scene in which a man with a broken spear is worsted by a bison. Comblike patterns painted near and on top of some animals might represent fenced enclosures to which they were lured. A human-shaped figure (known as the "sorcerer") wearing an antler mask, in Les Trois Frères Cave, Ariège, might be a decoy or a hunting magician. Hunting rites are evidenced by clay model animals, some with unmistakable signs of use as targets. Other models suggest magical increase of fertility (many painted animals are pregnant, and pregnant women are occasionally engraved on bone).

Toward the end of the Magdalenian period, naturalistic realism weakened and gave way to formalized arrangements of horns, antlers, and fur reduced to a pattern. Schematic female figures have been found from the earlier Paleolithic in Moravia; in the west, chamois and reindeer were reduced to formalistic ornaments. In western Europe, art was not to achieve such heights of abstraction until the appearance of formalized Celtic art of La Tène.

A branch of Franco-Cantabrian art is represented at Parpalló Cave, Valencia, where engraved bone pieces are stratified in Gravettian, Solutrean, and Magdalenian contexts; and where stones with animal paintings occur in the Solutrean. At La Pileta Cave, Málaga, a peripheral Magdalenian style of painting seems to have been introduced. The animals depicted, unlike those of France, are not Ice Age fauna but such forest dwellers as deer, wild boar, the smaller deer, and oxen; doubtless the southerly latitude is as much responsible for the difference as is the later date. The art of these two caves is possibly linked with engraved animals in caves in Liguria, Apulia, and west Sicily and may thus belong to an ill-defined "Mediterranean" province, possibly with African connections, which continued Paleolithic artistic tradition into Mesolithic times.

Mesolithic (Epipaleolithic) cave art of Spain. Another group of cave paintings, while difficult to date, can be largely attributed to the Mesolithic, or Epipaleolithic period. Found in southeastern Spain, they differ sharply in style and content from the paintings of the Franco-Cantabrian province. They incorporate an African style as seen in largely undatable paintings and rock engravings from Algeria, Tunisia, the Atlas Mountains, outer Sahara, and Bushman art in South Africa. These African examples, like those of southeastern Spain, are tribal rather than individual; hunting by small family groups in Paleolithic times had been taken over by organized males of the tribe. Spanish Levantine painted caves, discovered mostly in the early 20th century, are grouped in Albacete (Alpera and Minateda caves), in Teruel (Alcañiz and Tormón), in Murcia (Cogull and Yecla), in Valencia (Bicorp), in Castellón de la Plana, and in several shelters in the Valltorta gorge between Albocácer and Tirig. New paintings were brought to light at such sites as the Cueva del Polvorín, Castellón. The group has one outlyer, the cave of Las Batuecas between Salamanca and Cáceres.

Spanish Levantine caves

Engravings are very rare and the absence of stratified pieces of minor art makes the dating and culture attribution of the paintings difficult, but their beginning is probably to be associated with the Upper Paleolithic Capsian industry of southeastern Spain. While large-scale single animals are the rule in Franco-Cantabrian paintings, small-scale compositions of many figures were chosen by the southern Spanish artists. In most of the paintings, human groups play a large part, hunting single animals with bow and arrow. All figures are painted in solid silhouette; those of animals are true to nature while those of humans are highly distorted, with elongated bodies and thick legs. The colours are chiefly red, brown, and

black, largely derived from manganese and bound with blood, egg, or honey.

With tribalism came war, and many of the scenes depict lively arrow battles or mass execution of prisoners. Women, often drawn in long dresses, are shown dancing or walking with children. There is no evidence of fishing or trapping, but the dangers of the chase are vividly shown in Cueva Remigia paintings in which oxen and ibex turn

Instituto de Estudios Editoriales, Barcelona

Woman gathering honey, water-colour copy by F. Benitez Mellado of the original painting in the Cueva de la Araña, near Bicorp, Valencia, Spain, Mesolithic (*c.* 10,000/8,000–*c.* 3,000 BC). In the Museo de Prehistoria de la Diputación Provincial, Valencia, Spain.

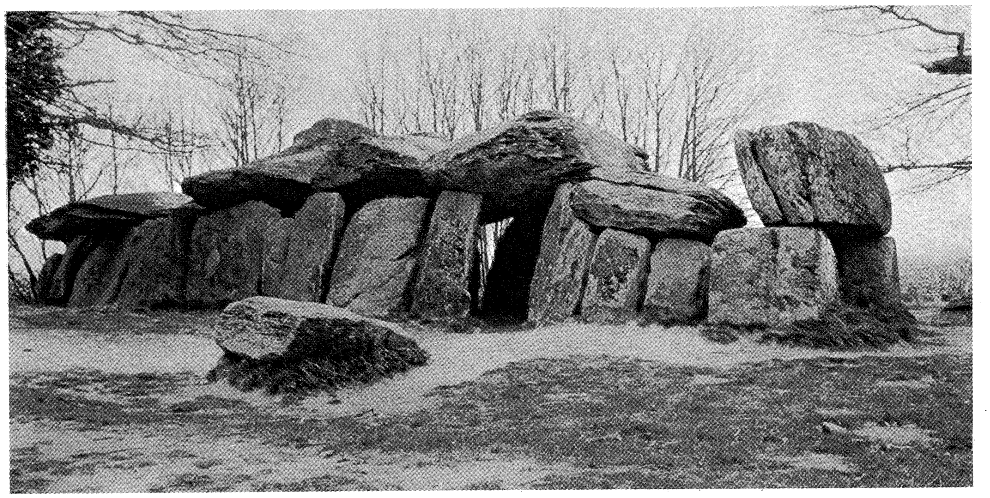
on fleeing hunters. Little domestic life is shown, but a painting in the Cueva de la Araña, Valencia, depicts a woman gathering wild honey; one in the Gasulla gorge shows a spider surrounded by flies.

Paleolithic and Mesolithic art of northern Europe. A third group of Stone Age art, largely from the northern limits of Europe, while again showing a generic relationship with Ice Age art of western Europe, cannot be related to an Upper Paleolithic culture. In Finland, northern Norway (Finnmark, Nordland, Troms), central Norway (Trøndelag), and on the upper Yenisey River at Shalobolinsk in western Siberia, the custom arose of engraving scenes of hunting and magic on largely inaccessible slabs of rock or cliff surfaces. The linear style of Arctic reindeer, elk, and bear lacks Magdalenian dimensional qualities but is very definite and simple. More naturalistic representations and those with perspective as seen in French Magdalenian art are found only in remotest northern Norway and Siberia. Groups of animals and disguised human decoys are sometimes shown, and great interest in the sea is evidenced by engravings of halibut and seal; and, on the White Sea coast, by boats of a type ancestral to those in later Bronze Age engravings from Scandinavia. Although hunting scenes are not shown, depiction of inner parts of animals strongly indicates that hunting magic was the primary purpose of these drawings. For decorative purposes, superb small animal models were carved in Danish Maglemose (Mesolithic) settlements. (W.Cu.)

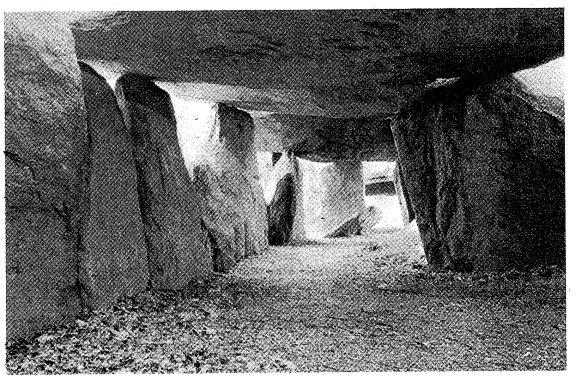
Linear style

NEOLITHIC AGE

The origins and history of European Neolithic culture are closely connected with postglacial climate and forest development. The increasing temperature during the period from around 8,000 to 5,500 BC caused a remarkable change in late glacial flora and fauna. Thus, the Mediterranean zone became the centre of the first cultural modifications leading from the last hunters and food gatherers to the earliest farmers. This was established by some important excavations in the Near East, which unearthed the first stages of early agriculture and stock breeding (7th and 6th millennia BC) with wheat, barley, dogs, sheep, and goats. Early pre-pottery Neolithic finds (probably 6th millennium BC) have been made in the Argissa Magula near Larissa (Thessaly, Greece), and excavations in Lepenski Vir (Yugoslavia) have brought to light some sculptures of the same period. The independent origin of European Neolithic was established, and it was thought highly probable that the cradle of farming in the Near East had not been the only one: there were others in Europe, too.



Early pre-pottery Neolithic finds



Neolithic farming in Europe developed on its own lines in the four different ecological zones: the Mediterranean zone of evergreen forest and winter rains; north of the Pyrenees, the Alps, and the Balkans, the temperate zone of deciduous forest and evenly distributed annual rainfall; still farther north the circumpolar taiga, or coniferous forest (the only zone to remain free of agriculture and stock breeding); and to the southeast the western end of the Eurasiatic steppes. Each zone itself is subdivided into natural regions by physiographic boundaries and peculiarities of climate or soil. Three major divisions of the temperate zone are western Europe, from the Atlantic to the Vosges and Alps and including the British Isles; the loesslands of central Europe, including the Ukraine and limited by the Balkans and the Harz; and the northern province, that portion of the Eurasiatic plain lying between the Rhine and the Vistula and including Denmark and southern Sweden. The substantial Neolithic communities that arose by the 6th millennium BC must have been largely recruited from indigenous Mesolithic hunters and fishers, attested to so abundantly by remains in western and northern Europe. (Some communities indeed seem to have been composed entirely of such Mesolithic stocks, though they had adopted a Neolithic equipment from immigrant farmers; such are sometimes termed "secondary Neolithic.") From these Mesolithic survivors, too, must be derived much of the science and equipment applied in Neolithic times to adapting societies to European environments. Upon the resultant distinctively European technology and economy was reared a no-less-original ideological superstructure expressed in distinctive sepulchral monuments, styles of pottery decoration, and fashions in personal ornaments.

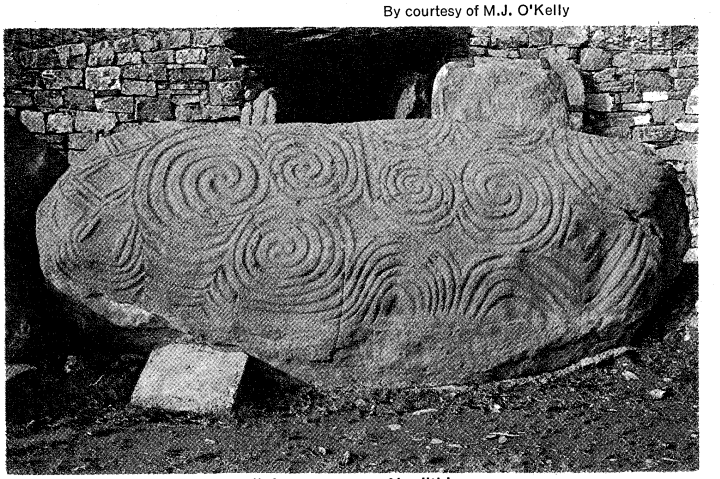
Architecture. Dwelling places in Greece, Sicily, and the Iberian Peninsula were built of mud brick on stone foundations. But in the Balkans and throughout the temperate zone, wood was used for the construction of gabled houses, stout posts serving to support a ridgepole and walls of split saplings or wattle and daub (a framework of woven twigs covered and plastered with clay). The earliest houses on the loessland of central Europe were very large, up to 135 feet (41 metres) in length and large enough to accommodate a whole lineage or small clan together with stalled cattle and grain stores. In the sequel, these communal houses gave place to smaller two-roomed dwellings, 24½ to 33 feet (7.5 to ten metres) long but still entered through one end. Finally in late Neolithic times clusters of one-roomed huts became the most widespread fashion. Round the Alps such two-roomed houses, and, less often, one-roomed huts were raised on piles above the shores of lakes or on platforms laid on peat mosses. These are known as Swiss lake dwellings (*Uferrandsiedlungen*).

Swiss lake dwellings

In northern Europe, as in other sections of the continent, the earliest villages consisted of two parallel long communal houses, but these were subdivided into 20 or more apartments, each with a separate door. Here again the communal houses eventually broke up into free-standing one-roomed huts. Finally, the Stone Age village of Skara Brae on the treeless island of Orkney illustrates an ingenious adaptation of one-roomed wooden huts to an

Megalithic gallery grave.
(Left) La Roche aux Fées, Essé, Ille-et-Vilaine, France, Neolithic (*c.* 3,000–*c.* 1,800 BC).
(Right) Interior of La Roche aux Fées.
D. Lesec—Ziolo

inhospitable environment. Skara Brae also shows how commodiously such huts must always have been furnished, despite their limited size.

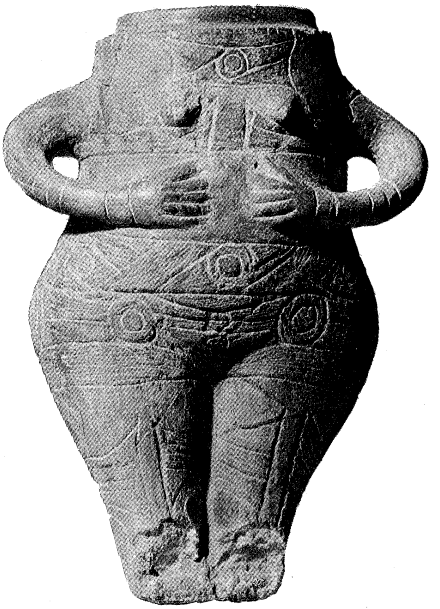


Megalithic tombs. Neolithic farmers were generally buried in a flexed or contracted position on the side except in northern Europe, where the corpse lay extended on its back, as was the custom also among the surviving hunter-fishers of the taiga and Russia. In Britain, Secondary Neolithic folk practiced cremation, burying the ashes in circular enclosures, one of which was destined in the Bronze Age to become the world-famous sanctuary of Stonehenge. But the most celebrated and imposing funerary monuments of the European Neolithic are collective tombs or family vaults, some built of huge undressed stones and thus rightly called megalithic, others walled with dry stone masonry and roofed by corbeling (arch supported by a bracket projecting from the face of the wall), others simply cut in the rock. Save for a cluster on the northern slopes of the Caucasus, such tombs are virtually confined to the Mediterranean coasts, the Iberian Peninsula, and western northern Europe and are most densely concentrated near the coasts. The simplest but not necessarily the oldest type of megalithic tomb, the true dolmen (consisting of four or more upright stones supporting a horizontal stone slab), is confined to northern Europe and was originally designed to contain a single extended skeleton. Passage graves, consisting of a polygonal chamber entered by a distinct passage and covered with a round tumulus, probably originated in Portugal and spread thence by seaways to Brittany, Britain, and Denmark.

Collective tombs

Finally gallery graves, which are long, narrow chambers with no distinct entrance passage, often covered by a long cairn (heap of stones) with a crescent-shaped forecourt at one end, are distributed from the Gulf of Lyons across France to Scotland and Northern Ireland. A special variant, generally subterranean, was developed in the Seine–Oise–Marne Basin and carried with a distinctive assemblage of pots, weapons, and personal ornaments by migrating bands to the Channel Islands and across Belgium and Westphalia to southern Sweden. (Ri.P.)

Chief expressions of Neolithic art. The migration of Neolithic agriculturalists from the Near East to Europe and the rise of European peasant communities brought the beginnings of a folk art expressed chiefly in weaving, basketry, and pottery making. Cave art was now confined to the engraving of simple magico-religious patterns on rocks, as at Newgrange and Lochcrew in Ireland, and standing stones at Morbihan in Brittany.



By courtesy of M.J. O'Kelly

Engraved rock with magico-religious patterns, Neolithic (*c.* 3,000–*c.* 1,800 BC), New Grange, County Meath, Ireland. Length 3.2 m.

From Anatolia the idea of pottery painting spread into southern and eastern Europe. A variety of techniques of painting and incision are known in the chief areas of Neolithic painted-pottery culture at Tripolye, U.S.S.R.; Cucuteni, Romania; Vučedol, Yugoslavia; and the Dimini and Sesklo cultures, Greece. In all of these, designs are abstract, often spiriform; the pottery tradition also includes figurines of women with painted or incised designs indicating elaborately embroidered clothing. Decorations

Pottery

on unpainted pottery from the rest of Europe show the predominant influence of basketry. In the process of perfecting techniques of shaping and polishing stone tools, the Neolithic craftsman brought to earlier Stone Age traditions a new combination of utilitarian and aesthetic feeling. (W.Cu.)

BIBLIOGRAPHY. Major modern studies of Paleolithic art should begin with the work of the pioneer, the Abbé HENRI BREUIL, *Quatre cents siècles d'art pariétal* (1952; Eng. trans., *Four Hundred Centuries of Cave Art*, 1952). His biography by ALAN H. BRODRICK, *The Abbé Breuil, Prehistorian* (1963), serves as an introduction to his work and method. There are two large and lavishly illustrated works on Paleolithic art: PAOLO GRAZIOSI, *L'Arte dell' antica età della pietra* (1956; Eng. trans., *Paleolithic Art*, 1960), which is indispensable and particularly good on the Mediterranean engraved caves; and ANDRE LEROI-GOURHAN, *Préhistoire de l'art occidental* (1965; Eng. trans., *The Art of Prehistoric Man in Western Europe*, 1967), which attempts a reclassification of styles and chronological evolution. Although the statistical evidence does not give strong support to many of the author's stylistic divisions, the work has great value both for its tabulation of motifs (particularly the abstract forms) and diagrams of cave layout. NANCY K. SANDARS in *Prehistoric Art in Europe* (1968), besides giving an excellent coverage of the works themselves, seeks to place the art of Paleolithic man in the context of his experience and spirituality. The author also treats technical problems of representation and perspective. The place of Paleolithic art in the total aesthetic experience of man is the subject of SIEGFRIED GIEDION, *The Eternal Present, Part One: The Beginnings of Art* (1962). Many caves have been given individual monographs and articles: reference should be made to the site index (for both caves and portable objects) in LEROI-GOURHAN above. Lascaux cave has been given detailed and well-illustrated treatment in FERNAND WINDELS, *Lascaux* (1948; Eng. trans., *The Lascaux Cave Paintings*, 1949); and GEORGES BATAILLE, *La Peinture préhistorique: Lascaux, ou la naissance de l'art* (1955; Eng., trans., *Lascaux; or, the Birth of Art*, 1955). For prospective visitors, ANN and GALE SIEVEKING, *The Caves of France and Northern Spain: A Guide* (1962), is an excellent companion. The pieces of Paleolithic mobiliary art in Britain (mostly from Cresswell Crags, Derbyshire) are described in DOROTHY GARROD, *The Upper Paleolithic Age in Britain* (1926). For Russia, EUGENE A. GOLOMSHTOK, "The Old Stone Age in European Russia," *Trans. Am. Phil. Soc.*, vol. 29, pt. 2 (1938), is one of the few source works in English.

The Epipaleolithic, or Mesolithic, art of peripheral regions is treated by SANDARS (*op. cit.*); more fully for Scandinavia by HERBERT KUHN, *Die Felsbilder Europas* (1952; Eng. trans., *The Rock Pictures of Europe*, 1956); and J.G.D. CLARK, *The Mesolithic Settlement of Northern Europe* (1936). For late Spanish cave painting the best illustrations are in RAMON MENENDEZ-PIDAL (ed.), *Historia de España*, ch. 3 and 6 (1963), where a bibliography of individual caves will be found. The fundamental work on Spain is JUAN CABRE AGUILO, *El Arte rupestre en España* (1915).

The instruments and pigments used by the Stone Age artists are treated by L.S.B. LEAKEY in ch. 7 of *A History of Technology*, ed. by CHARLES SINGER, vol. 1 (1954); and in more detail by KURT HERBERTS, *The Complete Book of Artists' Techniques* (1958), with interesting descriptions of experiments.

(W.Cu./Ri.P.)

Storage and Warehousing

Storage, an organized method of holding and protecting articles or commodities for future use, dates from earliest times, when it was involved in the preservation of agricultural products, later in commerce, and in increasingly complex ways with the introduction of mass production. Warehousing is the dynamic aspect of commercial storage; it includes material handling systems and control and information systems whose function is to facilitate the efficient placing of stored materials for convenient or scheduled retrieval.

ECONOMICS OF STORAGE AND WAREHOUSING

Functions of warehousing Commerce of almost any kind creates the need for ways to accumulate goods for subsequent distribution to the marketplace on the basis of fluctuating demand. Although the earliest emphasis in warehousing was doubtless on security from the weather, pests, and theft, in more recent years, increasing importance has come to be attached to the reservoir function of the warehouse in levelling out the cycles of commerce. This function applies particularly to (1) products such as crops, which are produced during a limited period but sold year round; (2) products such as seasonal or sports equipment, produced year round but consumed only during a limited period; (3) products for which demand is unpredictable, such as pharmaceuticals and drilling equipment; and (4) products that are manufactured in large production runs for economy's sake and dispensed over a long period. This is the most important single function of warehousing. If all products were manufactured as they were ordered, rather than held in large quantities for possible future sales, there would be little need for warehousing.

Transportation and warehousing. Like commerce, transportation is intermittent, or cyclical; a truck, railroad car, airplane, or boat is loaded and starts on its journey. Hours, days, or weeks may pass before another shipment is made; in the meantime, therefore, a means for accumulating the product in a systematic way is required so that when the next shipment is made the transportation equipment can be quickly loaded. At the receiving end each shipment equals a supply for a certain period and must be unloaded and stored systematically to permit delivery to users on demand. Warehousing accommodates transportation surges in the same way that it accommodates surges of production and market demand, and, as in its relation to the production cycle, warehousing reduces transportation costs, which also vary with volume; the more goods of particular type that are shipped at one time, the lower the unit transportation costs. Large numbers of small shipments over long distances incur high transportation costs; the availability of a warehouse permits the manufacturer to ship in large volume and then to dispense his goods locally from the warehouse.

Warehousing also permits economies through flexibility of transportation. Water carriers can move the largest volumes at the least cost, followed by railroad, truck, and air transport in that order. A manufacturer with sufficient volume can use warehousing to achieve the most economical combination while, at the same time, satisfying other requirements.

Place-time values. Although neither transportation nor warehousing adds value to products in the sense that manufacturing does, they create equivalent values (called place-time values) in the marketing process by facilitating the delivery of goods when and where they are need-

ed. Equally significant are the place-time values provided by warehousing in the production process. Raw materials, components, and subassemblies must be fed to production lines in a steady flow. To shut down production because of the unavailability of materials is extremely costly, and the warehouse gives insurance against this contingency.

The distribution centre. Although the warehouse as a marketing channel—a place to store goods pending their sale—is as old as commerce itself, the emergence in the 20th century of numbers of companies manufacturing at multiple points and distributing nationally or internationally has given rise to a new type of warehouse called a "distribution centre." Although the typical worldwide multiplant firm seldom if ever manufactures its complete product line at all of its plants, it is usually able to sell to its customers a selection that includes products from all of its plants. It is the distribution centre that makes this feasible. A manufacturer of appliances, for example, may produce stoves at one location, refrigerators at another, washers and dryers at a third, and small appliances at a fourth. Since dealers seldom order a single item in substantial volume lots, if plants at each location were to ship directly to a single dealer, the high cost of the multiple small shipments from the different plants would be a serious economic disadvantage. Given a number of dealers, however, the manufacturer can build a distribution centre at a point intermediate to his plants and principal market areas, shipping to this distribution centre volume shipments of the individual items for later mixing into specific orders.

A factor in this practice is the provision in most carrier rates that permits storage in transit, so that a single origin-to-destination rate, substantially lower than the rate for two separate shipments, is applied.

Forecasting

An important element in exploiting the mixing function of the distribution warehouse is accurate forecasting of market requirements, so that the right quantities can be shipped from each of the plants, assuring the distribution centre of adequate stocks on hand to fill customer orders. As in any warehouse, the risks and costs of not having all products in stock at all times must be weighed against the risks and costs of having an oversupply and paying the penalties of obsolescence and deterioration, as well as the cost of the products themselves and the warehousing expense of holding them.

Warehouses as either mixing points or distribution centres play a large role in chain-store retail operations, receiving products in volume from many different manufacturers and assembling orders for their different stores. A distributor's or a wholesaler's warehouse performs a similar service for a number of customers, while a public warehouse may serve as a distribution centre for many manufacturers. One advantage of the public warehouse is that by handling the merchandise of a number of different manufacturers it can consolidate orders for products destined for a single buyer and so obtain lower delivery costs. The wholesaler or distributor who handles products of different manufacturers has a warehousing operation that is similar to the public warehouse, with the important exception that the wholesaler can control the flow of goods into the warehouse.

Although the warehouse-distribution centre is thought of generally as handling finished products, it may also serve an important function in stocking parts and maintenance supplies. In the automotive industry, for example, the warehouse handles only parts and supplies, while the assembled product (automobiles) moves directly to the distributors or dealers. The ready availability of parts in the warehouse is important in the case of appliances, office equipment, and machinery of all types. When equipment is rented or leased, rather than sold outright, the ready availability of parts is essential to keep machines operative.

Large-scale warehousing of operating supplies is useful in large business firms. Central stockpiling and distribution of such supplies as stationery, printed forms, and office supplies may involve warehousing for both economy and efficiency.

Custody storage and warehousing. In contrast to the dynamic warehouses used in production and marketing are the warehouses used primarily to hold goods in long-term storage. The primary function of such warehouses is to protect the contents from the elements and from loss, theft, or deterioration. Depending on the products to be stored, warehouses may range from general purpose buildings to highly secure, climate-controlled structures. Since the emphasis is on capacity rather than on product movement or accessibility, and goods in custody storage may remain in the same place for months or even years, warehouses of this type need relatively little materials handling equipment and few permanent employees.

Custody storage generally involves household goods, high value goods, and business records. A bank vault is essentially a high-security storage facility; the term "repository," originally applied to banks, is also used to denote public warehouse facilities that specialize in records retention and, if required, phased destruction under secure conditions. The production and marketing applications of custodial storage are limited but do exist: in the case of a high volume production item (*e.g.*, canned food) during a limited season, the goods may be moved into custody storage for some months before going into normal marketing channels. Similarly, certain agricultural products may be held in custody storage in anticipation of price improvement or, in some countries, as part of government programs.

Since the basic requirement for warehousing is protected space, almost any warehouse is likely to contain some dynamic and some static storage. Dynamic warehousing activity, however, tends to take place in more modern and more expensive buildings designed for high turnover, while static, or custody, storage is more likely to be conducted in older buildings.

Alternatives to warehousing. Broadly speaking, a product is either in use or in storage. If it is being transported from the manufacturer to the buyer, from the manufacturer to the warehouse, or from the warehouse to the buyer, it is, in effect, being stored in a "warehouse on wheels." By definition, storage is the setting aside of goods for future use and is not limited to placement in a fixed structure. Since warehousing in many cases is a substitute for transportation, it follows that under some circumstances transportation may be an economical substitute for warehousing.

Transportation as an alternative

One of the principal attractions of transportation as an alternative to warehousing is its availability on an as-needed basis, without the necessity of large investment in facilities or commitment of stocks. In the chemical industry, for example, prompt response to customer orders is important for competitive reasons. Chemical firms can load railcars with material prior to receipt of orders and consign these carloads to themselves at distant points as "rolling warehouses." When an order is received, the firm can then check through computer connections with the railroads to determine the location of a carload moving in the customer's area. Through these same connections they can issue instructions to "divert and reconsign" the carload shipment to the customer, thus providing fast response without the additional expense of regional stockpiling.

Similar practices are followed with lumber and produce. Firms on the west coast of North America, for example, regularly consign uncommitted carloads to themselves at eastern points and, as markets change, divert the carload shipments to areas in which they can command the highest prices.

With products of higher value, truck or air shipment may provide a practical alternative to regional warehousing. Although air freight was formerly considered applicable mainly to "emergency" shipments, in recent years it has been recognized that the high cost of air freight may be more than offset by savings in warehousing, inventory, packaging, and insurance when goods of relatively high value are moved by surface carriers. The electronics industry regularly uses air shipment as a substitute for warehousing, since its products are generally small and have high value. Similarly, products that are perishable

and have a time value, such as expensive cut flowers, frequently move by air. In international trade, air freight now occupies an increasingly important place in commerce in electronics, high-value automobile replacement parts, and similar items.

On-site manufacturing

Another alternative to regional warehousing is on-site manufacturing or assembly. This approach is useful, for example, in the automotive industry, in which the regional assembly plant makes possible a limited storage of parts and components, with a high volume of inbound movement of these items and a similarly high volume of outbound movement of assembled cars consigned to distributors and dealers.

Finally, careful scheduling of production and close control of inventories can also provide a partial alternative to warehousing, particularly if there is also an effective coordination with transportation facilities.

In practice, freight cars and truck trailers have been widely used for short-term storage by receivers, who find that the charges assessed by the carriers for retention of their equipment (called demurrage charges) are usually less than the cost of building or leasing space. Carriers generally oppose such use of their equipment because the return from demurrage is substantially less than that received when the equipment is in actual transportation service. There has been some interest in the development of demountable containers, which permits short-term storage without tying up rolling stock. Some buildings have even been designed so that such containers may be physically attached to the outside and entered directly from the building, thus providing miniature warehouses from which parts and supplies can be drawn.

Factors influencing number, location, and size of warehouses. As the scale and geographical range of a business increase, so do the scale and range of its warehousing needs. Manufacturers distributing on a wide or international scale, generally warehouse in multiple locations. Firms operating multiple locations, either plants or retail outlets, develop their warehousing patterns accordingly. Most manufacturing plants require on-site warehousing to serve as a buffer or reservoir between production and shipping. It is generally impractical to attempt to manufacture goods in such a way that they may be moved directly from the end of the production line to the transportation equipment. Typically, a manufacturing firm must produce a large quantity of one item before changing its production lines over to another, and the plant warehouse functions as an interim reservoir, enabling shipment of goods in mixtures specified by customers or regional warehouses.

If the plant manufactures the firm's complete product line, it is likely that the plant warehouse also serves as a distribution warehouse for the area. If it does not manufacture the complete product line, its plant warehouse serves primarily as an intermediate point in the movement of goods to regional distribution warehouses, where they are mixed with other products from other plants.

In high volume, consumer-oriented businesses, the pattern of warehousing that emerges will be determined primarily by the location of plants and markets. Usually it will be the case that adequate service can be provided from a limited number of market-oriented warehouses located where there are good transportation facilities to and from plants and customers. But cost factors are so complex that careful studies will usually be undertaken to determine the exact number and location of such facilities. Such a study normally has two phases: first, determining the range of possible locations that would satisfy the customer service requirement, and then narrowing that range to the actual number and precise locations at which this requirement can be met at least total cost. The second step involves a study of transportation costs in comparison with warehousing costs, and may be performed by computer simulation techniques, by which a computer model is developed to represent the firm's distribution and used to test various combinations of transportation and warehousing.

Warehousing location study

While transportation is a major consideration in selecting a warehouse location, labour supply, power, and other factors that are important in locating manufacturing plants are only minor considerations. Terrain is a factor only as it affects access and construction costs. Climate may be important, since heating or cooling the typical warehouse is likely to be inefficient and costly. Because warehouse labour productivity drops sharply in extremes of climate, warehouses in cold climates are often equipped with special door-area heaters, while warehouses in warmer regions increasingly are air-conditioned.

The size of a warehouse is essentially a function of anticipated volume plus an allowance for growth. Operating efficiency tends to increase with size, within reasonable limits. Because of the dynamic character of warehousing, considerable technique is required to arrive at a precise determination of capacity requirements. A study may begin with measurement of the package sizes to be handled by the warehouse, proceeding next to a determination of the most efficient unit load dimensions and floor space requirements, with consideration of different storage alternatives such as floor stacking, racking, and binning. Computers have been applied to such studies. A final factor influencing the number, location, and size of warehouses is the availability of alternatives, such as flexible and economical transportation.

Public versus private, or captive, warehousing. A public warehouse offers warehousing services to the general public; a private, or captive, warehouse is maintained by a manufacturer for his exclusive use.

Operationally, a public warehouse functions much like its private counterpart. Goods are received in volume, placed in storage, and dispensed as orders are received at the warehouse. But because the public warehouse usually serves a number of stores that sell to the same customers, it can achieve important economies both in assembling orders and in consolidating deliveries or shipments. Each of four manufacturers selling to a given retail outlet might, for example, have an order amounting to a quarter truckload, in which case if the goods are stored in a public warehouse, the public warehouseman can consolidate all four orders into a single shipment at a lower rate.

Fungible goods

Such economies become even more significant in the case of so-called fungible goods; *i.e.*, products like grain and certain chemicals that have identical specifications and quality standards and are stored together without differentiation as to ownership. Thus a liquid chemical produced by manufacturer "A" may be stored in a tank along with chemicals of the same standard produced by manufacturers "B" and "C." The customer of "A" receives a product that is a mixture of the products of manufacturers "A", "B," and "C," but since the quality is identical, this is of no concern, and joint storage and economy of scale allow a lower price to be set than would otherwise be possible.

Although branded goods stored in a public warehouse are not fungible in the sense of standard commodities, a public warehouse may undertake to maintain in joint storage all products of a manufacturer placed in storage and subsequently sold but not removed from the premises. The public warehouse does not physically segregate the merchandise sold to retailer "A" from that sold to retailer "B" but merely insures that an adequate inventory is on hand to serve both as store orders come in. By eliminating the intermediate order picking and shipping directly to the stores of a chain rather than to its distribution centre for rehandling, the public warehouse can offer important advantages to both the storer and his customers.

From the user's point of view, another major advantage of public warehousing is its flexibility and availability for use on an as-needed basis. This is particularly attractive to the firm with highly seasonal items or fluctuating storage requirements, where facilities of sufficient capacity to accommodate the storage peaks would be seriously underutilized during storage valleys. The somewhat higher storage and handling costs involved in using a public warehouse are usually more than offset by the savings realized by not investing in an inefficient facility.

Public warehousing is also advantageous in test marketing in a single country or region. The availability of public warehousing makes it possible for a manufacturer to maintain an adequate supply of his product to meet the demand generated by advertising and promotion in the test market without a permanent commitment to large fixed facilities.

Many public warehouses perform a number of so-called accessorial services in addition to those directly associated with handling, storing, and documenting the goods of their customers. Among these are bottling, bagging, and drumming from products shipped in volume; repair and reclamation of damaged products, recall, storage and disposition of defective or contaminated products; equipment servicing; provision of office and display space; and performance of export-import services. Since these services, too, are available on an as-needed basis, the storer who requires them often finds it more practical to use the services of a public warehouse than to maintain his own staff and facilities.

Financial services available at public warehouses

A number of useful financial services are also often available from public warehousing firms. Important among these are loans on goods held in storage and "field warehousing," in which a public warehouse firm takes custody of goods at the manufacturer's location so that they may be used as collateral for a loan without having to be physically removed. A number of public warehousing firms have entered the business of financing and constructing warehouses to be operated by manufacturing firms as captive facilities, in some instances even assuming responsibility for their operation.

Though many firms find public warehousing advantageous, either as an alternative to operating their own facilities or as a supplement to existing captive warehouses, it must also be recognized that there are some disadvantages. One of these is curtailed control over the physical handling of their products and over the customer service function. While the public warehouseman may in actual fact perform both of these activities as well as the firm itself, the storer must compete for both service and attention with other customers of the public warehouse; he must recognize that if he is a small or intermittent customer his products and his customers may not get the same care and attention they would if he operated his own warehouse.

Advantages of private warehouses

An advantage of the private, or captive, warehouse is the degree of control the manufacturer can exercise over its operations. This is particularly important when the warehouse operation must be coordinated with both plant operations and customer requirements. If the product requires special handling or storage equipment, protection or climate control, the firm may have to operate its own facilities simply because there are no adequate public facilities available. For the retail firm, private warehousing is usually both desirable and necessary; by controlling both the warehousing and the actual distribution of its products and their movement to sales areas in the stores, the firm can exercise controls and achieve economies that would not normally be possible in a segmented operation using public warehousing.

A disadvantage of private, or captive, warehousing is that costs are frequently high because of periodic underutilization of personnel and facilities and fluctuating volumes. Too much emphasis on customer service may burden the warehouse with an excessive number of "emergency" orders resulting in high levels of overtime during some periods and equally high levels of idle time at others. Some management problems are inevitable; the firm that operates its own warehouses is in effect in the warehousing business on a relatively small scale, but with management problems comparable to those it would have were it in the warehousing business on a large scale.

TECHNOLOGY OF STORAGE AND WAREHOUSING

Warehouse design. The technology of warehousing is undergoing important changes in both building design and handling and storage equipment. Although most modern warehouses are of single story design, there is increasing recognition that these are inefficient in land use and impose a cost penalty in interior travel time; *i.e.*, the excessive amount of horizontal travel required because goods are spread out over a large area. Typically, in the past the multistory warehouse was handicapped by floor load limitations on upper stories, low ceilings, and slow elevators. In some instances these disadvantages have been partially offset by the installation of faster elevators with automated loading and unloading eliminating the bottlenecks of the older system. In modern structures there is increasing emphasis on high-ceiling warehouses permitting storage to heights of 20 feet or more for forklift trucks, and much higher for stacker-crane systems. Western European warehouses have pioneered the high-ceiling concept, with storage heights in certain West German installations of 95 feet (28 metres), and one in Switzerland of 103 feet (31 metres).

Building shape is an important design element in both construction cost and operating efficiency. A building 150 feet by 200 feet (45 by 60 metres) has the same floor area as a building measuring 100 feet by 300 feet (30 by 90 metres), but its perimeter measures only 700 feet (210 metres) as compared to the second building's 800 feet (240 metres). Besides adding a construction-cost penalty, the shape of the second building would also increase interior travel time and make supervisory control more difficult by dispersing personnel and operations over a wider area. Heating and air-conditioning costs are greater in long, narrow buildings, and generally the shape does not lend itself to efficient arrangement of aisles and storage slots. Buildings of irregular shape, built to fit into available land areas, are equally inefficient, but they may be necessary if location is more important than operating efficiencies. Refrigerated space usually costs three to four times as much as ordinary space.

Safety considerations

Since protection of contents is a paramount consideration, most modern warehouses employ fireproof materials and sprinkler systems. Lightweight concrete, fireproof and susceptible to prefabrication, is widely employed. This material also has good insulating and acoustical properties. Steel buildings, shop-fabricated and field-assembled, are also widely used. Although clear span construction is an asset in warehousing because it permits maximum use of floor space without obstructions, most warehouses are too large in floor area for clear span construction to be economically feasible; so, instead, conventional column supports, spaced to approximate the dimensions of storage bays and aisles, are utilized.

An important design question is the number of truck doors and railcar positions. Besides adding to construction cost, a large number of doors also adds to heating costs and creates security problems. There is a trend in more recent buildings to provide fewer door positions and improve their utilization by better scheduling of transportation equipment and mechanized loading and unloading. One large distribution centre warehouse—by scheduling trucks in at 20-minute intervals—is able to handle all shipments through a single truck door. There is also a trend to enclosed shipping and receiving docks for both railcars and trucks, in which equipment is loaded and unloaded inside the building, an advantage for both climatic and security reasons.

Because efficient layout and space utilization are critical to economical warehousing operations, warehouse design is based on forecasts of requirements and determination of the aisles and the shapes and volume of goods the warehouse will be handling. This may start with a study of package dimensions and determination of the most efficient unit loads, with stacks arranged in a specific pattern on a pallet or banded together, for handling by forklift trucks. Unit load dimensions of high-volume items, plus the quantities to be handled over a period of time, provide the basis for determining bay size and general storage plan, as well as overall dimensions and cubic capacity of the warehouse. Handling and storage methods to be used must also be considered at this juncture, since they will influence such layout features as aisle placement and width, storage racks, bins, and work areas.

Warehouse equipment. Two principal activities that are common to all warehouses are handling and storage.

Handling includes the steps involved in moving goods to and from storage, while storage is the condition of the goods at rest in designated areas of the warehouse. Major handling activities include unloading goods from railcar or truck; sorting; placing on pallets; moving by truck, forklift, or conveyor; placing goods in storage racks, slots, bins, or shelves; picking or assembling items ordered from storage positions; moving goods to the shipping area; checking; and loading goods into railcar or truck.

Non-automated equipment. Many mechanical devices are used to perform handling functions. The most common are the two- or four-wheeled hand truck, or cart, and the electric, gasoline, or liquid-propane forklift truck. The forklift truck, the workhorse of the warehousing industry, can transport loads both horizontally, for movement to and from the storage area, and vertically, to position and retrieve loads in upper positions of the storage system. The forklift is essentially a tractor with a mast and powered lifting mechanism that raises or lowers two flat prongs, or forks, running on tracks on the mast. The operator positions the forks underneath the pallet, or skid, by inching the truck forward. He then raises the forks until the load is clear of the floor and drives to the storage position where the load is raised or lowered as required, and placed in position. This completed, he backs the truck away and clears the forks, lowers the forks, and is ready for the next operation.

There are numerous attachments for forklift trucks: hooks, rams, clamps, suction devices, push-pull devices, side-shifters, drum-handling clamps, and other devices for special handling situations. Forklift trucks used in warehousing operations are generally in the range of 2,000 to 6,000 pounds' (900 to 2,700 kilograms') capacity.

Four-wheel carts are also widely used; the worker pushes the truck through the storage area, picking items from their storage positions and placing them on the truck. In some cases, these trucks are assembled into a tractor train and in still others are moved from the storage area to the shipping dock by a towline system, generally an underfloor chain that engages a vertical bar on the truck through a slotted track in the floor and switches or releases the truck at predetermined positions on the shipping dock. Fixed conveyers with wheels, rollers, or belts are also used for moving items in cartons; they operate either on gravity principles or with power drives, or a combination of the two. Special portable conveyors are sometimes used for loading and unloading operations.

Pallet stacking

The basic storage system in warehousing involves stacking pallet loads one on top of another. This has certain disadvantages, however; the weight of a high stack may crush packages on the bottom; stock rotation is difficult, because the oldest merchandise is on the bottom; and space utilization is poor because loads can seldom be stacked to the full available height. To overcome these problems, many warehouses use storage racks that permit placement or retrieval of a pallet load without disturbing neighbouring loads. These pallet racks consist of rails or track, welded to uprights, that support the edges of the pallet, keeping the pallets vertically separated. Drive-in space permits merchandise to be stored in depth without preventing access to the loads in the rear. Bins are typically used for small items, and shelves for larger and odd shaped items.

An important development in storage systems has been the gravity flow rack. This is similar to the conventional storage rack except that the rails are at a 3 to 4 percent grade and incorporate wheels or rollers. A pallet load placed in the rear of the rack rolls forward each time a pallet is removed from the front. A single line in the flow rack may hold 20 or more pallet loads, front to rear, and a typical flow-rack assembly may contain 75 or more such lines, allowing a total storage capacity of 1,500 or more pallet loads. As a pallet load is removed from the front of its line, another moves automatically into the forward position. This arrangement permits orders of merchandise to be assembled from the front of the system simultaneously with restocking operations at the rear. It also provides excellent space utilization by reducing aisle space requirements, and it ensures stock rotation.

Automated equipment. Automated warehousing using stacker cranes in combination with gravity flow racks is another important development in high-volume storage operations where space is at a premium. The stacker crane operates on principles similar to a forklift truck but moves by remote control in a fixed path by means of guide rails in the floor and on the warehousing ceiling, either to feed pallet loads into the gravity flow rack system from a production line, or to retrieve pallet loads and move them to the shipping area, or both. Feeding and retrieval lanes are preselected by an operator working at a console equipped with a card reader or computer that directs the crane to the proper location for pickup or delivery, and from there to its next assignment. A modern stacker-crane operation, operated by a brewing company in Kyōto, Japan, handles up to 2,400 pallets a day, each pallet loaded with 24 cases, in a warehouse with a total capacity of 8,748 pallets. This rapid turnover is made possible by the efficiency of ten stacker cranes, divided between two sides of the warehouse, one for receiving and one for loading.

Stacker-crane operation is adaptable to a wide variety of stored products; in Gütersloh, West Germany, a warehouse was specially designed for books. Its capacity of 7,000,000 volumes makes it one of the world's largest book repositories. The stacker crane is suspended from the rack framing. The system is particularly well adapted to refrigerated warehousing where space utilization is an important factor because of high construction costs, and where the work force can only work in the refrigerated area for short periods.

For smaller units of shipment, such as individual packages, automated warehousing takes the form of conveyor systems that divert packages at predetermined points to conveyor spurs, where they meet other packages drawn from other parts of the warehouse but consigned to the same buyer or scheduled for shipment on the same transportation equipment. The packages may be diverted by remote control by an operator visually inspecting each package as it passes him, or the system may employ a sensing or optical-scanning device that interprets package labels and activates the diverting mechanisms.

Computerized operations

Most automated warehousing systems employ some level of computerization. A typical example is a chemical-storage warehouse in Monthey, Switzerland, in which nine stacker cranes serve 20,000 pallet positions, with an annual handling volume of 120,000 pallets. Papers for inbound pallets are transmitted by television from control desks in the office to the control room for computer recording; the computer gives instructions to conveyors and to the stacker cranes and retains control of positioning and future movement of the pallets. A pharmacy warehouse at Nottingham, serving a chain of 1,300 drugstores in the United Kingdom, stores products according to size and turnover frequency in three differently equipped departments. The department for full cartons with high turnover is the most extensively automated, with a computer-controlled order-picking tower that controls dispatching, stockkeeping, and sorting of products according to customers' orders.

Although automation is still relatively expensive, it has proven to be substantially less expensive than conventional methods in a number of installations when the total cost of the installations has been taken into account. By permitting high-density storage, with loads stored both higher and deeper than is possible with manual methods, stacker-crane systems reduce warehouse space requirements by as much as 40 percent below that required by conventional warehouses, crisscrossed with aisles. Certain conditions must exist before automated warehousing is economically feasible; these include high construction costs, a high and relatively stable level of handling volume, and a limited range of package sizes. One disadvantage of automated systems is their relative inflexibility. They cannot readily be adapted to changing conditions in the warehouse in the way work crews can be shifted about, reassigned, or taught new skills. If an automated system reaches capacity, problems that arise cannot be solved by scheduling overtime or increasing the work force. Yet if an automated system has too much excess

capacity the added cost makes its operation uneconomical. Technological advances are overcoming many of these problems, however.

Terminaling

Other forms of warehousing and storage. Similar in principle to conventional warehousing, although employing somewhat different technology, is the storage of bulk products in either liquid or dry flowable form. Intermediate storage of these products comparable to warehousing is usually referred to as terminaling, because the point of storage is usually served directly by rail or water or both, and frequently by pipeline. Dry products requiring protection are typically stored in silos or elevators, while others are stored on the ground outdoors. Because of the high costs of ships, barges, and specialized rail equipment used to transport such products, most storage locations are equipped with high-speed loading and unloading systems employing conveyors and gravity and pneumatic devices. Some export coal-loading points are equipped with massive devices that grasp a railcar loaded with coal and turn it completely upside down, emptying the contents into a high-speed conveyor feeding directly into the ship's hold.

Liquid products are typically stored at "tank farms," which are either public or private operations. Often the tank farm is the terminus of a pipeline and serves as the distribution centre for the region, using tank trucks for final delivery. The use of pipelines for transporting an increasing range of liquid products, plus some limited success with slurried products (solids, such as coal, carried in a liquid), has caused a significant growth in this type of storage.

Household-goods storage follows the same general line as merchandise storage, although because of its static nature there is limited need for sophisticated handling or storage equipment. Often such goods placed in storage are put into pallet vaults—a large box with a pallet base, which both protects the contents and permits efficient handling and stacking by forklift truck.

Storage and warehousing occupy an increasingly important position in the modern, mass-production-oriented economy. Although the technology of warehousing has, in general, lagged behind production technology, sharp increases in the cost of land, buildings, and labour—plus increased dollar value of products—have led in recent years to the application of a systems approach, both to the operations of the warehouse itself and to its unique function in the procurement-production-distribution cycle underlying all manufacturing activity.

BIBLIOGRAPHY. C.H. JENKINS, *Modern Warehouse Management* (1968), is one of the few textbooks devoted to this field. Another is A.J. BRIGGS, *Warehouse Operations Planning and Management* (1960). An excellent chapter on warehousing is included in R.C. COLTON and E.S. WARD, *Practical Handbook of Industrial Traffic Management*, 4th rev. ed. (1965). W. BLANDING, *The ABC's of P.D.M.* (1967), is a booklet explaining warehousing and other physical distribution disciplines in layman's language. CONTROL FLOW SYSTEMS, *Economics of Automated Warehousing* (1970), examines the cost factors in automated versus conventional warehousing in an objective fashion. N.L. ENRICK, *Inventory Management* (1968), is a concise explanation of the inventory concepts and techniques underlying modern warehouse management. E.R. SIMS, JR., *Planning and Managing Material Flow* (1968), is a comprehensive treatment of industrial engineering approaches involved in the handling and storage of goods.

Strabo

The work of Strabo, the Greek geographer and historian, is a major source for contemporary knowledge of antiquity. His *Geography* is the only extant work covering the whole range of peoples and countries known to both Greeks and Romans during the reign of Augustus (27 BC–AD 14). Its numerous quotations from technical literature, moreover, provide a remarkable account of the state of Greek geographical science, as well as of the history of the countries it surveys. Yet, though chiefly a compiler, Strabo left his personal imprint upon his work through his shrewd criticism of the sources he used. Other features of his personality were a keen sense of the practical usefulness of scientific knowledge (under the influence of Stoical teaching) and his admiration for Roman policies.

Formative influences

Born in 64 or 63 BC in Amaseia (now Amasya), the former capital of the kings of Pontus, Strabo belonged on his mother's side to a famous family, whose members had held important offices under Mithradates V (around 150–120 BC), as well as under Mithradates the Great, the opponent of Rome (132–63 BC). His first teacher was the master of rhetoric Aristodemus, a former tutor of the sons of Pompey (106–48 BC), in Nysa (now Sultanhisar in Turkey), on the Maeander. He moved to Rome in 44 BC to study with Tyrannion, the former tutor of Cicero, and with Xenarchus, both of whom were members of the Aristotelian school of philosophy. Under the influence of Athenodorus, former tutor of Octavius, who probably introduced him into the future emperor's circle, he turned toward Stoical philosophy, the precepts of which included the view that one unique principle ceaselessly pervading the whole universe causes all phenomena.

It was in Rome, where he stayed at least until 31 BC, that he wrote his first major works, his 47-book *Historical Sketches,* published around 20 BC, of which but a few quotations survive. A vast and eclectic compilation, it was meant as a continuation of Polybius' *Universal History*. The *Historical Sketches* covered the history of the known world from 145 BC—that is, from the conquest of Greece by the Romans—to the Battle of Actium (31 BC), or to the beginnings of the principate of the Roman emperor Augustus (27 BC).

In 29 BC, Strabo visited the island of Gyaros (today known as Yiáros, or Nisós) in the Aegean Sea, on his way to Corinth, Greece, where Augustus was staying. In 25 or 24, together with Aelius, prefect of Egypt who had been sent on a military mission to Arabia, he sailed up the Nile as far as Philae. There are then no further references to him until AD 17, when he attended the triumph of the Roman general Germanicus Caesar (15 BC to AD 19) in Rome. He died shortly after AD 23, having devoted his last years to compiling his second important work, his *Geographical Sketches*. Judging by the date when he wrote his personal notes, he must have worked on the book after his stay in Egypt and then have put it aside from 2(?) BC to AD 14, when he started the final edition, which he brought to an end in AD 23.

The first two books, in effect, provide a definition of the aims and methods of geography by criticizing earlier works and authors. Strabo found fault with the map designing of the Greek scholar Eratosthenes, who lived from *c.* 276 to *c.* 194 BC; Eratosthenes had combined astronomical data with coast and road measurements, but Strabo found his work lacking in precision. Although Strabo closely followed the treatise against Eratosthenes of the Greek astronomer Hipparchus, who had lived in the 2nd century BC, he blamed Hipparchus for neglecting the description of the Earth. On the other hand, he appreciated Polybius, who, in addition to his historical works, had written two books on European geography that Strabo admired for their descriptions of places and peoples. Although he praised Posidonius, the Greek historian and philosopher who lived from about 135 to 51 BC, for his knowledge of physical geography and ethnography, he rejected Posidonius's theory of climatic zones and particularly his hypothesis that the equatorial zone was habitable. This critical study led him logically to decide in favour of a descriptive type of geography, based on a map with an orthogonal (perpendicular) projection. The problem of projecting the sphere on a flat surface is not dealt with at any length, for his work, as he said, was not designed for mathematicians but for statesmen who must know countries, natural resources, and customs.

In books III to VI, Strabo described successively Iberia, Gaul, and Italy, for which his main sources were Polybius and Posidonius, both of whom had visited these countries; in addition, Artemidorus, a Greek geographer born around 140 BC and author of a book describing a voyage around the inhabited Earth, provided him with a description of the coasts and thus of the shape and size of countries. Book VII was based on the same authorities and described the Danube Basin and the European coasts

His books on Greece

of the Black Sea. Writing about Greece, in books VIII to X, he still relied upon Artemidorus; but the bulk of his information was taken from two commentators of Homer —Apollodorus of Athens (2nd century BC) and Demetrius of Scepsis (born around 205 BC)—for Strabo placed great emphasis on identifying the cities named in the Greek epic the *Iliad*. Books XI to XIV describe the Asian shores of the Black Sea, the Caucasus, North Iran, and Asia Minor. Here Strabo made the greatest use of his own observations, though he often quoted historians who dealt with the wars fought in these regions and cited Demetrius on problems of Homeric topography in the region about ancient Troy. India and Persia (Book XV) were described according to information given by the historians of the campaigns of Alexander the Great (356 to 323 BC), whereas his descriptions of Mesopotamia, Syria, Palestine, and the Red Sea (Book XVI) were based on the accounts of the expeditions sent out by Mark Antony (about 83 to 30 BC) and by the emperor Augustus, as well as on chapters on ethnography in Posidonius and on the book of a Red Sea voyage taken by the Greek historian and geographer Agatharchides (2nd century BC). Strabo's own memories of Egypt, supplemented by the writings of Posidonius and Artemidorus, provided material for the substance of Book XVII, which dealt with the African shores of the Mediterranean Sea and with Mauritania.

Obviously, personal travel notes formed only a small part of the material used in this considerable work, although Strabo prided himself on having travelled westward from Armenia as far as the regions of Tuscany opposite Sardinia, and southward from the Black Sea as far as the frontiers of Ethiopia. Even on the subject of Italy, where he lived for a long time, Strabo did not himself contribute more than a few scattered impressions. His material, accordingly, mostly dates from the time of the sources he used, although the reader is not made aware of this. The value of firsthand observations, chosen from the sources with care, compensates, however, for his lack of originality and contemporaneousness. Strabo showed himself equally competent in selecting useful information—giving distances from city to city and mentioning the frontiers between countries or provinces as well as the main agricultural and industrial activities, political statutes, ethnographic peculiarities, and religious practices. He also took interest in the histories of cities and states, and—when he knew them—mentioned the circumstances under which they were founded, related myths or legends, wars they had instigated or endured, their expansion or recession, and their celebrities. Geological phenomena were reported when they were in some way unusual or when they furnished an explanation for other phenomena—such as the Atlantic tides in Iberia, the volcanic landscapes to be seen in southern Italy and Sicily, the fountains of naphtha occurring near the Euphrates River, and the rise and fall of the Nile waters. Paradoxically, although the description of Greece fills three whole books, such elements are virtually neglected in them. In this part, indeed, Strabo was more attracted by the problem of identifying the localities mentioned in Homer's works than in the geographical realities. These books, however, illustrate another side of his thought, based on the conviction that Homer was perfectly acquainted with the geography of the Mediterranean area and that the correct critical interpretation would reveal his vast learning. This classical thesis is abundantly defended in Strabo's introduction, which attacks the skepticism of Eratosthenes; moreover, it represents, in Strabo's work, the specific contribution to learning of the Greek cultural tradition.

Descriptions of natural phenomena

BIBLIOGRAPHY. The *Geography* was seldom used in ancient times but was often copied in Byzantium; it first appeared in Western Europe as a Latin translation issued in Rome in about 1469, and was then published in the Aldine edition of 1516, based on a faulty manuscript. The first critical edition was that of I. CASAUBON (1587, then 1620), which was followed by that of G. KRAMER—the first to be based upon an analysis of the manuscripts, 3 vol. (1844–52). Various scientific editions by F. SBORDONE, book 1–6 (1963–70); F. LASSERRE, G. AUJAC, and R. BALADIE, book 1–6, 10 (1966–71), with French translation; and W. ALY, book 1–6 (1972), are in progress. These include information from a newly discovered palimpsest from the library of the Calabrian theologian Cassiodorus (born *c.* AD 485). Meanwhile, H.L. JONES' edition, *The Geography of Strabo*, with an English translation, notes, and maps, remains usable ("Loeb Library," 8 vol., 1917–32); it also includes a select bibliography. Fragments of the *Historical Sketches* were last edited and commented upon by F. JACOBY, *Die Fragmente der griechischen Historiker*, vol. 2A (1925). W. ALY, *Strabonis Geographica*, vol. 4 (1957); and G. AUJAC, *Strabon et la science de son temps* (1966), are the best up-to-date standard works. E.H. BUNBURY, *A History of Ancient Geography Among the Greeks and Romans, from Earliest Ages till the Fall of the Roman Empire*, 2 vol. (1879); and J.O. THOMSON, *History of Ancient Geography* (1948), can also be read with profit.

Strafford, Thomas Wentworth, 1st Earl of

As one of Charles I's chief advisers before the English Civil War (1642–51), Thomas Wentworth, named earl of Strafford in 1640, was foremost in the struggle to consolidate the sovereign power of the king, as against Parliament. He was ultimately sacrificed by Charles, however, to appease Parliament.

By courtesy of Earl Fitzwilliam

Thomas Wentworth, oil painting by Sir Anthony Van Dyck, 1636. In the collection of Earl Fitzwilliam.

Wentworth was born in London on April 13, 1593, the eldest surviving son of Sir William Wentworth, a wealthy Yorkshire landowner. Educated at St. John's College, Cambridge, and at the Inner Temple, he was knighted by James I in 1611. His marriage to Lady Margaret Clifford, daughter of the impoverished Earl of Cumberland, established a link with an ancient and noble family still influential in the north. Following his marriage he completed his education by a leisurely journey through France, returning to England shortly before his father's death in 1614.

Wentworth represented Yorkshire in the Parliaments of 1614 and 1621, and Pontefract in 1624. His wife died childless (1622) and he married Arabella Holles, daughter of John, earl of Clare, a peer out of favour at court who brought Wentworth into touch with the critics of the King's expensive and inefficient policy of war against Spain and, from 1627, against France. Along with other critics of the court he was prevented from sitting in the Parliament of 1626, and later in the year he refused to subscribe to the forced loan, imposed to pay for the war, and was for some time under arrest.

Early opposition to the crown

Despite his record of opposition to the King's policy, Wentworth was approached by the crown—anxious to strengthen its position in the north—with the offer of a barony (1628). He was appointed lord president of the north (virtually governor of England north of the Humber) and in 1629 was given a seat on the Privy Council.

Wentworth's return to the service of the court, coming so soon after his vehement opposition to it in Parliament, startled even some of his closest friends. His conduct was no doubt partly inspired by personal ambition, though he had logical reasons for his change of front since in the summer of 1628 the King gradually abandoned his war policy.

On the Privy Council Wentworth seems to have advocated the paternalist government that distinguished the early years of the King's personal rule: closer supervision of justices of the peace, more effective implementation of the Poor Laws, of laws against enclosure, and of measures for dealing with famine, though he was not above privately making profit out of the corn shortage of 1631. As lord president of the north he quelled all defiance of his authority and made many enemies by his insistence on the honour due to him as the King's representative, but his administration was on the whole just and efficient; he supervised the local justices and curbed the often tyrannous excesses of local magnates. In 1631 he was deeply distressed by the death of his much-loved wife, though he provoked scandalous rumours not long afterward by secretly marrying (October 1632) Elizabeth Rodes, the young daughter of a neighbouring squire.

Lord deputy of Ireland

The King meanwhile had appointed him lord deputy of Ireland. Taking up his office in the summer of 1633, he immediately set himself to consolidate the royal authority, break the power of the dominant clique of "new English" landowners, extend English settlement, improve methods of agriculture, increase the productivity of the land, and stimulate industry and trade. His ultimate goal was to assimilate Irish law and customs to the English system and to make a prosperous Protestant Ireland into a source of revenue to the English crown.

Wentworth continued his effective and firm-handed administration of Ireland until 1639, when he was recalled to England by King Charles. The King needed advice and support in handling a Scottish revolt precipitated by an ill-conceived attempt to enforce episcopacy on the Scots. Wentworth was created earl of Strafford (1640) and was expected to resolve the crisis. But his policy of making war on Scotland proved disastrous for both himself and the King. The English Parliament, called especially to vote money for the war, proved recalcitrant, and Strafford, in command of the English army, failed to prevent the Scots from overrunning the northern counties. The King, unable to pay his own troops or to buy off the Scots, was compelled by joint English and Scottish action to call a new Parliament in November 1640.

Strafford was the chief target of attack from both nations. He was advised to leave the country, but the King relied on his help and assured him that he should not suffer in life or fortune. Detained by illness, he reached Westminster on November 10 with the intention of impeaching the King's opponents in Parliament for treasonable correspondence with the Scots. The leader of the Commons, John Pym, acted first by impeaching Strafford before he could take his seat in the House of Lords. His trial began in March 1641. The basic accusation was that of subverting the laws and was supported by a charge that he had offered to bring over the Irish army to subdue the King's opponents in England. More detailed charges rested on his administration in Ireland and the north. He conducted his defense with great skill, and it looked at one point as though he might be acquitted. Pym therefore introduced a bill of attainder (*i.e.*, a summary condemnation to death by special act of Parliament). The Commons passed it by a large majority; the Lords, intimidated by popular rioting, passed it, too, but by a much smaller majority. While an angry mob surged around Whitehall, Strafford wrote to the King releasing him from his promise of protection, and Charles, afraid for the safety of the Queen, gave his consent to the bill. Strafford went to the scaffold on May 12, 1641, in the presence of an immense and jubilant crowd. In his last speech he once more professed his faith in "the joint and individual prosperity of the king and his people," for which, in his view, he had always worked.

Strafford's execution

He remains an enigmatic figure in English history: ambitious, greedy for power and wealth, ruthless, and sometimes dishonest, but with a vision of benevolent authoritarian government and efficient administration to which he often gave persuasive expression. He made innumerable enemies, but his few close friends were deeply attached to him. In the last weeks of his life his dignity, eloquence, and loyalty to the King made a deep impression even on some of his enemies.

BIBLIOGRAPHY. C.V. WEDGWOOD, *Thomas Wentworth, First Earl of Strafford, 1593–1641: A Revaluation* (1961), is the fullest biography at present available, including an extensive bibliography. The *Earl of Strafford's Letters and Despatches*, ed. by WILLIAM KNOWLER, 2 vol. (1739–40), is still the largest printed collection of Strafford's papers, but it contains only about a twelfth of the manuscript material in the possession of Strafford's descendant, Earl Fitzwilliam. J.P. COOPER, "The Fortune of Thomas Wentworth, 1st Earl of Strafford," *Economic History Review*, Second Series, 11:227–248 (1958), is of great importance for Wentworth's financial interests and character.

Stratigraphic Boundaries

Stratigraphy has been defined broadly as the branch of geology that is concerned with the order and relative position of the stratified rocks of the Earth's crust. Such concerns are dependent upon the correlation of stratigraphic rock units and, hence, upon the stratigraphic boundaries that delineate these units. Stratigraphic correlations (*i.e.*, the tracing and matching of primarily sedimentary rock units of equivalent age) serve as the foundation for interpretations of past geologic history and may involve many facets of the Earth sciences. They are intimately related to such practical considerations as the exploration for ore bodies and fuels, and to such abstract questions as the origin of the Earth, the evolution of life forms, and the history of other planetary bodies on which stratified rocks occur. Most groundwater reservoirs, fuel deposits of coal and petroleum, many fissionable atomic substances, and substantial quantities of other economically important minerals are contained in the stratified rock succession.

Stratigraphic boundaries may be based upon purely physical differences, such as the nature of the rock types comprising the strata, or upon the kinds and distribution of fossils within the rock strata, or upon all physical and organic differences that may be related within a certain time span. The boundaries of some types of units may be delineated much more precisely than others.

Elements in the classification of stratigraphic units

A rock unit possesses many physical attributes, such as thickness, horizontal extent, or colour, that reflect some of the conditions prevailing at the time of its deposition as well as some qualities that may have come into existence after its deposition. The rock unit classification is based on such attributes. The fundamental rock units are formations, which may be subdivided into two lesser divisions—members or beds—or into the larger divisions—subgroups, groups, or supergroups—when combined with other formations.

The deposition or removal of rock units from the geologic record by geologic events required varying amounts of geologic time; the same is true for the evolutionary changes apparent in fossils. Early geologists gradually became aware of these time requirements, and thus developed time-stratigraphic and geologic time classifications. The large rock successions deposited during a specific interval of geologic time were called systems. They were recognized not on the kinds or thickness of rocks comprising them but by the inference of their existence within the specified time interval. Systems were combined to form larger divisions, erathems or terrains, smaller subdivisions called series, or still lesser stages, and many stratigraphers recognize a still lesser subdivision, the

zone. Units that dealt with time rather than the time-rock concept were (in descending order of magnitude) eras, periods, epochs, and ages.

Only rarely would rock units be deposited within a limited time interval over wide areas to permit their use as rock-stratigraphic, or lithochronologic, indicators. Ashfalls that result from very large volcanic eruptions during a brief interval of time might serve as such lithochronologic markers, but the actual time at which a geologic event took place can only be determined by radiometric dating or by relative dating based on the fossil content—biochronology. The most common method of dating geologic events is by biochronology, which involves biostratigraphy. In this scheme, rock or stratal units are defined and identified by their contained fossils and are subdivided into a variety of zones. The fourfold scheme of classification devised for time-stratigraphic, geological time, rock-stratigraphic, and biostratigraphic units is indicated in Table 1.

Table 1: Classification of Different Kinds of Stratigraphic Units

time–stratigraphic units	geological time units	rock–stratigraphic units	biostratigraphic units (no hierarchial order intended)
erathem (terrain)	era	supergroup	zones
system	period	group	assemblage
series	epoch	subgroup	faunizone
stage	age	formation	florizone
zone (Oppelian)		member	range zone
		bed	biozone
			teilzone
			ecologic zone
			community–zone
			zonule

Stratigraphic relationships

Stratigraphic data represent various attributes of layered rocks within a framework consisting of the two geographic dimensions (length and breadth) plus that of geologic time. For many years the notion prevailed that geologic time was conveniently divided into eras, periods, and epochs by some sort of worldwide convulsions of the geologic record that had left universally recognizable indicators behind. It has become increasingly evident, however, that the rock record is far from uniform. While erosion and removal of strata were taking place in one part of the world, an adjacent region might be receiving deposits and accumulating a stratigraphic record, and still a third region might remain in a state of equilibrium, undergoing neither deposition nor removal of strata. Illustrating such three-dimensional relationships is difficult. The great majority of interpretations of time-correlative strata are based on data that are sporadic in their distribution in space and time, such as fossils or radiometrically datable minerals, and many attempts at depicting such relationships have been unsuccessful in varying degrees because potentially barren or negative intervals were neglected in plotting.

This article treats the historical background and current practice of stratigraphic classification, and the stratigraphic boundaries and boundary problems that emanate from several kinds of stratigraphic division of the rock record. For further information on the chronology of the record, see GEOLOGICAL TIME SCALE; DATING, RELATIVE AND ABSOLUTE; PLEISTOCENE EPOCH; and ROCK MAGNETISM. For further detail on some of the principles and data germane to stratigraphic classification, see FOSSIL RECORD; SEDIMENTARY ROCKS; IGNEOUS ROCKS, PYROCLASTIC; SEDIMENTARY FACIES; PALEOGEOGRAPHY; UNIFORMITARIANISM; EVOLUTION; and CLASSIFICATION THEORY.

HISTORICAL REVIEW OF STRATIGRAPHIC CLASSIFICATIONS

The principle of superposition of strata. Such Greek scholars as Xenophanes of Colophon (6th century BC), Xanthus of Sardis (*c.* 500 BC), and Herodotus of Halicarnassus (5th century BC) began to record observational data and to discover the principles that governed natural phenomena. Although these classical scholars did not envision the necessity for stratigraphic classifications, they did provide several concepts basic to stratigraphy. Classic uniformitarianism (the concept that presently occurring Earth processes are similar in kind to those that occurred in the past) suggested that the presence of marine fossils on land was an indication of the greater extent of past oceans. Unfortunately, such sensible notions failed to be augmented or re-evaluated until the 16th century, except for the brilliant observations of a few scholars like Roger Bacon (*c.* 1220–*c.* 1292) or Leonardo da Vinci (1452–1519). It was da Vinci's rediscovery of the classical concept of uniformitarianism—in particular that fossils were remains of once-living animals, and that marine types in sedimentary rocks inland indicated the former presence of ocean waters—that seemed to mark the prologue to an era of geology whose first chapter was to be written by Nicolaus Steno in the 17th century. Steno's classic work in geology, the *Prodromus* (1669), laid down the foundation for the fundamental notion of superposition of rocks, a basic principle of stratigraphy vital to an understanding of the sequential relationships of rocks. It is, simply, that those rock layers superpositionally highest in a sequence of strata were formed at a later time. This made possible determination of the proper superpositional order of rock strata and the assignment of relative ages to each layer.

Contributions of Steno, Lehmann, and Arduino

Making use of Steno's principle, further efforts at recognizing rock successions during the 17th and early 18th centuries became increasingly common. Among the most important were those of the Englishman John Strachey, who made the earliest geological map in the modern sense (1725) and described the succession of strata in the coal district of southwestern England (1719, 1725).

Johann Gottlob Lehmann, a German geologist, was probably the first actually to measure the thickness of rock units and to record their sequence. He formulated a superpositional classificatory scheme that long influenced his contemporaries and successors and that is perhaps ancestral to the erathems and eras of the modern geological time scale. This subdivision encompasses: (1) an older, superpositionally lower category, the Primary (*Urgebirge*), made up of rocks of chemical origin thought to be older than "the origin of life," (2) a Secondary (*Flötzgebirge* or "flat-lying") group comprising fossiliferous strata, some derived from superpositionally earlier rocks, and (3) alluvial deposits (*Angeschwemmtgebirge*) resulting from "local revolutions and in part from the deluge of Noah." Lehmann thought that this threefold classification applied to mountains and their origin. Three contemporaries helped to demonstrate the superpositional succession and the utility of Lehmann's threefold classificatory scheme. Giovanni Arduino published in 1759 a work on northern Italy, George Christian Füchsel published in 1762 and 1773 on east central Germany, and Peter Simon Pallas published in 1777 on the Ural Mountains of central Russia. Arduino recognized a Primary and Secondary division that were essentially synonyms of the *Urgebirge* and *Flötzgebirge*, and a Tertiary division, composed of highly fossiliferous and more poorly consolidated sediments occurring on the flanks of the mountains, that was superpositionally older than the *Angeschwemmtgebirge* of Lehmann. The term Tertiary survives as a period name in modern geological classification. Füchsel worked only with the middle category of Lehmann, the *Flötzgebirge* or stratified fossiliferous rocks. He recognized that they could be divided into natural geologic entities, the formations of modern usage, and that such formations represented episodes in the history of the Earth marked by fossils that were distinct in stratigraphic position and unique in kind. This is one of the earliest statements noting differential time relating rock strata and fossils. Pallas recognized the threefold succession of rocks in the Urals but made no other contribution to rock-sequence classification.

Abraham Gottlob Werner (1750–1817), a German mineralogist, was perhaps one of the most renowned and influential geologists of the last quarter of the 18th century. He was a very popular professor of mining and mineralogy at the Freiburg Mining Academy; many of his students also achieved renown and so served to pro-

Werner, Neptunism, and the transition strata

mulgate many of his theories of the Earth. His theory (Neptunism) that formations were uniformly distributed over the globe and that all rocks had been precipitated from a universal ocean provoked one of the great scientific controversies of the 18th century until it was proven false before the century's close. Werner did emphasize the differences in age of successive rock strata and further advanced Füchsel's ideas of the diagnostic potential of fossils in strata. He recognized an additional subdivision within Lehmann's scheme, namely the Transition or *Übergangsgebirge*. This was said to occupy a position between the Primary and Secondary and to consist, he thought, of the earliest fossil-bearing strata of geologic time, one that marked the transition between the Earth's habitable and chaotic stages. This division would become what is now termed the Paleozoic Era. The essentially threefold classification of Lehmann thus had become a fourfold one with several potential subdivisions. Crudely, these divisions marked the pre-Paleozoic (Primary or *Urgebirge*), the Paleozoic (Transition or *Übergangsgebirge*), Mesozoic (Secondary or *Flötzgebirge*), and Cenozoic (Tertiary plus the *Angeschwemmtgebirge*).

By the first quarter of the 19th century the subdivisions of Primary, Transition, Secondary, Tertiary, and post-Tertiary, or Alluvium, were in general use throughout Europe and in eastern North America. In the second quarter of the 19th century the modern terms for geologic eras were substituted. The English geologist Adam Sedgwick first used the name Paleozoic in a lecture in 1838; another Englishman, John Phillips, proposed in 1840 both Mesozoic and Kainozoic (the latter subsequently changed to Cenozoic). All the eras of the geological time scale presently in use except for the Precambrian were thus formally proposed and soon supplanted usage of Transition, Secondary, Tertiary, and Alluvium in their era sense. Thus, although initial attempts by geologists had been to achieve a rock classification, it had now been transformed into a chronologic one and increasing attention was devoted to paleontologic aspects of the geologic record and methods of classifying them in their stratigraphical contexts.

Catastrophism versus uniformitarianism

A contemporary of Steno, Robert Hooke (1635–1703) actually made the suggestion almost a century before its final acceptance as a principle that fossils might be used "to raise a Chronology" and be of assistance in stating "the intervals of the time wherein such . . . catastrophies and mutations have happened." In the succeeding years of the 17th and particularly in the late-18th centuries, workers like Füchsel and Werner had clearly seen the importance of fossils in their stratigraphic context. Interest in them continued to grow apace in the 19th and 20th centuries. These investigations substantiated their importance in determining relative ages of their entombing strata, as well as in their usefulness for correlation and for other stratigraphical purposes.

The world of the 17th and 18th centuries was largely conditioned to thinking of geologic surface features as being caused by catastrophic processes, and of these the biblical Noachian Deluge was thought to have wrought all changes after the Genesis world creation. A few brilliant and brave souls challenged this view after the time of Leonardo da Vinci. Bernard Palissy, a French citizen, published a book in Paris (1580) asserting that fossils were indeed the remains of once living animals. Palissy did not survive his "heresy" but was burned at the stake, as also was Giordano Bruno in Rome in 1600 for denying that there had been a deluge and brashly stating that the positions of land and sea had often interchanged in the past.

For better than three hundred years the fossil controversy raged, and uniformitarian concepts of a dynamic Earth changed by natural, commonplace causes were suspect. Georges-Louis Leclerc, comte de Buffon (1707–88), strongly championed the cause of uniformitarianism, although his ideas of how changes in the geologic past had taken place were not convincing. He maintained that natural processes of a commonplace rather than catastrophic nature played a major role in producing geologic surface features of the Earth.

It remained for the Scotsman James Hutton finally to synthesize (1788, 1795) the data into a convincing hypothesis and demonstrate conclusively that uniformitarianism was a fundamental principle of the science of geology. This important principle and that of the superposition of strata were necessary before stratigraphy could progress beyond a mere classification of rock successions, or before a geological time scale could be devised as a framework for stratigraphic classifications. It now was inevitable that one of the directions taken by subsequent geological investigation would be that related to devising a time scale and determining the relationships of fossils with strata.

The work of Cuvier and William Smith

The idea of a fossil succession. Baron Georges Cuvier (1769–1832) stated that it would be possible to determine the greater or lesser age of some fossil species as compared to others. Baron Cuvier had seen the succession of fossil species in the stratigraphic record and realized their potential value in correlation, even remarking (1817) ". . . but for them, [the fossils] we could never have suspected that there had existed any successive epochs in the formation of our earth. . . ." Cuvier espoused a catastrophist doctrine of periodic destruction and recreation of organic life to explain the changes he saw in the fossil succession. In 1791–93 the Englishman William Smith was engaged in surveying and canal building in England, where his work led him to observe and be impressed with the constant relationship between certain strata and certain fossils. In 1799 Smith dictated a list of fossils common to certain strata that clearly demonstrated his hypothesis that there is not only a succession of rock strata but also a fossil succession, and that one may recognize the relative age of rocks by their contained fossils. In Smith's *Geologic Map of England and Wales with Part of Scotland* (1815), the hypothesis of fossil succession was demonstrated as a valid scientific principle that has since been recognized as one basic to geology in its historical aspects.

The application of the principle of fossil succession to rock successions previously classified on their lithologic (rock characteristics) superposition alone indicated that errors had been made in initial relative-age assignments. In several instances in which lithological characteristics had suggested the placing of rocks in the Primary, their fossil remains indicated that they belonged with much younger rocks. Other strata consisting of little-deformed rocks that had been assumed to be young were now placed with older successions on the basis of fossil content.

Jean-Baptiste-Pierre-Antoine de Monet, chevalier de Lamarck, departed from his colleagues' beliefs that the fossil succession was caused by periodic catastrophic annihilations of living organisms followed by repopulation by newly created forms. Lamarck believed that organisms had evolved by means of their responses to changes in their environment. After each successive environmental change, some organisms, through inability to adapt, did not survive. Others that proved to be more adaptable were able to change their form slightly to survive. Such long-continued adaptation resulted eventually in simple organisms evolving into more complex ones. On studying fossil shells collected by Cuvier and Alexandre Brongniart, a fellow Frenchman, Lamarck determined that almost all were of species unknown in modern seas, and that their nearest living kinship was to types still living in warmer waters of tropical areas. The publication of pictures and scientific descriptions of these shells by Lamarck did much to suggest the correlation of strata with similar fossils in the London Basin and in the region of the sub-Apennines of Italy.

The term Tertiary proposed by Arduino for those fossiliferous sedimentary rocks lying above the Secondary was applied to other rocks traced over broad regions of northern Italy, partially on the basis of lithologic similarity and fossil content. Because fossils from them compared favourably to those in the rocks studied by Cuvier and Brongniart in the Paris Basin, the name Tertiary was extended there and ultimately to rocks of similar age in the London Basin. The name Tertiary became a formal

Lyell and the subdivision of the Tertiary

period of geologic time through the work of Sir Charles Lyell and Gérard-Paul Deshayes. During analysis of the fossil mollusks collected from Tertiary rocks of France, England and Italy, Lyell noted that the stratigraphically oldest beds of the Tertiary (2,500,000 to 65,000,000 years ago) in the Paris and London basins contained only a few species that Deshayes had identified as still living. Stratigraphically higher, and therefore younger beds, on the other hand, contained increasing numbers of still-living species. These percentage differences suggested to Lyell a method for analyzing relatively large fossil aggregates from rock successions of Tertiary age by comparing the numbers of still-living species in them.

The facies concept. The method propounded by Lyell was that percentages of still-living species in large fossil aggregates collected from successive beds of strata could be used to make a subdivision into epochs. His demonstration of the principle resulted in an initial threefold subdivision (Eocene, Miocene, and Pliocene epochs) in 1833. This was subsequently modified into a fourfold classification (Eocene, Miocene, Older and Newer Pliocene epochs). The fossil aggregates used numbered more than 40,000 specimens, all identified by Deshayes. Although the fossils were collected from rock formations vertically arrayed, no attempt was made to discriminate fossil position within formations by horizon of occurrence. Thus, the fossil collections formed sort of a composite of organisms contained within certain formational units that could be distinguished on lithological grounds. Lyell's methods of collection and analysis unwittingly avoided some of the problems inherent in correlation by fossils. The distribution of organisms is a complex matter, and only in the last part of the 19th and first half of the present century have biologists and paleontologists begun to understand the complex patterns and some of the reasons for the sporadic distribution of fossils in rock strata. Organisms tend to adapt to their environment to the extent that their own genetic composition allows them. Populations of organisms, then, reflect these different environments as they are controlled by such physical factors as light, depth (or height), salinity of water, or temperature. Organic factors also influence the nature of the environment, such as the interaction of individuals within a species population or with other species for space in which to live, food to eat, or other factors. Organisms, then, live within an area called a habitat, which is defined by its limiting factors for their particular habitat adaptation. The net effect of this to the stratigrapher is to find fossils that were once living organisms also adapted to their particular environments, and in strata of similar age, different fossils might be present if environmental conditions had been different in both. If Lyell had collected his fossils by horizons of occurrence through successive formational units, he would have found that many stratal units that would seem to be equivalent in age to strata in some adjacent area on the basis of superpositional relationships, would not have seemed to be correlational by the different fossils because of differing environments. Lyell's collections had been made without discriminating horizons of occurrence, and hence were actually a crude random sampling of most of the species adapted to the varying habitats (or facies) represented by the stratal deposition.

Amanz Gressly (1838) demonstrated that although some lithologic types and some fossil faunas of the same age might be remarkably widespread and constant in character, there were many others in which both the lithology and fossil content varied greatly. The variation in lithology of strata of similar age he called facies. He inferred that rocks of a given stratigraphic unit will show more than a single aspect, and that this aspect reflects a variation in the original environment of deposition. That fossil facies exist also is implied, though not specifically stated, by Gressly. Facies, then, may be considered as the differing paleontologic or lithologic aspects of rocks of the same age but different geographic positions. For the discrimination by fossil content of subdivisions of greater refinement than those made by Lyell for the Tertiary, attention henceforth would have to be directed toward obtaining a better understanding of the evolution and causes of distribution of organisms within their stratigraphic and biogeographic context.

The stage concept. The French paleontologist and stratigrapher Dessalines Alcide d'Orbigny had made detailed studies of the exceedingly fossiliferous strata of Jurassic (136,000,000 to 190,000,000 years ago) and Cretaceous age (65,000,000 to 136,000,000 years ago) throughout France. The Jurassic had been subdivided for some years into three epochs on the basis of a fortuitous threefold lithology, and it was also possible to recognize these subdivisions on the basis of their fossil content. D'Orbigny's attempts at more refined correlations from one place to another often met with frustrations because the lithology and fossil content of stratigraphic units that seemed to be similar in age on superpositional grounds would prove to be dissimilar. He determined to devise a more refined classification of the epochs, and finally (1842) achieved a scheme using the principle of fossil succession that gave each successive layer of strata its characteristic fossils. Extensive travel throughout France and familiarity with fossil content of strata of similar age elsewhere convinced him that, despite lithologic variations, similar assemblages of fossils would always appear in the same superpositional relationships. He called these levels of similar fossils *étages* or stages.

D'Orbigny's subdivision of the Jurassic

D'Orbigny's observation was accurate in its general outlines as far as France was concerned, and some faunal elements could be recognized elsewhere in Europe. Facies still played a role in distribution of the fossils, however, and only coincidentally did it happen that the period of time involved (Jurassic) was one in which unusually uniform conditions of environment were to be found in many of the fossil-bearing strata investigated by him, and also that many of the fossils he used were the commonly occurring, extinct cephalopod mollusk, the ammonite. Ammonites were distantly related to nautiloids and were evolving with great rapidity during the Jurassic. Many kinds had remarkable swimming ability and wide ecological tolerances, and some probably also became widely distributed after death because gases buoyed the shells. The net effect was to allow some types to achieve distribution in many different facies. Although d'Orbigny's mode of implementing his hypothesis had many flaws (not the least of which was the fact that there had been little attempt at determining precise ranges of fossils), his notion of stages found quick acceptance among geologists on the Continent and in England. The concept was without question a brilliant one, and, when coupled with an adequate understanding of the geographic and stratigraphic distribution of fossils, has become the standard method of subdividing epochs. Of the ten Jurassic stages d'Orbigny proposed, most are still in use today, although the stratigraphic boundaries have been redefined.

Quenstedt, Oppel, and the refinement of stages

Recognition of zones. About ten years later (1856–58) a professor at the University of Tübingen, F.A. Quenstedt, criticized several of the more glaring flaws in d'Orbigny's work. One of the more important of these criticisms was that d'Orbigny's fossils had not been collected systematically through strata, and it was thus often impossible to recognize whether strata belonged to one stage or another. Quenstedt felt that the stage boundaries should be based upon the precise stratigraphic range of species. Distribution was not only a matter of vertical or time distribution but of horizontal or geographic distribution as well. He recommended that stratigraphers could better spend their time investigating the bed-by-bed occurrences of fossils than cataloging stages from the most remote corners of the world. The check lists of fossil occurrences would show range of species in each stratigraphic section. An evaluation and synthesis could then be made of the check lists, showing the range of each species in strata from many localities. Only in this way, he argued, could a true understanding be obtained of the ranges of individual species in strata. An understanding of the succession of faunas in strata would result from such studies, and this would provide an idea of the development of evolution within fossil lineages.

Quenstedt's pupils and a following generation of their

pupils continued to make detailed investigations of Jurassic strata throughout the world. The most important of these pupils, Carl Albert Oppel, not only refined the stage but also subdivided it into Zones. (The use of an initial capital letter in "Zone" is a convention indicating that the term is being used in the sense defined by Oppel.) His achievement was more than just the subdivision of stages into Zones, however, for he established a principle based upon the ranges of lineages of fossils that could be applied to units of any magnitude within the geologic time scale. He was able to define distinctive faunal aggregates within stratal successions by the overlap of ranges of several species. By carefully delineating both the upper and lower boundaries of these subdivisions on the basis of the appearance of new species or the disappearance of old species, his Zones could be made both contiguous with each other and mutually exclusive. The boundaries could be more precisely located than any previously devised. He redefined the stage as being made up of groups of Zones, and he therefore defined on the same basis—that is, by overlap of species ranges. In his method of delineating Zones, he determined the range of species throughout the region of outcrop of Jurassic strata in Europe by employing Quenstedt's method of making a synthesis of the range of a species in many local stratigraphic sections. He then selected the Zones on the basis of the overlapping ranges of species that were also of widespread occurrence. Contiguous zones were selected by overlaps in ranges of other widespread species for the subjacent and superjacent Zones. The Zone, in Oppel's words (1856–58), is ". . . marked in any place by a number of species that are constant for it . . .," or, in other words, those with widespread distribution and overlapping ranges. If quantitative data for relative abundances are presented, they allow paleoecologic analysis as well, and thus facies occurrences may be distinguished from those significant of chronologic events.

Zones of the Jurassic and Miocene

Figure 1 illustrates six of the Jurassic Zones and some of the fossil species on which they are based. The Zone of *Arietites bucklandi* is based on the joint occurrences of two species with differing ranges in time, here called "species J" and "G," of the *Arnioceras semicostatum* Zone by overlap in the range of "species G" and "Q," and so on. The zonal fossils are characteristic but are not necessarily confined in their occurrence to the Zone.

Based on Arkell in James R. Beerbower, *Search for the Past: An Introduction to Paleontology*, 2nd ed., © 1968; by permission of Prentice-Hall, Inc.

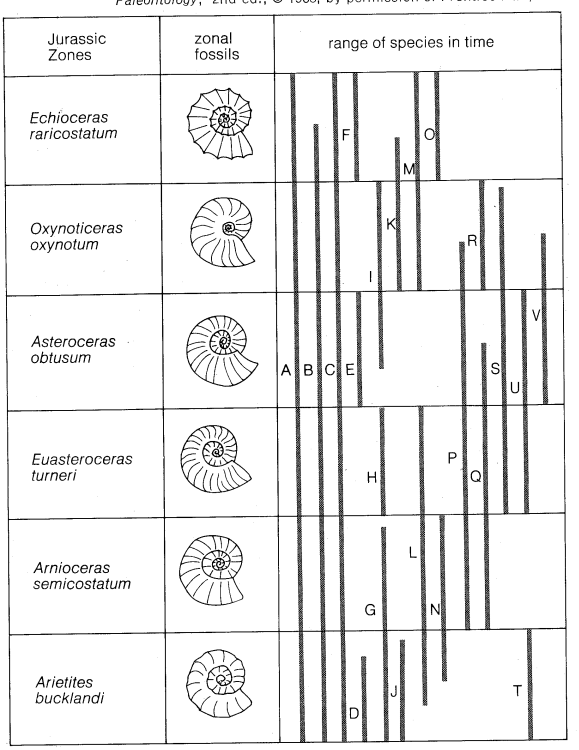

Figure 1: *Jurassic fossil zones and zonal fossils.* These six ammonite species never overlap in stratigraphic distribution and therefore provide a guide for correlation wherever they occur. The ranges of hypothetical species (indicated by letters) within the Jurassic are also shown.

Many successful applications of zonal subdivisions have been made since Oppel's time. Perhaps the most rigorous and innovative, as well as successful, has been the work of the American paleontologist and stratigrapher Robert M. Kleinpell. Kleinpell's six stages and their zonal subdivisions for the California Miocene series (7,000,000 to 26,000,000 years in age) were based upon collections of fossils deliberately made to represent the majority of faunal facies within the strata. His check lists served not only to present distributional data for chronological evaluation but also relative abundances of species. These latter were used in paleoecological evaluation. The final synthesis of data presents a comprehensve picture of the paleogeography of the Miocene and indicates major transgressive cycles (advance and retreat of seas) and orogenic events (mountain building and volcanism), suggesting their possible relation to cycles and events of similar ages in areas remote from California.

It must be noted that a vast gap exists between theory and practice with regard to stages and Zones. D'Orbigny's concept of stages delineated over the whole Earth would hold if well-documented species ranges existed for each succession of epochal strata over the world. Oppel's work extended Zones enormously and transferred them from mere local records of succession to correlational planes of much wider (theoretically universal) application. One of the more significant subsequent contributions to Oppel's method of zonal determination has been the realization that geographic limits do exist within which a Zone is valid. Outside these limits, it may not be recognized. The limitation results from the fact that most species are confined in their distribution to a particular region, termed a biogeographic province; or if they have migrated beyond this province, then their range in time is frequently so great as to not be practical for the discrimination of Zones. The Zone in the sense intended by Oppel is considered to be biostratigraphic rather than time-stratigraphic by some authorities and is called concurrent range zone.

Introduction of radiometric dating. The development of radiometric dating of rocks has been accomplished only in recent years, and a radiometric time scale is still in its infancy. Because most radiometric dates are obtained from intrusive igneous rocks (those crystallizing from silicate melts within the Earth), which often cannot be related with stratigraphic precision, large gaps occur in the dates, and the accuracy of others is open to question. The eras, periods, epochs, and some of the stages and Zones of geological time have been given absolute values in years by radiometric dating. Within the most recent geological period, the Quaternary (the last 2,500,000 years), it has been possible to date many carbon-bearing organic substances that are not older than approximately 40,000 years by the carbon-14 method. Within this time interval many major advances and retreats of glaciers, climatic changes, important dates in human history, the times of migration of animal and plant species, and past volcanic eruptions have been dated by the carbon-14 method.

STRATIGRAPHIC NOMENCLATURE IN THEORY AND PRACTICE

Terminology and standards. Since the first half of the 19th century, the work of constructing a standard time-stratigraphic and geologic time chronology has been vigorously pursued by geologists in many parts of the world. Without an organized body to suggest uniform standards, there was great divergence in terminology used by different stratigraphers. By the last quarter of the 19th century it was evident that greater uniformity would be desirable, and the First International Geological Congress was held in 1878 in Paris. The primary purpose was to study "uniformity in geological reports with respect to nomenclature and map symbols." The International Commission appointed during the First Congress made its report at the Second Congress, held at Bologna in 1881. The classification adopted at the congress was a dual hierarchy of chronologic and stratigraphic terms.

Stratigraphic commissions and codes

Table 2: Classification of Stratigraphic Units

time–stratigraphic units	geological time units	rock–stratigraphic units	biostratigraphic units (no hierarchial order intended)	geological climate units (for use in the Quaternary)
—	eon	supergroup	assemblage zone	glaciation
—	era	group	subzone	stade
system	period	subgroup	zonule	interstade
series	epoch	formation	range zone	interglaciation
stage	age	member, tongue, lentil bed	local range zone	
			concurrent range zone	

Source: American Commission on Stratigraphic Nomenclature (1961).

The Eighth Congress (1900) in Paris adopted a somewhat revised code in which the subdivision of age is called phase, and the term Zone is substituted for a subdivision of stage. No subdivision of Zone is indicated.

Usage in North America has tended to diverge somewhat from that of Europe. A general committee was appointed in 1930 by the Association of American State Geologists to study the question of a more general uniformity in stratigraphic and geologic nomenclature. The stratigraphic code that resulted from the committee's deliberations was presented in 1933. It differs from those of the International Commissions in replacing the stage and Zone by local rock unit names.

An American Commission on Stratigraphic Nomenclature was established in 1946. It adopted a code involving the idea of multiple categories of stratigraphic units, a device that is of great utility. Table 2 indicates this fourfold classification into rock-stratigraphic, soil-stratigraphic (no formal nomenclature), biostratigraphic, and time-stratigraphic units. Two additional categories that are considered to be closely related to stratigraphic units are included: namely, geological time units and geological climate units that have a unique usage in Quaternary stratigraphy (the last 2,500,000 years).

Formations, groups, members, and beds

Rock-stratigraphic units. The rock-stratigraphic classification is based upon lithologic changes in the stratigraphic record. Boundaries between units are placed either at sharply bounded differences in lithology or are fixed arbitrarily in gradational intervals. The fundamental unit is the formation, which is characterized as being lithologically homogenous, "prevailingly but not necessarily tabular," and permitting mapping at the surface or tracing in the subsurface. Its homogeneity might consist of a uniform lithology (sandstone for instance), or it might be composed of members or beds of varying lithology (*e.g.*, alternating sandstone, shales, limestones, and conglomerates). Its deposition may have occupied a large or small amount of geologic time, and the layers need not have been continuously deposited but may include breaks in the time-stratigraphic succession. Both sedimentary and extrusive igneous-layered rocks may properly constitute formations—for instance, a limestone that is interbedded (alternates vertically) with a volcanic ash or tuff layer. Only those metamorphic rock bodies in which original textures or structures allow the geologist to recognize mappable units may be considered stratigraphic. Intrusive igneous bodies that are discriminated by mineralogic or textural characteristics or chemical composition may be classed as formations or groups but not treated in the time-stratigraphic sense.

Formal assemblages of several associated formations are called groups; several formations within groups that are designatable may be defined as subgroups. Supergroups are formal assemblages of two or more related groups or groups and formations.

Rock-stratigraphic categories of next inferior magnitude to formations are the members, and units inferior to them in magnitude are beds. Such inferior categories are used to designate distinctive rock-stratigraphic subsidiary units within larger bodies. They may or may not be restricted geographically, but are frequently of local significance only as cartographic units.

Names for rock-stratigraphic units are compounded from a binomial consisting of a geographic name derived from characteristic exposures in combination with either the lithologic term, if appropriate, or the word formation, if made up of more than a single rock type. Examples are Cowlitz Formation, Stillwater Member of Cowlitz Formation, Roop Sandstone, or Pereira Shale. Names applied to beds are rarely given formal recognition in the body of stratigraphic nomenclature, and they may apply to coal beds, oil sands, beds of significance in rock quarries, aquifers, or conspicuous fossil horizons.

Soil-stratigraphic units

Also recognized are soil-stratigraphic units, which are rock-stratigraphic in nature, though no formal nomenclature has been proposed for them. Such units are composed of residual soils (soils formed mostly in place from underlying rock-stratigraphic units) exhibiting sufficiently distinctive features and stratigraphic relations to permit them to be constantly recognized and mapped in the manner of a stratigraphic unit. Although a soil-stratigraphic unit may coincidentally constitute a pedologic (soil) unit also, it might be distinct from others by comprising one or more pedologic units or parts. Boundaries of soil-stratigraphic units are placed at sharp differences in lithology or within gradational intervals. Formal names are given by rules governing rock-stratigraphic nomenclature but should not conflict with either the latter or with pedologic names.

Time-stratigraphic units. The time-stratigraphic unit differs from a rock-stratigraphic unit because time plays only a coincidental role in the deposition of the latter and none in its definition. Lithology, on the other hand, although playing only a coincidental role in time-stratigraphic boundaries, is all important for rock-stratigraphic designations.

Systems, series, and stages

The Commission recognizes the system as the fundamental unit for the worldwide time-stratigraphic classification of rocks of the Paleozoic, Mesozoic, and Cenozoic eras. The systems of Precambrian time (*q.v.*) are not yet sufficiently defined or widely accepted. The series is next in rank below the system, and is defined in the same way as system but of lesser magnitude. A stage, according to the Commission, is the time-stratigraphic unit of lower rank than series, and is based on a succession of biostratigraphic zones.

Historically many of the early geologists selected boundaries that fell at hiatuses (breaks or gaps) in the record because these frequently marked drastic changes in lithology or faunal content or some pronounced physical break. The percentage of living species used by Lyell for time-stratigraphic subdivision of the Cenozoic was previously noted. The system was the first time-stratigraphic unit to be named. This naming was the historical accident wrought by Arduino's introduction (1759) of the term "Tertiary," which is the only term of those from the earliest classifications of rock successions to survive into modern times.

Faunal evolution and biostratigraphic units. For much of the 19th and early 20th centuries, many geologists believed that diastrophism (the deforming and building processes of geology that result in continent or mountain making) was the ultimate basis for dividing geologic history. The theory holds that diastrophic movements are cyclic and synchronous on a worldwide scale. Biologic events such as fossil evolution were thought to occur in conformity with stratigraphic systems and series because like them they were closely influenced by diastrophic events. The concept seemed to offer a simple explanation for the occurrence of those times of apparent rapid evolution in the geologic past when accelerated rates of morphologic change resulted in increased complexity or anatomical specialization. Many more new species and genera were developed in a shorter span of time during inter-

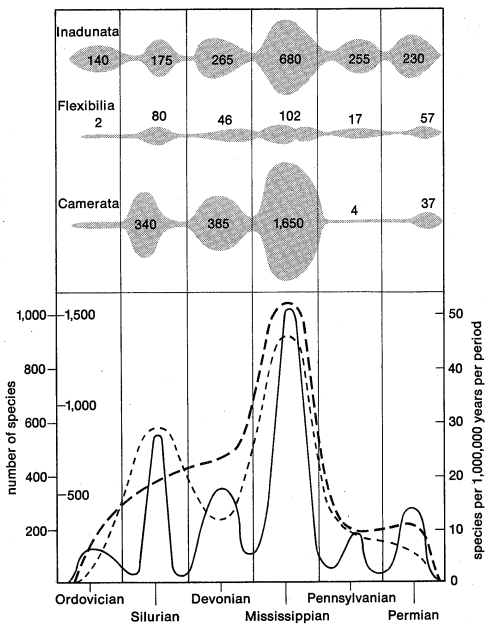

Figure 2: *Paleozoic crinoids of various ages.*

vals termed explosive or eruptive. Whether such evolution was really rapid or only seems so because of (1) missing parts of paleontologic history, (2) unusually detailed study of some groups that resulted in recognition of many more species and genera in certain groups than in others, or (3) had actually been more rapid than in more conservative lineages is a subject of some dispute. Diastrophism has often been cited as the major causative agent for evolutionary changes in groups of organisms. If it did indeed play such a role, it affected different groups in different ways at different times. The evolution of crinoids (sea lilies) and trilobites, for instance, does not follow the same pattern. The crinoids reached a peak in described numbers of genera (one measure of rapidity of evolution) in the Middle Mississippian Period (325,000,000 to 345,000,000 years ago; see Figure 2). Diversity is also greatest at this time in the three subclasses of the group. Trilobites, on the other hand, are most diverse in numbers of species in the Cambrian (500,000,000 to 570,000,000 years ago) and Ordovician (430,000,000 to 500,000,000 years ago). Figure 3 illustrates the varying importance of different fossil groups throughout geologic time. The most useful groups stratigraphically are those with a complex morphology, widespread geographic distribution, fairly common occurrence, and rapid evolution. It is apparent that the crinoid maximum does not correspond with their time of greatest stratigraphic usefulness, whereas the trilobite maximum does. Some of the difference in stratigraphic usefulness of the two groups is related to a possibly more restricted environment of development for crinoids than for trilobites, resulting in greater representation in the stratigraphic record for the latter. Many so-called intervals of explosive evolution reflect preserved lithologic facies, accidents of discovery, concentration of research, or other factors; some others may reflect diastrophism. Several important stocks of invertebrate animals (trilobites, brachiopods, corals) show extinctions or marked evolutionary change toward the close of the Paleozoic Era (Pennsylvanian [280,000,000 to 325,000,000 years ago] and Permian [225,000,000 to 280,000,000 years ago] periods) when one of the large widespread diastrophic events of the geologic record took place. On the other hand, the nautiloid evolutionary peak seems to have occurred in Ordovician times, the crinoids in Mississippian time, and the ammonites in Jurassic time; yet none of these periods is regarded as one of outstanding diastrophic activity. Figure 1 illustrates the use of a rapidly evolving invertebrate group (ammonites) during its peak period (Jurassic) for classification. Although many species of ammonites were present in the strata, each one's time of existence as a species was variable: some were long ranging in time, and others were of relatively short duration. The most refined correlations of strata are made by selecting short ranging species or combinations of first and last occurrences of mutually occurring species. It is evident that evolution has not been uniform in all fossil groups, and that it has not coincided with stratigraphic events reflecting diastrophism. Each geologic period has some groups whose evolutionary and distributional attributes make them better suited than others for classification of geologic time. It is probable that diastrophism has played an important though not dominant role in evolution by affecting lineages of species where tectonic activity has been prevalent. Any change in the physical and chemical environment will introduce conditions favourable to some organisms but not to others. Because some species cannot adapt to such changes or be stimulated to evolve eventually into types that can, they are forced to either migrate or perish. It is evident that diastrophism cannot be invariably or regularly related to fossil evolution, and from this standpoint it also cannot be used as the "ultimate basis" for correlation or subdivision of the geologic record.

Evolution of crinoids and trilobites

The solid line indicates the group is important for worldwide zoning and correlation; the dashed line means that it was important in regional correlation; the dotted line signifies only occasional or rare use as zonal fossils.

Assemblage zone and biozone

A biostratigraphic unit is one defined as a body of rock strata characterized by its content of fossils contemporaneous with the deposition of the strata. The assemblage zone is a descriptive unit defined as a bed or group of beds characterized by an assemblage of organisms, one of which is chosen to give its name to the unit, although it need not be confined to this unit or found in every part of it. It is evident that the unit is defined by its directly observable fossil content and requires no interpretation (as does a Zone in the sense of Oppel) for its recognition. Fossils may occur jointly because they were part of an ecologically adapted community (*i.e.*, faunule) or as a result of transport that has brought some or all organisms from geographic sites other than that of their final deposition. Not all fossils in such an assemblage, or possibly none, are of value in interpretation of time, paleoecology, or biogeography. Three successive assemblage zones at three geographically separate sections are depicted in Figure 4. The top part of the figure illustrates the predominant fossils in each and their distribution in the strata; the middle portion depicts the lithologies in each section and the time lines between the sections, based upon an interpretation of the range of brachiopod and graptolite species in each. The lower diagram illustrates the distribution of the five range zones. None of the zones, based on either assemblage or range, need be mutually exclusive, or contiguous, nor need they maintain the constant lateral relationships that an Oppelian Zone or other time-stratigraphic unit would display. Detailed collecting of fossils from the graptolite-bearing shales of

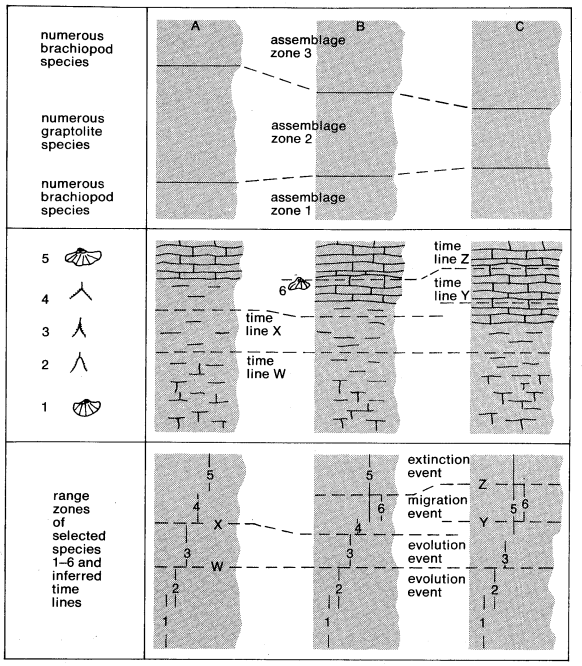

Figure 4: Assemblage zones, selected range zones, and time lines inferred with varying degrees of confidence, in three stratigraphic sections (see text).
From Don L. Eicher, *Geologic Time* (1968); Prentice-Hall, Inc., Englewood Cliffs, New Jersey

assemblage zone 2 shows a vertical gradation of species that appears to represent an evolutionary line or phyletic lineage. The evolutionary event of appearance of a new species or its extinction is a unique event in time, and therefore for each new species and its extinction within these strata, one can infer a time-stratigraphic unit for which many stratigraphers utilize the term biozone. This refers to the deposits formed during the life span of a taxon, which can be any rank, such as species, genus, family, order, or higher rank, in a hierarchial system. Some geologists have rejected the term biozone, declaring that it has been used in the time-stratigraphic sense for the strata deposited during the life span of a taxon and for the total time span of a taxon. It has been recommended that the term be retained in its time-stratigraphic sense and redefined to include all the rocks deposited anywhere during the entire life span of the taxon.

Teilzone, peak zone, and concurrent range zone

The German term teilzone was introduced for the local time of existence of a taxon. Arkell proposed the substitution of teilchron for this term and redefined teilzone in conformity with his definition of biozone as the rocks deposited during the teilchron of any taxon. A geographically widespread taxon might, with such a definition, have an infinite number of teilchrons and teilzones, and unless agreement were reached as to geographic limitations, the terms would be of limited utility. For this reason, and because natural aggregates of organisms tend to occupy areas of land or water termed provinces as floras or faunas, the American stratigrapher V.S. Mallory proposed that the local extent of the teilchron and teilzone be constituted by a biogeographic province. The Commission does not separately classify the time value of a range zone from its biostratigraphic value. Many stratigraphers, however, would consider a range zone as an observational unit in strata, the biozone or teilzone as interpretive and time-stratigraphic, and the biochron or teilchron as interpretive and geological time terms. Figure 5 illustrates the various factors that influence biostratigraphic occurrences of fossils. These are: (1) evolution (first appearance of a taxon), (2) extinction (last appearance of a taxon), (3) nondeposition, (4) erosional removal, (5) environmental exclusion, and (6) migration.

The term subzone is recognized by stratigraphers as a subdivision of zone, and the term zonule as the smallest recognized subdivision of a zone. Zonules need not be vertically contiguous, but can be recognized only when a zone has been subdivided into subzones. Unfortunately, the term duplicates a biostratigraphic term for the preserved remains of a fossil community in strata, zonule.

Peak zones are zones characterized by an exceptional abundance of a taxon, such as an abundance of species reflecting a near optimum or optimum environmental condition. The terms epibole, acme zone, and flood zone have been commonly used for somewhat similar phenomena that express environmental optima. Characteristically, because such environmental conditions may change in time, migrate laterally, and frequently be of sporadic occurrence, the peak zone has environmental rather than temporal significance; locally, if its distribution is well understood, it may be useful in the latter sense.

A concurrent range zone is a biostratigraphic unit defined by the overlapping ranges of specified taxa from one or more of which it takes its name. This zone has a type section that serves as a standard of reference. The specified taxa are only those that form a unique association, however, because of an overlap in their ranges. Normally, only a few of the species that occur jointly in a sample will be useful for establishing such a zone. Some will be too long ranging in time, others may represent the peak zone of time-recurrent epiboles, others may represent some other paleoecologic control on distribution, and still others may be of too short range to define zonal boundaries. Many stratigraphers consider concurrent range zones to be time-stratigraphic, because the boundaries are based on such time-related events as evolution or provincial migrations in first and last appearances of taxa in strata. These zones are based on designated rock successions through which the vertical ranges of the contained fossils have been determined.

Modified after Teichert in James R. Beerbower, *Search for the Past: An Introduction to Paleontology*, 2nd ed., © 1968; by permission of Prentice-Hall, Inc.

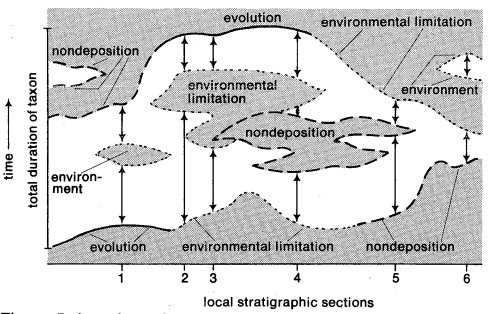

Figure 5: Local stratigraphic sections showing the factors limiting the stratigraphic range of taxon. The total potential stratigraphic range is set by evolution (lower limit) and by evolution or extinction (upper limit). In any particular local section, nondeposition (or erosion) and environmental exclusion further limit the range. The ranges in any two local sections, therefore, may or may not indicate an overlap in time.

Biostratigraphic boundaries differ from rock-stratigraphic in fundamental concept because fossils define the one, rock type the other. It may happen that a lithologic change also is reflected in responses of the fossil community to a change in the depositional environment, but the boundaries may also cross or lie at quite different horizons. Biostratigraphic units are bounded physically by the strata characterized by a certain fossil or fossils and extend no further than the limits of these fossils in the strata. Commonly, biostratigraphic data provide the best means for defining time-stratigraphic boundaries.

Geological time units. Geological time units are nonmaterial units that represent specific segments of time distinguished on the basis of the rock succession. Time terms are useful in geology, particularly for correlation, and in historical geology, despite the fact that a fossil or a rock succession can be related to a certain time interval only by inferring its position within a rock succession. Boundaries of such units depend on specified sections of the type area of the systems, a time-stratigraphic unit. A period was the time interval spanned by the deposition of the system. The boundaries of time units are probably imprecise because paleontologic and radiometric correla-

Period, epoch, and age

tions lack precision. The epoch is the time of deposition of its time-stratigraphic equivalent, the series, and the age is the time equivalent of the stage. The post-Precambrian systems are grouped together into three subdivisions that lack a time-stratigraphic name in the Commission's recommendations, but that are called erathems by many stratigraphers or terrains, a name widely employed in Europe. The time equivalents of these latter are termed eras. George Halcott Chadwick in 1930 proposed the use of the term Cryptozoic Eon for Precambrian time, and Phanerozoic Eon for the post-Precambrian eras. The term eon is recognized by the Commission as being a combination of several eras.

Stratigraphic boundary problems. *Lower Paleozoic boundaries.* The great significance of the Cryptozoic-Phanerozoic boundary (essentially, the base of the Cambrian, which marked the beginning of the principal fossil record) was crudely recognized by Werner's recognition in the 18th century of the "Transition" as being distinct from the *Urgebirge* and *Flötzgebirge*. Of the many people who subsequently studied Werner's Transition rocks, the British geologists Adam Sedgwick and Sir Roderick Impey Murchison were paramount. In 1831 they jointly began field work on thick successions of Transition rocks in Wales. Sedgwick recognized a stratal sequence of rocks in North Wales that he named the Cambrian System (500,000,000 to 570,000,000 years old), while Murchison defined the superpositionally higher Silurian System (395,000,000 to 430,000,000 years old). The formal names were proposed in 1835, as was a recommendation that "Transition" be abolished in favour of Cambrian Silurian. Sedgwick's studies emphasized structure and lithology, and although he described the rocks in detail, he included none of the fossils. Murchison, on the other hand, clearly used Smith's principle of faunal succession and implied that the Silurian System could be recognized elsewhere by its characteristic fossils. In 1842 Murchison's further studies indicated to him that the oldest fossiliferous rocks were Silurian and that fossils from Sedgwick's Cambrian were the same as those in his Lower Silurian. Since Sedgwick had failed to define the fossils as well as the rocks in the system, and Murchison by now had claimed all fossiliferous rocks in both his Silurian and the pre-Silurian of Wales, he was hard put to defend the existence of a Cambrian. Not until the middle of the 19th century were fossils from Cambrian rocks finally described, and the Murchison-Sedgwick controversy, on which the fate of the Cambrian system hung, was not resolved until 1879. In that year another British scientist, Charles Lapworth, published the result of his studies of Cambrian and Silurian rocks. He recognized the existence of three distinctive faunas. One was characteristic of the Lower Silurian, one of the Upper Silurian described by Murchison, and a third consisted of the lower part of Sedgwick's Cambrian rocks. Lapworth proposed that the name Silurian be restricted to the upper strata of Murchison's Silurian with its distinctive fauna. Cambrian, he suggested, should be redefined to include the lowest fauna and strata found in Sedgwick's original type. He further proposed that the distinctive middle fauna and the strata included both in the type Lower Silurian and type Upper Cambrian be defined as a new system, the Ordovician (430,000,000 to 500,000,000 years old). And so, about a half dozen years after the deaths of the two disputants the Gordian knot of one of the early boundary disputes was finally untied.

Upper Paleozoic boundaries. In the years 1836 through 1839, prior to their controversy, Sedgwick and Murchison spent some time investigating the stratal succession next above the Silurian. Lying above Murchison's Silurian System was a distinctive red-coloured sandstone unit that was called the Old Red Sandstone. These sandstones were recognized as a widespread lithologic unit in many places in South Wales and on its border. The age of these beds was thought to be Carboniferous (280,000,000 to 345,000,000 years old). Fossil plants collected from strata in Devonshire and thought to be possibly Cambrian or Silurian in age attracted their attention, and the two scientists traveled to Devonshire. The plant fossils were finally determined to belong to Carboniferous rocks lying above some deformed graywacke (a sandstone with a muddy matrix and rock fragments) and interbedded limestones that lithologically were similar to some Cambrian strata in Wales. The limestones at Devon differed in bearing fossils, including corals, that were lacking in the Cambrian and differed from known Silurian corals. William Lonsdale, an amateur paleontologist, became interested in the problem. He had become a specialist on Carboniferous corals and was familiar with those from Silurian strata. He concluded that the corals collected by Murchison and Sedgwick were intermediate in age between those of the Silurian and Carboniferous systems. In 1839 Sedgwick and Murchison published a paper in which the name Devonian System was formally proposed for the strata lying beneath the Carboniferous and bearing fossils intermediate in characteristics between those of the Carboniferous and the Silurian. The Devonian was considered to be equivalent to the Old Red Sandstone, which bore only plant and fish remains.

Determination of the Devonian, Carboniferous, and Permian systems

Murchison learned of fossiliferous strata exposed in European Russia and accepted an invitation in 1840 from the Tsar to study them. Together with the French paleontologist M. de Verneuil and the Russian Count Keyserling, an excursion to the region was made. Murchison was able to recognize strata of a succession representing the Silurian and red sandstones containing fossil fishes similar to those contained in the Old Red Sandstone of Great Britain. Interbedded marine fossils of Devonian age were interbedded with the red beds and thus conclusively demonstrated that the Old Red Sandstone was indeed of Devonian age. On a return to Russia the following summer, Murchison and de Verneuil studied a thick deposit of fossiliferous limestone containing fossils younger than the Carboniferous but superpositionally below and grading upward into deposits of red sandstone and shale. Although these rocks contained fossils somewhat similar to those contained in the Carboniferous, they contained fossil fishes and amphibians similar to known post-Carboniferous fossils. The Magnesian Limestone of England contained such fossils. It was known to pass from limestones into a red bed facies as it was traced westward. The red bed facies was called the Lower New Red Sandstone and assumed to belong to the Triassic System. A similar relationship between the Zechstein, a fossiliferous unit in Germany (with similar vertebrate fossils), and the Triassic suggested that it was correlative with the Russian unit also. Murchison determined that these strata lying between the Carboniferous and Triassic (190,000,000 to 225,000,000 years old) belonged to a new system, the Permian (225,000,000 to 280,000,000 years old). The previous inclusion of Zechstein and Magnesian Limestone in the Triassic was shown to be in error.

The type Permian has yet another boundary problem, one of several that plague geologists today. Murchison's type Permian had a lower boundary in sandy strata that overlay a limestone. Subsequently, it was found to contain a fossil fusulinid fauna younger than any known in the type Carboniferous. The question of the appropriate inclusion of these beds within either the Permian or Carboniferous systems is not yet settled.

Boundaries of all systems have been the subject of different interpretations by geologists from their first formal naming. Physical boundaries were found to be lacking or in a different position outside the type areas. Fossil facies were discovered to differ from one geographic place to another. With more detailed knowledge of the stratigraphic succession, unconformities were found to mark many of the boundaries in some places, whereas more complete successions were present elsewhere. A proposal was made at the International Geological Conference in 1964, in New Delhi, that a reinvestigation be made of systems in general, and that subsidiary types be redesignated in sections where more continuously deposited strata could be found. Although the suggestion contains much merit, many geologists believe that boundary disputes will always exist.

Cenozoic boundaries. Cenozoic boundaries (the Cenozoic Era began 65,000,000 years ago) present some

unique problems. Lyell was careful to point out (1833) that the epochs and series subdivisions he proposed for the Tertiary (2,500,000 to 65,000,000 years ago) were not necessarily the only ones ever to be delimited within the Tertiary. He was quite aware that further analysis of its faunas might lead to more refined subdivisions, which later took place. In 1839 Lyell modified his original terminology and renamed his Newer Pliocene the Pleistocene (10,000 to 2,500,000 years ago), and restricted the Pliocene (2,500,000 to 7,000,000 years ago) to his former Older Pliocene. Shortly thereafter, investigations of glaciation in Europe, particularly in the Alps, led Edward Forbes, an English naturalist, to declare in 1846 that the glacial epoch was synonymous with the Pleistocene. In 1873 Lyell abandoned his original basis of defining Pleistocene on the fossil content and accepted the idea of the glacial epoch (*i.e.*, time of glaciation) as the criterion for delineating the Pleistocene. The climatic basis for definition has brought about its own peculiar set of problems. It is difficult to relate alpine glaciation in regions with continental glaciation of the lowland areas. It is also difficult to relate the events of glaciation with those of nonglaciated areas, and frequently difficult to relate the continental succession of rocks to the more completely preserved succession of marine fossiliferous sediments. Moreover, the advent of glaciation occurred much earlier in some places (as in more northern areas) than in others, so as a time-defining characteristic, glaciation is not appropriate on a worldwide basis.

The Pliocene–Pleistocene and Pleistocene–Recent boundaries

Somewhat similar problems beset the recognition of the Recent or Holocene Epoch (the last 10,000 years, approximately). Lyell originally defined it rather loosely as the strata deposited subsequent to the Pleistocene. If the Pleistocene ended by the retreat of the last glaciation, then the meaning of the term is evident. If, however, as many geologists believe, the present is merely one of several interglacial intervals that have occurred, then the designation Pleistocene would seem more appropriate than Recent for the strata and life of today (see below *Climatic units*).

Other terminologies and divisions. *Sequences of strata.* Cyclic or supposedly cyclic phenomena have received much attention as possible methods of classifying geological events. The strongly catastrophist viewpoint about geologic events of many 17th and 18th century geologists undoubtedly coloured 19th and early 20th century views of diastrophism on a worldwide and intermittent basis. During uplifts of land areas, there was universal retreat of the seas with consequent erosion and formation of unconformities, whereas during submergence of land areas, universal deposition of sediment occurred. One of the strongest advocates of correlating geologic events by means of diastrophism, either by reference to unconformities or related effects, was the American geologist T.C. Chamberlin, who in 1909 referred to it as the ultimate basis of correlation. Although some widespread diastrophism has undoubtedly taken place in the geologic past, there is little evidence or belief today that tectonic activity involving uplifts or subsidence of land areas with consequent withdrawal or advance of seas has been synchronous everywhere, but rather at times affected some areas a great deal, others not at all. Among modern usage of diastrophic effects in classifying stratigraphic, the term sequence should be mentioned. The sequence concept has done much to revolutionize historical geologic interpretations. The name was proposed by the American geologists L.L. Sloss, W.C. Krumbein, and E.C. Dapples (1949) and later modified by H.E. Wheeler (1960 and 1964) and L.L. Sloss (1963). It is defined by the rock-stratigraphic units that are bounded by regional unconformities. Such major unconformities as those subdividing the stratigraphic record into sequences may be recognized over far greater geographic areas than any of the component individual rock-stratigraphic units. Because the sequence concept emphasizes not only the preserved record between the unconformity but also the physically nonrecorded parts that constitute the lacuna, it makes it possible to relate all the events in the geologic history of an area to the stratigraphic record. In the past most geological interpretations ignored or did not reflect the role of hiatus and degradation; yet, the missing units record diastrophic events at least equal to and sometimes of greater importance than depositional events.

Effects of diastrophism

Subdivision of the Precambrian. Cryptozoic time (prior to 570,000,000 years ago) presents very great problems for classification and subdivision. The problems arise principally because Cryptozoic rocks, although similar to Phanerozoic rocks in other respects, lack either diagnostic or common fossil remains. They can be readily classified as to their rock-stratigraphic classification but not as to the time, time-stratigraphic, or biostratigraphic classifications. So-called systems and series of some Precambrian rocks are not time-stratigraphic terms, but rock-stratigraphic. Precambrian time constitutes about 80 percent of all known geologic time. Because fossils do not allow the recognition of subdivisions of a time-stratigraphic succession of rocks, it seems probable that radiometric dating will be the only possible solution to an orderly stratigraphic classification and correlation of Cryptozoic rocks.

Precambrian systems

One of the classical attempts at subdivision of the Cryptozoic was attempted by the Canadian Geological Survey under Sir William Logan in 1863. Two systems were defined in eastern Canada. The older, the Laurentian, was composed of gneissic (metamorphosed) granitoid rocks, and the younger system of phyllitic and schistose rocks. The younger was named Huronian and was supposedly Cambrian in age. Subsequent studies in Canada and the United States have indicated that not only was the Huronian older than Cambrian, but that its classification is infinitely more complex than indicated. Other system names proposed find limited applicability within certain regions, but have not proven to be valid when extended elsewhere. Lake Superior studies resulted in two formally described systems, the older Archean and the younger Algonkian eras. Today, these subdivisions are considered to be of much greater magnitude than systems; the terms Archeozoic and Proterozoic are now preferred for these subdivisions. They are used in the sense of era terms, although not so defined. Other names in use find local acceptance, but none is truly time-stratigraphic or time terms except coincidentally.

Climatic units. The use of geological climatic units has been recommended when these can be established from inferred widespread climatic episodes of the Quaternary. The defining criteria are contained in the rocks or soil either in the form of minerals, type of weathering, or kinds of fossils. Although local stratigraphic boundaries may be isochronous (*i.e.*, represent equivalent values of time), it is unlikely that the boundaries defining geologic time units in different latitudes or at different elevations will be, because climate varies with both latitude and elevation and has so varied in the past. Glaciation and interglaciation are fundamental units of the geological climate classification. Glaciation refers to a period of intensive ice action marked by characteristic erosional or depositional activity. Interglaciation refers to the interval between two glacial advances as marked by characteristic erosion, deposition, and weathering. Stade and interstade represent subdivisions of times of glaciation and interglaciation, respectively: stade is the amount of time represented by a glacial deposit, and interstade is that represented by an interglacial deposit.

Remanent magnetism and magnetic reversals

Paleomagnetism and chronology. Paleomagnetism is the residual magnetism that remains in some kinds of rocks at the time of their formation. Such magnetism is termed remanent and may be produced in a variety of sedimentary or igneous rocks that contain one of several magnetic minerals. These minerals, such as magnetic iron oxides, align their magnetic polarity with the Earth's magnetic field at the time of the rocks' origin. Such original remanence can be measured to indicate the declination, or direction, of the Earth's ancient magnetic field and its inclination, or angle with respect to the horizon, at the collecting site. By making a large series of measurements of rocks of many ages, it has been determined that remanent magnetism of rocks found no earlier than the Late Tertiary reflect fairly well the position of the mag-

netic poles of the Earth today. As one measures magnetism of older rocks, however, one discovers that rocks of different ages seem to reflect differing positions of the magnetic poles. If the Earth's magnetic field has been a dipole (*i.e.*, similar to the present field, which is best represented by two principal magnetic poles) throughout geologic time, and if the residual magnetism found in rocks was induced at the time of their formation, it would appear that the poles have gradually changed position with respect to that of the continents. This polar wandering, as it is termed, can be most simply explained by assuming that some or all of the continents involved have changed their relative position subsequent to the formation of remanent magnetism in their rocks. Such displacements of the geomagnetic pole with respect to the present rotational axis can be measured at many times through the geological past, and can be used to construct polar-wandering curves showing the curving path of the computed position of the magnetic poles at different points in geological time. It should be possible, then, to date, at least in a general way, a rock with remanent magnetism of unknown age by determining the position of the geomagnetic pole at the time of its formation and comparing it with the polar-wandering curve. Where paleontologic data or radiometric dates are not available, such time-stratigraphic or time units would be of value, even if the accuracy were not as great as that obtained under more favourable conditions. Their value for Cryptozoic correlations, for instance, once a suitable polar-wandering curve was established, would be enormous.

Many deep-sea cores from certain oceanic areas have been correlated on the basis of comparison of polarity changes between adjacent cores. Most such correlations have been based on the additional phenomenon of magnetic reversals. It has been discovered that remanence in certain rocks is directed about 180° from the predicted direction. Although it is not completely clear why such reversals take place, a widely accepted theory explains them as occasional reversals in the direction of the electric currents that are responsible for the geomagnetic fields or that, additionally, some rocks have the property of self-reversal of their fields. In the drill cores cut from the ocean bottom a succession of alternating normal and reversed polarities sometimes occurs. When coincidence in successions is found between cores from different locations, a correlation is assumed.

Dendrochronology and coral growth. The stratigraphic and paleontologic literature also contains other useful methods of classifying or dating stratigraphic units. Methods of dating geologic events by using an absolute indication of age are extremely varied and employ physical rather than organic phenomena, but the latter sometimes provide a record of seasonal changes. The growth patterns of some plants and animals show such changes; perhaps tree rings are the best known of these. Dating by tree rings can extend back several thousand years under ideal conditions. Certain animals also respond to seasonal changes by showing lines of concentric growth or regularly added shell or bone layers. The regular concentric ridges found on many extinct Paleozoic horn corals probably represent increments of yearly growth. By counting such ridges the age of a horn coral can be determined. Modern corals possess very fine striations between the ridges, which represent regular increments of daily growth, and Paleozoic corals also exhibit such "daily" growth striations. Growth ridges on corals suggest that the Devonian year had more days than a modern year, and that a year in the Pennsylvanian Period had fewer days than the Devonian but more than the present. These results are remarkably close to other calculations that indicate occurrence of a slow decrease in the Earth's rate of rotation throughout geologic time because of friction caused by the tides.

Seasonal growth of plants and animals

Zonules and faunules. Stratigraphic successions may be subdivided by defining units on the basis of the inferred paleoecology of the fossils and the environment of sedimentary deposition. The term zonule has been defined as the subdivision of a biostratigraphic subzone, but also has long been used in the sense of an inferential paleoecologically controlled unit. As defined originally, a zonule was a group of rocks containing a faunule, or fossil community, the horizontal and vertical extent of such a zonule in strata being determined by the horizontal and vertical extent of the faunule. Such zonules were dependent for their existence on both biological and physical-chemical attributes of the environment. Under favourable ecologic conditions a zonule might recur several times in geologic time. Thus zonules are paleoecologic in significance rather than time-stratigraphic. The analysis of such zonules in fossils from stratigraphic successions is basic to the discrimination of temporal fossil range from simple occurrence in strata. So-called ecostratigraphic units, or ecozones, are vertically successive units based on paleoecologic analysis.

Quantitative correlation. An ingenious method of quantitative paleontologic correlation for two or more local successions of rocks has been described by the American geologist Alan Shaw. The method involves the detailed collection of fossils, carefully allocated by stratigraphic position to each fossil section. A check list establishes the range zone of all species for each locality and indicates the stratigraphic distance of first and last occurrences above a datum, such as the base of a formation. If the sections to be correlated are closely spaced, facies may be no problem. First and last occurrences of species may be almost synchronous, in the event of similar facies, and, of course, any synchronous events, whether or not organic, such as ash falls, would also be plotted. If time-coincident points measured from each datum are plotted on a graph in which one axis represents one section and the second represents the one to be correlated, they will form a series of points along a sloping line. Because species rarely will appear simultaneously, even in geographically closely spaced successions, because of facies, there is usually no actual coincidence of points, but rather a scatter. Only points that are actually synchronous will fall exactly along the line.

Plotting of time-coincident points

Equations can be established for the correlation line,

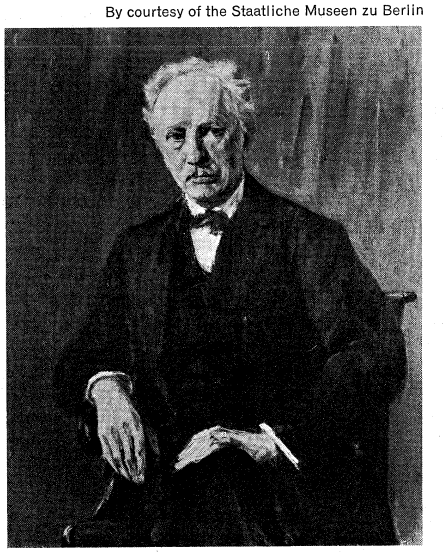
thus allowing the correlative points in each section to be located. By analyzing a great number of local sections throughout a biogeographic province, for instance, the teilzones or possibly biozones of a number of species could be compiled from analysis of their local range zones. These teilzones or biozones when plotted against a composite standard section would be useful information for geologists engaged in regional stratigraphic analysis.

The large number of mathematical calculations that are necessary for computing the equations of correlation for such regional studies make access to calculating machines and to computers a great asset.

The left portion of the diagrams in Figure 6 depicts two local rock successions that have been correlated by Shaw's technique. The lines leading from one column of rocks to the adjacent column indicate time-equivalent correlations based on the correlation equation. It will be seen that the deposition of the Hickory Sandstone at Morgan Creek did not begin as early in geologic time as at White Creek. Limestone deposition began at White Creek while sandstones were still being deposited at Morgan Creek. More sediment was deposited at White Creek than at Morgan Creek during the same time interval. The graph at the right of Figure 6 illustrates the correlation lines drawn through the coincident and near-coincident points of the lithologic successions shown in the left part of Figure 6. The points plotted on the graph are based on first and last occurrences of species in the two sections. The decimal figures given for White Creek ($\hat{W}$) and Morgan Creek ($\hat{M}$) are the computed values of the equation of correlation and relate to the x and y axis of the sloping correlation lines.

This method, like that of Lyell's percentage correlation, avoids problems of faunal and lithologic facies when carried out over a biogeographic region because of the numerous observations throughout all facies of a province. Other methods for statistical correlation and for devising quantitative classification schemes for strata have been less successful as a rule. Usually such quantitative measures depend upon a sufficiently large and well enough preserved statistical sampling of paleontologic taxa to produce reliable confidence limits. Rarely, except when collecting has been intensive, are samples either large enough or well enough preserved for such purposes.



BIBLIOGRAPHY. The following works provide background material for the many topics treated in this article: F.D. ADAMS, *The Birth and Development of the Geological Sciences* (1938, reprinted 1954), a narrative review of geologists and the development of important ideas from the classic origins to the beginning of modern times; AMERICAN COMMISSION ON STRATIGRAPHIC NOMENCLATURE, "Code of Stratigraphic Nomenclature," *Bull. Am. Ass. Petrol. Geol.*, 45:645–665 (1961), the codification of biostratigraphic, time-stratigraphic, geologic time, and rock stratigraphic terms; W.B.N. BERRY, *Growth of a Prehistoric Time Scale Based on Organic Evolution* (1968), an authoritative and well-written account of the role of organic evolution in the geologic time scale, time-stratigraphy, and biostratigraphy; C.O. DUNBAR and JOHN RODGERS, *Principles of Stratigraphy* (1957), an excellent introductory presentation of stratigraphic principles in a standard college textbook, including a good description of sedimentary rocks and a comprehensive bibliography of both general and specific articles; D.L. EICHER, *Geologic Time* (1968), an elementary, but comprehensive treatment of geologic time and its classification; HENRY FAUL, *Ages of Rocks, Planets and Stars* (1966), a discussion of astronomic and radiometric dating; A.W. GRABAU, *Principles of Stratigraphy*, 2nd ed. (1924; reprinted in 2 vol., 1960), a classic and monumental work and a pioneering endeavour in presenting principles and methodology (although many concepts are outdated, the thoroughness and clarity of presentation make this an important historical reference); JAMES HUTTON, *The Theory of the Earth, with Proofs and Illustrations*, vol. 1–2 (1795, reprinted 1959), vol. 3 (1802), an important classic with initial statement and proofs of uniformitarianism; W.C. KRUMBEIN and L.L. SLOSS, *Stratigraphy and Sedimentation*, 2nd ed. (1963), a standard and much employed college textbook with excellent coverage of the majority of classical and modern phases of stratigraphy, including its historical development—also contains a complete bibliography arranged by topic for easy reference and supplementary readings with each chapter; BERNHARD KUMMEL, *History of the Earth*, 2nd ed. (1970), a college textbook of historical geology with discussions of the formations, fossils, and inferred geologic history of the world (emphasis on North America); CHARLES LYELL, *Principles of Geology*, 3 vol. (1830–33, reprinted 1969), a classic in the field of geology that laid the foundation for the science—vol. 3 contains the first subdivision of the Tertiary on the basis of percentage of living to fossil forms; V.S. MALLORY, "Biostratigraphy: A Major Basis for Paleontologic Correlation," *Proc. N. Am. Paleont. Conv. 1969*, pt. F, pp. 553–566 (1970), a comprehensive review of biostratigraphical concepts and their major refinements, with a complete bibliography of important classical works; A. OPPEL, "Die Juraformation Englands, Frankreichs und des südwestlichen Deutschlands," *Jh. Ver. Württ. Natur.* (1856–58), the classical work in biostratigraphy and time-stratigraphy that is the major foundation for all subsequent definitions of stage and zone; F.A. VON QUENSTEDT, *Der Jura* (1856–58), a classical work in which d'Orbigny's "stage" is critically evaluated, and the methodology of arriving at fossil range through species checklists is depicted; H.G. SCHENCK and S.W. MULLER, "Stratigraphic Terminology," *Bull. Geol. Soc. Am.*, 52:1419–26 (1942), a short paper, but a most important one that was influential in shaping the modern stratigraphic classification; A.B. SHAW, *Time in Stratigraphy* (1964), an exposition of statistical methods of correlation of strata; NICOLAUS STENO, *De solido intra solidum naturaliter contento dissertationis prodromus* (1669; Eng. trans., *The Prodromus of Nicholaus Steno's Dissertation Concerning a Solid Body Enclosed by Process of Nature Within a Solid*, 1916; new ed., 1968), the historically important first presentation of the principle of superposition of strata; CURT TEICHERT, "Some Biostratigraphical Concepts," *Bull. Geol. Soc. Am.*, 69:99–120 (1958), a comprehensive review of terminology and a glossary of many terms used by stratigraphers; J.M. WELLER, *Stratigraphic Principles and Practice* (1960), a well-balanced treatment of stratigraphy, its historical development, principles, and methodology—the properties of sedimentary rocks are emphasized and a bibliography arranged by chapter is included.

(V.S.M.)

Strauss, Richard

A musical iconoclast, Richard Strauss was the leading German composer-conductor in the early part of the 20th century and the last of the great Romantic composers. His reputation is based chiefly on his tone poems, such as *Don Juan* and *Also sprach Zarathustra* (*Thus Spoke Zarathustra*), and on his operas, the best known of which are *Der Rosenkavalier* (*The Knight of the Rose*), *Salome*, and *Elektra*.

Richard Strauss, portrait by Max Liebermann, 1918. In the National-Galerie, East Berlin.

Early life and works. Richard Georg Strauss was born on June 11, 1864, in Munich. His father, Franz Strauss, was Germany's most celebrated French-horn player, and his mother, Josephine Pschorr, was the daughter of a successful Munich brewing family. At the age of four he began piano lessons. When he was six, he took violin lessons and composed his first song, "Weihnachtslied" ("Christmas Song"). He began receiving instruction in theory and composition when he was 11. Immature works followed quickly and naturally with praise and no pressure, so that his musical development was second nature, whereas his academic learning needed effort and concentration. He was devoted to his family, which lived comfortably, though without luxuries. They were depen-

dent upon the paternal income, which was derived from playing and teaching and from conducting Munich's semiprofessional orchestra, the Wilde Gung'l, in which Richard played the violin for a few years, thus early acquiring orchestral discipline and experience.

In 1882 Strauss began a course of philosophy, aesthetics, and the history of art. His private reading on these subjects was sustained for the rest of his life. A meeting with the celebrated conductor Hans von Bülow led to Strauss's conducting (for the first time and without rehearsal) his own *Suite for 13 Winds*, Opus 4. As a result he went as Bülow's assistant to the Meiningen court orchestra in October 1885; a month later, following Bülow's departure, he found himself in complete charge. He stayed with the orchestra for only six months and quickly absorbed the basic orchestral repertory of the time. Ambitious for a more prominent engagement, he went as third conductor to Munich. Strauss's musical mentors were Richard Wagner (early works) and Johannes Brahms. At first his understanding of the later Wagner operas was discouraged by his father, but because of the influence of his philosopher friend, Alexander Ritter, Strauss overcame his father's prejudices. In 1887 in Munich he conducted his *Aus Italien* (*From Italy*), Opus 16, a symphonic fantasy based on his own vivid impressions of Italy. It was booed by many of the audience—to Strauss's great satisfaction, for he at last knew he had created an impression. In the summer of 1889 he worked as a musical assistant at the Wagner festival in Bayreuth and in October moved to Weimar, because Munich had become too constricting for him and he could not bear the jealousy of his superiors. The poor opinion of *Aus Italien* was overcome in November at the Court Theatre in Weimar, when the tone poem *Don Juan* burst triumphantly on an astounded audience. It was the start of Strauss's successful composing career. Cosima Wagner, the composer's wife, who had ruled Bayreuth since Wagner's death in 1883, had designs on Strauss—as a senior member of her staff and as a son-in-law; but he was already courting Pauline de Ahna, daughter of a Prussian general, whom he had first met in 1887.

Conductor at Meiningen and Munich

Mature life and works. In 1890 Strauss was a guest conductor with the Berlin Philharmonic Orchestra. He suffered two serious illnesses, caused by overwork, in 1891–92. He went to the Mediterranean to convalesce and discovered a strong mental and spiritual affinity with Greece. In Egypt at Christmas 1892, he finished his first opera, *Guntram*, which was totally Wagnerian in concept. It was produced in Weimar in May 1894, when Strauss announced his engagement to the leading soprano, Pauline de Ahna. They were married four months later. In October Strauss obtained a senior appointment as court conductor at Munich, where he and his wife set up house and lived for the next four years. Strauss also obtained another year's engagement with the Berlin Philharmonic Orchestra, and so, at 30, he was well established as a composer and conductor of ability and promise. As soon as they moved to Munich, Pauline Strauss ordered her husband's way of life so that time for composition always came first and was never interrupted to make room for less important matters. They loved each other dearly, although her eccentric and overbearingly tasteless behaviour had given rise to much criticism and many anecdotes. He was inclined to be lazy but grew to rely on her management of him, without which he might never have written as much as he did. At the same time, she was as devoted to him as he was utterly faithful to her. Their marriage existed more on a mental than a physical understanding, and Strauss's wedding present to Pauline, the set of songs, *Vier Lieder*, Opus 27, is a true expression of this. They had one child, Franz Alexander, born in 1897.

Marriage to Pauline de Ahna

For the next 13 years Strauss's frequent conducting tours proclaimed his remarkable stamina. He travelled mainly in Europe, but he also visited Russia, and, in America in 1904, he gave the first performance of his *Sinfonia Domestica*—like the earlier *Ein Heldenleben* (*A Hero's Life*), an autobiographical tone poem. By the turn of the century he had composed seven tone poems and 85 songs, a practical and useful way of learning how to set words with the maximum effect, which showed in his second opera, *Feuersnot* (*Fire-Famine*; Dresden, 1901), far removed in style and effect from *Guntram*.

Strauss was delighted at the receipt of an honorary Doctor of Philosophy degree from the University of Heidelberg in 1903, the idea of which greatly appealed to him; and in this year he began to work for the rights of German composers, a selfless task that he undertook voluntarily and in face of opposition from music publishers. His two operas *Salome* and *Elektra* confirmed him as Europe's most advanced composer. With his royalties from the first year's performances of *Salome*, Strauss built himself an ideal villa at Garmisch, where he hoped to live and compose from the age of 50. In 1908 he was appointed musical director of the Berlin Court Opera.

Elektra had been Strauss's first work written to a libretto by Hugo von Hofmannsthal, then Austria's most talented and interesting poet. The success of their next collaboration, *Der Rosenkavalier*, earned them both a fortune, and Strauss invested his funds in England. The alliance with Hofmannsthal was, however, a mixed blessing. Strauss, the Bavarian, aimed to write music that was universally understood and appreciated; Hofmannsthal was an intellectual and an aristocrat to whom the masses were anathema. His philosophical symbolism from *Ariadne auf Naxos* (1912) and onward was not for the general public. Had Strauss been able to control his librettist's direction or to insist on the choice of subjects for their operas, he might well have explored further than the few moments of atonality in *Elektra* and into the realm that seemed from then on denied him.

Partnership with Hofmannsthal

Josephslegende (*Legends of Joseph*) was an hour-long ballet commissioned from Strauss by the Russian impresario Sergey Diaghilev. It displayed a Strauss entirely uninterested—composing from the wealth of his astonishing musical technique, not from his heart. He conducted the ballet in Paris and in London in the summer of 1914, immediately after which war was declared between England and Germany. His fortune in England was sequestered and his plans for retiring at the age of 50 were aborted. He was thus obliged to continue with heavy conducting schedules to help re-establish his finances.

Strauss did not understand politics, nor did he consider himself to be personally involved. He refused to allow his name to be used for propaganda (although he wrote for the Kaiser), and considered the whole affair a nuisance, an unnecessary interruption of his and Hofmannsthal's work on their next opera, *Die Frau ohne Schatten* (*The Woman without a Shadow*). During the war Strauss was engaged on three further tasks: a large, descriptive work of the symphonic poem genre, the *Alpensinfonie* (*Alpine Symphony*; 1911–15), Opus 64; the founding, together with Hofmannsthal and the theatrical producer Max Reinhardt, of a Salzburg Festival Association, a far-sighted enterprise; and the revision of *Ariadne auf Naxos*, separating it from Hofmannsthal's translation of Molière's *Le Bourgeois Gentilhomme* to which it had formerly been attached. This brought the Strauss–Hofmannsthal relationship to its lowest ebb, with the poet being hurtfully rude and the composer remaining good-natured and generous.

After the armistice in 1918 Strauss was called temporarily to Berlin to direct the State Opera; then he moved to Vienna to become co-director (with Franz Schalk) of the opera there. *Die Frau ohne Schatten* failed to meet public taste in an impoverished Vienna of 1919.

Late life and works. Over the next 20 years Strauss's prestige as a composer declined along with his health. He could not achieve artistic and financial successes of the order of *Salome*, *Elektra*, or *Der Rosenkavalier* and had long since yielded his position as Europe's leading composer; but he was still enormously successful as a conductor. By the end of the 1920s he had reduced his movements on the podium to a minimum, although his control was still complete. He was tall, with a large, domed and bald forehead, pale blue eyes, and a seemingly aloof and haughty manner that belied his true, kindly nature.

Decline in Strauss's influence

The operas of the interwar years, with the possible exception of *Intermezzo* (1924), lacked the authority of their predecessors. This was an extension of the earlier *Heldenleben—Sinfonia Domestica* idea, in that it presented Strauss and Pauline as they really were: through Strauss's eyes. It also showed him attempting an altogether new kind of sung speech and precisely judged orchestral texture and vocal balance, all clearly described in an essay in the score. The work was to his own libretto, but he returned to Hofmannsthal for *Die ägyptische Helena* (*The Egyptian Helen*; 1928) and *Arabella* (1933). Work on the last opera revived the friendship and rapport between them; unhappily, Hofmannsthal died suddenly after completing the libretto of the latter work. Although he may have led Strauss away from more suitable texts, together they achieved a great deal, and it is significant to note that all Strauss's operas after 1928 contained elements of Hofmannsthal's invention.

Collaboration with Zweig

In 1932 another Austrian poet, Stefan Zweig, became Strauss's librettist, and their collaboration on *Die schweigsame Frau* (*The Silent Woman;* 1935) progressed well. By 1933 the Nazi Party was in command of Germany. Toscanini, then a leading conductor in Europe, strongly disapproved of the Nazis and refused to conduct Wagner's *Parsifal* at Bayreuth. Strauss replaced him and also took over a Berlin concert from Bruno Walter, who as a Jew was unacceptable to the Nazis. In this instance Strauss gave his fee to the orchestral orphans' fund. He found his own actions high-principled and defensible for the saving of artistic enterprises; others saw them differently. In November he was made president of the Reichsmusikkammer (Chamber of State Music), which he accepted only because he felt that by taking the position he could exercise an influence that would be advantageous to musicians.

For Strauss there were only two kinds of humans—the talented and the rest. In a letter to Zweig in connection with the production of their opera in Dresden in 1935, he propounded these views at the expense of the Nazis. The letter was intercepted, Strauss was forbidden to work with Zweig, who was Jewish, and further performances of *Die schweigsame Frau* were banned. Strauss was not permitted to conduct anywhere in Germany or in Salzburg, and for a year he was in a political vacuum. Zweig had managed to escape to South America, and this event affected Strauss profoundly. He was not only again without a librettist, but the significance of the fact that his daughter-in-law was Jewish was now brought forcefully to him. He was forced to resign his office but was permitted to conduct his new *Olympische Hymne* at the opening of the Olympic Games in Berlin, in July 1936. In November he went to London, with the Dresden State Opera, where he received the Gold Medal of England's Royal Philharmonic Society.

Munich had been giving model performances of his operas for some years, and they now produced two one-act operas: *Friedenstag* (*Day of Peace*) and *Daphne* (both 1938) to librettos by his latest, distinguished librettist, Joseph Gregor. His 75th birthday celebrations in 1939 were not hindered, despite the fact that he had fallen from Nazi grace. World War II marked a return for Strauss to the bitterness of 1914–18. Then it had been the loss of his fortune; now it was loss of respect and real danger to his family. He did everything—including self-effacement before the local Nazi official—to protect them, and he succeeded. Strauss was forbidden to go abroad for imperative Swiss cures and spent a miserable four years between his villa at Garmisch and his house in Vienna. He was shocked by the destruction of his four most beloved opera houses (Berlin, Munich, Dresden, and Vienna) and never really recovered from these events.

Between 1942 and 1948 he composed a number of works in which he returned to the power and sweetness of former years. Immediately after the war was over, Strauss went to Switzerland, where he and Pauline stayed, penniless, for four years, deaf to calls to attend denazification trials. He was found guiltless and was invited to London, where he conducted at a festival of his music in 1947. He returned to Germany in 1949 and died on September 8 in his house at Garmisch-Partenkirchen, in Bavaria, leaving the richly scored, poignantly retrospective *Vier letzte Lieder* (*Four Last Songs;* 1948) as his final completed composition. He was the last Romantic composer of the 19th century, a master of orchestration, a composer of distinction, a magnificent conductor, and a patriot, faithful to the soil of Bavaria rather than to Germany's political leaders.

Strauss, having begun as an avant-garde composer in his early tone poems and operas (*Salome* and *Elektra*), became in later years a conservative, unaffected by the advances and experiments going on around him. In his last years his style became leaner, more classical in the Mozartian sense; indeed, the opera *Capriccio* (1942), *Metamorphosen*, for 23 solo strings (1944–5), and the *Four Last Songs* may be said to have achieved a perfect fusion of the Romantic German and the Neoclassical manner. His reputation has fluctuated wildly over the years, and his music is apt to provoke violent advocacy or dislike. In spite of his conservatism, he remains one of the 20th century's controversial figures.

MAJOR WORKS

OPERAS: 15 including *Salome*, op. 54 (first performed 1905), *Elektra*, op. 58 (1909), *Der Rosenkavalier*, op. 59 (1911), *Ariadne auf Naxos*, op. 60 (*Adriadne on Naxos*, 1912, rev. 1916), *Die Frau ohne Schatten*, op. 65 (*The Woman Without a Shadow*, 1919), *Intermezzo*, op. 72 (1924), *Die ägyptische Helena*, op. 75 (*The Egyptian Helen*, 1928), *Arabella*, op. 79 (1933), *Die schweigsame Frau*, op. 80 (*The Silent Woman*, 1935), *Friedenstag*, op. 81 (*Day of Peace*, 1938), *Daphne*, op. 82 (1938), *Die Liebe der Danae*, op. 83 (*The Loves of Danae*, 1952), and *Capriccio*, op. 85 (1942).

BALLETS: *Josephslegende*, op. 63 (*Legends of Joseph*, 1914); *Schlagobers*, op. 70 (1924).

INSTRUMENTAL WORKS: 7 symphonic poems, including *Don Juan*, op. 20 (composed 1889), *Till Eulenspiegels lustige Streiche*, op. 28 (1894–95), *Also sprach Zarathustra*, op. 30 (*Thus Spoke Zarathustra*, 1895–96), and *Ein Heldenleben*, op. 40 (*A Hero's Life*, 1898); *Don Quixote*, op. 35 (1897), fantastic variations based on Cervantes; *Sinfonia Domestica*, op. 53 (*Domestic Symphony*, 1903); *Alpensinfonie*, op. 64 (*Alpine Symphony*, 1911–15); 2 horn concertos (op. 11, 1882–83; 1942); *Burleske* for piano and orchestra (1885); oboe concerto (1945–46); *Metamorphosen* for 23 strings (1945–46).

SONGS: About 200, including *Vier letzte Lieder* (*Four Last Songs*, 1948), for soprano and orchestra.

BIBLIOGRAPHY

In English: NORMAN DEL MAR, *Richard Strauss*, 3 vol. (1962–72), the standard, technical source of information on the compositions; WILLIAM S. MANN, *Richard Strauss: A Critical Study of the Operas* (1964), a detailed study of the operas; ERNST KRAUSE, *Richard Strauss: Gestalt und Werk* (1963; Eng. trans., *Richard Strauss: The Man and His Work*, 1964), the most convenient single-volume book; *The Correspondence Between Richard Strauss and Hugo von Hofmannsthal, 1907–1918* (1927, reprinted 1961), an illuminating description of the way in which the two men worked—gives a clear profile of their characters and adds much to our knowledge of the 7 major works that they created; *The Correspondence Between Hans von Bülow and Richard Strauss* (1955), the only translation of any of Strauss's letters during the period 1873–93; *Betrachtungen und Erinnerungen* (1949; Eng. trans., *Recollections and Reflections*, 1953), sharp and often cynical musings by Strauss, written near the end of his life; ALAN JEFFERSON, *The Leider of Richard Strauss* (1971), an analysis in great detail of 50 songs with general information about them all.

In German: MAX STEINITZER, *Richard Strauss* (1911; 4th ed., 1927), contains much unique observation on the early works especially, but it stops 22 years before the end of Strauss's life; FRANZ TRENNER (ed.), *Richard Strauss: Dokumente seines Lebens und Schaffens* (1954); WALTER PANOFSKY, *Richard Strauss: Partitur eines Lebens* (1965), both contain new material but are not in themselves comprehensive; MUELLER VON ASOW, *Richard Strauss: Thematisches Verzeichnis* (begun in 1955 and not yet completed), contains precise and elaborate details of all the known compositions; FRANZ GRASBERGER and FRANZ HADAMOVSKY (comps.), *Richard Strauss-Ausstellung zum 100. Geburtstag* (1964), a useful checklist and source of elusive information. The main Strauss Archive is in the composer's house at Garmisch, Bavaria.

(A.R.J.)

Stravinsky, Igor

Undoubtedly one of the greatest composers of the 20th century, Igor Stravinsky dazzled successive generations of musicians with his protean ability to change and renew his musical thought. Frequently, the work of a great composer establishes an immediate currency in his native country and only gradually acquires a wider significance in the context of the world's musical heritage. The case of Stravinsky was at variance with this general rule, and his achievement must be assessed in light of the fact that at least twice in the course of his long life he changed his country, his nationality, his language of words, and his musical idiom. As a Russian, he lived in St. Petersburg and (in exile) in western Europe; as a Frenchman, he lived mainly in Paris; and as an American, he lived mainly in Hollywood. Until the end of World War I his musical idiom was closely related to Russian sources, and his music exercised a somewhat exotic appeal on audiences outside Russia. The Neoclassical works of his middle period were more obviously rooted in traditional western European musical procedures. The serial idiom (*i.e.*, music featuring rows of tones) that he adopted during the last 15 or so years of his life produced shortish works of comparatively dense musical content, which may take some time to establish themselves in the international repertory. His working life as a composer covered about two-thirds of a century; and the originality and the strength of his compositions were maintained throughout this period.

Stravinsky, 1929.

Russian period. Igor Fyodorovich Stravinsky was born at Oranienbaum (now Lomonosov) near St. Petersburg (now Leningrad) on June 17 (June 5, old style), 1882. His father, Fyodor Ignatyevich Stravinsky, was a bass singer of great distinction, who had made a successful operatic career for himself, first at Kiev and later in St. Petersburg. Igor was the third of a family of four boys. As a child he loved music. He was accustomed to hearing his father practicing his operatic roles at home. From an early age he attended opera and ballet performances at the neighbouring Mariinsky Theatre in St. Petersburg. Regular piano lessons started when he was nine, and a little later he received training in harmony and counterpoint. Despite his obvious bent for music, his parents refused to allow him to pursue a musical career. Sent to St. Petersburg University to study criminal law and legal philosophy, he was graduated in 1905.

Meanwhile, his musical interests had turned to composition. In the summer of 1902, a few months before his father's death, he obtained an introduction to the Russian composer Nikolay Rimsky-Korsakov through one of Rimsky-Korsakov's sons, who was also a student at the university. Rimsky-Korsakov was sufficiently interested in the young man's early attempts at composition (of which an interesting example has survived in manuscript, a piano *Scherzo* dated 1902) to advise him not to enter the conservatory for conventional academic training but to pursue his studies privately. This advice was followed. A year later Rimsky-Korsakov agreed to tutor him privately, mainly in instrumentation. The arrangement continued for about three years (1903–06). It was Stravinsky's habit to discuss his compositions with his mentor as they were planned and written. Rimsky-Korsakov arranged for several of these, including the *Symphony in E Flat Major* (1905–07), to be performed at private or public concerts in St. Petersburg. The last composition to be presented in this way was *Fireworks* (1908), a brief symphonic poem that Stravinsky intended as a wedding present for Rimsky-Korsakov's daughter. Rimsky-Korsakov died in the summer of 1908, before it could be performed. After his death the mourning pupil wrote a funeral dirge (1908) in memory of his master. It was performed in St. Petersburg the following season; the score is lost.

Influence of Rimsky-Korsakov

Stravinsky left the university in 1905. The following year he married his first cousin, Catherine Nossenko. They lived in two rooms of his family's apartment in St. Petersburg and spent their summers in the country at Ustilug in Volhynia, an area of the Ukraine. A son (Theodore) was born to them in 1907 and a daughter (Ludmila) a year later.

Collaboration with Diaghilev and the Ballets Russes. When *Fireworks* and an earlier orchestral piece, *Scherzo Fantastique* (1907–08), were performed in St. Petersburg on February 6, 1909, they were heard by the impresario Sergey Diaghilev (*q.v.*), who was then busy making preliminary arrangements for the summer season of his Ballets Russes to be held in Paris. He was so favourably impressed by Stravinsky's promise as a composer that he invited him to join his small group of artistic collaborators. For the 1909 ballet season Stravinsky was invited to orchestrate various pieces of ballet music, including two piano numbers by Chopin for *Les Sylphides*. For the 1910 season, Diaghilev commissioned from him a completely new ballet score, *The Firebird*.

The next few years were a period of intensely close collaboration between the two men, for Diaghilev was anxious that all of Stravinsky's major new works should be mounted by his company. After the decisive success of *The Firebird* at the Paris Opéra (June 25, 1910), Stravinsky started to write a *Konzertstück* ("concertpiece") for piano and orchestra; but, yielding to Diaghilev's arguments, he agreed to adapt the music he had already written to fit a new ballet scenario, and this work, *Petrushka*, received its first performance during the Ballets Russes 1911 season in Paris. Before this, Stravinsky had had the idea of writing a kind of primitive spring symphony to be called *Great Sacrifice;* here, too, Diaghilev persuaded him that it should be cast in the form of a ballet. The composition of *The Rite of Spring* (as it was finally called) was spread over two years (1911–13). The music of this dynamic, profoundly disturbing score created a major scandal when the ballet had its first performance at the Théâtre des Champs Élysées, Paris (May 29, 1913). Stravinsky then reverted to the task of finishing a short opera based on the Danish writer Hans Andersen's tale "The Nightingale," which he had started in 1908–09 but which had been interrupted by the commission to write *The Firebird*. This opera was now requested by the Moscow Free Theatre; but when that new venture suddenly collapsed, Diaghilev saw his chance and, taking over the work, arranged for it to be produced as part of the Ballets Russes seasons in Paris and London in the summer of 1914.

Composition of *The Rite of Spring*

That summer also marked the conception of a new ballet cantata to be called *The Wedding*, which Stravinsky decided to base on Russian peasant themes and customs. Had World War I not intervened, this new score might have been ready for production by the Ballets Russes in 1915 or 1916. Although the actual composition was completed by 1917, the final form of the instrumentation was not decided on until 1923.

Stravinsky's close connection with Diaghilev and the Ballets Russes meant that during the five years 1910–14 he spent a considerable part of his time outside Russia. He was usually in Paris for the company's summer sea-

sons and occasionally followed them on tour to Rome, Berlin, Vienna, Budapest, and London. He still managed to spend part of each summer in his Russian country home at Ustilug, the quiet atmosphere of which he found conducive to composition. His visits to St. Petersburg, however, became increasingly rare. The health of his family was precarious; and a tendency to tuberculosis made the climate of Switzerland attractive. His second son (Soulima) was born at Lausanne, Switzerland, in 1910, his second daughter (Milena) at Leysin in 1914. Parts of *The Rite of Spring* and *The Nightingale* were written at Clarens, Switzerland, in the intervening years, and the war years were spent entirely in Switzerland, first at Clarens and later at Morges.

Years of exile. These were years of isolation that ultimately led to years of exile, for as the war progressed, Stravinsky became cut off, not only from Russia but also from the Ballets Russes—the European engagements of which had to be abandoned and replaced by an American tour—and from his music publishers who had their headquarters in Berlin. He tried to overcome these difficulties in various ways. He found a local publisher in Geneva for many of his wartime compositions. In collaboration with the Swiss novelist Charles Ferdinand Ramuz he created *The Soldier's Tale* (1918), an entertainment "to be read, played, and danced" which was intended to be played on tour by a small travelling theatre. The project collapsed after a successful first performance in Lausanne, owing to a sudden epidemic of Spanish influenza.

French period. As soon as the war was over, Stravinsky decided to move from Switzerland and settle in France; during the next 20 years (1920–39) he lived in various places there—Biarritz, Nice, Voreppe, and Paris. These years were marked by an important change in his music—the abandonment of the Russian features of his earlier style and the adoption of a Neoclassical idiom. Such a radical change cost him a great effort and only after several years of what he called "samplings, experiments, amalgamations" did he find his way to new works such as *Oedipus Rex* (1927) and the *Symphony of Psalms* (1930), capable of holding their own against such masterpieces of the Russian period as *The Rite of Spring* and *The Wedding*.

Adoption of Neoclassicism

In the early postwar years, Stravinsky's ties with Diaghilev and the Ballets Russes were renewed. They were now on a much looser basis, however, than in the prewar years, for he saw that in the case of an itinerant company, without a firm base, there could be no guarantee of permanence. The only new ballet commissioned by Diaghilev from Stravinsky was *Pulcinella* (1920), the score of which consisted of music by Giovanni Battista Pergolesi that was arranged by Stravinsky and adapted to a Neapolitan commedia dell'arte scenario. *Apollo Musagetes* (1928) was the last new ballet of his to be mounted by the Ballets Russes. The following year (1929) Diaghilev died, and his ballet company melted away almost overnight.

By this time Stravinsky was no longer so dependent on Diaghilev and the Ballets Russes as he had been previously. The need to build up his income as a result of the loss of his private property in Russia had led to his embarking on subsidiary careers as concert pianist and conductor. Some of his new works, such as the *Concerto for Piano and Wind Instruments* (1923–24), *Sonata* for piano (1924), *Serenade in A Major* for piano (1925), *Capriccio* for piano and orchestra (1929), and *Concerto for Two Solo Pianos* (1935), were written primarily for himself as soloist. A considerable part of each year was devoted to touring, either as solo performer or conductor. Most of these tours were in Europe. He also made three visits to North America in 1925, 1935, and 1937 and one to South America in 1936.

Stravinsky's composition of ballet scores did not come to an end with Diaghilev's death. In the late 1920s, the Russian dancer Ida Rubinstein assembled a company of her own and commissioned two ballet scores from Stravinsky—*The Fairy's Kiss* (1928) and *Persephone* (1934). The former was based on a selection of the piano and vocal music of the Romantic Russian composer Peter Ilich Tchaikovsky. The latter was a setting of a poem by the 20th-century French writer André Gide as a melodrama with song and speech, dance, and mime. For the then recently founded American Ballet he wrote *The Card Party* (1937).

The years 1938 and 1939 were marked by a succession of family bereavements. In the autumn of 1938 his elder daughter died of tuberculosis. The deaths of his wife and mother followed in March and in June 1939.

American period. The outbreak of World War II in 1939 led to a completely new orientation of his life. An invitation from Harvard University to deliver the Charles Eliot Norton Lectures during the 1939–40 academic year gave him the opportunity to leave Europe and settle in the United States. Early in 1940 he remarried. His second wife was the artist Vera de Bosset, whom he had known for many years. When the lectures at Harvard on the poetics of music had been given, the Stravinskys travelled to California and acquired a house in Hollywood, where they were to live for more than a quarter of a century.

During the war years, two important symphonic works were composed—the *Symphony in C Major* (1938–40) and *Symphony in Three Movements* (1942–45). Whereas the *Symphonies of Wind Instruments* (1920) display an original and ingenious treatment of typical musical material from his Russian period on symphonic lines, the *Symphony in C Major* represents a summation of Neoclassical principles in symphonic form, and the *Symphony in Three Movements* successfully combines the essential features of the concerto with those of the symphony.

Symphonic works

The immediate postwar years were devoted to an attempt to regain the copyright on his early scores, which, having been originally published while he was a Russian citizen, were unprotected outside Russia because his native country had not adopted the Berne Convention. He achieved his objective by issuing revised versions of the scores concerned. These revisions amounted to little more than corrections, except in the cases of *Petrushka* (revised 1947) and the *Symphonies of Wind Instruments* (revised 1947), in which each work was given a completely new instrumentation.

During the years 1948–51 he worked on *The Rake's Progress*, a full-length, Neoclassical opera with a libretto by the Anglo-American poet W.H. Auden and the American writer Chester Kallman. When it was finished, Stravinsky returned to Europe for the first time since 1939 and conducted the first performance of the work at the Teatro la Fenice, Venice.

While he was working on this score, he invited a young American musician, Robert Craft, to help him with certain musical tasks at his home in Hollywood. The visit was a success, and Craft eventually became established in the Stravinsky household as friend, consultant, and musical assistant. This was a particularly important moment in Stravinsky's musical development because after the composition of *The Rake's Progress* he felt he had outgrown "the special incubator" in which the works of his Neoclassical period had gestated. Craft's natural liking for serial music stimulated Stravinsky into examining carefully the music of the Austrian composer Anton von Webern and also some of the works of the Austrians Arnold Schoenberg and Alban Berg, with which he was not very familiar at that time. His interest was aroused and he found his own idiom becoming profoundly affected. To begin with, his serial essays were cautious experiments carried out within a framework of tonal music, featuring note rows and procedures involving inversion, retrogression, and retrograde inversion. The *Canticum Sacrum* (1955) and the ballet *Agon* (1953–57) were larger scale works, in which the music travelled from a modal and tonal beginning (*i.e.*, with harmonies derived from traditional scales and modes) into a fully serial core, reverting at the end to the modal and tonal music of the beginning. The first of his fully serial compositions was *Threni* (1958); this was followed by *Movements* (1959), *Variations* (1964), and *Requiem Canticles* (1966), which occupy just as honoured a place

Serial works

in his output as the masterpieces of his Russian and Neoclassical periods. It is a characteristic of these serial works that in comparison they are much briefer than the composer's tonal works but seem to have a much greater musical specific gravity.

After the *Requiem Canticles*, ill health caused a slowing down of Stravinsky's compositional activity, but even as late as 1970 he was working on instrumental transcriptions of some of Bach's preludes and fugues. He died in New York on April 6, 1971, and was buried in Venice on the island of San Michele.

Contribution to music. Stravinsky's special contribution to music in the 20th century was wide and varied. He never seemed to start a composition with preconceived ideas but always examined his raw material with a fresh and critical ear. He was not prepared to accept established practice about development but preferred to subject his musical material to a personal system of tests. This had particularly interesting results whenever time, metre, and dynamics were concerned. He explored with zest the asymmetrical patterns of compound metres and, by using devices of prolongation and elision, broke down the tradition of symmetrical phrasing. He was meticulous about degrees of articulation and emphasis. He restored to music the sense of a healthy, unwavering pulse, and this helped to make so many of his compositions suitable for dancing. His music made a "clean" sound—there was no filling in merely for the sake of filling in—and after his symphonic poem *The Song of the Nightingale* (1917), his orchestral practice became mainly a question of using concertante groups of instruments with plenty of breathing space around them. He never worked to an instrumental formula, but every work, regardless of idiom, had a different instrumental specification and a different sound.

MAJOR WORKS

Stage works

OPERAS: *The Nightingale* (1914); *Mavra* (1922); *Oedipus Rex*, opera-oratorio (1927); *The Rake's Progress* (1951).

BALLETS: *The Firebird* (1910); *Petrushka* (1911); *The Rite of Spring* (1913); *Pulcinella* (1920); *The Wedding* (1923); *Apollo Musagetes* (1928); *The Fairy's Kiss* (1928); *Persephone* (1934); *The Card Party* (1937); *Orpheus* (1947); *Agon* (1957).

OTHER STAGE WORKS: *Renard*, "a burlesque in song and dance" (1916); *The Soldier's Tale*, "to be read, played, and danced" (1918); *The Flood*, "a musical play" (1962).

Vocal music

CHORAL WORKS: *The King of the Stars* (1911); *Symphony of Psalms* (1930); *Babel* (1944); *Mass* (1948); *Cantata* (1952); *Canticum Sacrum* (1955); *Threni* (1958); *Requiem Canticles* (1966).

OTHER VOCAL WORKS: *A Sermon, a Narrative and a Prayer* (1961); *Abraham and Isaac* (1963); various songs.

Instrumental music

ORCHESTRAL WORKS: *Symphony in E Flat Major* (1907); *Fireworks* (1908); *Symphonies of Wind Instruments* (1920); *Symphony in C Major* (1940); *Danses Concertantes* (1942); *Circus Polka* (1942); *Ode* (1943); *Scènes de Ballet* (1944); *Symphony in Three Movements* (1945); *Variations* (1964).

CONCERTOS: *Concerto for Piano and Wind Instruments* (1924); *Capriccio* for piano and orchestra (1929); *Violin Concerto in D Major* (1931); *Dumbarton Oaks* for 16 wind instruments (1938); *Ebony Concerto* for clarinet and jazz band (1945); *Concerto for Strings in D Major* (1946); *Movements* for piano and orchestra (1959).

CHAMBER WORKS: *Three Pieces for String Quartet* (1914); *Three Pieces for Clarinet Solo* (1919); *Concertino for String Quartet* (1920); *Octet for Wind Instruments* (1923); *Duo Concertant* for violin and piano (1932); *Elegy* for solo viola (1944); *Septet* (1952); *Double Canon* for string quartet (1959).

PIANO: *Piano Rag-Music* (1919); *Sonata* for piano (1924); *Serenade* (1925); *Concerto for Two Solo Pianos* (1935); *Sonata for Two Pianos* (1944).

Writings

Chroniques de ma vie, 2 vol. (1935; *Chronicle of My Life*, 1936), written in collaboration with Walter Nouvel; *Poétique musicale* (1942; *Poetics of Music*, 1947), in collaboration with Roland Manuel; *Conversations with Igor Stravinsky* (1959); *Memories and Commentaries* (1960); *Expositions and Developments* (1962); *Dialogues and a Diary* (1963); *Themes and Episodes* (1966); *Retrospectives and Conclusions* (1969). The last six works were written in collaboration with Robert Craft.

BIBLIOGRAPHY. *Igor Stravinsky: A Complete Catalogue of His Published Works* was issued in 1957 (new ed. with addenda, 1962). Manuscripts of Stravinsky's compositions may be found in many public institutions throughout the world; but the most comprehensive collection to date is in the Library of Congress, Washington, D.C. The *Sketches* (1911–13) for *The Rite of Spring* were published in facsimile reproduction in 1969.

From the large array of biographical and critical material the following books may be recommended: EDWIN CORLE (ed.), *Igor Stravinsky* (1949), a symposium with essays and articles by a number of distinguished contributors; PAUL HENRY LANG (ed.), *Stravinsky: A New Appraisal of His Work* (1963), critiques by six eminent musicologists dealing with various aspects of his style; MINNA LEDERMAN (ed.), *Stravinsky in the Theatre* (1949), essays and articles by various contributors on his music for the stage, with a useful bibliography; NICOLAS NABOKOV, *Igor Strawinsky* (1964), a short monograph (in German) written by a personal friend; CHARLES F. RAMUZ, *Souvenirs sur Igor Strawinsky* (1929), vivid reminiscences written by a close friend and collaborator covering the years 1915–20; ANDRE SCHAEFFNER, *Strawinsky* (1931), one of the best of the early studies (in French) of his music, particularly well illustrated; ALEXANDRE TANSMAN, *Igor Stravinsky* (1948; Eng. trans., 1949), a study of his music and aesthetics by a musician who was in close touch with him in the 1940s; ROMAN VLAD, *Strawinsky* (1958; Eng. trans., 1960), detailed analyses of most of his works up to 1958; ERIC WALTER WHITE, *Stravinsky: The Composer and His Works* (1966), a biography and a fully documented register of all his compositions up to 1965, with numerous appendixes, including a catalog of manuscripts (1904–52) in his possession, and a bibliography; ROBERT CRAFT, *Stravinsky: Chronicle of a Friendship, 1948–1971* (1972), a fascinating account by the composer's assistant detailing their activities over a period of 23 years; LILLIAN LIBMAN, *And Music at the Close: Stravinsky's Last Years* (1972), a highly personal portrait of Stravinsky's last years (1959–71) as seen by a close associate.

(E.W.W.)

Stresemann, Gustav

Gustav Stresemann, chancellor of the Weimar Republic of Germany in 1923 and foreign minister from 1923 to 1929, was the man chiefly responsible for the restoration of his country's international status after World War I. The re-entry of the German *Reich* into the family of nations after the defeat of 1918, the beginning of a reconciliation with France in 1925, the continuing settlement with the Soviet Union, and the admission of Germany into the League of Nations were largely the work of Stresemann. A Prussian German monarchist who was among the proponents of an annexationist peace during World War I, Stresemann, after the defeat of the empire, gradually became an advocate of a European settlement, no doubt in the hope that his policy would restore Germany to a position of power.

Youth and education. Stresemann was born in Berlin on May 10, 1878, the son of Ernst Stresemann, an innkeeper and beer dealer. He was the only one of five children able to attend high school and ultimately the university. He grew up in a petit bourgeois environment in which his parents were able to contribute little toward the formation of his intellect. From early childhood he displayed a strong "inclination towards solitude," as he put it as a high school student, as well as a tendency to be melancholy and to daydream.

At school he displayed an unusual gift, an "almost unhealthy partiality" for history, especially modern history. He was particularly interested in the lives of great personalities, particularly Napoleon and Goethe, both of whom fascinated him throughout his life and inspired several of his literary studies. His intense preoccupation with historical figures may well have compensated the young Stresemann for the lack of intellectual stimulation in his environment.

It was from his parents, however, that Stresemann assumed the opinions and ideals of the left-liberal middle class. Attending the universities of Berlin and Leipzig

from 1897 to 1900, he first studied literature and history but changed to economics, probably to improve his professional prospects rather than because he recognized his practical gifts.

By courtesy of the Staatsbibliothek, Berlin

Stresemann.

During his student years Stresemann belonged to a relatively progressive fraternity and retained a lifelong attachment to the sentimental glories of student life. In 1900 he received his doctorate with a dissertation entitled "The Growth of the Berlin Bottled-Beer Industry." The subject of his study, which was based on his knowledge of his father's business and dealt with the decline of a sector of small business as a result of competition from giant industry, was characteristic of his origins as well as of his point of view. It was used against him in future political struggles by the right-wing opposition.

As a liberal Prussian Protestant, Stresemann became a typical representative of the chauvinistic spirit prevailing in imperial Germany. He believed in the spiritual, military, and economic superiority of the German empire over other nations and frequently gave literary expression to this conviction. His political idealism manifested itself in a sentimental enthusiasm for the heroic liberalism of 1848, as well as in a romantic style of speech. A youthful carelessness and emotional exuberance remained lifelong characteristics.

Political rise. After completing his studies, Stresemann began his professional career in a trade association. Unusually rapid success in commerce gave him a springboard into politics. As an administrative assistant in the German Chocolate Makers' Association from 1901 to 1904, he gained a reputation as an accomplished organizer and negotiator. Already, in 1902, he had succeeded in founding the Saxon Manufacturers' Association. As its legal representative until 1911, he occupied an important position in economic life at the age of 25.

Marriage

His wife, whom he married in 1903, was the sister of a fraternity brother and the daughter of the Berlin industrialist Adolf Kleefeld. Of Jewish extraction, the charming and elegant Frau Stresemann played a leading role in Berlin society of the 1920s. The couple had two sons.

After initially sympathizing with the ideas of the Protestant social reformer Friedrich Naumann and collaborating with his National Social Union, Stresemann joined the rightist National Liberal Party in 1903. Strongly represented in Saxony at the time, the party became Stresemann's political home. Often involved in conflicts over his support of social-welfare measures with the right wing of his party (which was dominated by representatives of heavy industry), he attracted general notice at his first appearance at a party congress in 1906.

As a Dresden city councillor from 1906 to 1912 and editor of the Dresden magazine *Sächsische Industrie* ("Saxon Industry"), Stresemann became a well-known writer on economics and an expert on municipal affairs. Recognizing the importance of the press in influencing public opinion, he took advantage of it to support his aims.

Election to the Reichstag

He was elected in 1907 to the Reichstag (Parliament) as a National Liberal from the Annaberg district in the Saxon metal-mining country, and thus he succeeded in gaining a foothold in national politics. At 28 he was the youngest deputy in the Reichstag. The party chairman, Ernst Bassermann, helped to advance his political career, and he was soon considered Bassermann's "crown prince." Stresemann was primarily interested in economic policy both as a journalist and a deputy. He energetically defended the interests of the commercial middle class, but his advocacy of extended social-welfare legislation embroiled him in a conflict with the representatives of his party's right wing, which in 1912 prevented his re-election to the National Liberal Party executive committee. After losing his seat in the new Reichstag elections in the same year, he travelled with other business leaders to the United States to study economic conditions.

By this time Stresemann, who had moved to Berlin, was already one of the best-known leaders of German economic life. He occupied leading positions in a number of trade associations including the German-American Economic Association, established at his suggestion.

Stresemann's many offices brought him financial independence. He was known for his organizational gifts, knew how to handle people, and was well aware of the power he wielded. As a member of the Pan-German Deutscher Kolonialverein (German Colonial League) and an advocate of a strong naval construction program, he supported the imperialist goals of German policy carried out under the aegis of Alfred von Tirpitz and Bernhard, Fürst von Bülow. Tirpitz had served from 1897 as state secretary of the Imperial Naval Office, in which post he created the German battle fleet, and Bülow was chancellor of Germany from 1900 to 1909.

Policies during World War I. Stresemann was a part of the great majority of Germans who, in the firm belief that Germany was conducting a purely defensive war, greeted the outbreak of World War I with enthusiasm. Because of his poor health he was exempted from military service. His political hour struck, however, in December 1914, when he was returned to the Reichstag in a special election in Hanover.

During the war, Stresemann emerged as one of the most vociferous exponents of Pan-Germanism and as a champion of Germany's extensive claims on Polish and Russian territory in the east and on French and Belgian territory in the west. He virtually took over leadership of his party's Reichstag faction from Ernst Bassermann, whom military service and illness kept away from Berlin much of the time. During these years Stresemann moved increasingly to the right.

From 1916 he worked closely with the German Army Supreme Command under Field Marshal Paul von Hindenburg and General Erich Ludendorff and became their parliamentary mouthpiece. He thus advocated unrestricted U-boat warfare and opposed the policy of Chancellor Theobald von Bethmann Hollweg, who held to a moderate course and did not allow himself to be committed to expansionist war aims.

Role in dismissal of Chancellor Bethmann Hollweg

Stresemann played a leading role in Bethmann Hollweg's overthrow in July 1917 but failed to bring back to power the former chancellor Bülow, whom he admired. After Bassermann's death in the same month, Stresemann succeeded him as leader of the party's Reichstag faction, becoming chairman of the entire party later in the same year. Despite radical differences within the National Liberal ranks, Stresemann was able to prevent a party split between the Reichstag faction and its more conservative counterpart in the Prussian House of Deputies over the Prussian three-class suffrage system, in which a citizen's vote was weighted according to the value of his property. Hoping to strengthen the monarchy, Stresemann advocated abolition of the voting system. On the other hand, he allowed himself to be deceived about the seriousness of the military situation of the *Reich* and its allies until the Supreme Command admitted defeat at the end of September 1918.

Conversion into a "realistic republican." The defeat, the collapse of the monarchy on November 9, 1918, and Emperor William II's flight to Holland were cruel blows to Stresemann. Nonetheless, he quickly accommodated himself to the realities of a republican Germany. When, however, the newly formed left-liberal German Democratic Party, led by Friedrich Naumann and the renowned sociologist Max Weber, refused to admit him to its higher councils, Stresemann founded his own party, the German People's Party (DVP). A right-liberal grouping of educated and propertied elements, it sought to rally the right-wing supporters of the former National Liberal Party. Stresemann, fundamentally a monarchist and an opponent of the Weimar Republic, assumed an ambiguous "wait-and-see" attitude during the rightist Kapp Putsch of March 1920. When the putsch was suppressed, however, he prepared to cooperate politically with the republic. He tried to persuade the democratic parties that the DVP was qualified to participate in a coalition and pressed for a position in the government. For the time being, however, he was still counted among the "national opposition" to the Weimar coalition—the Social Democrats, the German Democratic Party, and the Centre Party.

A member of the German National Constituent Assembly in Weimar in 1919–20, Stresemann was among the opponents of the new German constitution. He also opposed the Treaty of Versailles and was to devote his political life to its revision. From 1920 until his death Stresemann was a Reichstag deputy and chairman of the DVP, and in August 1923 he became chancellor of the *Reich* at the head of a government of the "Great Coalition," comprising representatives of the Social Democrats, of the Centre, and of the German Democrats, as well as of his People's Party.

As chancellor of Germany

As chancellor from August 13 to November 23, 1923, during the national crisis over the Allied occupation of the Ruhr, and as foreign minister from August 1923 to his death in 1929, Stresemann exercised decisive influence over the fate of the Weimar Republic, and he became a statesman of European stature. His first decision as chancellor was to abandon the policy of passive resistance in the Ruhr, which in January 1923 had been occupied by French and Belgian troops to enforce payment of German war reparations. This policy had accelerated inflation and was precipitating Germany's financial collapse.

On the domestic scene, he sought to steer his way among opposing domestic forces. While proceeding harshly against Communist-influenced state governments in Thuringia and Saxony, he displayed a lenient attitude toward revolutionary attempts of the radical right, such as Adolf Hitler's putsch of November 9, 1923, in Munich. At the height of the internal political crisis of November 1923 there was danger that the occupied territory west of the Rhine (occupied by the Allies) might withdraw from the *Reich*. Only the stabilization of the currency in the middle of November—the last significant achievement of Stresemann's government—restored domestic order and created the basis for economic recovery.

Years as foreign minister. Overthrown by a vote of no confidence, the Cabinet resigned in November 1923. Stresemann took over the post of foreign minister in the new government and held it, unchallenged until his death, in coalition governments of varying composition under three chancellors ranging from the left to centre. His policy was aimed at securing a reconciliation with the victorious Western powers, especially France, for Germany had already renewed ties with Russia through the Treaty of Rapallo in 1922. By meeting the reparation payments, for the reduction of which he fought as stubbornly as he did for removal of French troops from the territory west of the Rhine, he hoped to gain a favourable position for his negotiations with the victorious Allies. His enduring aim was to obtain equal rights for Germany and to restore it to its former position among the nations of Europe.

Principally, however, this meant a revision of Germany's eastern border of 1919, which would require Poland to return Danzig, the Polish Corridor, and Upper Silesia, as well as the annexation of Austria. Realistically appraising Germany's central position in Europe and exploiting Anglo-French and Anglo-Soviet tensions, Stresemann tried to achieve his goals through negotiation, but his seesaw policy between East and West was strongly criticized by many contemporary critics. Yet Stresemann retained his optimistic outlook, which, if anything, was strengthened by his poor health. This optimism, however, which he often carried to extremes, especially in his speeches, frequently led him to underestimate opposition both at home and abroad.

Stresemann's successes in dealing with the Allied powers during those years can be marked out in stages. In 1924 the U.S.-proposed Dawes Plan was signed, providing for reduction in payment of reparations and stabilization of German finances. It was followed by the Pact of Locarno in 1925, which included acceptance of the new Franco-German border, agreements to arbitrate disputes with other nations, and immunity from new sanctions by the victors of World War I. In 1926 the first Rhineland zone was evacuated by the Allies, Germany was admitted to the League of Nations, and the Berlin Treaty with the Soviet Union, an agreement providing for mutual neutrality, was signed. In 1928 the Kellogg–Briand Pact outlawing war was signed by Germany. Stresemann did not live to see the complete evacuation of French troops from the Rhineland and the completion of the new settlement reducing German reparations through the Young Plan (also a U.S. proposal) in 1929, although he had conducted the negotiations when already marked by death. He had reached the zenith of his career in 1926; at the end of that year, together with the French foreign minister Aristide Briand, he was awarded the Nobel Peace Prize for his policy of reconciliation and negotiation.

Rapprochement with Allies

Any summary of Stresemann's diplomatic successes should not obscure the fact that he had to devote an extraordinary amount of effort to combatting strong domestic opposition that arose, above all, from his own party. Stresemann, who took the importance of the press into consideration, used publicity and propaganda to promote his policy but, by making premature statements, often aroused political hopes that could not be realized. After his spectacular secret meeting in 1926 with Aristide Briand, which gave rise to exaggerated hopes, Franco-German rapprochement came to a standstill. In the last two years of his life, which were marked by illness, Stresemann became increasingly dissatisfied at his failure to further his foreign policy, especially after his party dwindled, and large sections of it went over to the extreme right. He himself contemplated formation of a new party of the liberal centre. The domestic struggle in particular weakened his already precarious health, and he died unexpectedly, after two strokes, on October 3, 1929, at the age of 51.

Assessment. By virtue of his six years of service as foreign minister and the esteem he enjoyed, particularly abroad, Stresemann made an essential contribution to securing the Weimar Republic's stability and survival for a few years. Because of domestic undercurrents and opposition, he succeeded at the cost of extraordinary personal effort. He was the target of malicious defamation by the "national" right opposition in its struggle against democracy and the Weimar Republic, and his nationalist past offered convenient points of attack from the left.

On his death, the republic, which honoured him with a state funeral, lost one of its few statesmen. In his personal as well as his political development he embodied the uncertainty of the period of transition from monarchy to republic. Yet he was unable to integrate his own party, over which he jealously maintained leadership, into the Weimar state and thus failed, as he wrote in March 1929, to form the bridge "between the old and the new Germany."

As an advocate of a "policy of national realism," as opposed to a "pacifist policy of resignation," he was by no means a champion of European unification. He supported its objectives, however, since he could thus more easily obtain the urgently sought revision of the Treaty of Versailles.

Stresemann's image is still controversial. Historically,

Continuing controversy over Stresemann

he was first pronounced a hero after 1945, when he was viewed as a champion of a united Europe. This view was succeeded in the 1950s by an increasingly critical evaluation, especially during the disclosure of his voluminous literary estate, which was at first exclusively at the disposal of U.S. historians. He was then portrayed as a flexible and opportunistic politician of nationalistic sympathies who shrewdly adjusted his aims to meet the needs of the time; and it was said that Stresemann had not become a democrat out of conviction but rather that he had raised "finessing," which he mentioned in 1925 in a well-known letter to the former crown prince, to the level of a principle. His volatile character and sentimental attachment to uniforms and tradition were also emphasized. The Communists, meanwhile, regarded him as a representative of monopoly capitalism and a forerunner of Hitler.

One of his more recent biographers has convincingly characterized Stresemann as a "pragmatic conservative" who remained flexible in his choice of political means while pursuing his national aims of restoration of German wealth and power and the continuation of German traditional social and economic order. Others have emphasized the European aspect of the German "patriot" Stresemann, a viewpoint from which German historical research has in the meantime departed. Yet, his political changeability notwithstanding, Stresemann is counted among the few statesmen of his time, as well as among the "great Germans."

Strigiformes

Owls constitute a homogeneous order (Strigiformes) of primarily nocturnal birds of prey, nearly worldwide in distribution. Their secretive habits, quiet flight, and weird calls have made them the objects of superstition and even fear in many parts of the world. The same characteristics have made the scientific study of them more difficult, with the result that the ecology, behaviour, and taxonomy of many species remain poorly understood.

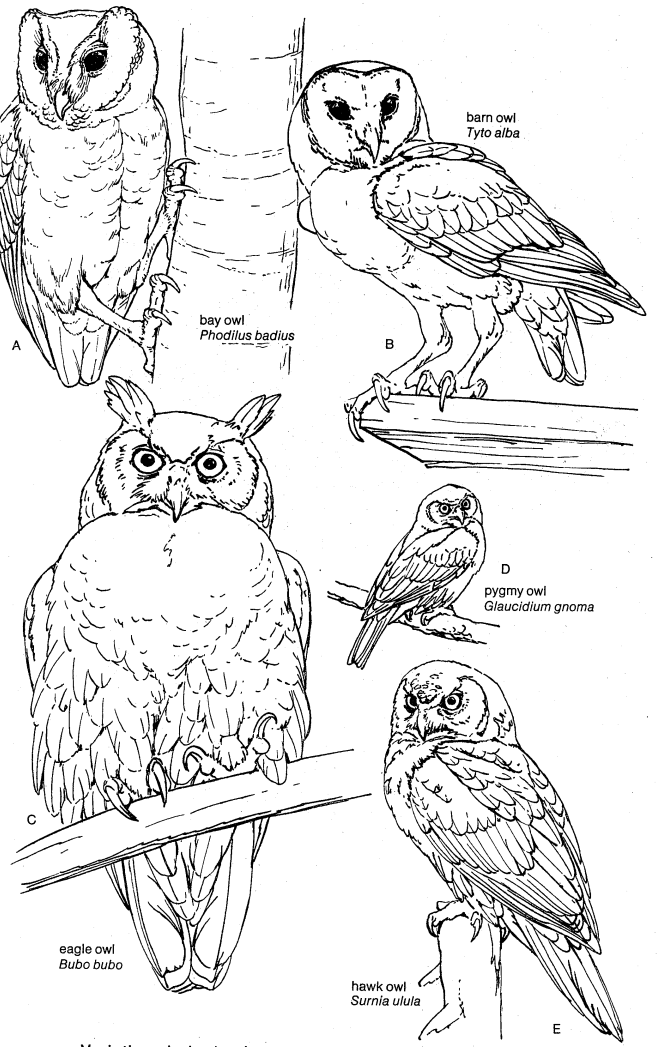
This article is divided into the following sections:

General features
Natural history
  Ecology
  Behaviour
  Reproduction and development
  Locomotion
Form and function
Paleontology and classification
  Fossil history
  Distinguishing taxonomic features
  Annotated classification
  Critical appraisal

GENERAL FEATURES

The size range of owls is about the same as that of their diurnal counterparts, the hawks (exclusive of the eagles and vultures), with lengths of around 13–70 centimetres and wingspreads around 30–200 centimetres. There are more owl species at the lower end of the size range. Owls apparently feed exclusively on animals. The most common prey is rodents; the smaller species, however, eat insects. All owls have the same general appearance: large head; hooked beak; large, forward-looking eyes; short tail; rather long, rounded wings; and large feet with sharp talons. Diversity occurs in size, in the presence or absence of decorative "ear" tufts, and in the extent of the facial ruff.

Owls are found on all continents except Antarctica and on most oceanic islands. Some, such as the barn owl (*Tyto alba*) and the short-eared owl (*Asio flammeus*), are among the most widely distributed of bird species; others, such as the Palau owl (*Pyrroglaux podargina*) and the Seychelles owl (*Otus insularis*), are endemic island species with small populations. Owls often attain higher population densities than hawks and have survived better in areas of human activity. Their nocturnal habits and inconspicuous daytime behaviour provide them some protection from shooting. The greatest densities are attained by small, territorial, insectivorous species, with pairs spaced about 200 metres apart in suitable woodland.



NATURAL HISTORY

Ecology. Owls utilize virtually all habitats, from grassland and tundra to dense woodland and rain forest. The distribution and density of most species apparently are limited by the availability of suitable nesting sites, rather than by the number of potential prey animals. In general the type of prey taken is governed by the size of the owl and by the relative abundance of potential prey species. Owls that hunt over grassland, such as the barn owl and short-eared owl, hunt by sustained flight, dropping into the grass to catch rodents. Many woodland owls secure prey by dropping from perches at the edges of forest openings. The Southeast Asian hawk-owl (*Ninox scutulata*) sallies from a perch to take flying insects. The whiskered owl (*Otus trichopsis*) takes flying insects in foliage. Owls of two genera (*Ketupa* and *Scotopelia*) are adapted for taking fish. Specialized forms of feeding behaviour are sometimes observed. The elf owl (*Micrathene whitneyi*) has been seen hovering before blossoms, scaring insects into flight with its wings and then catching them with its beak. A bay owl (*Phodilus badius*) has been observed stationed within a bat cave, catching bats as they issued forth at dusk. Although each species normally feeds on the type of prey for which it is adapted, a variety of owls may depend on a single prey animal when it becomes exceptionally abundant. Prey is generally swallowed whole, and indigestible material, such as feathers, fur, and bones, are regurgitated in the form of a compact pellet.

Behaviour. Sound communication is important to owls, especially in mating and territorial defense. With their camouflage, immobile daytime stance, and silent flight, owls may be as difficult for each other to see as for natural enemies and human observers. Their sounds used include snaps of the bill, claps of the wings in flight, and a variety of vocalizations, with pitch, timbre, and rhythm unique to each species and with pitch, at least, differing between sexes (the female higher). Although less melodious than the calls of some birds, the vocalizations of many owls are "songs" in the biological sense and may even be musical to the human ear. The song varies from deep hoots in some large species to chirps, whistles, or warblings in many small owls. When the nest is threatened, nestling burrowing owls (*Speotyto cunicularia*) emit a buzzing call that resembles the warning buzz of the rattlesnake, a frequent inhabitant of rodent burrows.

Vocalizations

In the North American screech owl, a duet that seems to reinforce the pair bond starts with a special song by the male, eventually answered in kind by the female, often from a distance. After ten to 15 minutes of antiphonal (answering) singing, during which the two approach each other, the pair switches to a duet with a second song pattern, during which they meet. In the early spring this may be followed by precopulatory calls and posturing,

Variations in body plan among owls.
Drawing by (A) R. Keane and (B,C,D,E) D. Malick

then mounting. Other calls of the screech owl include: a note uttered by the female to stimulate the young to reveal their location after they have left the nest; a food soliciting call by the young; after the breeding season, barking calls, accompanied by bill-snapping, which indicate that the young are being ejected from the territory, or the adjustment of territorial boundaries.

In many smaller species that do not normally sing duets, the male may sing all night from a single perch. The nocturnal routine of most owls involves peaks of activity at dusk and dawn. The owl leaves its secluded roost about dusk and moves to a perch overlooking the hunting area. There is a brief period of song, followed by about half an hour of foraging, then a longer period of song. Most of the darker hours of the night are spent inactively, with a period of alternating singing and hunting just before dawn.

Posturing by singing owls indicates that they communicate by sight as well as by sound. The male horned owl bows deeply with each song and raises the tail over the back. The wood owls (*Strix* species) engage in bowing, bobbing, and dancing, especially when courting. A defense display given by most large owls when threatened or when defending the nest involves increasing apparent body size by half spreading the wings and rotating them forward. The body feathers are raised and the fearsome appearance enhanced by snapping the bill and rocking the body from side to side. When seeking to avoid attention at its daytime roost (especially when being attacked by small birds), the owl compresses the plumage, elevates the ear tufts, and half closes the eyes. Combined with the bark-like colour pattern of the plumage, this behaviour provides the appearance of a broken branch.

Reproduction and development. Most owls nest in natural cavities in trees or cliffs or in woodpecker holes. The barn owls and the Eurasian little owls (*Athene* species) frequently use cavities in buildings. Some of the larger owls utilize old hawk or crow nests. Grassland and tundra owls nest on the ground, sometimes on an elevated hummock, and the burrowing owl digs a nest chamber in a rodent burrow. Frequently the nest cavity provides a daytime roost for one or both of the pair during the non-breeding months. Most owls add no nesting material to the site, but the fur and feathers of accumulated prey remains and regurgitated pellets may provide some cushion for the eggs. When an open nest is used, leaves, grass, or other soft material may be added as a lining. The great gray owl (*Strix nebulosa*) occasionally constructs its own platform nest in a tree. In desert areas the smaller owls rely primarily on holes made by woodpeckers in large cacti. Intense competition has been observed among nesting birds, including owls, for occupancy of a limited number of nest sites. The invasion of the saguaro desert by the European starling (*Sturnus vulgaris*) has had a serious effect on small owls and other saguaro birds. The aggressive and abundant starlings occupy cavities before the other species have returned from wintering grounds and successfully defend the holes against native species. Nesting sites

Egg laying is timed so that the young become independent of their parents at a time when populations of prey species are greatest. At northern latitudes, many owls nest a month or two earlier in the spring than hawks of the same regions. An incubating owl is frequently covered by several inches of snow. Barn owls have been found nesting in every month of the year, even at the northern edge of their range, but the peak of nesting is in the spring. Owls lay more eggs than most diurnal raptors, with clutches of up to twelve (in the snowy owl, *Nyctea scandiaca*). In years of lemming abundance, snowy owls attain higher nesting densities, nest earlier, lay more eggs, and have higher fledging rates than when lemmings are scarce. The eggs of owls are more nearly spherical than those of any other bird group, the long diameter averaging only about 1.2 times the short diameter. They are laid at one or, more often, two day intervals, and incubation begins when the first is laid. The result is that the oldest and youngest nestlings of a large brood may be two or three weeks apart. If the prey populations are inadequate for the adult owls to support the entire large brood, the younger nestlings starve, while the more aggressive older ones are able to maintain normal growth rates and are strong at fledging.

While in the nest, young owls grow two successive coats of white natal down. In the smaller species, the down is replaced by the immature juvenal plumage of softer, lacier texture than that of the adult. At this age, about two-thirds of the way to fledging, the young owls may leave the nest and spend the day several metres from it. In the screech owl, the juvenal plumage has fine barring, unlike the streaking of the adult. The first flight feathers, which appear about the same time, are like those of the adult but are more pointed. In the fall, only a few weeks after its acquisition, this plumage is replaced in a complete molt that introduces a plumage identical to that of the adult. In the larger owls that have been extensively studied (several species of *Bubo*), the juvenile plumage resembles the adult except that in *B. nipalensis* and *B. sumatranus* it is mostly white, with a different pattern of black marking from the adult. Plumage succession

Locomotion. Most owls use their feet only for perching and grasping prey. The burrowing owls, being terrestrial, can run rapidly over the ground and rarely perch in vegetation. The typical perch of other owls is a horizontal branch in a tree. The bay owl habitually perches on the vertical trunk of a tree, with the legs reaching sideways, one foot above the other. The body is held in a vertical position as though the owl were perched on a horizontal limb.

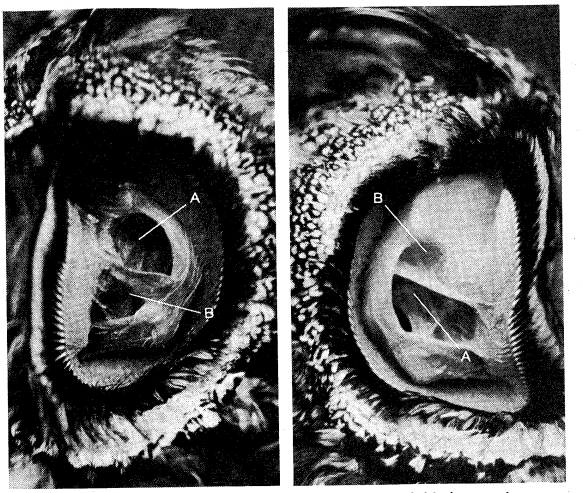
The flight of owls is a steady flapping on a straight path, ending in a short upward glide to the perch. Hunting, usually done from a perch, rarely involves extensive flight, requiring only a short burst of speed to surprise the

prey on the ground. Forest owls rarely fly above the canopy of the foliage, but the Southeast Asian hawk-owl has been observed high in the air, flapping—or, on one occasion, soaring—in circles through swarms of bats, apparently without catching any. A few grassland and tundra owls hunt in sustained flight and have proportionately more wing area than their forest-dwelling relatives. The short-eared owl flaps slowly, the large area of the wings causing the light body to bob up and down, and sails for a brief period of time with the wings held in a high V over the back.

FORM AND FUNCTION

All owls share the same general body plan. The wings are long and rounded, the tail short. The legs and toes are of medium length and exceptionally strong for the size of the bird. Each toe is provided with a needle-sharp, curved talon. The outer toe is reversed in perching and is normally directed outward or backward in taking prey, providing the maximum possible toe spread.

The head is broad, to accommodate the exceptionally large eyes. The owl eye is elongated forward and encased in a tube made up of joined bony elements. The eye is virtually immovable, rigidly encased in the bony socket. Remarkable flexibility of the neck compensates for the immobility of the eyes; an owl can turn its head more than 180° in either direction and can thus look directly backward. The vision is binocular, and depth perception is often enhanced by moving the head away from the central plane. Owls that are mostly active at night have only rods in the retina, resulting in an absence of colour vision but a great increase in visual acuity and light sensitivity. Contrary to popular opinion, owls are not blind in strong light. The pupils, which operate independently, can be greatly reduced, protecting the sensitive retina and providing better daytime vision than that found in man.



Hearing

The ear is large and is surrounded by a ruff of papery feathers that serve to concentrate the sound. The feathers covering the ear opening are lacy and permeable to sound. A movable flap (operculum) on the anterior margin of the opening may function as a baffle to focus sounds. Some owls can locate and capture prey in total darkness, relying on their ability to localize the rustle of a mouse in leaves and to fly to that spot. In many owls the relative position of the ear opening is asymmetrical, being above a so-called blind cavity on one side of the head and below it on the other. The asymmetry is thought to be related to the sensitivity of each ear to sounds of various frequencies and provides the owl with the ability to localize sound sources in two planes simultaneously.

Many owls have erectile tufts of feathers ("ears" or "horns") above the eyes. In some cases the tufts give the owls a feline appearance and might frighten potential predators, but it is more likely that the erect "ears" serve to break the rounded outline of the head, adding to the concealment gained from colour and pattern.

The plumage of owls is soft, dense, and loose. A thick layer of down provides northern owls with insulation against cold. The upper surfaces of the flight feathers of most species are provided with a nap that makes the flight perfectly noiseless, allowing the owl to hear prey without interference of flight sound.

Owls vary in coloration from white through many shades of tan, gray, brown or rufous to deep brown. A few are solidly coloured, but most are cryptically patterned, with streaks, bars, or spots, often resulting in the bird being almost invisible against bark. The concealing bark pattern is well exemplified in the small owls of the genus *Otus*. The soft brown, rufous, buff, or gray ground colour of each breast feather is adorned by a blackish bar, shaft streak, or combination of both, sometimes outlined in white or rufous. In some widespread species, such as the Eurasian scops owl (*O. scops*) and the screech owl, geographic variation is so great that the more divergent races are more different than some full species. In the far north there is only a faint pattern on a whitish background; in humid, temperate forests a bold pattern on a sooty background; in desert areas a medium to fine pattern on pale gray; in arid tropics a fine pattern on rufous; and in humid tropics a coarse pattern on fulvous. Size variation is also present, with northern birds weighing about twice as much as those of southern races. The horned owl (*Bubo virginianus*) exhibits similar variation.

Asymmetry of the ear canal in the long-eared owl (Asio otus). In the left ear (left), the opening of the ear canal (A) is above the transverse fold and the blind cavity (B), below. In the right ear, the situation is reversed.
Heinz Meng

Colour dimorphism

Screech, scops, and whiskered owls may be either gray or rufous, apparently controlled by a single gene. Such dimorphism in ground colour is found in only certain populations of each species: the southern in the whiskered owl and the eastern in the North American screech owl and the Eurasian scops owl. In each case, interbreeding between the uniformly coloured monomorphic and sexually distinct dimorphic populations is limited. J.T. Marshall, Jr., regards the dimorphic strains as "incipient species." The mechanism by which natural selection maintains colour dimorphism is poorly understood. Moreover, little is known about the type and degree of predation on small owls. The red phase of the screech owl may have survival value in the predominantly deciduous forest of eastern North America, blending with the foliage of summer and autumn, in which reds and browns are strongly represented.

PALEONTOLOGY AND CLASSIFICATION

Fossil history. The earliest recognizable fossil strigiform is *Protostrix* from the Eocene of Wyoming. A number of genera from the later Tertiary have been assigned to Recent strigiform families. Some early owls reached far greater size than their modern descendents. A giant barn owl, about twice the size of the modern *Tyto alba*, inhabited Puerto Rico in the Pleistocene. Another large owl, *Ornimegalonyx oteroi* from the Pleistocene of Cuba, apparently was flightless. Both owls must have exceeded the modern eagle owls in size.

Distinguishing taxonomic features. The owls form a homogeneous group readily distinguished from all other orders by their general body plan, soft plumage, and osteological peculiarities. To determine relationships within the Strigiformes, taxonomists utilize the osteology of the skull and the sternum, relative specializations of the eye and ear, and the development of the facial disk. Within some genera the taxonomy is very complex, relying on general proportions, behaviour, voice, and ectoparasites (Mallophaga or feather lice).

Annotated classification.

Order Strigiformes. Nocturnal predatory birds with hooked beaks; nostril marginal to fleshy cere; broad skull, facial disk, with forwardly directed eyes; reversible outer toe; talons for securing prey. One fossil and 3 extant families.

Family Protostrigidae. Fossil. Known only from lower Eocene of Wyoming.

Family Tytonidae (barn owls and grass owls). Lower Miocene to present. Medium-sized owls (30–54 cm long) with heart-shaped facial disk completely encircling face; bill relatively long and slender; legs rather long, middle claw

with comb. One pair of sternal notches, clavicles separate and not fused to sternum. One genus (*Tyto*), about 9 species. Worldwide, except in polar and subpolar regions and on some oceanic islands.

Family Phodilidae (bay owls). Miocene and Recent. Like a small *Tyto*, but clavicles fused to sternum, which has 2 pairs of notches. Facial disk differs from *Tyto* in forming 2 movable lappets that can be focussed at sound, like mammalian ears. Disk interrupted at forehead. Wings short, broad. Legs and toes shorter and thicker than in *Tyto*. Voice, syrinx, behaviour, and ecology differ from both Tytonidae and Strigidae. One Recent genus (*Phodilus*), with 1 species widespread in Southeast Asia, and another (known only from a single specimen) in central Africa.

Family Strigidae (typical owls). Upper Eocene to Recent. Clavicles fused to sternum, which has 2 pairs of notches. Facial disk consists of a semicircle on each side. Middle claw without comb. About 22 Recent genera, 125 species. Length about 13–70 cm. Worldwide, except Antarctica and some oceanic islands.

Critical appraisal. Most recent taxonomists have divided the Recent Strigiformes into two families, Tytonidae and Strigidae. The bay owl (*Phodilus*) has been placed in the Tytonidae by some authorities and in the Strigidae by others. F.E. Beddard, in 1898, suggested that the distinctive characteristics of the bay owl justified separation in a monotypic family, Phodilidae, a view recently endorsed by J.T. Marshall, Jr., after observations in the field.

Within the Strigidae, most current taxonomic problems are concerned with the placement of certain genera within the family and with the specific status of some populations of complex genera, such as *Otus*. Some of these problems await the development of new information on species isolating mechanisms, especially vocal behaviour.

BIBLIOGRAPHY. O.L. AUSTIN, *Birds of the World*, ed. by H.S. ZIM (1961), presents an excellent general account of owls, with fine colour illustrations that include some rarely seen species. A.C. BENT, "Life Histories of North American Birds of Prey, Part II," *Bull. U.S. Natn. Mus. 170* (1938; reissued in 1961 as vol. 2 of series of same title), contains complete accounts of the natural history of North American owls. J.J. and F.C. CRAIGHEAD, *Hawks, Owls and Wildlife* (1956, reissued in pa. 1969), is a classic in the ecology of raptorial birds. M.L. GROSSMAN and J. HAMLET, *Birds of Prey of the World* (1964), provides range maps for each species, good photographs, and a reading list by geographical region and by genus. G.P. DEMENTIEV *et al.*, *Birds of the Soviet Union*, vol. 1 (Eng. trans. 1966; orig. pub. in Russian, 1951), contains an extensive and well illustrated section on Eurasian owls. E.C.S. BAKER, *Fauna of British India (Birds)*, vol. 4 (1927), includes an excellent discussion of the anatomical traits used in the classification of owls. Of a more specialized nature: R.S. PAYNE and W.H. DRURY, JR., "Marksman of the Darkness," *Nat. Hist.*, vol. 67, pp. 316–323 (June 1958), describes the discovery of the hearing ability of the barn owl. D.J. LIGON, "The Biology of the Elf Owl, *Micrathene Whitneyi*," *Misc. Publs. Mus. Zool. Univ. Mich. No. 136* (Feb. 1968), is a detailed study of the life history of the smallest owl, compared with other owls. A. ROSS, "Ecological Aspects of the Food Habits of Insectivorous Screech-owls," *Proc. West. Fdn. Vertebr. Zool.* vol. 1, no. 6, pp. 301–344 (1969), is a definitive correlation between body size and prey size, one of the few such papers in which stomach contents are correctly identified. L.W. WALKER, "Nocturnal Observations of Elf Owls," *Condor*, vol. 45, no. 5, pp. 165–167 (Sept.–Oct. 1943), is a model of excellence in photography and concise scientific writing. B.E. SMYTHIES, *The Birds of Burma*, 2nd ed. rev. (1953), and *The Birds of Borneo* (1960), provide the best and most reliable information on the habits and calls of Asian owls.

Strindberg, August

Although he led a tortured, half-mad existence, August Strindberg, the greatest Swedish playwright, wrote a series of novels, short stories, and plays that marked the beginning of modern Swedish literature and exercised a profound influence on European and American drama.

He was born in Stockholm on January 22, 1849, the son of Carl Oskar Strindberg, a bankrupt aristocrat who worked as a steamship agent, and of a former waitress. His childhood was marred by emotional insecurity, poverty, his grandmother's religious fanaticism, and neglect, as he relates in his remarkable autobiography *The Son of a Servant* (1886). He studied intermittently at the University of Uppsala, preparing in turn for the ministry and a career in medicine but never taking a degree. To earn his living, he worked as a free-lance journalist in Stockholm, as well as at other jobs that he almost invariably lost. Meanwhile he struggled to complete his first important work, the historical drama *Mäster Olof* (published in 1872), on the theme of the Swedish Reformation, influenced by Shakespeare and by Henrik Ibsen's *Brand*. The Royal Theatre's rejection of *Mäster Olof* deepened his pessimism and sharpened his contempt for official institutions and traditions. For several years he continued revising the play—later recognized as the first modern Swedish drama—thus delaying his development as a dramatist of contemporary problems.

Strindberg, lithograph by Edvard Munch, 1896. In the Munch-Museet, Oslo.

In 1874 he became a librarian at the Royal Library, and in 1875 he met the Finno-Swedish Siri von Essen, then the unhappy wife of an officer of the guards; two years later they married. Their intense but ultimately disastrous relationship ended in divorce in 1891, when Strindberg, to his great grief, lost the custody of their four children. At first, however, marriage stimulated his writing, and in 1879 he published his first novel, *The Red Room*, a satirical account of abuses and frauds in Stockholm society: this was something new in Swedish fiction and made its author nationally famous.

First plays of social criticism

He also wrote more plays, of which *Lucky Peter's Travels* (1881) contains the most biting social criticism. In 1883, the year after he published *Det nya riket* ("The New Kingdom"), a withering satire on contemporary Sweden, Strindberg left Stockholm with his family and for six years moved restlessly about the Continent. Although he was then approaching a state of complete mental breakdown, he produced a great number of plays, novels, and stories. The publication in 1884 of the first volume of his collected stories, *Married*, led to a prosecution for blasphemy. He was acquitted, but the case affected his mind, and he imagined himself persecuted, even by Siri.

He returned to drama with new intensity, and the conflict between the sexes inspired some of the outstanding works written at this time, such as *The Father*, *Miss Julie*, and *The Creditors*. All of these were written in total revolt against contemporary social conventions. In these bold and concentrated works, he combined the techniques of dramatic naturalism—including unaffected dialogue, stark rather than luxurious scenery, and the use of stage props as symbols—with his own conception of psychology, thereby inaugurating a new movement in European drama. *The People of Hemsö*, a vigorous novel about the Stockholm skerries (rocky islands), always one of Strindberg's happiest sources of inspiration, was also produced during this intensively creative phase.

The years after his return to Sweden in 1889 were lonely and unhappy. Even though revered as a famous writer who had become the voice of modern Sweden, he was by now an alcoholic unable to find steady employment. In 1892 he went abroad again, to Berlin. His second marriage, to a young Austrian journalist, Frida Uhl, followed in 1893; they finally parted in Paris in 1895.

Period of religious crisis

A period of literary sterility, emotional and physical stress, and considerable mental instability culminated in a kind of religious conversion, the crisis that he described in *Inferno*. During these years Strindberg devoted considerable time to experiments in alchemy and to the study of theosophy.

His new faith, coloured by mysticism, re-created him as a writer. The immediate result was the drama in three parts, *To Damascus*, in which he depicts himself as "the Stranger," a wanderer seeking spiritual peace and finding it with another character, "the Lady," who resembles both Frida Uhl and Siri von Essen.

By this time Strindberg had again returned to Sweden, settling first in Lund and then, in 1899, in Stockholm, where he lived until his death. The summers he often spent among his beloved skerries. His view that life is ruled by the "Powers," punitive but righteous, was reflected in a series of historical plays that he began in 1889. Of these, *Gustav Vasa* is the best, masterly in its firmness of construction, characterization, and its vigorous dialogue. In 1901 he married the young Norwegian actress Harriet Bosse; in 1904 they parted, and again Strindberg lost the child, his fifth.

Yet his last marriage, this "spring in winter," as he called it, inspired, among other works, the plays *The Dance of Death* and *A Dream Play*, as well as the charming autobiography *Ensam* ("Alone") and some lyrical poems. Renewed bitterness after his parting from his last wife provoked the grotesquely satirical novel *Svarta Fanor* ("Black Banners," 1907), which attacked the vices and follies of Stockholm's literary coteries, as Strindberg saw them. *Kammarspel* ("Chamber Plays"), written for the little Intima Theatre, which Strindberg ran for a time with a young producer, August Falck, embody further developments of his dramatic technique: of these, *The Ghost Sonata* is the most fantastic, anticipating much in later European drama. His last play, *The Great Highway*, a symbolic presentation of his own life, appeared in 1909.

To the end, Strindberg debated current social and political ideas (returning to the radical views of his youth) in polemical articles, while his philosophy was expounded in the aphoristic *Zones of the Spirit* (1907–12). He died of cancer on May 14, 1912, in Stockholm, ignored in death, as in life, by the Swedish Academy but mourned by his countrymen as their greatest writer. On Swedish life and letters he has exercised a lasting influence and is admired for his originality, his extraordinary vitality, and his powerful imagination, which enabled him to transform autobiographic material into dramatic dialogue of exceptional brilliance.

Assessment

The pregnant, colloquial style of Strindberg's early novels and, especially, of his short stories, brought about a long-overdue regeneration of Swedish prose style, and *The Son of a Servant* gave perhaps the strongest impulse since Jean-Jacques Rousseau's *Confessions* to the publication of discreditable self-revelations. His greatest influence, however, was exerted in the theatre, through his critical writings (such as the introduction to *Miss Julie*), his plays, and the production devices that their staging dictated. The continuous, brutal action and phonographic dialogue of *Miss Julie* and other plays written between 1887 and 1893 reached the *ne plus ultra* of naturalistic drama. With the later phantasmagoric plays, such as *To Damascus, A Dream Play*, and *The Ghost Sonata*, Strindberg led that section of the revolt against stage realism that issued in the Expressionist drama, which was developed mainly in Germany after 1912 and which influenced such modern playwrights as Sean O'Casey, Elmer Rice, Eugene O'Neill, Luigi Pirandello, and Pär Lagerkvist.

MAJOR WORKS

PLAYS: *Den fredlöse* (first performed 1871, published 1881; *The Outlaw*, 1912); *Mäster Olof* (poetic version published 1878, performed 1890; *Master Olof*, 1915); *Lycko-Pers resa* (published 1881, performed 1883; *Lucky Peter's Travels*, 1930); *Fadren* (published and performed 1887; *The Father*, 1899); *Kamraterna* (published 1888, performed 1905; *Comrades*, 1912); *Fröken Julie* (published 1888, performed 1889; *Countess Julie*, 1912; *Miss Julie*, 1918); *Fordringsägare* (first published in Danish trans., 1888; *Creditörer*, published and performed 1890; *Creditors*, 1914); *Paria* (performed 1889, published 1890; *Pariah*, 1913); *Till Damascus* (parts 1 and 2 published 1898, performed 1900; part 3 published 1904, performed 1916; *To Damascus*, 1913); *Folkungasagan* (published 1899, performed 1901; *The Saga of the Folkungs*, 1931); *Gustav Vasa* and *Erik XIV* (published and performed 1899; Eng. trans. 1931); *Påsk* (published and performed 1901; *Easter*, 1912 and 1929); *Dödsdansen* (published 1901, performed 1905; *The Dance of Death*, 1912); *Kronbruden* (published 1902, performed 1906); *Drömspelet* (published 1902, performed 1907; *A Dream Play*, 1929); *Brända tomten* (performed and published 1907; *After the Fire*, 1913); *Spöksonaten* (published 1907, performed 1908; *The Spook* [or *Ghost*] *Sonata*, 1916); *Stora landsvägen* (published 1909, performed 1910; *The Great Highway*, 1954).

NOVELS: *Röda rummet* (1879; *The Red Room*, 1913); *Hemsöborna* (1887; *The People of Hemsö*, 1959); *I havsbandet* (1890; *By the Open Sea*, 1913).

SHORT STORIES: *Giftas*, 2 vol. (1884–85; *Married*, 1913); *Fagervik och skamsund* (1902; *Fair Haven and Foul Strand*, 1913); *Sagor* (1903; *Tales*, 1930).

AUTOBIOGRAPHY: *Le Plaidoyer d'un fou* (first published in French, 1888; enlarged, 1893; *The Confessions of a Fool*, 1912); *Inferno* (1897; Eng. trans., 1912); *Ensam* (1903).

TRANSLATIONS: There is no English-language edition of the complete works of Strindberg, which fill 55 volumes in Swedish. Individual works are, however, readily available. Recommended modern translations include *Twelve Plays* by Elizabeth Sprigge (1963); and *The Plays of Strindberg* by Michael Meyer, which began publication in 1964.

BIBLIOGRAPHY. There is no definitive biography or full up-to-date bibliography.

Editions: *Samlade Skrifter*, ed. by JOHN LANDQUIST, 55 vol. (1911–21); several collections of letters (*Brev*, ed. by TORSTEN EKLUND, 1948–).

Stringed Instruments

This article covers the family of musical instruments known as stringed instruments, or chordophones, and includes their structure and history and their comparative, symbolic, and acoustical qualities. All chordophones produce sound by the vibration of strings, which may be made of vegetable fibre, metal, animal gut, or plastic. In nearly all stringed instruments the sound of the vibrating string is amplified by the use of a resonating chamber or soundboard. The string may be struck, plucked, or rubbed (bowed); in each case the effect is to displace the string from its normal position of rest and to cause it to vibrate in complex patterns.

Since most stringed instruments are made from wood or other easily perishable materials, their history before written documentation is almost unknown, and contemporary knowledge of "early" instruments is limited to the ancient cultures of the Far East, India, the Mediterranean, and Mesopotamia; but even for these places histori-

ans must depend largely on iconographic sources rather than surviving specimens.

Chordophones seem to have spread rapidly from one society to another across the length and breadth of Eurasia by means of great population shifts, invasions and counterinvasions, trade, and, presumably, through sheer cultural curiosity. In the Middle Ages the Crusades stimulated Europe in the adoption of a whole set of new instruments; similarly, the Chinese accepted many new instruments from their Central Asian invaders. Indeed, the only world area that did not echo to the sound of strings was pre-Columbian America.

No system of classification can adequately categorize the interactions of natural material, craftsmanship, and man's exuberant imagination that produced an endless variety of stringed instruments. The most widely accepted system of classification is one devised in 1914 by the writer-musicologists Erich Moritz von Hornbostel and Curt Sachs, a method based on the type of material that is set into vibration to produce the original sound. Thus, stringed instruments are identified as chordophones; that is to say, instruments in which the sound is produced by the vibration of chords, or strings. This main category is then further divided into four subtypes arranged according to the manner in which the strings are positioned in relation to the body of the instrument. Within these categories, the descriptive nomenclature of an instrument is given in terms of parts of the human body: for example, the belly (front), back, sides, and neck. Instruments are not necessarily related only to others in the same classification. Transformations continually occur, and "hybrids," according to the Sachs–Hornbostel system, may in fact represent altogether viable subtypes of their own. The instrument maker, who usually has been a forgotten link in the musical chain, has always represented a blend of conservatism with the ability to quickly seize on and use a new constructional technique, a new tool, or a new material. The instrument maker's contribution to both the history of music and the history of musical instruments has been enormous and little appreciated.

The role of the instrument maker

This article is divided into the following sections:

The production of sound
Types of instruments
  Lutes
  Zithers
  Lyres
  Harps
The music of stringed instruments
  Solo uses
  For accompaniment
  Ensembles
Social and cultural associations
Stringed instruments as objects of art
The development of stringed instruments
  The harp
  The lyre
  The zither
  The lute
  Bowed instruments

THE PRODUCTION OF SOUND

The ear, because of its own structure, adds to and subtracts from the outside sound. It is, for instance, relatively insensitive to low-frequency sound pressure but is extremely sensitive to fine degrees of pitch change. At the same time it can accept a great number of pitch and tuning systems. On a worldwide basis, there is a large and varied number of tonal systems. The oldest known of these in the West is the so-called Pythagorean system; others include mean-tone tuning, just intonation, and the even-tempered system, methods of tuning calculation that vary slightly in the exact size they assign to the intervals within an octave. All of these systems represent theoretical mathematical concepts to some degree, and their origins must be sought in arcane numerological systems rather than in practical musicianship. Thus, "tuning" and "playing in tune" do not necessarily refer to the same thing; players and tuners make constant adjustments to any basic mathematically determined framework according to their judgment and experience. Again, a given "scientific" tuning system outlines scales and modes; the instrumentalist who plays an instrument with great pitch flexibility (the violin, for instance) spends much time in the spaces between the notes assigned in the given scale. Again, the Japanese zither, koto, can be tuned according to a number of fixed systems, and, even so, its player produces many microtonal variations on these fixed pitches by manipulation of the strings. Even in such a technological society as that of the modern West, the well-tempered scale is honoured more in the breach than in the observance: a piano tuner would not think of tuning altogether according to its dictates and uses a so-called stretched tuning, in which he imperceptibly sharpens (raises) pitches as he ascends, thus making the highest notes relatively sharper than the lowest ones. Again, investigation has disclosed that string players tend to play in the Pythagorean rather than the well-tempered system.

Inconsistencies, then, are inherent in all tuning systems; makers of fretted lutes (the guitar or the Greek lute, *laghouta*, for example) operate according to a combination of ear and rule of thumb when they insert frets (note-position markers—*e.g.*, of gut or wire) in the fingerboard. Such instruments are fretted according to the "rule of the eighteenth," in which the first fret is placed at one-eighteenth of the distance from the top to the bottom of the string, the second, one-eighteenth of the distance from the first fret to the bottom, and so on. Even if this method produced an acoustically perfect scale (which it does not), the player would not be able to reproduce this exactly, for as he presses the string to the fingerboard, the string is stretched and is thus slightly lengthened. That is why the act of stopping a string at its exact centre gives a note slightly sharper than the expected octave above the open string. Despite all of this, the search for an acoustically perfect tuning system goes on.

Though constructional methods differ widely from one area and instrument to another, there are a limited number of basic problems to be overcome by the maker of stringed instruments. The very principle that makes it possible for chordophones to sound is string tension; at the same time, tension is destructive to the instrument since it tends literally to pull it apart. So the body of an instrument must be made of strong material; it must be reinforced, and at the same time it must not be so rigid that it cannot easily resonate; *i.e.*, produce a supplementary vibration intensifying that of the string. The challenge of reconciling these opposite needs is the central one for the chordophone maker. Climate, too, has a marked effect on musical instruments: humidity expands a wooden instrument, and dryness contracts it. Of these factors, dryness is the most harmful, since the contraction of the wood actually pulls the instrument apart. Much energy has been expended over the centuries in investigations of various varnishes, shellacs, glues, and sealers. Many makers prefer to make their instruments in dry conditions, for the expansion caused by humidity is unlikely to prove as harmful as the contraction caused by dryness.

Effect of climate on instruments

However common the practice may have been in the past, wooden instruments are not now usually gouged out of one piece of wood (though the Japanese lute, *biwa*, portions of the koto, and often the Puerto Rican lute, *cuatro*, are thus fashioned); it is too painstaking and time-consuming for the maker. Instead, the instrument is built up of many pieces of wood glued together; the shaping of curved pieces is accomplished by gouging and planing (as in the belly of the violin) or by heating and pressing in a frame (the sides of the violin or guitar). Soundboards, the most important part of the resonance system of stringed instruments, are carefully planed to close tolerances. Mass-production methods are unsuitable for the production of high-quality chordophones because no two pieces of wood are precisely alike in their acoustical qualities; each piece of wood requires special judgment and treatment. Ideally, therefore, stringed instruments of the highest quality must be individually

Making of modern pianos

made. Piano manufacture is a partial exception to this rule, but even in a piano factory, individual treatment and craftsmanship are allowed full sway. The modern piano is a product of several different factories. The cast-iron frames are made by specialized foundries—the steel strings, the keyboards, and the actions by specialized firms. Each of these processes requires experienced craftsmen; and the work of assembly, polishing, tuning, and tone regulation calls for hours of individual attention to each instrument.

The construction and maintenance of stringed instruments has been complicated over the centuries by a continual rise in standard pitch, requiring strings to be tightened. Older instruments (such as a Stradivarius violin) have been subjected to additional physical strain and therefore needed heavier bass-bars (braces under the belly).

As already stated, the three possible methods of sound production on a stringed instrument are plucking, striking, and bowing. A string vibrates in a complex way: the entire string vibrates in one segment (producing the fundamental pitch), and various segments at the same time vibrate independently to produce overtones. The resulting sound is weak indeed unless the instrument is provided with a resonator to amplify the sound. The shape of the resonator varies greatly. It has been influenced by the materials, tools, and technology available in the society, the symbolic meaning of the shape, and the sound desired by the culture. The last factor seems to be governed by the first three: that is to say, the prescribed shape of the resonator affects the overtone structure of the instrument, producing a certain timbre, which the society in question then defines as attractive sounding.

Importance of the shape of the resonator

One of the clearest illustrations of the basic importance of the shape of the resonator to a musical instrument is the African mouth bow (a musical bow in which the player inserts the bow in his or her mouth). By varying the size and shape of the oral cavity while striking or plucking the single, unfingered string, the player produces a clearly perceptible, if quiet, melody that exists only because the changes in the mouth emphasize various overtones. On stringed instruments with permanently fixed resonators, the size, dimensions, shape of apertures, thickness, and bracing of the resonating surfaces largely determine which overtones will be emphasized and, thus, what the instrument will sound like. On a good violin, for example, the resonances of the body of air enclosed in the body of the instrument and of the belly should be close in pitch to the two strings A and D, thus amplifying and colouring these pitches and their overtones. The sound quality of a stringed instrument is also influenced by the thickness and material of the strings; primarily, however, it is the size and shape of the resonating body and especially the material, density, and thickness of the soundboard that determine the sound of an instrument. A well-known Spanish guitar maker, in a successful attempt to prove the importance of the belly of the guitar, once constructed an instrument—an excellent one—from the acoustically dead material papier-mâché, except for a carefully chosen and wrought wooden soundboard. Makers, then, devote a large part of their skill and knowledge to the choice of material for the soundboard; the maker of wood-bellied instruments prefers old wood because it is dry and well seasoned.

The Puerto Rican *cuatro* maker uses wood obtained from old houses; some guitar makers find the soundboards of discarded pianos unusually suitable for their purposes; makers of the classical Chinese zither, ch'in, preferred old coffins.

The timbre of a struck or plucked stringed instrument is also affected by the manner of setting the string into motion. A string plucked with a sharp point (the player's fingernail or a plastic plectrum) emphasizes the higher overtones, thus creating a "bright" tone quality. By contrast, a soft pad, such as that on a piano hammer, emphasizes the fundamental pitch. The relative hardness of the hammer on the piano is thus of critical importance to the sound of the instrument, and the final process in piano manufacture is voicing. A skilled worker adjusts the timbre of the instrument by the simple expedient of pricking the felt hammers with needles until he achieves a unified quality throughout the range of the instrument. The tone of an instrument is markedly affected by the place where the string is struck. The permanently fixed striking place on keyboard instruments has to be chosen with a combination of concern for the timbre and the mechanical requirements of the instrument. On all other stringed instruments the player varies the tone quality by choosing to pluck, strike, or bow at various places along the length of the string.

"Voicing" a piano

Another way in which musicians and musical instrument makers influence the sound of their instruments is by the use of sympathetically vibrating strings. On the piano, for example, when the so-called damper pedal is raised, thus leaving the strings free to vibrate, the act of striking one note causes all closely related pitches to vibrate in sympathy, thus modifying the loudness and tone of the struck note. This effect (which is encountered also on the zither and harp) is not a central feature of these instruments, but there are a number of Eurasian chordophones on which the principle is of fundamental importance. The North Indian plucked instruments, sarod and sitar, each possess about a dozen sympathetic strings tuned according to the notes of the mode being played. The Indian fiddle, sarangi, has from 35 to 40 sympathetic strings; the Norwegian Hardanger fiddle (*Hardangerfele*) has four sympathetic strings, the viola d'amore six or more. Sympathetic strings are generally made of thin brass or steel, and their vibration reinforces the upper harmonics, thus producing a bright, silvery sound.

TYPES OF INSTRUMENTS

Lutes. Probably the most widely distributed type of stringed instrument in the world is the lute (the word is used here to designate the family and not solely the lute of Renaissance Europe). The characteristic structure consists of an enclosed sound chamber, or resonator, with strings passing over all or part of it, and a neck along which the strings are stretched. The player moves his fingers up and down the neck, thus shortening the strings and producing various pitches.

In the lute the part of the resonating chamber over which the strings pass is called the belly and the other side of the resonator is called the back. The portion between the back and belly is the side, or rib. A lute may be plucked with the fingers or a plectrum or may be bowed, but the means of sound production do not affect the essential morphological identity of plucked, struck, and bowed lutes.

Lutes may be subdivided into those with skin and those with wood bellies; in most Eurasian cultures examples of both types exist side by side. In Japan the wood-bellied lute is the *biwa*, the skin-bellied one the samisen; in the Near East the wood-bellied one is the *ʿūd* and the skin-bellied, the tār; in the United States it is the guitar and the banjo, respectively. The two different varieties of lute are distinct in sound and structure; and methods of construction, timbre, history, and symbolic associations differ markedly. A second subdivision concerns the shape of the instrument; for instance, the lute proper has a round back, the guitar a flat one. These two basic constructional principles (the shape of the resonator and whether the belly is constructed from wood or skin) constantly interact, producing all sorts of combinations.

The string vibrations of the lute are transferred to the resonating chamber by a bridge; the resonator magnifies them and transmits them to the air. Makers lavish great attention on the choice and fashioning of material for the belly: if it is of wood, it must be selected and aged with much care and planed to a prescribed thickness; if it is of skin, it must be made only from certain materials. (The belly of the Japanese samisen is preferably made from the skin of a female cat; the wooden belly of the Puerto Rican *cuatro* is best constructed from wood of the female *jagrumo* tree.)

Lute strings

The lute strings themselves have traditionally been made of animal intestines (gut) or metal or silk, though nylon has now replaced these older materials all over the

world. Whatever the material, each string must be of equal thickness throughout its length. Some lutes have only a single string, but the great majority have three, four, or more. Very often there are sets, or courses, of two strings to a pitch, so that an instrument that produces four pitches with open strings actually has eight strings arranged in pairs.

In the tunings of lutes, though fourths and fifths (intervals the size of four and five tones of a Western seven-note scale, as C–F and C–G) predominate in many places, any given instrument is likely to be tuned differently from one location, piece, or player to another. Functionally more important is the question of whether a lute is fretted or unfretted. It is clearly easy to change from one pitch to another on an unfretted instrument by sliding the finger along the string, but it is also possible to do this on an instrument with extremely high frets (Japanese *biwa*, Indian vina) by pressing—hence stretching—the string into the cavity between two frets. Instruments with low frets (the guitar, banjo, European lute, viola da gamba) are in use mainly in Europe, where a limited and clearly defined tonal system is in use and where significant microtonal changes in pitch are not necessary.

The fiddle can be distinguished from other lutes only by the manner in which it is played—with a horsehair bow. The practice of rubbing the strings with this implement is of uncertain age and origin, but it seems to have appeared almost simultaneously (9th–10th centuries AD) in China, Java, the Arab world, Byzantium, and Europe. As with the other lutes, there is a fundamental division between skin and wood-bellied instruments. (The former are far more common on the fiddle than the latter, which occur mainly in Europe.) Musically more significant, however, is the division between the stick fiddle, in which the player's finger does not actually press the string to a fingerboard (but rather slides up and down the string itself), and the fiddle with a fingerboard (for example, the violin). On fiddles without fingerboard (including the Chinese *erh-hu*, the Javanese and Arab *rabāb*, various African fiddles, and the east Indian sarangi), the player's left hand is able to move with extreme flexibility up and down the string, thus making the subtlest kind of inflection possible.

As with other lutes, fiddles may have only one string (the Tuareg *imẓhad*) or as many as 40 (the sarangi); on the latter, sympathetic strings are not directly touched or sounded by the player but vibrate sympathetically when other strings are set into motion, thus giving a fuller resonance. Examples, in addition to the sarangi, include the Norwegian *Hardangerfele*, the Swedish nyckelharpa, and the viola d'amore.

The fiddle bow itself generally is constructed so that the player can tighten or loosen the hair at will; on most stringed instruments the player is able to make immediate changes by manipulating his hand on the bow hair while playing, thus producing various tone qualities. The modern Tourte bow of the violin has a screw mechanism that cannot be changed while playing. Most bows, again, are actually bow shaped, but the Tourte bow is made in a compound curve to which considerable tension can be applied, making it possible to apply much pressure to the strings.

The fiddle bow

The bowing principle has been applied to non-lutes from time to time: the old Icelandic *fidla* was a bowed zither; the Scandinavian *talharpa* was a bowed lyre.

Zithers. Instruments of the zither family, in which the strings lie parallel to and are of the same length as the resonator, are widely distributed in Eurasia, the Americas, and Africa. There are two important subdivisions of this category. The so-called long-zither family is found only in the Far East; its characteristic resonating chamber is slightly convex, as much as six feet (180 centimetres) long, and about a foot (30 centimetres) wide; there is a varying number of strings frequently provided with movable bridges. These instruments, of which the best known example is the koto, seem to devolve ultimately from zithers made directly from lengths of bamboo. The bamboo prototypes are said to be idiochordic because their strings, part of the bamboo itself, are worked loose from the tough surface of the tube, to which they remain attached at either end. The maker then inserts small bridges at the extremes of the strings. (Various modifications and transformations of this principle exist, as the bamboo-tube *valiha* of Madagascar and Malaya, in which wire strings replace the idiochordic ones). All long-bodied, curved-surfaced Far Eastern of koto type may owe something to this idiochordic principle. In Eastern tradition the most ancient zither is the seven-stringed ch'in, which seems to have originated in the Shang dynasty (*c.* 1400 BC). The Japanese *wagon* and koto, the Korean *kayagum*, and the Chinese *cheng* fit into this general category. All these ancient instruments are rich in symbolic associations.

The other important subdivision of the zither family is the flat zither; in Africa it is made either from a hollowed plank over which strings are fastened (board zither) or from individual narrow canes lashed together, each having one idiochordic string (raft zither). The box zither, which seems to be native to the Middle East, is a rectangular- or more often trapezoid-shaped hollow box the strings of which are either struck with light hammers or plucked. Examples of the former are the Persian *santūr* and its modern Chinese derivative, the *yang ch'in* ("foreign zither"), the cimbalom of East Central Europe, and the piano (which is a sort of cimbalom with keyboard). The most prominent plucked box zither is the Arab *qānūn* and its various derivatives, including the harpsichord (a plucked zither controlled by a keyboard). In Europe a variety of plucked zithers developed having a fretted fingerboard under one or a few of the strings.

The flat zither

Struck zithers are occasionally termed dulcimers, unfretted plucked ones psalteries, after European instruments using those names.

Lyres. The lyre family, though it was of great importance in the ancient centres of Babylonia, Egypt, and Greece, is now found only in a few areas of East Africa. A lyre is made from an oval, round, or rectangular sound chamber (usually skin bellied); from this resonator two arms protrude; they are joined at the top by a crosspiece; the strings extend from this crosspiece over the belly, with which they are connected by a bridge. These strings are not normally stopped but are allowed to vibrate throughout their entire length when plucked by the performer.

In Ethiopia, where the lyre remains in extensive use, there are two distinctive types, as there were in ancient Greece. The ten-string *begenna* (which corresponds to the ancient Greek kithara) is a large, heavy, rectangular-shaped instrument that is considered by the Christian Ethiopians to be a God-given instrument that came to them from King David; it is used, of course, for sacred music. The smaller lyre, *krar* (the ancient Greek *lyra*), is emphatically secular in its use and connotations; indeed, Ethiopians think of it as the instrument of Satan. The construction of this five-stringed instrument illustrates the sort of change that is of wide occurrence in contemporary instrument making everywhere, for though the traditional *krar* was made from wood, the resonator of the present-day instrument is made of an easily available metal pan. The *krar* can be played in two ways: in the first (called muting) the left hand mutes the unwanted strings while the right hand strums with a plectrum; in the second, the fingers of the left hand pluck while the right hand plucks a drone on tonic strings tuned to the tonic, or focal note, of the melody.

The *begenna* and the *krar*

The lyres of medieval Western Europe (4th–12th centuries) had from five to seven strings and, to judge from iconographic evidence, were played in a way that closely resembled the muting technique of Ethiopia. Northern European shapes are considerably varied, but both the rectangular kithara-like shape and the rounded *lyra* shape apparently existed.

Harps. The harp family exhibits an extraordinary variety of constructions, but in all harps the strings are of unequal lengths and are fastened at either end to a frame that lies in the same plane as the strings. The least complex, and prototypical, harp type of instrument is the musical bow, shaped very much like a hunter's bow. The

single string is tapped or struck, and the pitch can be varied by varying the tension of the string or by using the player's mouth as a resonator and varying its size and shape, thus emphasizing different harmonics. It is a favourite instrument in equatorial Africa.

The arched, or bow-shaped, harp, known in Egypt as early as 3000–4000 BC, is a multistringed version of this musical bow; its player kneels or stands, supporting the harp on the shoulder. Harps of this type may be found in Western and Central Africa, where they are often provided with elaborate anthropomorphic carvings and skin-covered resonators. The bow harp, then, is a traditional African form that has been in use in that continent for at least 5,000 years.

On an angle harp the bowlike support is replaced with two crosspieces at right angles to one another; the strings are stretched between these at an angle of 45°. This type seems to have originated in Assyria, though occasionally it is found in Egypt and Greece.

The closed, or frame, harp is characteristic of both medieval and modern Europe; the shape of its frame is more or less triangular, the frame being strengthened by a pillar that encloses the strings in a kind of tripartite structure. It is to this category that the modern orchestral harp of Europe and the old Irish and Scottish harps belong. In all of these instruments the crosspiece held nearest the player is a hollow resonating chamber. The so-called Brian Boru harp (14th century), now at Trinity College, Dublin, is 32 inches (81 centimetres) high, with 36 brass strings; the sound box is carved from a single piece of willow, and the harp was plucked by the fingernails.

THE MUSIC OF STRINGED INSTRUMENTS

Solo uses. Music for a solo instrument is often, though not always, used to accompany dancing or is derived from dance music. In Europe and America, the violin is widely used to play dance music; for instance, the Norwegian Hardanger fiddle player performs rhythmically complex polyphonic music (*i.e.*, composed of several simultaneous melodic strands) to accompany the *halling, gangar,* or *springar.* In Scotland, Ireland, and rural North America, the violin is favoured for accompanying country dances. It is known that a single fiddler played for dancing among the upper classes in medieval Europe and also probably among the common people, with whom the fiddle was popular. In all areas, the fiddler has an additional repertory not for dancing, which shows off his compositional and improvisational ability as well as his virtuosity. A skillful medieval fiddler constantly improvised new pieces. It is no coincidence that the violin solo sonatas and partitas of Bach, like their country cousins, are polyphonic compositions having a liberal sprinkling of stylized dance movements.

A second genre of solo piece is the descriptive composition. In such diverse places as Ireland, West Africa, and the United States are found fiddle pieces picturing the hunt, in which the player delights in the depiction of such realistic sounds as the baying of the hounds, the sound of hooves, and the groans of the exhausted animal. In China there is a genre of highly realistic descriptive compositions for *p'i-p'a*—including some that depict famous battles from start to finish. Among numerous descriptive pieces in Renaissance and Baroque Europe, a well-known example is a sonata for viola da gamba, by the French virtuoso gamba player Marin Marais (1656–1728), that graphically and in detail describes a gallstone operation in the days before anesthetics.

Solo music of the Middle Ages and Renaissance

In the European Middle Ages and Renaissance, an important type of composition for solo stringed instruments was the transcription of polyphonic songs; in the medieval period fiddle and hurdy-gurdy players frequently rendered elaborated versions of well-known strophic songs. In Northern Europe, songs intended to accompany dance could also be played on the fiddle, and in Spain the *vihuela de arco* filled a similar function. In the Renaissance, a string player was expected to have the ability to perform highly elaborated versions of pre-existent melodies on the viol, lute, or keyboard; and many manuals provided the player with exercises designed to teach him to elaborate the basic melody in a stylistically correct manner. Similar techniques continued to be practiced during the Baroque period and even into the 19th century.

For accompaniment. All over the world, stringed instruments have as one of their central functions the accompaniment of bards, who sing tales of heroes and otherwise reflect the preoccupations of their societies. The example of Homer and his lyre is of course the best known, and even today in the Balkans, bards, self-accompanied on the fiddles, *gusla,* or *lira,* play preludes and interludes while they sing tales of heroes in the wars against the Turks. The harpers of Celtic Ireland and Scotland devoted their skills to the accompaniment of learned bards; the *azmari* of Ethiopia sings lengthy historical epics and strophic love songs to his own accompaniment on the fiddle or lyre. In Japan, blind *biwa* players chant a narrative style of music known as *katarimono,* and here again the *biwa* is used only between verses, as it performs interludes and commentaries. A similar technique is in use among the minstrels of North Africa: the lute, *gunbrī,* is played only between verses of the story, as a descriptive comment. Again, the 19th-century European art song for solo voice and piano belongs to this genre.

Ensembles. Musical ensembles everywhere have their own internal social structure, mirroring that of their society at large in the degree of authoritarianism, the type of leadership, amount of freedom available to the individual players, and so on. The audience for a given ensemble also tends to be socially stratified. Large, authoritatively ruled ensembles tend to be found in societies that have a complex bureaucratic and pyramidal social order. Such groups are most typically to be found clustered around the royal or princely courts of China, Japan, and Korea, of Java and Bali, of North Africa, and in the court-derived music of Europe and America. In all of these instances a more or less fixed and archaic repertory remains in use. In Japan, Korea, and, to an extent, Southeast Asia, the court music has derived from an archaic (and no longer extant) court music of China. The two types of stringed instruments in use in Japan are the zithers, koto and *wagon,* and the lute, *biwa.* The koto has 13 strings and the *biwa* four.

The gamelan orchestras of Indonesia employ but two chordophones in ensembles, which are otherwise dominated by struck metallophones, or metal instruments, such as tuned gong sets and xylophone-like instruments with metal bars. The bowed *rebab* (probably entered the orchestra from the Near East, where it was called *rabāb,* ancestor of the European rebec, when Java was converted from the Hindu religion to Islām). It plays in sliding fashion around the fixed pitches of the orchestra; its player is thought of by Javanese as the "rajah" of the gamelan, with the drummer as his "prime-minister."

In Islāmic countries and in Europe, stringed instruments predominate numerically in the orchestra; the classical ensembles of the Maghrib, which mainly perform the ancient Andalusian suites, typically consist of about one dozen musicians. The instrumentalists include a number of violin or viola players, a *rabāb* player, lute players, drummers, and sometimes flutists, cellists, and a pianist. All of the string players play the melody together but not in unison, for they are expected to vary it individually with ornaments and improvised passages. A true unison, therefore, is neither expected nor desirable. The ensemble is normally led by an *ʿūd* player who indicates the pitch, mode, mood, the changes of tempo, and so on.

Orchestral stringed instruments

In Europe as in North Africa, the greater number of stringed instruments in use in the orchestra are bowed; Europe, however, is distinctive in that these bowed chordophones exist and are played in families of graduated size (violin, viola, cello, bass), and this phenomenon derives from the extent to which European musicians have been preoccupied with harmony and multipart composition. In the development of the European orchestra two great—but gradual—changes have occurred over the centuries: first, stringed instruments have increased dramatically in number in the orchestra; and second, higher and higher notes and hence finger positions have been de-

manded of string players. Socially and musically, the role of the player in an early 18th-century symphony (in which there would be no more than two or three players to each part) is very different from the anonymous function allowed the violinist in a symphony by Berlioz, say, or Mahler. The symphonic orchestra seems to represent the merger of two functionally and aesthetically different groups that medieval Europe probably derived from Arab civilization. One of these, used for outdoor ceremonial music, consisted originally of shawms (oboes), drums, and trumpets; the other, for indoor (chamber) use, was made up of stringed instruments, quiet percussion instruments, and flutes. The modern orchestra preserves vestiges of these two ensembles in its seating arrangements, orchestration, and leadership.

The European concept of chamber music is nowadays thought of as being entirely distinct from orchestral music; in the 17th and early 18th centuries, however, the distinction would have been difficult to draw, since there was no clear difference either in the music, the size, or the sociological position of the two types of ensembles. The symphonic orchestra arose because of middle class demand for public concerts and from the desire of composers after the French Revolution to provide democratic music for the masses; thus, mass audiences demanded large orchestras, and the striking multiplication of instrumentalists affected the strings above all others.

Modern Japan cherishes a number of traditional chamber-music ensembles; of these, the commonest one consists of the koto, the samisen, and the flute, *shakuhachi*. The *jiuta* is a common form played by this group; here, the koto plays the principal melody, and the samisen and *shakuhachi* simultaneously produce a variant of it. The Japanese picturesquely describe this ensemble by saying that the koto is the bone, the samisen the flesh, and the *shakuhachi* the skin.

Basic elements of Indian ensembles

The basic ensemble in South Indian music consists of a drone instrument (usually the tamboura), a tuned drum (mṛdaṅga), a violin, and a singer. The group is often augmented to include a number of other instruments, but the basic elements must be present. The violinist is an accompanist to the singer; he must be able to play in unison with him in fixed pieces and to follow him in immensely complicated improvisational sections, maintaining all the while the correct raga (melodic mode) and *tāla* (rhythmic mode). An analogous group in North India might include the sitar or sarod as solo instrument, with the accompaniment of the drums, *ṭablā*, and a drone. Often the fiddle, sarangi (with three main strings and 35–40 sympathetic ones), accompanies a singer.

Rather similar principles apply in the Eastern Mediterranean: a chamber-music ensemble must include instruments—usually strings—to play the melody and to improvise in the introductory sections known as *taqsīm* and percussion instruments to deal with the rhythmic modes, known as *īqāʿāt*. To these, in modern Greek music, the element of harmony has been added so that a solo instrument (clarinet or violin) plays the highly ornamented melody and another instrument (guitar, or *laghouta*) plays the chordal background and maintains the reiterated rhythmic pattern. Similar ensembles are found in the Americas and in Africa.

In Puerto Rican traditional music a guitar plays the harmony, the five double-stringed lute, *cuatro*, plays the melody with the singer, and the scraper, guiro, and drums, *timbales*, produce the rhythmic part. Among the Berbers of North Africa, groups of itinerant professional musicians typically play one or two lutes, *gunbrī*, a one-stringed fiddle (rendering a highly adorned melody), and percussion. In Senegal, lutes similar to the *gunbrī* are played by the musicians known as *griots*, often in ensembles of three or four flutes, drums, and rattles. The so-called Bluegrass style of Appalachian North America largely conforms to this Mediterranean and African pattern; the ensemble typically includes only bowed and plucked strings and singers.

Rock groups also adhere to these general principles: they also represent a blend of African and European traditions. The typical rock ensembles use plucked electric stringed instruments, electric keyboard instruments, voice, and drums. The electric guitar plays the melody, and the electric bass renders the bass part. In the American blend of Mediterranean, African, European, and indigenous tradition, the African element includes the percussion instruments and the skin-bellied lute (banjo); the Mediterranean element includes the wood-bellied guitar and *cuatro*. The bass parts are derived from Europe, the scraper from the American Indians, and the singing style from various of the four traditions.

SOCIAL AND CULTURAL ASSOCIATIONS

Throughout the world, particular instruments are associated with particular functions, social levels, areas, ages, and sexes. Certain instruments preserve the same function all over the world: the bard (a singer-poet) recounts tales of heroes, recites the genealogies of the great, and preserves and disseminates the precious traditions of a given society; this bard everywhere accompanies himself on a stringed instrument. An early example would be the blind Homer, who, presumably accompanied by his lyre, sang of gods and heroes. Similar traditions survive even today in Greece and the Balkans, but the instrument of the modern "singer of tales" is the fiddle. In Ethiopia, where so many traditions remind one of Greece, the *azmari* accompany themselves with a lyre or fiddle. In North Africa and West Africa *griots* sing and play skin-bellied lutes called *gunbrī* or *halam;* in Morocco they play and sing alone in the squares of the towns for coppers; in Senegal (where they perform in groups) they are employed by the wealthy. The Japanese *biwa* (often, again, played by blind bards) was used to accompany epic narratives, the texts of which usually concern the adventures and battles of the samurai: the *biwa* is used also to accompany Buddhist chanting. In medieval Europe, minstrels, self-accompanied on the *vielle* (fiddle), sang of the heroism of such as Charlemagne.

Very often, stringed instruments are identified with a certain social class, either in the sense that the player himself occupies a particular caste position or in that the instrument is the prerogative of a particular rank in society.

A well-known example is that of the Irish and Scottish harp of the periods during which the Celtic kingdoms flourished; harpers, who were highly respected members of society, were employed in the households of only the very wealthy and the high nobility. By the same token, harpers were regarded with great suspicion by English officials in Ireland, for they were suspected of spreading sedition. In sharp contrast is the attitude of respectable members of medieval Arab society toward lute players; their status was low indeed (certain judges even held that the lute was an unlawful possession which could be destroyed at will). Paradoxically, the *ʿūd* player's skill and imagination was highly valued by the courts. These attitudes are old indeed in the Mediterranean; Aristotle regarded professional kithara players as low caste and of questionable morals. In his view (and this is still prevalent in the West) the highborn should learn to play as an accomplishment but not professionally. In the 17th century, members of the English upper class were swept with a craze for playing consort music for ensembles of various sizes of viola da gamba ("leg viols," held, cello-fashion, between the knees). It was a common—and much valued—accomplishment to be able to play a part in a viol consort, and, as Samuel Pepys recorded in his diary, servants were often chosen because of their ability as violists.

The violin family in Europe has had two very different social connotations. In the string quartet and orchestra the instrument has been associated with the entertainment of the upper class and the bourgeoisie, and this represents the continuity of the medieval tradition under which the fiddle was highly regarded by the upper class. Alfonso X, the Wise, King of León and Castile, was one of many rulers who supported a group of fiddlers at his court.

In opposition to this, the violin has long had great popularity among the folk. In almost every country in Europe

The aural technique of the country fiddler

and the Americas the rural fiddler has provided the music for dances and entertainments. This country fiddler is distinguished from his urban colleague by his nonstandardized technique, playing position, and tunings and by his learning process, which is totally aural. His virtuosity may be of a high order. The pleasures of the common folk have long been associated with the fiddle, though the medieval fiddler usually played the bagpipes, sang, juggled, and told jokes as well.

The role of musical instruments in religious and healing practice is complex: at one time or another Judaism and Islām and Christianity have been generally hostile to the use of instruments in places of worship. The Church Fathers made frequent allegorical and symbolic reference to instruments, and it is common to find depictions of angels, cherubs, or of King David playing on the very instruments that were not permitted to sound in Christian worship. The Hindu attitude toward stringed instruments is very different. Though Vedic chanting is the oldest known music of India, the Ṛgveda nevertheless mentions the use of such chordophones as the *karkari* and a number of vinas.

Caste and symbolic associations of the ch'ins

The Chinese scholars' lute, ch'in, had definite caste and symbolic associations. No scholar would have been without one, for it restrained licentiousness and purified the heart; it compelled man to return to his divine origin and restrain his passions. Thus, the ch'in could not be played when drunk or after sexual intercourse; it could not be played for a courtesan, a merchant, or a barbarian. The ch'in was often played by Buddhist monks; complex cosmological and symbolic meanings existed for every aspect of its shape, constructional material, tone, and playing technique. The ch'in, therefore, was involved with healing, religion, and philosophy; and of these three, its therapeutic function was perhaps the most pervasive; this instrument harmonizes the blood circulation and regulates breathing; it leads to health and long life. It cures melancholy and can, it is claimed, even make a devoted player immortal.

The function of stringed instruments in the healing process is very often an indirect one: a healing specialist may sing his powerful songs to the accompaniment of a lute (the *gunbrī* of the North African Gnāwa) or a fiddle (Central Asia). Beyond this relatively prosaic association, stringed instruments have symbolic meanings that transcend their technological, sound-producing function. The horse-headed fiddle of the Mongols is directly a part of the Mongol system of belief in the horse as a symbol of fecundity and rebirth; the winged horse that the shaman is believed to ride in his quest for enlightenment and healing power is equivalent symbolically to the fiddle.

This close connection of stringed instruments with ideas of birth and rebirth explains why so often a particular instrument is typically played, or even listened to, by members of one sex only; in certain instances instrumentalists, whether they were Greek kitharodists or Arab *ʿūd* players, were slaves with a low moral reputation. The playing of many stringed instruments by women has been either a low-caste occupation or an accomplishment to be savoured in the confines of the home. In India during the Vedic period there seem to have been stringed instruments (such as the *kāṇḍa-vīṇā*) that were played only by women; and Chinese tradition has it that the long zither, *cheng*, was invented by a woman. In the Western continents, instrument makers seem usually to be men, since in most societies the manipulation of woodworking tools has been a male occupation. In medieval Europe, and in some places (such as Puerto Rico) today, minstrels made their own instruments. Since the making and playing of instruments have until recently been mainly in male hands, women have not had available to them this particular link to musical instruments through manufacture.

STRINGED INSTRUMENTS AS OBJECTS OF ART

There is no reason to suppose that the shape of an instrument is governed by acoustical requirements; it seems rather to be the other way around: the symbolically appropriate shape preferred by a given culture produces a particular tone quality, which then becomes the desirable one. Available materials, manufacturing techniques, and complex historical, symbolic, and artistic considerations guide the craftsman who creates musical instruments. Transformations occur as old meanings are lost: the scroll surmounting the pegbox of the violin may well be a faint visual echo of the horse's-head carving that surmounts the fiddle in its ancestral lands in Central Asia. Craftsmen are well aware that the soundboard of an instrument is responsible for the best part of its resonance; they are aware that other portions can be considerably altered without making much change in the sound quality. Instrument makers have long delighted in producing modifications of existing designs and in experimenting with new materials. In all this they are limited only by the essential technological requirement of a chordophone—ability to withstand the constant strain imposed by the tension of the strings and proper resonation.

A limited number of basic woodworking techniques are used almost the world over in the production of stringed instruments. In lute construction the entire sound box (and sometimes the neck as well) can be hewn from one block of wood. Instruments that are often made in this fashion are the Japanese *biwa*, the North African *gunbrī*, and the Puerto Rican *cuatro*. Existing side by side with this technique is another, in which the lute is made out of a kind of composite box in which any bent portions are fashioned by heating the wood and putting it into a mold. (Common examples include the violin and the guitar.) Again, the resonator can be made of pre-existent natural materials, as in the case of the Malagasy *valiha* zither (bamboo), the South Indian vina (gourd), or the lyre invented by Apollo (tortoiseshell).

Though occasionally (as in the case of many harpsichords and virginals) instruments with pictures painted upon them are encountered, this decorative technique is most unusual—probably because it requires a separate craftsman—and most instrument makers prefer to show their skill by the choice of woods, by complex inlays, and by carving.

The anthropomorphic harp

Anthropomorphic and zoomorphic shapes surmount many of the harps and lyres of ancient Mesopotamia and Egypt. The anthropomorphic harp of ancient Egypt and modern Africa represents another example of this visually symbolic approach to instrument making, which has been described as producing "sounding statues." In Europe, anthropomorphic and zoomorphic carving exists side by side. Notable examples are the Irish Brian Boru harp (at Trinity College, Dublin), which exhibits a profuse variety of animal shapes; the Norwegian *Hardanger* fiddle, surmounted with a dragon's head; and the viola d'amore, which often is surmounted with the head of a blindfolded woman. The Balkan fiddle, *gusla*, and the Central Asian horse fiddle are usually crowned with a carved horse's head, and the South Indian vina possesses a carving of a dragon. These shapes are not mere decoration or fancy; they represent important symbols in the society from which the instruments come.

In East Asia the craftsman's emphasis is on beauty of wood, excellence of finishing, and apparent simplicity of construction. Occasionally, on instruments such as the ch'in, one finds pictures painted or calligraphy inscribed. The proper material is extremely important: the belly of a good Japanese samisen should be made from the skin of a female cat; a ch'in should be made of wood taken from an old tree that had nestled next to a bubbling stream. Phoenix-bird symbolism of rebirth is abundant in the nomenclature of Far Eastern instruments, and this fact serves to point up a profoundly important truth about musical instruments everywhere: they are intimately connected in folktale, myth, and legend to local symbols of rebirth. Thus, legend relates that Apollo made the first lute from a turtle carapace; similarly, the first Arab lute was modelled after the body of a beloved male child; the Finnish culture hero, Väinämöinen, made the first zither, kantele, from the body of a giant pike; the Celts made their first legendary harp from whalebones. In each case, the symbolically significant creature is "reborn" as an instrument which "sings" as well as appears in a shape reminiscent of the creature modelled.

THE DEVELOPMENT OF STRINGED INSTRUMENTS

Little or no evidence is available concerning the chordophones of prehistoric times: the earliest iconographic evidence and the oldest surviving specimens come from Mesopotamia and Egypt, and evidence concerning instruments earlier than these can be gleaned only from myth and legend.

The harp. The harp clearly evolves from the musical bow, which must have been in existence prior to the establishment of Mesopotamian and Egyptian civilizations. Since this instrument is identical in shape with the simple hunter's bow, it has been assumed that the musical bow derives from the hunter's implement. There is, however, no evidence for this; quite the opposite: the musical bow is very often played by women, who do not usually hunt, and, further, there is absolutely no way of knowing whether or not man hunted with a bow-shaped implement before he made musical sound with a bow. The three early harps found in the burial chambers at Ur were bow-shaped instruments with 12 to 15 strings; nearly identical instruments were played in Egypt at roughly the same time. Iconographic evidence suggests that both in Egypt and Mesopotamia the harp, often played by women, was used in secular, erotic entertainments, although it had sacred uses as well.

Although the harp family is known to exist in Burma and to have been in use in China and India, it is not characteristic of these areas; it is, rather, musically important in equatorial regions of Africa, in Europe, and in the Americas. In Africa it clearly is related to the Egyptian harps, and again it is associated with women.

The Celtic harp

The harp has maintained and increased its importance in Europe. It is omnipresent in folktales and legends; it is the national symbol of Ireland. The Celtic harp must have been in use as early as the 10th century, and fragments of one were found in the 7th-century Sutton Hoo burial ship unearthed at Suffolk, England. In Gaul, Ireland, Wales, and Scotland, the harp was an important and favoured symbol; it was said that there were but three things necessary to a comfortable household—a virtuous wife, a chair cushion, and a harp. By the end of the 18th century the harp had almost gone out of use in the Celtic realms, but by then the large orchestral harp had made its appearance in other places in Europe.

This basic instrument (with the addition of a set of pedals for instantaneously altering the pitch of a note) is found—often still played by a woman—in the modern symphony orchestra; but the older European harp tradition flourishes best in Mexico and South America, where the harp is a component of various folk ensembles.

The lyre. Greek legend credits the invention of the lyre to Apollo, who had stolen Zeus's cows and, in order to atone for his transgression, presented the great god with the lyre, which he had accidentally discovered when he had brushed against a turtle carapace that lay on the ground and, as he did so, heard its sinews begin to vibrate. The tale is interesting for two reasons: first, the turtle shell *was* frequently used as the resonator of the Greek *lyra;* and second, the tale makes an explicit relationship between the lyre and cattle. Similarly, in Mesopotamia the lyre was surmounted with a carved bull's head, and in modern East Africa the lyre is most frequently encountered in cattle cultures.

A famous lyre from Ur (now at the University Museum, Philadelphia) is one of nine dug up at the burial ground; these and similar instruments seem to have been used both to accompany bardic recitations and for religious purposes. The "harp" that the Hebrews hung in the tree in their Babylonian captivity was actually a lyre, as was the instrument used by Homer (*phorminx*). In view of the importance of the bull in the worship ceremonies of Crete and Mycenae, it is not surprising to find lyres among the stringed instruments of these peoples. In Celtic society, depictions of lyres are found on the coins of pre-Christian Gaul. These instruments, which were U-shaped, may have come to western Europe from Southwest Asia with groups of Indo-European peoples who spread across Europe. Other types of lyres were found in Europe, too, and it is possible that these variously shaped but still related instruments might be analogous to the various Indo-European languages in that they are basically closely related but quite different in detail.

In medieval Germany and Scandinavia long, narrow lyres with four to seven strings were played, and similar lyres (the Finnish *jouhikantele*, the Swedish *talharpa*, the Welsh crwth) were played with a bow in parts of Europe until recent years. Today the lyre flourishes only in Ethiopia, in the Sudan, among the fishermen of the Persian Gulf, and in restricted areas of East Africa.

The zither. Several different types of instruments are classified as zithers; they are used today in all continents. The long zithers of China, Japan, and Korea are venerable indeed. Their curved surface and long, narrow shape betrays their affinity with the prototypical idiochordic bamboo zithers of the Pacific, Southeast Asia, and southeast Africa. The importance of bamboo to music in the Orient is literally legendary; in Java, music is thought to have been first produced by the accidental admission of air into a bamboo tube. In China, the source of Far Eastern civilization, musical instruments are classified according to their constructional material; one of the eight substances in the system is bamboo, which the Chinese relate to the direction East, the season Spring, and the phenomenon Mountain. The Chinese zither *cheng* includes the radical meaning "bamboo" in its ideograph. The ideographs of the older zithers, ch'in and *se*, are more difficult to interpret; but the narrow, curved shapes of the instruments themselves betray their affinity with the ancient principle. Zithers of this type are known to have existed in the Shang period (*c.* 1766–*c.* 1122 BC); the *cheng*, with either 13 or 16 strings, came into use during the Ch'in period (221–206 BC). By the 18th century, interest in this instrument had waned in China, but at an early date it was introduced to Japan, where, as the 13-string koto, it flourishes today. The koto, like the *cheng*, is played frequently by women.

Bamboo zithers

A relative newcomer to the spectrum of Chinese zithers is the *yang ch'in* (foreign zither), which reached China from Persia a number of centuries ago; it is the only representative of the box zither in the East. The history of this type of chordophone is obscure indeed, but two instruments of this general shape that may be very old are the African raft and board zithers. The raft zither is constructed on the idiochordic principle, but it uses a number of canes about half an inch in diameter; each of these has one string raised out of its own surface, and all of the canes are then lashed together. The board zither is made from a hollowed-out board over which a number of strings are attached. This latter instrument is found only in restricted areas of East Africa; it is possible that its principle of construction was carried to the Middle East by traders. Medieval Arab authors (including Ibn Khaldūn) mention the plucked trapezoidal zither, *qānūn* (derived from Latin *canon*, "rule"). Nowadays, the instrument has a range of three chromatic octaves with three strings to each pitch, and a complex system of levers by which its many strings may be finely and quickly retuned to the various Arab scales. Closely related is the Persian-derived *santūr*, another trapezoidal zither that is struck by two light hammers. Versions of this zither are found in China (*yang ch'in*), Greece (*santouri*), and Eastern Europe (cimbalom). These two zithers are the prototypes for the later keyboard instruments of western Europe: the *qānūn*, which is played with two plectrums, became, with the addition of a keyboard, the harpsichord; the cimbalom, with the addition of a keyboard, became the piano. In the Middle Ages, the keyboard was attached to a number of instruments, including the lute, the hurdy-gurdy, and the various Scandinavian keyed fiddles, of which the Swedish nyckelharpa survives. The experiment was truly successful, however, only on the clavichord, harpsichord, and later the piano; on the fiddle, it always remained of peripheral importance.

The lute. The first surviving evidence of the existence of the lute comes from Mesopotamia and Egypt. One of the earliest Babylonian delineations (*c.* 2500 BC) shows a shepherd with a long-necked, small-bodied lute; this in-

Earliest known lutes

strument, which was doubtless skin bellied, had a rounded back that might well have been made from a turtle carapace (as in modern North Africa) or a gourd (as in Puerto Rico). A similar instrument is also found in Egypt, and from specimens surviving from ancient times it is known that the stick forming the neck passed through the body of the instrument, ending at the sound hole, where it served as a fastener for the ends of the strings. This instrument, like the harp, survives in West Africa and in North Africa (as the *gunbrī* or *halam*).

The Greeks of old seem to have made rather sparing use of the lute, but it was commonly encountered in Rome. Though the skin-bellied lute predominated in the ancient Mediterranean, the wood-bellied lute has been more typical of Europe; indeed (with the exception of the African-derived banjo) more recently, all currently used European lutes and fiddles have wood bellies. The most important model for the European lute was the classical Arab lute, *al-ʿūd* ("the wood"), which has been the most important instrument of classical Arab music for 1,000 years. Not only the instrument itself, with its characteristically curved back, but also its name entered Europe, probably through a number of different gateways, including Sicily, Andalusia, and Palestine with the crusaders.

Though European and Arab lutes are very similar in general construction, the Arab lute is not fretted as is the European lute, and the European lute little by little acquired additional courses of strings during the Renaissance, when it became a standard instrument for solo playing and the accompaniment of singers. The many courses of strings caused numerous problems: "When a lute-player is 80 years old," wrote the 18th-century German theorist Johann Mattheson sarcastically, "he has spent 60 years tuning his instruments."

The many lutelike instruments of modern India (tambura, vina, sitar, and sarod) are, technically speaking, lute-zithers, since their fingerboards are hollow; in appearance and playing technique, however, they are indistinguishable from lutes. They seem to represent a special, and quite recent, subfamily of chordophones. In the Far East, again, the lute family exists only in a comparatively recent manifestation, but both in wood-bellied form (Chinese *p'i-p'a*, Japanese *biwa*) and skin-bellied version (Chinese *san-hsien*, Japanese samisen). In Japan, these instruments existed in the year 752, and the Imperial Treasury at Nara preserves three *biwas* used at a great concert held in that year. The *biwa–p'i-p'a* family can be traced ultimately to Persia, where, as the *barbat*, it influenced the music of Afghanistan and Turkestan on its way to China and Japan. The skin-bellied lute, *san-hsien*, can be traced in China only to the 13th century; from there it was taken to the Ryukyu Islands and thence to Japan (mid-16th century), where it still plays an important musical role as the samisen.

Lutes of the Far East

Bowed instruments. The principle of bowing is nearly always applied to stringed instruments of the lute class, though one occasionally finds it used with zithers or lyres. It is difficult, if not impossible, to make a clear-cut distinction between plucking with a plectrum and bowing, since plucking sometimes involves rubbing the string. But bowing, defined as the use of the almost universally encountered horsehair bow, can be traced as far back as the Islāmic civilization of the 10th century. The stroked *rabāb* evidently possessed a long neck and up to four strings. There is no iconographic evidence of such instruments before the 13th century in Islām itself, though an illustration (*c.* 930) from Christian Spain delineates a bowed instrument with three strings. In Byzantium, too, the bowed *lira* existed by this time, and it seems likely that the principle of bowing originated among the horse cultures of Central Asia, whence it spread quickly through Islām and the East, so that by 1000 it had almost simultaneously reached China, Java, North Africa, the Near East and Balkans, and Europe. Modern scholarship has shown that a word meaning "horse" is given to the bridge of the fiddle throughout Eurasia, from Japan (*koma*) to western Norway (*hest*). In China the fiddle is acknowledged to have come from the "barbarians" of Central Asia; in those days it was in China an instrument of the people; later, at the time of Kublai Khan, it began to be used in court music. In Africa, the fiddle seems to have entered the continent with Islām.

In Europe the bow appears first in Spain and shortly thereafter in Italy, and it is suspected that it entered through Muslim Spain and Sicily, though it is possible that other fiddles entered Europe through the Balkans, Hungary, and Scandinavia. Even in early illustrations, evidence is found of the uniquely European method of holding the fiddle against the shoulder. (Everywhere else in the world, the fiddle is held vertically.) At the same time, other European fiddles were held vertically, in the Oriental manner. Early European fiddles were made (by their players) in only two parts: the belly was a thin piece of spruce or fir wood, and the back was hollowed out of one piece of hardwood. These medieval fiddles divide into two types, one of which has a clearly discernible neck; the other possesses a neck that merges imperceptibly into the body; second type, exemplified by the rebec, is equivalent to the North African *rabāb* and the Byzantine–Greek *lira*. As the centuries passed, Europe continued to have two distinct types of fiddles: one, relatively square shaped, held in the arms, became known as the viola da braccia ("arm viol") family and evolved into the violin; the other, with sloping shoulders and held between the knees, was the viola da gamba ("leg viol") group. The gambas, which were important and elegant instruments during the Renaissance, lost ground to the louder (and originally less aristocratic) braccia-violin family.

The bowed instrument in Europe

BIBLIOGRAPHY. The standard history of instruments is CURT SACHS, *The History of Musical Instruments* (1940). A recent book that traces bowing on a global scale is WERNER BACHMANN, *Die Anfänge des Streichinstrumentent spiels*, 2nd ed. (1966; Eng. trans., *The Origins of Bowing*, 1969). Articles on the symbolic meaning of musical instruments are THEODORE GRAME, "Bamboo and Music: A New Approach to Organology," *Ethnomusicology*, 6:8–14 (1962), "The Symbolism of the *ʿŪd*," *Asian Music*, 2:25–34 (1972), and with GENICHI TSUGE, "Steed Symbolism on Musical Instruments," *Musical Quarterly*, 63:57–66 (1972). Two standard books on African instruments are PERCIVAL R. KIRBY, *The Musical Instruments of the Native Races of South Africa* (1934); and MARGARET TROWELL and K.P. WACHSMANN, *Tribal Crafts of Uganda* (1953). Instruments of Mesopotamia are discussed in H.G. FARMER, "The Music of Ancient Egypt," and "The Music of Ancient Mesopotamia," in EGON WELLESZ (ed.), *The New Oxford History of Music*, vol. 1 (1957); and F.W. GALPIN, *The Music of the Sumerians and Their Immediate Successors, the Babylonians and Assyrians* (1937). Articles on various African instruments are collected in H.G. FARMER, *Studies in Oriental Musical Instruments* (1931). An excellent work on the history and symbolism of the Chinese ch'in is ROBERT VAN GULIK, *The Lore of the Chinese Lute*, rev. ed. (1969). NICHOLAS BESSARABOFF, *Ancient European Musical Instruments* (1941), is a full and complete treatment of European instruments through the 18th century; HORTENSE PANUM, *Middelalderens Strengeinstrumenter og deres forløbere i oldtiden* (1915; Eng. trans., *The Stringed Instruments of the Middle Ages*, 1939), is an older but still useful work on European chordophones and their analogues; IRVING SLOANE, *Classical Guitar Construction* (1966), is an illustrated practical account of the process of guitar making. Two important Scandinavian instruments are fully treated in OTTO ANDERSSON, *The Bowed Harp* (1930); and JAN LING, *Nyckelharpan* (1967), with summary in English; Celtic harps are discussed in JOAN RIMMER, *The Irish Harp* (1969); and FRANCIS COLLINSON, *The Traditional and National Music of Scotland* (1966). *Ellenika Laika Mousika Organa* (1965), is an illustrated catalog of modern Greek instruments; and S. KRISHNASWAMI, *Musical Instruments of India* (1965), is a similar work on the instruments of the Indian subcontinent. Two standard works on Japanese music and instruments are SHIGEO KISHIBE, *The Traditional Music of Japan* (1966); and WILLIAM P. MALM, *Japanese Music and Musical Instruments* (1959). The standard work on Javanese instruments is JAAP KUNST, *Music in Java*, 2nd rev. ed., 2 vol. (1949), while a specialized study of the Javanese fiddle is found in M. HOOD, "The Javanese Rebab," in *Music, Libraries and Instruments* (1961).

(T.Gr.)

Submarine

A submarine is a naval vessel capable of operation underwater. Submarines first became a major factor in naval

warfare during World War I (1914–1918), when Germany employed them as commerce destroyers; they played a similar role on a larger scale in World War II (1939–1945), in both the Atlantic (by Germany) and the Pacific (by the United States). In the 1960s the nuclear-powered submarine, capable of remaining underwater for months at a time and of firing long-range nuclear missiles without surfacing, had come to be regarded by most military strategists as the most important of all strategic weapons. Nuclear submarines armed with torpedoes as well as antiship and antisubmarine missiles were in the 1970s considered a key element of naval warfare.

HISTORY

For centuries man has attempted to descend into the depths for scientific observation, for salvage, to reap the animal and mineral riches of the oceans, and for the purpose of attacking enemy ships in time of war. Herodotus, Aristotle, and Pliny the Elder all mentioned attempts to build diving bells or other such devices. A 13th-century French manuscript, *La Vrai Histoire d'Alexandre*, described a fictitious underwater venture by Alexander the Great (356–323 BC) in a glass barrel. Among the many inventions associated with the genius of Leonardo da Vinci was a device for underwater exploration.

The first submarines. The first serious discussion of a "submarine"—a craft designed to be navigated underwater—appeared in 1578 from the pen of William Bourne, a British mathematician and writer on naval subjects. Bourne published *Inventions or Devises*, in which the "18th Devise" was a completely enclosed boat that could be submerged and rowed underwater. It consisted of a wooden frame covered with waterproof leather; it was to be submerged by reducing its volume by contracting the sides through the use of hand vises. Bourne did not actually construct his boat, and Cornelis Brebbel (or Cornelius van Drebel), a Dutch inventor, is usually credited with building the first submarine. Between 1620 and 1624 he successfully manoeuvred his craft at depths of from 12 to 15 feet (four to five metres) beneath the surface during repeated trials in the Thames River, England. King James I is said to have gone aboard the craft for a short ride. Drebbel's submarine resembled that proposed by Bourne in that its outer hull consisted of greased leather over a wooden frame; oars extended through the sides and, sealed with tight-fitting leather flaps, provided a means of propulsion both on the surface and underwater. Drebbel's first craft was followed by two larger ones built on the same principle.

A number of submarine boats were conceived in the early years of the 18th century. By 1727 no fewer than 14 types had been patented in England alone. An unidentified inventor, whose work was described in the *Gentleman's Magazine* of 1747, proposed an ingenious method of submerging and returning to the surface: his submarine design had goatskin bags attached to the hull with each skin connected to an aperture in the bottom of the craft. He planned to submerge the vessel by filling the skins with water and to surface by forcing the water out of the skins with a "twisting rod." This arrangement was a forerunner of the modern submarine ballast tank.

Bushnell's "Turtle"

The submarine was first used as an offensive weapon in naval warfare during the U.S. Revolution (1775–1783). The "Turtle," a one-man craft invented by David Bushnell, a student at Yale, was built of wood in the shape of a walnut standing on end. Submerged, the craft was powered by propellers cranked by the operator (Figure 1). The plan was to have the "Turtle" make an underwater approach to a British warship, attach a charge of gunpowder by a screw device operated from within the craft, and leave before the charge was exploded by a time fuse. Piloted by Ezra Lee, an army sergeant from Lyme, Conn., the "Turtle" made a night attack on HMS "Eagle" in New York harbour. After repeated failures to force the screw through the copper sheathing on the warship's hull, Lee gave up, released the charge, and withdrew safely. The powder exploded without damaging the "Eagle," which shifted to a berth farther out in the harbour.

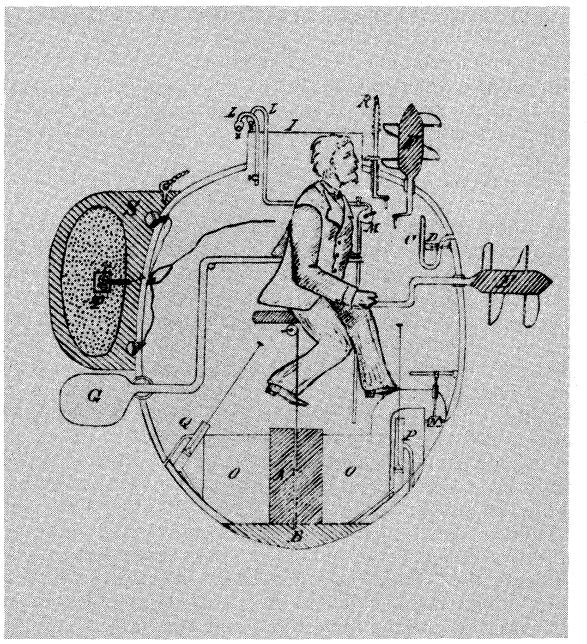

Figure 1: Bushnell's submarine torpedo boat, 1776. Drawing of a cutaway view made by Lieut. Comdr. F.M. Barber in 1885 from a description left by Bushnell.
By courtesy of the U.S. Navy

Robert Fulton, famed U.S. inventor and artist, experimented with submarines several years before his steamboat "Clermont" steamed up the Hudson River. In 1800, while in France, Fulton built the submarine "Nautilus" under a grant from Napoleon Bonaparte. Completed in May 1801, this craft was made of copper sheets over iron ribs. A collapsing mast and sail were provided for surface propulsion, and a hand-turned propeller drove the boat when submerged. A precursor of a conning tower fitted with a glass-covered porthole permitted observation from within the craft. The "Nautilus" submerged by taking water into ballast tanks, and a horizontal "rudder"—a forerunner of the diving plane—helped keep the craft at the desired depth. The submarine contained enough air to keep four men alive and two candles burning for three hours underwater; later a tank of compressed air was added.

The "Nautilus" was intended to attach an explosive charge to the hull of an enemy ship in much the same manner as the "Turtle." Fulton experimentally sank an old schooner moored at Brest but, setting out to destroy British warships, was unable to overtake those he sighted. France's interest in Fulton's submarine waned, and he left for England, offering his invention to his former enemy. In 1805 the "Nautilus" sank the brig "Dorothy" in a test, but the Royal Navy would not back his efforts. Fulton then came to the United States and succeeded in obtaining congressional backing for a more ambitious undersea craft. This new submarine was to carry 100 men and be powered by a steam engine. Fulton died before the craft was actually finished, however, and the submarine, named "Mute," was left to rot, eventually sinking at its moorings.

During the War of 1812 between the United States and England, David Bushnell built another submarine, which attacked HMS "Ramillies" at anchor off New London, Conn. This time the craft's operator succeeded in boring a hole in the ship's copper sheathing, but the screw broke loose as the explosive was being attached to the ship's hull. The attempt failed, but again the submarine escaped.

The next U.S. attempt at submarine warfare came during the Civil War (1861–1865) when the Confederate States resorted to "unconventional" methods to overcome the Union Navy's superior strength, exerted in a blockade of Southern ports. In 1862 Horace L. Hunley of Mobile, Alabama, financed the building of a Confederate sub-

marine named "Pioneer," a craft that was 34 ft (10 m) long and was driven by a hand-cranked propeller operated by three men. It probably was scuttled to prevent its capture when Union forces occupied New Orleans (although some records say the "Pioneer" was lost with all hands during a dive while en route to attack Union ships).

The second submarine developed by the same builders was a remarkably advanced concept: a 25-ft (7.5 m) iron boat intended to be propelled by a battery and electric motors. Not surprisingly, no suitable motors could be found, so a four-man-cranked propeller was again adopted. The submarine sank without loss of life in heavy seas off Mobile Bay while seeking to attack the enemy.

Confederate submarines

The third submarine of the Confederacy was the "H.L. Hunley," a modified iron boiler lengthened to between 36 and 40 ft (11 and 12 m). Ballast tanks and a system of weights submerged the craft; it could travel at a speed of four miles an hour, powered by eight men cranking its propeller. Its armament consisted of a "torpedo," filled with 90 pounds (41 kilograms) of gunpowder, towed behind the submarine at the end of a 200-foot line. The "Hunley" was to dive under an enemy warship and drag the torpedo against its hull. After a successful test against a barge, the "Hunley" was moved by railroad to Charleston, South Carolina. There the vessel suffered a number of disasters, sinking three times and drowning a number of crewmen including Hunley himself. Manned for a fourth time, the "Hunley" was fitted with a "torpedo" on the end of a long spar and made several successful dives. On the night of February 17, 1864, the submarine attacked the Union warship "Housatonic" in Charleston harbour. The torpedo's detonation exploded the warship's magazines: the "Housatonic" sank in shallow water with the loss of five men, but the "Hunley" also was destroyed and her crew killed.

One of the more intrepid submarine inventors of the same period was Wilhelm Bauer, a noncommissioned officer of Bavarian artillery, who built two boats, "Le Plongeur-Marin" (1851) and "Le Diable-Marin" (1855). The first boat sank in Kiel harbour on February 1, 1851, but Bauer and his two assistants escaped successfully from a depth of 60 ft (18 m) after the craft had been on the bottom for five hours. His second craft, built for the Russian government, was successful and reportedly made 134 dives before being lost at sea. In September 1856, during the coronation of Tsar Alexander II, Bauer submerged his submarine in Kronstadt harbour with several musicians on board. An underwater rendition of the Russian national anthem was clearly heard by persons inside ships in the harbour.

Advent of the machine-powered submarine. A major limitation of these early submarines was their lack of a suitable means of propulsion. In 1880 an English clergyman, the Rev. George W. Garrett, successfully operated a submarine with steam from a coal-fired boiler that featured a retractable smokestack. The fire had to be extinguished before the craft would submerge (or it would exhaust the air in the submarine), but enough steam remained in the boilers for travelling several miles underwater.

Similarly, Swedish gun designer Torsten Nordenfelt constructed a steam-powered submarine driven by twin propellers. His craft could be submerged by vertical propellers to a depth of 50 ft (15 m) and was fitted with one of the first practical torpedo tubes. Several nations built submarines to Nordenfelt's design.

In an effort to overcome the problems of propulsion, two French naval officers built the 146-ft (45-m) submarine "Le Plongeur" in 1864, powered by an 80-horsepower (hp) compressed-air engine, but the craft quickly exhausted its air tanks whenever it got underway. Development of the electric motor finally made electric propulsion practicable. The submarine "Nautilus," built in 1886 by two Englishmen, was an all-electric craft. This "Nautilus" was propelled on the surface at a speed of six knots by two 50-hp electric motors operated from a 100-cell storage battery. But the battery had to be recharged and overhauled at short intervals, and the craft was never able to travel more than 80 miles (130 km) without a battery recharge. In France, Gustave Zédé launched the "Gymnote" in 1888; it, too, was propelled by an electric motor and was extremely manoeuvrable but tended to go out of control when it dived.

The end of the 19th century was a period of intensive submarine development, and Zédé collaborated in a number of designs sponsored by the French Navy. A most successful French undersea craft of the period was the "Narval," designed by Maxime Laubeuf, a marine engineer in the Navy (Figure 2). Launched in 1899, the

The French "Narval"

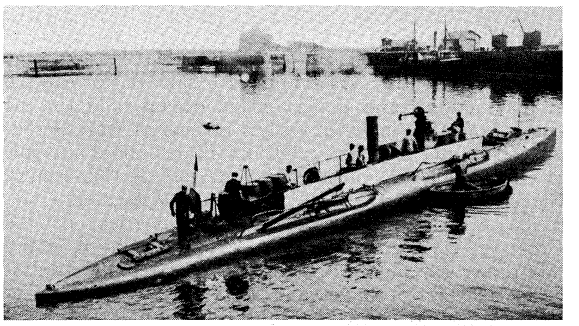

Figure 2: French "Narval" submarine, *c.* 1905.

"Narval" was a double-hulled craft, 111½ ft (34 m) long, propelled on the surface by a steam engine and by electric motors when submerged. The ballast tanks were located between the double hulls, a concept still in use today. The "Narval" made a large number of successful dives. To demonstrate her capabilities, the "Narval" once cruised for 48 hours in the English Channel during a simulated combat mission, then forced the narrow and carefully watched entrance of the roadstead at Brest and fired her four externally carried torpedoes at targets. French progress in submarines was marked by the four Sirène class steam-driven undersea craft completed in 1900–1901 and the "Aigrette," completed in 1905, the first diesel-driven submarine of any navy.

Similarly, there were submarine successes in the United States by rival inventors John P. Holland (an Irish immigrant) and Simon Lake. Holland launched his first undersea craft in 1875. This one and its successors were significant in combining water ballast with horizontal rudders for diving. In 1895, in competition with Nordenfelt, Holland received an order from the U.S. Navy for a submarine. This was to be the "Plunger," propelled by steam on the surface and by electricity when submerged. The craft underwent many design changes and finally was abandoned before completion. Holland returned the funds advanced by the navy and built his next submarine (his sixth) at his own expense. This was the "Holland," a 53¼-ft (16-m) craft launched in 1897 and accepted by the navy in 1900. For underwater propulsion the "Holland" had an electric motor and was propelled on the surface by a gasoline engine. The submarine's armament consisted of a bow torpedo tube, for which three torpedoes were carried, and two dynamite guns. The guns, one pointing forward and one aft, were built into the hull and aimed by pointing the submarine directly at or away from the target. With its nine-man crew the "Holland" was a successful boat and was modified many times to test different arrangements of propellers, diving planes, rudders, and other equipment.

Holland's chief competitor, Simon Lake, built his first submarine, the "Argonaut I," in 1894, powered by a gasoline engine and electric motor. This and Lake's other early boats were fitted with wheels for the submarine to roll over the ocean floor. He envisioned submarines sending out divers to cut cables, destroy enemy mines, and telephone enemy ship movements back to the submarine; in peacetime, such submarine-diver operations could be used for sea-floor mineral mining. In 1898 the "Argonaut I" sailed from Norfolk, Virginia, to New York under its

own power, predating the cruises of the French "Narval" and marking the first time an undersea craft operated extensively in the open sea. Lake's second submarine was the "Protector," launched in 1901. After the U.S. Navy rejected this craft, Lake offered the "Protector" to Russia and Japan. Tsarist Russia bought the vessel and five more like it. Simultaneously, Japan bought several Holland boats, but neither side used them during the Russo-Japanese conflict (1904–1905).

Of the major naval powers at the turn of the century, only Britain remained indifferent toward submarines. Finally, in 1901, the Royal Navy ordered five of the Holland-design undersea craft. Germany completed its first submarine, the *Unterseeboot* No. 1, in 1905. This craft was 139 ft (42 m) long, powered on the surface by a heavy oil engine and by an electric motor submerged, and was armed with one torpedo tube. Thus, the stage was set for the 20th-century submarine, a craft propelled on the surface by diesel engines and underwater by electric motors, submerging by diving planes and taking on water ballast, and armed with torpedoes for sinking enemy ships. The quarters inside these early craft were cramped, generally wet, and stank from diesel oil.

World War I. By the eve of World War I all of the major navies included submarines in their fleets, but these crafts were relatively small, were considered of questionable military value, and generally were intended for coastal operations. The most significant exception to the concept of coastal activity was the German Deutschland class of merchant U-boats, each 315 ft (95 m) long with two large cargo compartments. These submarines could carry 700 tons of cargo at 12- to 13-knot speeds on the surface and at seven knots submerged. Manned by a crew of 8 officers and 21 enlisted men under the command of Capt. Paul Koenig, a veteran merchant-ship skipper, the "Deutschland" herself made two successful cargo trips between Germany and the United States in 1916 despite a British naval blockade. The "Deutschland" became the "U-155" when fitted with torpedo tubes and deck guns and with seven similar submarines served in a combat role during the latter stages of the war. In comparison, the "standard" submarine of World War I measured slightly over 200 ft (60 m) in length and displaced less than 1,000 tons on the surface.

The prewar submarines generally had been armed with self-propelled torpedoes for attacking enemy ships. During the war submarines also were fitted with deck guns. This permitted them to approach enemy merchant ships on the surface and signal them to stop for searching (an early war policy) and later to sink small or unarmed ships that did not warrant expenditure of torpedoes. Most war-built submarines had one and sometimes two guns of about three- or four-inch calibre (diameter of the projectile); however, several later German submarines carried 5.9-inch guns (including the Deutschland class in military configuration).

Late in the war the British completed the first of three M class submarines, each armed with a 12-inch gun (in addition to four torpedo tubes and an anti-aircraft gun). These submarine monitors were intended to steam off an enemy coast with their decks submerged and only the muzzle of the 12-inch gun and a sighting periscope protruding through the water. Capable of firing far inland, these giant submarines were 296 ft (90 m) long, displaced 1,650 tons on the surface, and had diesel-electric propulsion that could drive them at 14 knots on the surface and 8 knots submerged.

Another armament variation was the submarine modified to lay mines during covert missions off an enemy's harbours. The Germans constructed several specialized submarines with vertical mine tubes through their hulls; some U-boats carried 48 mines in addition to their torpedoes.

Anti-submarine submarines

Also noteworthy was the development, during the war, of the concept of an antisubmarine submarine. British submarines sank 17 German U-boats during the conflict; the early submarine-versus-submarine successes led to British development of the R class submarine intended specifically for this role. These were relatively small craft, 163 ft (50 m) long and displacing 410 tons on the surface, with only one propeller (most contemporary submarines had two). Diesel engines could drive them at nine knots on the surface, but once submerged, large batteries permitted their electric motors to drive them at the high speed of 15 knots for two hours. Thus, they were both manoeuvrable and fast. Advanced underwater listening equipment (asdic/sonar) was installed, and six forward torpedo tubes made them potent weapons. Although these submarines appeared too late to have any actual effect on the war, they pioneered a new concept in the development of the submarine.

All World War I-era submarines were propelled by diesels on the surface and by electric motors submerged, except for the British Swordfish and K class. These submarines, intended to operate as scouts for surface warships, required the high speeds then available only from steam turbines. The Swordfish was of conventional size, but the K boats were 340 ft (100 m) long and displaced 1,780 tons on the surface; the steam plant of the K boats propelled them at 23½ knots on the surface, while electric motors gave them a ten-knot submerged speed, a common underwater speed for submarines until after World War II.

Interest in submarines continued high within the world's navies during the period between World Wars I and II. A particularly attractive notion was that of developing large, heavily gunned submarines for commerce raiding. The British "X-1," completed in 1925, was a long-range submarine with four 5.2-inch guns in twin, armoured turrets, in addition to six torpedo tubes. The French "Surcouf," completed in 1934, mounted two eight-inch guns in a single turret, in addition to ten torpedo tubes, and also had a small hangar to accommodate a seaplane. The aircraft was to be used to search for merchant ship victims. The seaplane–submarine team also was investigated by the Royal Navy, which removed the 12-inch gun from the submarine monitor "M-2"—the 12-inch gun being unsuitable for use against surface ships—and fitted her to carry a seaplane. The U.S. Navy similarly fitted the submarine "S-1" with a hangar and small seaplane, while the Japanese Navy modified a number of submarines to operate small seaplanes.

Commerce raiding

During this period the U.S. Navy built its first large, long-range submarine, the "Argonaut." Completed in 1928, she was 381 ft (116 m) long, displaced 2,710 tons on the surface, was armed with two six-inch guns and four forward torpedo tubes, and could carry 60 mines. The "Argonaut," the largest non-nuclear submarine ever built by the U.S. Navy, led to the highly successful Gato and Balao classes used in World War II.

During the 1930s the rejuvenated Soviet shipyards began producing large numbers of submarines, primarily coastal craft, in an attempt to make the U.S.S.R. a sea power without major expenditures for surface warships. But though the Soviet program achieved quantity, their ships were unsuitable for operations against the German Navy, their crews were poorly trained, and Soviet bases were blocked by ice much of the time.

World War II. World War II (1939–1945) saw extensive submarine campaigns on all of the world's oceans. In the Atlantic the principal German U-boat was the VII type, a relatively small but effective craft when properly employed. The Type VIIC variant was 220¼ ft (67 m) long, displaced 769 tons on the surface, and was powered by diesel-electric machinery at a speed of 17 knots on the surface and 7½ knots submerged. Armament consisted of one 3.5-inch deck gun, various anti-aircraft guns, and five torpedo tubes, four forward and one aft. Either 14 torpedoes or 14 tube-launched mines were carried. Manned by a crew of 44, these submarines had a surface endurance of 6,500 miles at 12 knots, but, when they were submerged, their batteries would remain active a little less than a day at four knots.

Three German designs warrant special mention: The VIIF design was an elongated boat 254¾ ft (78 m) long intended to replenish other U-boats at sea with torpedoes —25 spares were carried, above a normal complement of 14—and fuel oil—199 tons carried, compared with 114

tons in Type VII submarine. The ultimate diesel-electric submarine evolved in the war was the German Type XXI, a 250-ft (75-m), 1,600-ton craft that could attain 17½ knots submerged for more than an hour, could travel at six knots underwater for two days, or could "creep" at slower speeds for four days. These submarines were fitted with *schnorchel* devices (see below) that made it unnecessary for them to surface fully to recharge their batteries after operating submerged. The Type XXI had an operating depth of 850 ft (260 m), more than twice what was then normal, and was armed with four 33-millimetre guns and six forward torpedo tubes (23 torpedoes carried). Existing Allied antisubmarine forces would have had serious trouble coping with these craft had the war continued past the spring of 1945.

A final German war design of particular interest was the Walter turbine propulsion plant. The need for oxygen for combustion had previously prevented the use of steam turbines or diesels while the submarine was submerged, and air was at a premium. Hellmuth Walter, a German scientist, developed a turbine propulsion system using oxygen generated by hydrogen peroxide to operate the turbine while submerged. A simplified submarine, the "V-80," built in 1940 and propelled by a Walter turbine system, could attain speeds of more than 26 knots submerged for a short period of time. After many delays, the first Walter-propelled Type XVII combat submarines were completed and could reach 25 knots underwater for brief periods, and a submerged run of 20 knots for 5½ hours was achieved on trials. But these submarines, like the Type XXI, were not ready for full-scale operations when the war ended.

A notable German submarine development of World War II was the *schnorchel* device (anglicized by the U.S. Navy to "snorkel"). Its invention is credited to a Dutch officer, Lt. Jan J. Wichers, who in 1933 advanced the idea of a breathing tube to supply fresh air to a submarine while running submerged. (Robert Fulton had a similar device in his "Nautilus" of 1801.) The Netherlands Navy began using snorkels in 1936, and some fell into German hands in 1940. With the advent of radar to detect surfaced submarines, the Germans fitted hundreds of U-boats with snorkels to permit operation of diesels at periscope depth to recharge batteries for underwater propulsion with less of a possibility of detection by Allied radar-equipped ships and aircraft.

Japanese submarines

In the Pacific War the Japanese employed a large number of submarines of various sizes and types, including submarine-carried aircraft, midget submarines, and "human torpedoes" carried by larger submarines. Two Japanese designs are of special interest. The Japanese I-201 class was a high-speed submarine 259⅙ ft (79 m) long, displacing 1,291 tons, that had diesel propulsion for 15 knots on the surface; while underwater, large batteries and electric motors could drive the vessel at a speed of 19 knots for almost one hour. Each boat had two 25-millimetre guns and four forward torpedo tubes and carried ten torpedoes. The Japanese, who constructed one-man submarines, also built the largest conventionally powered undersea craft ever built, the I-400 class. These submarines were intended as underwater aircraft carriers and had a hangar that could accommodate three floatplanes and parts for a fourth. The I-400 submarines were 400¼ ft (122 m) long and displaced 5,700 tons, about the size of a light cruiser. The aircraft were housed in a hangar 12 ft (3.7 m) in diameter and 102 ft (31 m) long and launched by a catapult built into the deck. Each submarine was armed with a 140-millimetre deck gun plus seven 25-millimetre anti-aircraft guns, eight torpedo tubes, and 20 torpedoes. (They were never actually used for their intended purpose, which was to launch planes against the Panama Canal, but were employed as cargo submarines to supply bypassed island garrisons in the Pacific.)

The highly successful U.S. submarine campaign in the Pacific war was waged mainly with the Gato and Balao class submarines. These were approximately 311½ ft (94.9 m) long, displaced 1,525 tons, and had diesel-electric machinery for 20-knot surface and 9-knot underwater speeds. The principal difference between the two designs was the 300-ft (90-m) operating depth for the Gato class and 400-ft (120-m) depth for the Balao boats. Manned by 65 to 70, these submarines had one or two five-inch deck guns plus smaller anti-aircraft weapons, ten torpedo tubes (six forward, four aft), and carried 24 torpedoes.

After the war the Allies were quick to adopt advanced German submarine technology. The British built two peroxide turbine-propelled experimental submarines, the "Explorer" and "Excalibur," but this concept lost favour because of the unstable properties of hydrogen peroxide and because of American success with nuclear propulsion. The U.S.S.R. began building a modification of the Type XXI submarine. Some 235 of these W class submarines were completed between 1950 and 1958, more submarines than built by all of the world's other navies combined between 1945 and 1970. (In that period Soviet shipyards produced a total of 560 new submarines.)

In the postwar period the U.S. Navy studied German technology and converted 52 war-built submarines to the Guppy configuration (an acronym for Greater Underwater Propulsion Project with the "y" added for phonetics). These submarines had their deck guns removed and streamlined conning towers fitted; larger batteries and a snorkel were installed; four torpedoes and, in some craft, one of the four diesel engines were removed. The result was an underwater speed of 15 knots and increased underwater endurance. During the postwar years the U.S. Navy built 21 diesel-powered submarines, several of which were highly specialized craft for antisubmarine warfare, guided-missile launching, underwater research, training, and radar picket operations in support of surface ships. Several war-built submarines were converted to these roles and also were used for the transport of Marine reconnaissance troops and frogmen.

Nuclear propulsion. The first efforts to develop a submarine nuclear power plant were made at the U.S. Naval Research Laboratory in Washington, D.C., under the direction of Ross Gunn, beginning in the spring of 1939. A report submitted that summer by Gunn noted that such a power plant would not require oxygen to operate, "a tremendous military advantage [which] would enormously increase the range and military effectiveness of a submarine." All work on nuclear propulsion was halted, however, as efforts in this field were devoted toward the atomic bomb development. After the war Gunn and Philip Abelson of the Carnegie Institution resumed work on a nuclear power plant, resulting in a report in the spring of 1946 calling for a nuclear submarine. The U.S. Navy took no action in this regard until Capt. Hyman G. Rickover, appointed to head the navy's cooperation in a nuclear project at the Oak Ridge, Tenn., research centre became a crusader for this type of submarine propulsion. Subsequently, a land-based prototype submarine power plant was constructed, followed by installation of a duplicate plant in the USS "Nautilus."

The USS "Nautilus"

The "Nautilus" got underway on January 17, 1955. Resembling a conventional submarine in appearance, it is 320 ft (98 m) long, displaces 3,530 tons, and has six forward torpedo tubes. Her top speed of 20 knots, both surface and submerged, was good but not spectacular compared with her diesel-electric contemporaries. But her underwater range at high speed is virtually unlimited. Measured in terms of "years" rather than miles, this endurance made her a revolutionary ship, in fact the first true submarine. All of her predecessors had been merely surface craft capable of brief operation under water.

Seven additional nuclear submarines were built to conventional hull designs, including one for launching guided missiles and one for radar picket missions. The navy then combined the advanced "tear drop" hull design of the research submarine Albacore with a nuclear propulsion plant to produce the Skipjack class of very fast submarines, capable of underwater speeds estimated at over 30 knots. This design has been incorporated in the subsequent Thresher and Sturgeon classes. These later nuclear submarines, however, have their large bows devoted entirely to detection equipment (sonar) and have their four torpedo tubes amidships, angled out with two on each side (a concept tested by the Germans in World War II).

This places their sonar at the most advantageous position, as far forward as possible and away from the ship's machinery and propeller noises. The Sturgeon class submarines are 292 ft (89 m) long and displace 3,860 tons; however, they probably are slower than the earlier Skipjack class because they have the same propulsion machinery but larger hulls.

Almost all U.S. nuclear submarines are primarily intended to detect and attack enemy submarines, except for those armed with strategic Polaris or Poseidon missiles. Beginning with the "George Washington," the U.S. Navy completed 41 Polaris-armed submarines between 1960 and 1967. Of these, 31 are Lafayette class submarines that are to be converted to fire the improved Poseidon missile. The Lafayette class submarines, each carrying 16 missiles plus four torpedo tubes, are 425 ft (130 m) long and displace 6,650 tons. The only larger nuclear submarine is the "Triton" completed in 1959; she is a radar picket craft 447½ ft (136 m) long and displacing 5,940 tons. The "Triton" also was the first submarine propelled by two nuclear reactors; the Soviet Yankee class missile submarines also may have two reactors, according to some U.S. Navy estimates, but all other nuclear submarines have only one.

Soviet nuclear submarines

The U.S.S.R., maintaining the largest and newest submarine fleet in the post-World War II era, reached a maximum strength of almost 500 diesel-electric submarines in the early 1960s. The first Soviet nuclear submarine, designated November class, was completed in 1959 or 1960 and was 360 ft (110 m) long and displaced about 3,500 tons. The November class submarines generally are credited with a surface speed of about 25 knots and a submerged speed of 25 to 30 knots, with some of the later November submarines possibly exceeding 30 knots submerged. Armament consists of six bow torpedo tubes.

During the 1960s the U.S.S.R. produced large numbers of diesel-electric and nuclear submarines for three distinct missions: attack or torpedo-armed submarines to attack surface ships and other submarines; cruise missile-armed submarines to attack enemy surface warships, especially aircraft carriers; and ballistic-missile submarines armed with long-range strategic missiles. By 1971 the U.S. and Soviet navies each had built some 90 nuclear-powered undersea craft and had a rate of production of just over four atomic submarines per year for the United States and 12 to 14 per year for the Soviet Union.

The first British nuclear submarine was the "Dreadnought," completed in 1963, a torpedo-armed submarine of advanced design and fitted with an American propulsion system. Subsequent British nuclear submarines, attack and ballistic missile types, have British-designed and fabricated machinery. The first French nuclear submarine was to have been the hull designated "Q-244" begun in 1958; however, the project was cancelled, and the hull subsequently completed as the diesel-electric missile trials submarine "Gymnote." Subsequently the French built four nuclear-powered, ballistic-missile submarines, the first being "Le Redoutable," completed in 1969. During the 1960s the Soviet, British, and French navies continued constructing advanced diesel-electric submarines. In many roles the diesel-electric submarine can perform equally to a nuclear craft, especially when very quiet operation for limited periods is required. Also significant is the higher cost of nuclear propulsion; the European nations can sell conventional submarines to lesser navies that cannot afford nuclear craft.

The overall superiority of nuclear-propelled submarines cannot be questioned. Only this form makes possible the relatively invulnerable ballistic-missile submarines that can cruise the oceans for months without surfacing or extending an air-intake tube to the surface. Nuclear submarine performance can be measured by such exploits as: "Nautilus" (U.S.), making the first submerged polar transit from Point Barrow, Alaska, to the Greenland Sea, travelling 1,830 miles (2,945 km) under the polar ice pack (August 1–5, 1958); "Skate" (U.S.) (Figure 3), a similar polar-icepack voyage (August 9–20, 1958), travelling 2,405 mi (3,870 km) and surfacing 40 mi (64 km) from the North Pole; "Seawolf" (U.S.), remaining submerged

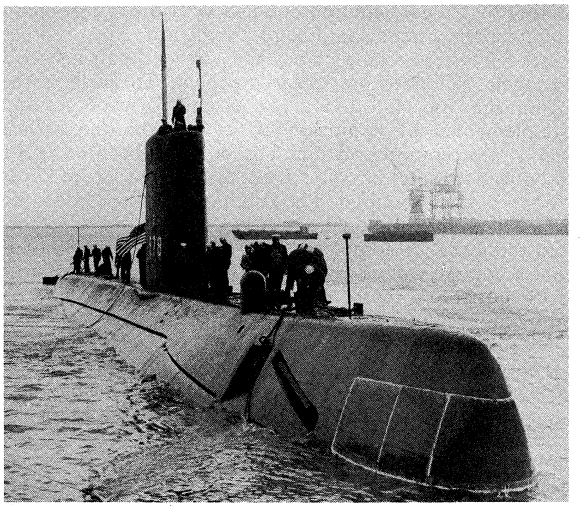

Figure 3: USS "Skate," a nuclear-powered submarine, arriving in Portland, Dorset.
Wide World Photos

for 60 consecutive days and travelling 13,761 mi (22,146 km; August 5–October 6, 1958); "Triton" (U.S.), circumnavigating the world submerged, following roughly the route taken by Magellan (1519–1592), and travelling 36,014 mi (57,946 km) February 24–May 10, 1960); "Leninsky Komsomol" (U.S.S.R.), reportedly operating under the polar ice pack and surfacing near the North Pole in 1962; a November class submarine (U.S.S.R.), remaining submerged for almost 50 consecutive days while steaming about 25,000 mi (40,000 km). None of these feats is considered possible with conventionally propelled submarines.

Like their conventional sisters, nuclear submarines have encountered difficulties in the hostile depths. To the list of submarines sunk accidentally in both peace and war, by 1971 three nuclear submarines had been added: the USS "Thresher," off New England, with 129 lives lost, April 10, 1963; USS "Scorpion," off the Azores, with 99 lives lost, May 1968; and a Soviet November class, in the eastern Atlantic, April 12, 1970 (no loss of life).

MODERN STRUCTURE AND USES

Construction features. To operate underwater a submarine has a strengthened steel pressure hull that provides protection from water pressure to the crew, machinery, and certain equipment. A double-hull technique is generally used, with the space between the inner (pressure) hull and outer hull providing room for water ballast and fuel tanks. This double-hull feature also provides additional protection for the pressure hull from nearby detonations of antisubmarine weapons. Until recently, above the hull and extending the length of the submarine there was a nonwatertight, free-flooding superstructure that formed the main deck for use when the submarine was surfaced. Modern high-speed submarines, both diesel-electric and nuclear, do not have the superstructure deck, as it interferes with optimum underwater shape. Also, nuclear-powered submarines do not have the normal double-hull configuration because they require only small amounts of diesel fuel for their auxiliary machinery; hence, these fuel tanks and water-ballast tanks are fitted within the pressure hull and a partial double hull.

Above the submarine's hull is a conning tower or sail structure. In older submarines this was a watertight conning tower that served as the command centre during combat. On post-World War II submarines there is a streamlined "sail" structure that does not contain a watertight compartment. The conning tower and sail structure both house the retracting periscopes, radar and radio antennas, and snorkel tubes and provide a platform or bridge for the navigating officers and lookouts when the submarine is on the surface.

Normally, the submarine submerges by flooding the water-ballast tanks to attain a neutral buoyancy and then

diving by forward motion coupled with the use of small diving planes, somewhat like rotating wings. Most submarines have stern diving planes and a second pair installed on their sail structure or at the bow. To surface, the submarine uses the diving planes and forward motion, supplemented by expulsion of water from the ballast tanks with compressed air. The compressed air can be produced within the submarine and stored in tanks or "bottles" until required. The submarine is kept in a state of neutral buoyancy with water-trim tanks that are partially flooded to compensate for changes in the submarine's volume caused by increasing pressure as the craft goes deeper and by the effects of changing water temperature and salinity or by weight changes from firing torpedoes or missiles.

Control room

The control room in a modern submarine is carefully designed to achieve the maximum efficiency during operations, with centralized command positions from which the submarine and its weapons can be directed. The modern submarine relies more on its sonar than on the periscope for detecting and attacking an enemy; in addition, the modern submarine has a complex inertial-navigation system that provides information on its position independent of any outside sources except gravity and earth rotation. These data are periodically checked by a special star-tracking periscope device or radio navigation antenna that is projected above the water for very brief periods. The actual control of the submarine is achieved by aircraft-line controls, with one or two men sitting in "pilot" chairs and manoeuvring the craft. Some undersea craft have analog "pictures" of a simulated roadway, presented to the "pilots" on a television-like screen, in addition to the conventional dials and pointers that indicate course, speed, and depth with numbers.

The modern submarine is a relatively comfortable craft, dry inside and fully air-conditioned, the latter feature for both crew habitability and for the great amount of sophisticated electronic equipment that requires carefully maintained humidity and temperature conditions. Modern, especially designed electric kitchens provide food that is traditionally considered of high quality. The crew sleeping or dining spaces also are used for motion pictures and as game rooms. The officers have their own sleeping area and wardroom.

Oceangoing submarines can remain at sea for two or three months, carrying all provisions required by the crew during that period. Diesel-electric submarines periodically raise a snorkel device to draw in air for the diesel engines and crew and to carry away exhaust gases. Nuclear-powered submarines need not draw in air for their engines and can manufacture oxygen for the crew from the surrounding seawater to supplement oxygen carried in tanks.

Two-way communication with submerged submarines is difficult because radio waves cannot be produced underwater. Thus, the modern submarine cannot send radio messages while fully submerged but must raise an antenna mast up into the air to communicate by radio. The submarine can receive radio transmissions while submerged, however, through built-in antennas or by trailing a wire antenna through the water.

Sensors. The prime sensors of a submarine are sonars, periscopes, and radars (see also SONAR; RADAR). Submarines employ both passive sonar (sound detection and ranging), which listens for the noises generated by another submarine or a surface ship, and active sonar, which sends out an acoustic pulse that is reflected upon hitting another submarine or ship. The submarine uses sonar for detection of an enemy, for sea-floor and under-ice navigation, and for directing torpedoes.

The periscope

The periscope is the "eye" of the submarine. Early submarines had small glass portholes for direct observation. This required the submarine to be partially surfaced. In 1854 E-H. Marié-Davy of France designed a submarine sight tube containing two mirrors, one above the other, held at a 45° angle and facing in opposite directions. The mirror-tube provided some degree of sight from a submerged submarine but was faulty at best, and in 1872 prisms were substituted for mirrors.

Subsequently, the prism periscope was improved and made to telescope, so that it could be housed within the submarine's hull when not in use and extended above the submarine for reconnaissance. Modern periscopes are about 40 ft (12 m) long and taper to about one inch in diameter at the top to reduce detection from the surface. Special features permit considerable magnification, night reconnaissance, photography through periscopes, sextant use for celestial navigation while submerged, and viewing of the air around the submarine as well as the surface.

Radar (radio detection and ranging) was fitted to most U.S., British, and German submarines during World War II, initially to detect aircraft while the submarine was operating at periscope depth or on the surface. Subsequently, surface-search radar was provided, and during the latter part of the war radar-approach attacks against surface ships were common. Submarine radars are now used primarily for navigation in coastal waters. The antenna is mounted on a retractable mast and is withdrawn into the sail structure when not in use.

Propulsion. Shortly after the beginning of the 20th century, most submarines were fitted with diesel engines for surface propulsion and to recharge the batteries needed for electric-motor submerged propulsion. (The steam-turbine and peroxide-turbine variants are discussed above.) Engines burning diesel oil had a significant advantage over gasoline motors for surface propulsion because of the highly volatile properties of gasoline, and advantages over steam propulsion because of the high temperatures generated by the boilers necessary for steam turbines before the advent of nuclear propulsion.

Once submerged, the diesel engines are shut down, and electric motors are started, turning the same propeller shafts. The electric motors, drawing their energy from storage batteries, require no combustion and can be used without regard for the submarine's air supply. Electric motors have the additional advantage of being quiet, an important factor in submarine operations.

The nuclear power plant

The submarine nuclear power plant consists of an atomic reactor that generates enormous amounts of heat through nuclear fission (see also NUCLEAR REACTOR). The reactor is controlled by inserting and withdrawing control rods that penetrate the reactor core. When the rods are completely inserted the reaction ceases, and when they are completely withdrawn the reaction is at its maximum. The heat is carried by the primary coolant (pressurized water) to a steam generator, where the heat is transferred to a secondary water system that creates steam to drive the submarine's turbines. The primary coolant water is radioactive from passing near the radioactive core and thus cannot be used directly with the turbine. On most nuclear submarines reduction gears are used between the turbines and the propeller shaft; however, a few incorporate turbo-electric drive (notably the USS "Tullibee" and USS "SSN-685"). Here the steam turbine drives an electric generator, which in turn drives the electric motors coupled to the propeller shaft.

Nuclear-powered submarines are "refuelled" by replacement of the uranium core in their nuclear reactor. The "Nautilus" steamed 62,562 mi (100,681 km) on her first nuclear core, which was replaced in 1957; 91,324 mi (146,968 km) on her second core, which was replaced in 1959; and approximately 150,000 mi (240,000 km) on her third core, replaced in 1964. The cores now being installed in U.S. nuclear submarines will have an endurance of approximately 400,000 mi (640,000 km).

All nuclear-powered submarines are fitted with auxiliary diesel-electric machinery (and snorkel) for use in the event of a main machinery casualty and to generate power when the main machinery is shut down while in port.

Weapons. The primary weapon of the submarine traditionally has been the self-propelled torpedo. Modern submarines are fitted with internal torpedo-launching tubes 21 inches (53 centimetres) in diameter and about 21 ft (6.4 m) long. The tubes are horizontal in the bow or amidships, with some submarines also having stern tubes. The tubes are loaded from within the submarines and normally are loaded with reloads kept within the submarine when the craft goes to sea. Each tube has doors at both ends so that the inner door can be opened when the outer

door is closed and vice versa, permitting firing and reloading without water entering the submarine. The tubes are fired electrically or mechanically by hand.

Most torpedoes today are intended for use against other submarines; they either home on their target acoustically with self-contained sonar or are guided by electronic commands passed to them through a threadlike wire paid out behind the torpedo as it travels away from the launching submarine. Another submarine-to-submarine weapon is the U.S. Navy's submarine rocket (Subroc). Fired from a torpedo tube while the craft is submerged, Subroc streaks to the surface, leaves the water, and, propelled by a rocket, travels through the air on a ballistic trajectory. The weapon re-enters the water an estimated 25 to 30 mi (40 to 48 km) from the launching submarine, and a nuclear warhead detonates.

During World War II, the German Navy experimented with small guided missiles and large ballistic missiles launched from submarines and submarine-towed containers, respectively. After the war, the U.S. and Soviet navies developed guided cruise missiles, jet- or rocket-propelled vehicles with stub wings that resembled pilotless aircraft. These were carried in watertight hangars on the submarine deck and fired after the submarine surfaced. The U.S. Navy operated the Regulus I missile with a 500-mi (800-km) range from several submarines between 1958 and 1964 and developed but did not use the Regulus II missile with a range of 1,000 mi (1,600 km). The Soviets developed similar missiles and now use the Shaddock missile with a maximum range of 450 mi (720 km) from a number of conventional and nuclear submarines. These missiles, which have a variable flight path, are considered the most potent threat to surface warships. (Some newer Soviet submarine-launched cruise missiles may be capable of underwater launching.)

Submarine-launched ballistic missiles are strategic weapons intended for use against cities and other fixed land targets. They cannot be effectively used against ships. The Soviet Navy began deploying conventional submarines with short-range ballistic missiles in the late 1950s, while the first U.S. Navy strategic missile submarine, the "George Washington," was first deployed in 1960; it carried 16 Polaris A-1 missiles, each with a nuclear warhead and a range of 1,380 mi (2,220 km). These and subsequent ballistic missiles can be fired when the submarine is submerged. Subsequent U.S. Polaris submarines were fitted with the A-2 missile with a range of 1,725 mi (2,775 km) and then the A-3 missile with a 2,875-mi (4,625-km) range. Some A-3 missiles also have three-vehicle warheads that can "shotgun" three nuclear bombs at the target. In 1970 the U.S. Navy began to rearm most Polaris submarines with the Poseidon missile, which has about the range of the A-3 missile but which carries ten small warheads that can be aimed at individual targets. Similarly, British strategic missile submarines are armed with the Polaris A-3 missile, French submarines with the MSBS missile with a range of 1,900 mi (3,000 km), and Soviet submarines with the 1,300–1,500-mi (2,000–2,400 km) SS-N-6 missile. (A longer range, 2,700–3,000-mi submarine missile, developed by the Soviets, was scheduled for deployment during the 1970s.) All of these strategic submarines carry 16 missiles in addition to torpedoes. The Soviet Navy also operates a number of smaller nuclear and conventional submarines that fire three strategic missiles with lesser range.

Subsidies

A subsidy is a direct or indirect governmental payment, economic concession, or special privilege granted to private firms, households, or other governmental units in order to promote a public objective. Identification of a subsidy is generally complicated because of the amorphous variety of subsidy instruments, the multiplicity of the public objectives that they are designed to serve, and the complexity of their effects.

Varieties and functions of subsidies

Subsidies to transportation, housing, agriculture, mining, and other industries have been instituted on the grounds that preservation or expansion of these industries, even at a cost to the general public, is in the public interest. Subsidies to the arts, sciences, humanities, and religion have also been instituted in many nations because of the inability of the private economy to support these functions at a level consistent with public policy. The term also comprehends grants of money or other aid made by a central government to a local one to promote objectives in which the central government has an interest (*e.g.*, grants-in-aid). More broadly defined, subsidies include welfare payments designed to ameliorate inequalities in the distribution of income and also other governmental programs designed to mitigate the effects of market forces. Regardless of the form that subsidies take, their purpose is to alter the results created by otherwise free markets and unimpeded competition in a direction considered more consistent with the objectives of public policy. The effect of subsidies is to encourage the growth of subsidized industries relative to industries that do not receive subsidies and thus to alter the uses to which an economy puts its resources.

Subsidies have a long history in all nations and were extensively employed by governments during the mercantilist period preceding the Industrial Revolution when it was thought that the accumulation of gold through a favourable balance of trade required the protection of domestic manufacturers. Such protectionist doctrines have often been viewed with skepticism since the British economist Adam Smith published *Wealth of Nations* in

1776, refuting mercantilist doctrine and establishing a modern theoretical basis for the abandonment of government protection in favour of unimpeded trade and competition. Nevertheless, protectionism continues as a part of national economic policy in most nations of the world, which try to justify subsidy programs on the grounds of a need for national self-sufficiency, for the development of emerging industries, for the aid of small businesses, for the encouragement of home ownership, for the elimination of slums, for the preservation of local government, for the alleviation of depression and unemployment, for the promotion of religion, marriage, and other cherished institutions, and so on. Subsidy as a distinct tool of public policy has somewhat more significance in nations, such as the United States, that rely primarily on a competitive market to perform basic economic functions and that seek only to induce or nudge the action of such markets. In nations in which a strong central government exerts influence over the price and production policies of domestic industries, the subsidy device is replaced by comprehensive economic planning.

Subsidies are implemented through a variety of financial techniques, such as (1) direct payments in cash or kind, (2) governmental provision of goods or services at prices below the normal market price, (3) governmental purchase of goods or services at prices in excess of the market price, and (4) tax concessions and similar inducements. In addition, there are numerous governmental policies that have subsidy effects, such as regulatory statutes that soften the full force of competition, policies that require the purchase of goods from favoured producers or nations, and protective wage and price legislation. A distinction is sometimes made between direct or visible subsidies (such as direct payments for ship construction and airline operation), which are easy to identify and measure, and indirect or concealed subsidies (such as price ceilings or floors, tariffs, and tax concessions), which are difficult to identify and always difficult to measure. Concealed subsidies are more susceptible to abuse by special-interest groups and politicians and, from an economic point of view, achieve their objectives at a higher real cost to the community. Since the term subsidy often carries a connotation of opprobrium, it is seldom employed in official descriptions; most subsidies are implemented indirectly through government manipulation of the prices received or paid by producers. Narrowly defined and conservatively measured, the subsidy programs of the United States government, for example, amounted to about $10,000,000,000 a year during the 1960s; estimates vary upward from this figure to as high as $30,000,000,000 or $40,000,000,000 depending on the comprehensiveness of the definitions employed.

Direct subsidies. Historically, direct subsidies have been employed most extensively to promote the development of the transportation industries. Ocean shipping and aviation have been viewed as important instruments of defense and foreign policy by all nations, and the development of land transportation has been considered a prerequisite for domestic economic development. Direct maritime subsidies in France, Italy, Japan, the United States, and other nations involve (a) construction-differential subsidies, whereby the government absorbs the excess cost of construction in foreign shipyards, or (b) operating-differential subsidies, which compensate certain operators of ships for higher operating costs than those borne by their foreign competitors.

Transportation subsidies

In no instances are railroads a purely private endeavour. The initial costs of construction are high, the risks are great, and the buildup of traffic and revenue is delayed. When a railroad network is finally completed, it is frequently discovered that many miles of track yield little revenue but that the maintenance of a basic minimum service is socially desirable. As a result, many national railroads are either government owned or considered instruments of public policy and, if necessary, receive direct subsidy payments to cover deficits. The principal types of subsidies include cash contributions, tax concessions, government purchase of railroad securities at favourable prices, and land grants. In recent years, the survival of railroads has been threatened by competition from other carriers. As a result, such countries as Great Britain have inaugurated a system of grants for the operation of passenger trains.

Direct subsidies to the aviation industry include cash payments to recover operating deficits and government financing of the costs of developing new aircraft. Competition between nations, notably Great Britain, France, the United States, and the Soviet Union, has led to huge public expenditures for the development of commercial aircraft.

Direct cash subsidies are also awarded, especially in Europe and Asia, to finance the construction and operation of various public utilities, including power plants, water plants, piers, communications and broadcasting systems, and the like. In such instances, management is usually vested in quasi-public bodies that receive direct governmental payments. Cash payments have been employed to promote the cultivation of idle lands as well as to encourage the removal of other lands from production. Cash payments and readjustment allowances for disabled veterans and for the victims of floods, fires, and other disasters are used throughout the world. Bounties have been given for a wide range of acts, including the apprehension of criminals and tax evaders, for the destruction of rats, and for the birth of children. The promotion of the arts, science, humanities, and research is frequently implemented through cash grants to individuals, foundations, and private firms.

Grants-in-aid

An important form of direct cash payment made by most central governments is the intergovernmental grant-in-aid received by local governments. The British Industrial Development Act of 1966, for example, instituted an elaborate system of cash grants to local governments and private firms to encourage the economic growth of less developed regions. Similarly, the United States, France, and other countries have instituted grants to local governments in order to encourage urban redevelopment programs and slum removal. In international affairs, nations have subsidized the wars of smaller or less affluent allies through direct cash payments, the provision of war materials, and favourable loans (see FOREIGN AID PROGRAMS).

Indirect subsidies. Indirect subsidies arise when governments purchase directly from private producers at higher-than-market prices, maintain higher prices through manipulation of markets, provide services to private enterprises at prices below the cost of providing the service, or grant special tax concessions.

Perhaps the best examples of direct purchases at high prices have been governmental purchases of metals for monetary reserves and strategic materials for defense stockpiles. For many years the U.S. government purchased silver from domestic producers, sometimes at prices more than double the world-market price. It also paid premium prices to producers of rare metals during and following World War II as a part of the stockpiling programs. The amount of subsidy involved in such transactions is the difference between the free-market or world price and the price actually paid. Rules and regulations requiring the domestic government to buy all or a specified minimum of the purchases from domestic producers are common and typically result in subsidies to high-cost domestic producers. Properly employed, such purchase programs can encourage infant industries, mitigate short-term balance-of-payments problems, and contribute to national self-sufficiency. At the same time, they increase the costs of operating the government and may, unless carefully monitored, result in the preservation of inefficient producers, and the storage of essentially useless supplies.

Price-support programs

Indirect subsidies are frequently implemented through price-support and tariff programs. All developed nations have used price supports in one form or another to protect the income of producers in the presence of surplus production; similarly, tariffs have been used to exclude foreign competition or alleviate balance-of-pay-

ments problems. The farm price-support program in the United States, for example, is designed to maintain the prices of farm products—principally wheat, corn, and cotton—at levels designed to maintain a parity relationship between farm prices and other prices in the economy. If the market price is below the government support price, the government lends the farmer an amount equal to the difference. If the market price rises above the support price, the grower retains the crop and repays the loan. When the market price remains below the support price, the government becomes the owner, and storage and disposal of the surplus production becomes a costly undertaking. Since price-support programs encourage surplus production, they are usually supplemented by production controls and quotas, surplus-removal programs, soil-conservation programs, and other devices aimed at offsetting the undesirable side effects.

Great Britain and a number of other nations allow the price of farm products to seek the market level and then subsidize the difference between the market price and one considered fair to the farmer. This type of subsidy program has the advantage of lowering prices to the final consumer while reducing or eliminating storage and surplus removal costs. South Africa requires millers to pay the support price to farmers and then subsidizes millers who sell their flour at a loss to bakers; the consumer receives the benefits of a low price for bread. A major problem with farm price-support programs is that large, efficient, and affluent farmers may receive the bulk of the subsidy. To avoid this, Great Britain places a limit on the amount of output that will be subsidized; and the United States is experimenting with a dollar limit on the total amount of subsidy a grower may receive. Farm price-support programs may also prevent the development of effective trade relations between nations. One of the major stumbling blocks in the development of the Common Market in Europe has been the inability to reach agreement on the prices of farm products. To enter the Common Market, for example, Great Britain would have to buy agricultural products from France and Germany at prices well above the prices available in other Commonwealth countries.

Tariffs

Import tariffs are fundamentally a form of selective price support for particular domestic industries. Such tariffs frequently seem motivated by a desire to protect the employment, incomes, and profits of producers threatened by foreign competition. Though tariffs, especially if they are temporary, may be justified in certain instances, they deprive the domestic consumer of inexpensive foreign products, discourage advantageous international trade, and deny the domestic economy the most advantageous use of its resources. Though international efforts to remove tariff barriers have met with some success, they have also been frustrated by the imperatives of domestic policy and politics.

Governments may also encourage price-stabilization programs by permitting or actually administering concerted trade association activity designed to raise or maintain prices when competition threatens the existing structure of prices, employment, or balance-of-payments. Resale-price maintenance, fair mark-up, and other types of price regulation are common in almost every nation.

Free or low-priced government services

Subsidies are also created when governments provide services to private firms at prices that do not recover costs. Statistical, research, and informational services and technical, managerial, and marketing aids are often provided to farmers, small businesses, and various other groups at no charge. Postal rates on some classes of mail may not be remunerative. Transportation industries may receive indirect subsidy in the use of government-financed rights-of-way—highways, airports, airways, waterways, and canals.

Government promotion of housing and home ownership takes a variety of forms, including financing of mortgages at reduced interest rates, provision of publicly owned housing for low-income families at rents below cost, and broadening the availability of credit by insuring or guaranteeing home mortgages. Governments provide agricultural credit to meet emergencies created by crop failure, to finance the purchase and enlargement of farms and farm buildings, and to purchase feed, fertilizer, livestock, and machinery. Favourable loan terms also have been extended to rural electric cooperatives, railroads, and other enterprises characterized by public service.

Tax concessions

Tax exemptions, tax credits, differential tax rates, and other forms of special tax treatment represent another major source of indirect subsidy. Central governments employ their income tax systems to encourage consumer expenditures on housing, health services, charity programs, and education. Systems of business taxation may promote particular industries, particular forms of business and social organization, or specific business practices. The oil-depletion allowance in the United States, for example, has promoted the exploration of oil by permitting firms to deduct more than the actual cost of production in calculating taxable income. Provisions for accelerated depreciation and investment tax credits have stimulated business investment and encouraged improved levels of economic activity. Partial or complete tax exemptions have been used by governments to attract industry, to reward veterans, and to aid the aged and disabled.

Economic effects. Although subsidies are initiated and justified in terms of benefits that inure to the general public, they result in either a higher level of general taxation or higher prices for consumer goods. They may also encourage the preservation of inefficient producers. The test of the desirability of subsidy hinges on a comparison of the public benefits (which are usually diffuse and difficult to measure) with their costs in terms of higher prices, taxes, and inefficiency. In some cases, the public benefits are more illusory than real; and, in cases in which the subsidy is implemented through interference with the price system, it may create inefficiencies that more than offset the gain. When subsidies are not required in order to maintain production or other economic activities at a socially desirable level, they amount to a pure income transfer from the public to the favoured industry. In such instances, subsidies still may be justified on the ground that they may raise the income of subsidized individuals and industries to levels that the community considers desirable. Even in these cases, however, resources that the economy could employ in more productive uses are encouraged to remain in the subsidized industry, where the value of output to the community may be low.

As a general rule, subsidy programs should be so contrived as to eliminate the necessity for their continuation. Failure to adapt subsidy policy to changing circumstances may perpetuate an unnecessary payment and may prevent the most efficient use of resources in the subsidized activities as well as in other types of economic endeavour. Many economists have a preference for direct subsidies. This improves the level of social bookkeeping, creates less confusion in the political process, encourages a more direct comparison between public and private benefits and costs, and minimizes interference in the operation of the price system.

(M.Z.K.)

Sudan, The

The Democratic Republic of the Sudan (Jumhūrīyat as-Sūdān ad-Dīmuqraṭīyah) is the largest African nation. It is bounded on the north by Egypt; on the east by the Red Sea and Ethiopia; on the south by Kenya, Uganda, and Zaire; on the west by the Central African Republic and Chad; and on the northwest by Libya. Its total area of 967,491 square miles (2,505,805 square kilometres) represents more than 8 percent of the African continent and almost 2 percent of the world's total land area. The population is small in relation to the country's size, with an estimated 16,489,000 persons. Khartoum, the national capital, is located in the northern half of the country at the junction of the Blue and White Nile rivers. The name Sudan comes from the ancient Arabic expression *bilād as-sūdān* ("land of the blacks") for the Upper Nile Valley.

An ancient corridor between Egypt and Central Africa, The Sudan is the home of Arabs in the north and black Africans in the south. Its economy is based on pastoralism and subsistence agriculture, and the limited development in commercial agriculture and industry is concentrated in the north. Plagued with political instability since its independence in 1956, the country has no formal constitution. Among its problems, perhaps the most important is that of the unification of its peoples. Successive regimes were unable to placate the fears and suspicions of the southern tribes, and guerrilla warfare continued throughout the south from the 1950s to the early 1970s. Costly in both men and money, the war delayed development in both sections of the country and prevented The Sudan from fulfilling its promise as representative of both the Arab and black African worlds. The settlement ending the war, reached in March 1972 at Addis Ababa, granted the Sudan's southern provinces a certain measure of autonomy.

(For related physical features see NILE RIVER; RED SEA; and SAHARA DESERT. For history see NILOTIC SUDAN, HISTORY OF THE.)

THE LANDSCAPE

Relief features. The Sudan is comprised of an immense plain that is bounded on the west by the Nile–Congo watershed and the highlands of Darfur and on the east by the Ethiopian Highlands and the Red Sea Hills (ʿAtbāy). The plain can be divided into the northern area of rock desert of the Sahara; the western Qawz, an area of undulating sand dunes that merges northward into the rock desert; and the central and southern wedge-shaped clay plain, the centre of which is occupied by an enormous swamp known as as-Sudd.

Three physical regions

The centre of the clay plain is diversified by inselbergs (isolated mountains rising abruptly from the plains), the largest group of which forms the Nuba Mountains (Jibāl an-Nūbah). The volcanic pile of the Jabal Marrah (*jabal*, "mountains" in Arabic) rises out of the Darfur Plateau in the west to altitudes between 3,000 and 10,000 feet above sea level. The mountains form the Nile–Congo watershed and the western boundary of the central plain. Local small plateaus, such as Jabal Maydūb and Boma in Upper Nile province (*mudīrīyah*) in the southeast, are formed by outlines of lava; volcanic craters retain their form in many areas, such as Jabal Marrah, and Maydūb and Bayyūḍah, in Northern province.

The western plain is mainly composed of Nubian sandstones, which form a dissected plateau region with flat-topped mesas and buttes. Along the western frontier, the Erdi Plateau stands at 4,760 feet (1,450 metres), the Wādī Howar Pleateau at 4,170 feet (1,270 metres), and Jabal al-ʿUwaynāt at 2,790 feet (850 metres).

The Red Sea Hills region is an uplifted escarpment. The scarp slope facing the Red Sea forms rugged hills that are deeply incised by streams. The western slope dips more gradually into the plain, with inselbergs, partly drowned in sediments. On the east, the escarpment overlooks a narrow coastal plain that is ten to 25 miles wide and festooned with dunes and coral reefs. Further south the eastern uplands constitute the foothills of the Ethiopian highland massif.

In the south there are two contrasting upland areas. The Ironstone Plateau lies between the Nile–Congo watershed and the southern clay plain; the level country is diversified with inselbergs. On the Uganda border there are massive ranges with peaks rising to more than 10,000 feet. The Imatong Mountains contain Mt. Kinyeti (10,456 feet [3,187 metres]), the highest in The Sudan.

Drainage and soils. The drainage pattern of The Sudan may be divided into the four hydrographic regions: the southeastern perennial streams; the central seasonal watercourses; the northern zone of no surface drainage; and the southern clay plain, where—despite heavy and frequent rainfall—the level surface impedes drainage.

The Nile River

All streams and rivers drain either into or toward the Nile. The White Nile enters the country through rapids at Nimule on the Uganda border. It flows northward as the Baḥr al-Jabal until its confluence with the left-bank tributary of the Baḥr al-Ghazāl, after which it is known as the Baḥr al-Abyad. The White Nile receives most of its water from the right-bank Sobat River, which flows from the Ethiopian Highlands to join the Nile near Malakāl. The main stream loses most of its water in as-Sudd as it flows northward to Khartoum.

Most of the Nile system's waters are brought from Ethiopia by the Blue Nile (al-Baḥr al-Azraq), which rises in Lake Tana and flows south and west to enter The Sudan near Juba, Ethiopia. The river continues northwestward to meet with the White Nile at Khartoum and then flows in a great, curving northward course as the Nile (Nahr an-Nīl).

The land varies from an absence of soils in the extreme north, through a range of arid and semi-arid soils characterized by gypsum, salt, and calcium carbonate, to leached humid soils exhibiting lateritic tendencies (*e.g.*, containing iron oxides and aluminum hydroxide).

The surface of the soilless desert is either bare rock, a mantle of bare waste, or sandy expanses of mobile dunes known as ergs. In the semi-arid zone, the layer of rock waste is slightly modified to form immature soils; in the Qawz region, soils are brownish red and of low fertility. Alluvial soils occur at the desert deltas of the Gash and Barakah rivers, along the two Niles, and in the alluvial plains of rivers radiating from Jabal Marrah.

The alkaline soils of the central and southern plains are heavy cracking clays. The soil of Gezira (al-Jazīrah) plain south of Khartoum is deep-cracking, uniform clay that has been deposited during the annual inundations of the Blue Nile, while the clays of as-Sudd were deposited in the area of impeded drainage. The more steeply sloping plain between Gezira and as-Sudd is an extensive area of cracking clay.

Alkaline soils are also found in the extensive crystalline outcrops of the central plain. The soils of the Ironstone Plateau vary from deep-reddish loams to light soils with a high content of ironstone (a hard rock rich in iron) pebbles. Immature montane soils are found in the Jabal Marrah, the Boma Plateau, and the Imatong Mountains.

Climate. The fundamental climatic factor is the seasonal migration and pulsation of the northern tropical continental air mass and the southern maritime continental air mass, which are divided by the Intertropical Convergence Zone. In winter, the north winds of the tropical air mass blow across The Sudan toward the front, which may be as far south as the Tropic of Capricorn. These winds are relatively cool and dry and bring no rain except when they blow across the Red Sea. By April the front begins to move northward across the country, and moist unstable air of the maritime air mass is drawn in from the South Atlantic Ocean. Central and southern Sudan have rainy seasons the total lengths of which vary according to their latitude.

The Sudan is a hot country, for temperatures are rarely

mitigated by altitude. The central region experiences the highest mean annual temperatures; at Khartoum temperatures of more than 100° F (38° C) can be recorded during any month of the year. The highest temperatures normally occur just before the rainy season.

Rainfall patterns

Rainfall varies from almost nothing in the north to more than 57 inches annually in the extreme south. Along the Red Sea the climate is alleviated by sea breezes, and most of the rain falls during winter. Precipitation usually occurs during the summer in showers or thunderstorms in the afternoon or evening. Dust storms are common in the north, while the rainy season lasts for eight to nine months a year in the south.

Vegetation and animal life. The Sudan includes five main vegetational belts that run from east to west, more or less in coincidence with rainfall patterns. The desert region in the north forms about one-fourth of the total area. It is followed southeastward by semidesert, low- and high-rainfall savanna (grassland) with inland flood plains, and mountain vegetation regions.

Natural vegetation is largely absent because of the effects of centuries of cultivation and grass fires that annually sweep across more than half the country. Further dangers to plant life are the effects of overstocking, soil erosion, the lowering of the water table, and the advance of the desert into the central region.

Wild life includes the lion, leopard, and cheetah as well as the elephant, giraffe, zebra, wild ass, rhinoceros, buffalo, hippopotamus, ibex (a type of wild goat), wild sheep, and numerous antelopes. The chimpanzee, baboon, grivet (a white and green monkey), and colobus monkey are found in the forests. Resident birds include bustards, guinea fowl, several kinds of partridge, geese, cranes, Egyptian vultures, storks, pelicans, plover, weaverbirds, shrikes, and starlings. Thousands of seabirds, waterfowl, and other birds winter in The Sudan during their migration north. Reptiles include the crocodile and various lizards; snakes are not numerous, but eight poisonous varieties are found. Insect life is abundant; the vicinity of rivers and swamps is infested with mosquitoes, seroot flies (large blood-sucking houseflies) are a scourge during the wet months, and scorpions attain eight inches in length. The tsetse fly is found south of latitude 12° N whenever suitable conditions are found.

Traditional regions. The northern Sudan largely corresponds to Northern province (*mudīrīyah*) and includes the narrow ribbon of cultivable land beside the Nile to the Sixth Cataract at Wad Hāmid. The western Sudan includes the entire area of mixed nomadism and peasant agriculture that lies west of the White Nile in Kordofan and Darfur provinces (*mudīrīyāt*). This region is subdivided into the four subregions of western Darfur, the Qawz sands, the semidesert, and the Nuba Mountains. The central clay plains area roughly corresponds to Blue Nile province and the southern extent of Kassala province.

Most of Kassala province falls in the eastern Sudan, which is generally devoted to nomadism, but includes the irrigated deltas of the Gash and Baraka rivers. The southern clay plains area includes all of the heavy clay soil subject to flooding in the Upper Nile basin. Throughout the region the sources of livelihood are cattle raising, agriculture, and fishing. The Ironstone Plateau and the southern hills region is comprised of the area between the Upper Nile basin and the Nile–Congo watershed, the large hill masses east of the Nile in Equatoria province, and the arid hills and plains of the southeast.

The landscape under human settlement. Rural settlement is invariably clustered because of problems of water supply, especially during the dry months. Along the northern Nile villages are often linear and run parallel to the river. In the extreme south, however, dispersed settlement is favoured.

House types vary from north to south. In the north, flat-topped roofs and sun-dried bricks daubed with clay prevail, while, in the central and southern regions, round huts are built with thatched conical roofs made of grass, millet stalks, and wood poles. In the central region, compounds of buildings are often surrounded by walls made of millet stalks.

Towns are few and widely scattered; only 10 percent of the population can be considered urban. The prime function of the town is undoubtedly administrative rather than commercial. Each of the three southern provinces of Bahr el-Ghazal, Upper Nile, and Equatoria has one major town of between 10,000 and 15,000 inhabitants and no other settlement of comparable size. Urbanization is slightly more advanced in Kordofan and Darfur provinces, where trade is more highly developed. The urban proportion of 11 percent of the total population of Northern province is attributed to ʿAṭbarah, the administrative centre that contains the main workshops of Sudan Railways. The high proportion of 16 percent urban population in Kassala province is caused by Port Sudan, The Sudan's only outlet to the sea and the numerous towns in the cotton-growing deltas of the Gash and Barakah rivers. In Blue Nile province the proportion of urban population is low—7 percent. With few exceptions all towns lie along one of the Niles, because a permanent water supply is necessary in a region of few wells and little surface drainage.

The Three Towns

Khartoum, the smallest of the provinces, contains the Three Towns of Khartoum (population 300,000), Omdurman (289,000), and Khartoum North (149,000). Khartoum was founded on a defensive site by the Egyptians in 1824. As the seat of the government and higher education and the centre of commercial and industrial undertakings, it is firmly established as the centre of power in the country. Omdurman contrasts with Khartoum in being more traditionally Sudanese than Khartoum, which is Arabized. Khartoum North has a more functional atmosphere because of its new light-industrial area.

The Sudan, Area and Population

	area		population	
	sq mi	sq km	1956 census	1972 estimate
Provinces (*mudīrīyāt*)				
Bahr el-Ghazal (Baḥr al-Ghazāl)	82,529	213,751	991,000	1,537,000
Blue Nile (an-Nīl al-Azraq)	54,879	142,138	2,070,000	3,398,000
Darfur (Dārfūr)	191,648	496,369	1,329,000	1,825,000
Equatoria (al-Istiwāʾīyah)	76,495	198,121	904,000	1,403,000

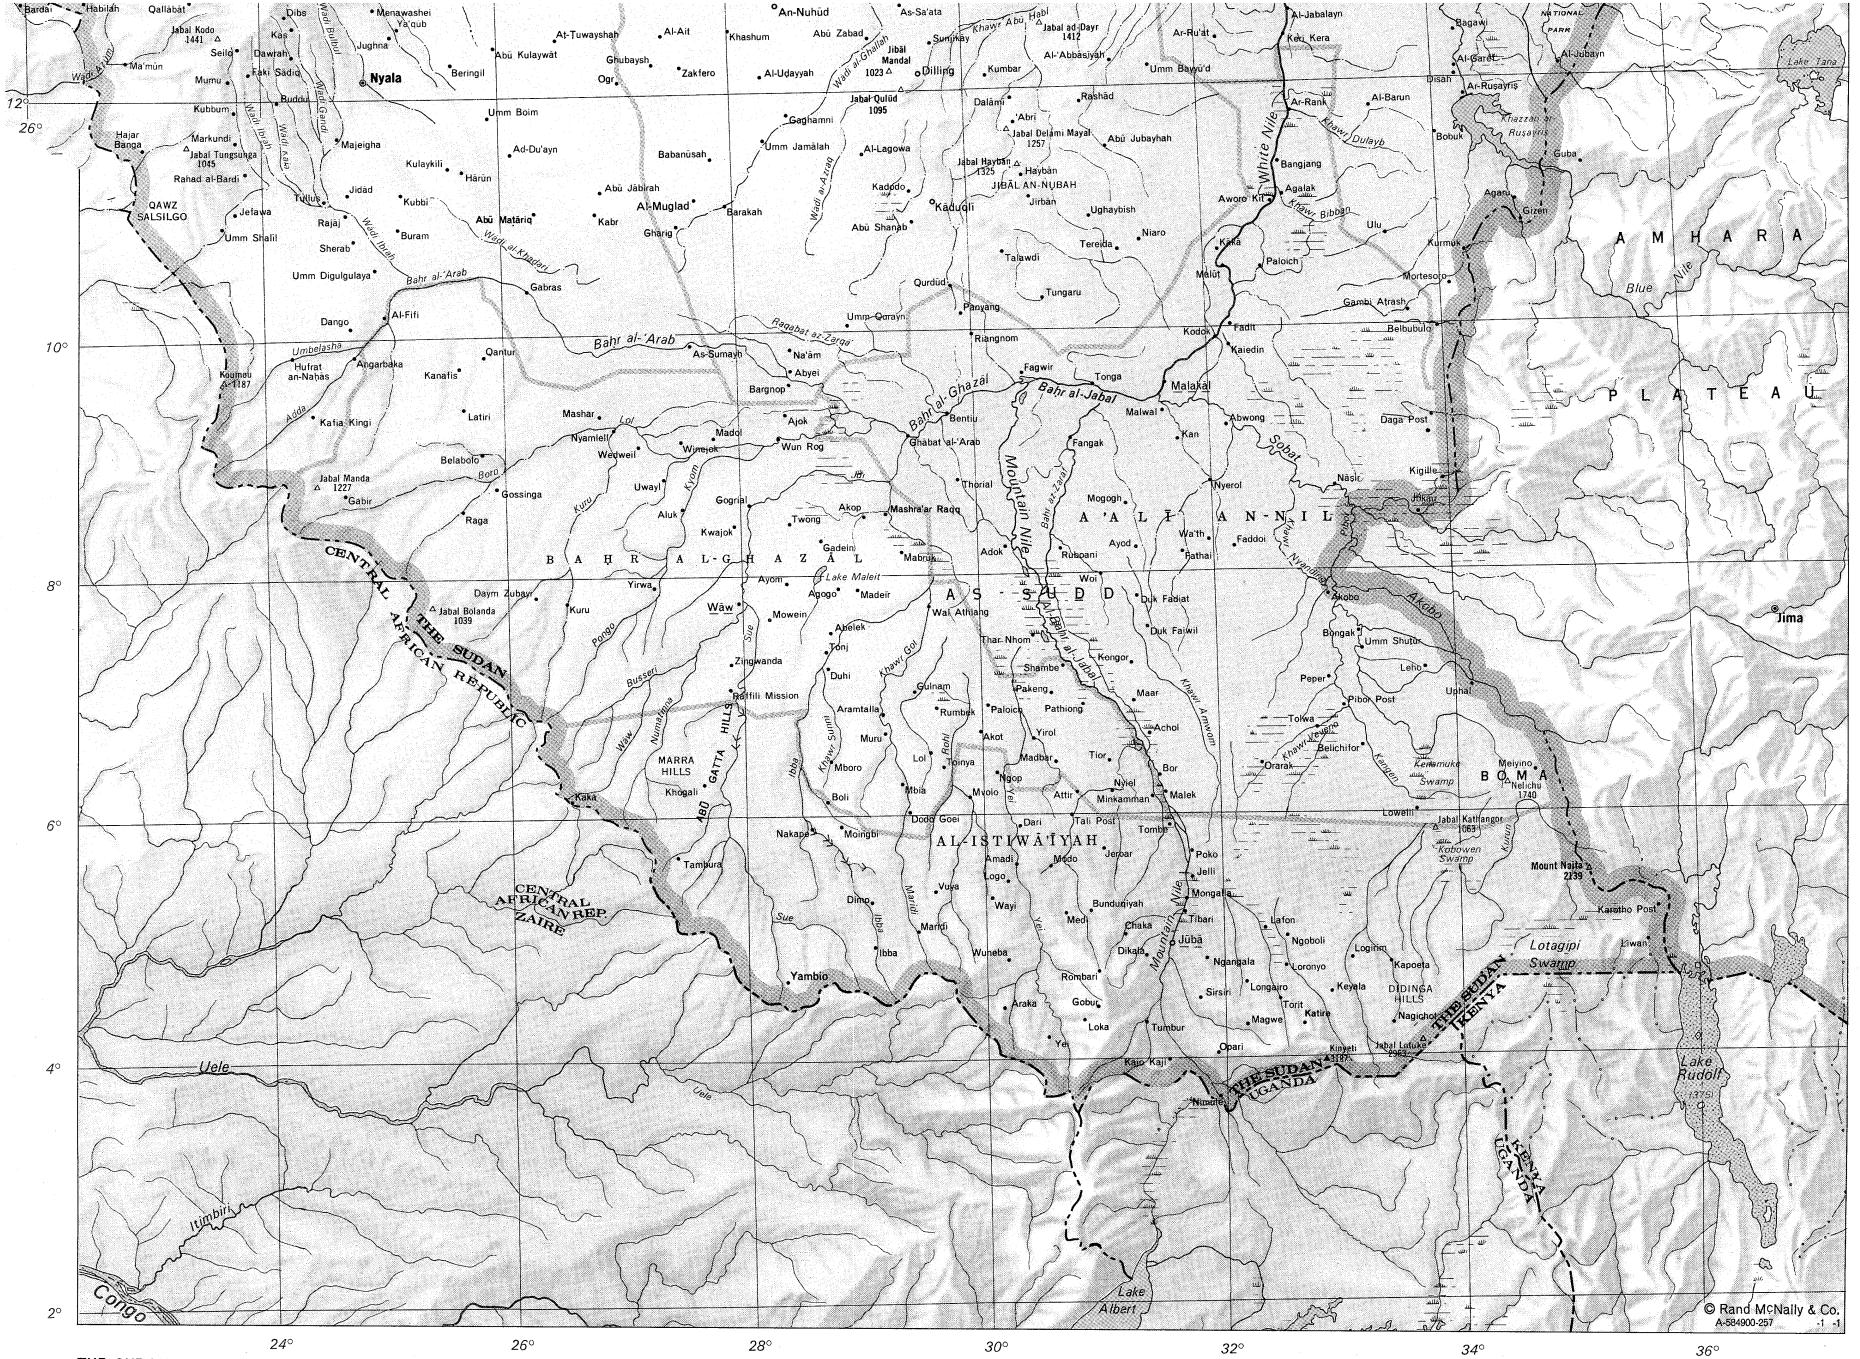
PEOPLE AND POPULATION



Population groups. The northern Sudan is predominantly Muslim, and its people speak Arabic, the official language. Although commonly called Arabs, the people are of mixed Arab, Hamitic, and Negro ancestry. The actual infusion of Arab blood may be slight, but almost all northern Sudanese are agreed on the acceptance of the Arabic cultural heritage. Discernible ethnic groups include the Arabs, the Nubians, the Beja, and the black Funj (Fung), Nuba, and tribes of the Darfur regions.

The Nubians are the dominant element of the population of the northern Nile. The inhabitants of the Halfa district and Dunqulah as far south as ad-Dabbah speak the Nubian language, although most Nubians speak Arabic. Situated astride the Nile corridor linking Egypt with The Sudan, the ancient Nubian kingdom was the country's historic avenue of contact with the Mediterranean world.

The ancestors of the Beja, a Hamitic group of cattle owners, arrived in the eastern Sudan between 4000 and 2500 BC. They are remarkably similar to predynastic Egyptians but have an admixture of Arab and Negro blood. The Beja are unique among the northern peoples because their language has survived Arabization.

The principal Arab migrations into The Sudan from the north and east began in the 14th century and continued spasmodically until the 19th century. The Arabs occupy most of the fertile lands along the Nile and constitute the

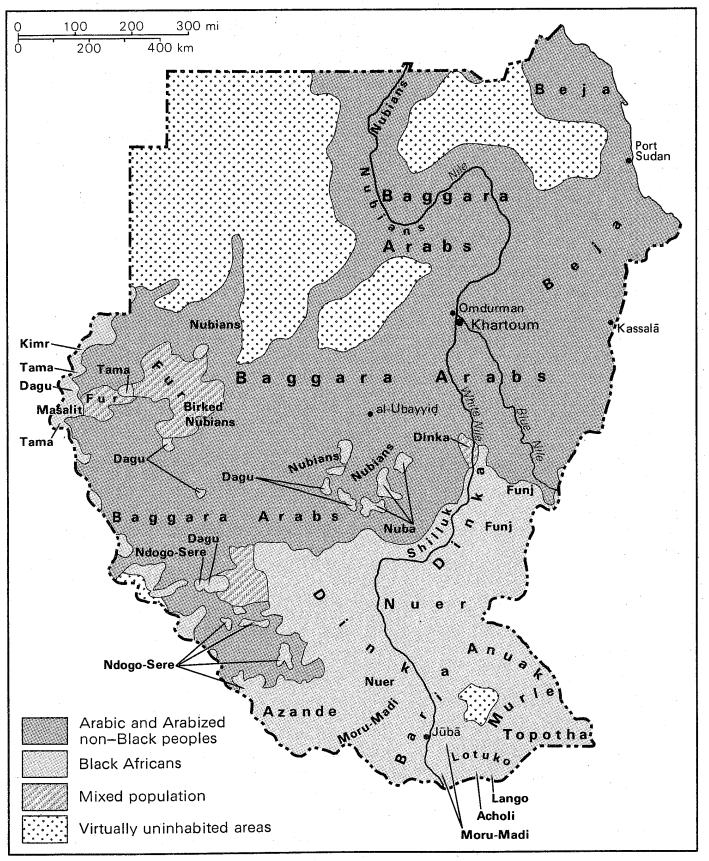
greater part of the nomads of northern and central Sudan.



The black African peoples

Of the black northern peoples, the Funj inhabit the land on either side of the Blue Nile upstream of Sannār; the Nuba, who are probably related to groups that stretch toward West Africa, are found in northern Kordofan province; and the Fur, Daju, Beigo, Birked, Masalit, Gimira, and Tama occupy central Darfur province.

The Nilotes of southern Sudan include the Dinka, Nuer, Shilluk, Anuak, Acholi, and Lango. All are conspicuous for their absorbing interest in cattle, which enters widely into their customs and traditions. The Nilo-Hamitic people, including the Bari, Lotuko, Taposa, and Murle, are by tradition cattle owners and, like the Nilotes, are to be found both within and beyond the borders of The Sudan. The tribes of the southwest belong to the eastern Sudanic linguistic group. They include the Azande, the Ndogo-Sere, the Moru-Madi, and the Bango-Baka.

The southern peoples speak their individual tribal languages. Although attempts have been made to establish Arabic as a lingua franca, it is used only in the towns.

Islām is the religion of the Arabs and Arabized peoples of the north; it provides a common cultural basis and unifies social and political ideas. In the south the majority hold to a multiplicity of animist religions, while a small percentage have converted to Roman Catholicism and Protestantism.

General ethnic composition of The Sudan.

Demography. About 90 percent of the population of 16,489,000 lives in rural areas, with an average population density of 17 persons per square mile. The population is concentrated along the Nile and its tributaries, with the highest densities occurring in Khartoum (117 per square mile) and Blue Nile (62 per square mile) provinces. It is a young nation, with almost half the population under 15 years of age and less than 4 percent over 60 years. A joint study of the 1955 census by the Sudanese government and the United Nations revealed that there were about 52 births per 1,000 population and 24 deaths per 1,000, with a natural increase of 28 per 1,000 in that year. It is believed that improved medical facilities since then have resulted in a lower death rate and a higher rate of natural increase. The United Nations estimate for the period of 1965–70 had indicated a birth rate of 49 per thousand, a death rate of 18 per thousand, and a natural increase rate of 31 per thousand. Life expectancy at birth is 48 years of age.

Since the mid-1950s there has been significant emigration from the south in response to the civil war. The United Nations estimated about 180,000 Sudanese refugees in the Central African Republic, Zaire, Ethiopia, and Uganda. It is possible that there are actually about 500,000 refugees, most of whom have been absorbed into their host countries and have not been officially counted. Further dislocation was caused by the government's peace villages; southern Sudanese were moved from contested areas or areas of suspected guerrilla activity to villages guarded by the army. Eight months after the end of the war it was estimated that 250,000 refugees had returned from surrounding countries.

In 1955 immigration amounted to only 249,000 persons, or less than 3 percent of the population. Aliens are concentrated in Kassala, Blue Nile, Kordofan, and Khartoum provinces. They are comprised mainly of West Africans in the south and Egyptians, Asians, and Ethiopians in the north. (M.e.D.S.)

THE NATIONAL ECONOMY

Mineral potential

The extent and distribution of resources. The Sudan is believed to be rich in mineral resources, although it has not been adequately surveyed. There are small quantities of iron ore near the Red Sea, deposits of gold, manganese, chromite, quartz, and marble and reserves of copper in Darfur province, and asbestos near al-Qaḍārif. The search for oil and natural gas has so far been unfruitful, but there is mild optimism concerning offshore oil deposits in the Red Sea. Mining is conducted on a small scale and contributes little to the overall economy.

There is a great potential for the generation of hydroelectric power from the Nile River system. Thermal resources are limited because of the inaccessibility of the southern forests and the lack of coal or oil.

Sources of national income. About one third of the gross domestic product is created in agriculture. The main crops of cotton, durra (common millet), *dukhn* (bulrush millet), sorghum, peanuts (groundnuts), sesame, maize (corn), wheat, and castor are raised on land that is either rain fed (three-fourths of the cultivated area), irrigated, or subjected to flooding. The amount of rain-fed and flooded land varies greatly annually, but irrigation is gradually being extended and irrigated land doubled between 1960 and 1970. The irrigated areas in the north and east produce the bulk of the commercial crops; they are centred on the Gezira Scheme (al-Jazīrah)—with its Mangil extension—between the Blue and White Niles south of Khartoum and the Gash and Baraka deltas. Further irrigation is provided by the Khashm al-Qirbah Dam on the 'Aṭbarah River, which in 1972 irrigated 470,000 acres (190,000 hectares); ar-Ruṣayriṣ Dam, completed in the 1960s was expected in the early 1970s to provide irrigation water for the Rahad Scheme, consisting of some 310,000 acres to the east of the Blue Nile. Smaller irrigation schemes also obtain water from

ar-Ruṣayriṣ. Parts of the rain-fed areas are mechanized, and some irrigation is carried out by use of pumps. Crop production varies annually because of changes in weather conditions and the incidence of pest attacks, of which grasshoppers and desert locusts are the most virulent.

The Gezira Scheme

Cotton is the major cash crop; it provides the country with about 60 percent of its total earnings of foreign exchange. The bulk of the cotton crop is produced on the irrigation schemes of Gezira and its extensions, and future expansions in the irrigated area promise considerable increases in production. In the early 1970s production accounted for about 2 percent of the world's cotton. The Sudan's importance in the world cotton market, however, derives from the fact that the country produces between 40 and 45 percent of the total world production of extra-long-staple cotton (*i.e.*, one and three-eighths of an inch or longer). Less than 1 percent of the crop is used domestically. Cotton production is substantially nationalized through The Sudan Gezira Board, which is responsible for the operation of the Gezira Scheme. Profits are shared among the government, which owns and irrigates the land; the tenant farmers; the Board; local governments; and the Social Development Fund, which provides services to the tenants.

Although extensive areas are potentially suited for growing vast quantities of fruit and vegetables, production is limited mainly to the north and east. Important fruits include dates, mangoes, guavas, citrus fruits, and bananas; the most important vegetable crop is onions. Tobacco is raised in Darfur provinces. Commercial agriculture is undeveloped in the three southern provinces, where most farms are self-sufficient and some produce is sold in local markets. The civil war greatly disrupted farm production.

Livestock is ubiquitous. Camels, sheep, and goats are kept in the north and west, and cattle are raised in the central region and the south. There is some export of animals, hides, and skins, but most livestock is raised for local use.

The Sudan is the world's largest producer of gum arabic, a water-soluble gum obtained from acacia trees and used in the production of adhesives, candy, and pharmaceuticals. The southern forests yield hardwood timber such as mahogany and *sant* (a type of acacia) and softwoods, and there are sawmills near Wāw, Loka, and Katire. The northern woodlands have been deforested by the extraction of wood for fuel and charcoal.

The Nile rivers are an important source of fish, especially Nile perch. Most of the catch is consumed locally. Significant quantities of fish and shellfish are believed to be produced from the Red Sea.

Manufacturing

The manufacturing industry, which is concentrated in the three towns, contributed about 9 percent of the gross domestic product in 1969. Manufacturers include cement, petroleum products, ginned cotton, textiles, leather and footwear, and processed foods. Most factories operate well below full capacity, and low incomes have depressed demand. A considerable part of large-scale manufacturing production takes place in the public sector. The Industrial Development Corporation controls and administers government-owned factories that produce sugar, cardboard, and processed foods. The government tannery processes skins from government-owned and administered slaughtering houses.

In 1970 The Sudan had an installed electrical capacity of about 117,000 kilowatts. The Sannār Dam supplies electricity to Gezira (al-Jazīrah) and Khartoum, and hydroelectric dams have also been built at Khashm al-Qirbah on the ʿAṭbarah River and ar-Ruṣayriṣ on the Blue Nile.

All banks operating in The Sudan were nationalized in 1970. The Bank of Sudan issues all currency and acts as banker to the government. It also holds bilateral trade accounts on behalf of the government and supervises the operations of the seven commercial banks. The Agricultural Bank and the Industrial Bank provide development funds and credit. There are also more than 40 insurance companies. The banking system is geared primarily to the finance of foreign trade and especially the cotton trade.

The Sudan suffers from a chronic unfavourable balance of trade and a growing national debt. Most foreign exchange is earned from cotton, which accounts for more than half of total exports. Other exports include gum arabic, oil seeds, and livestock products. Imports consist largely of manufactured goods, such as textiles, machinery, vehicles, petroleum products, and iron and steel. The most important trading partners are members of the European Economic Community, India, Japan, and Egypt. China and the Soviet Union became substantial trading partners after 1967.

The government's economic role

Management of the economy. All major economic units, whether in agriculture, mining, or manufacturing, are owned or operated by the government. The private sector consists largely of subsistence activities, mainly in farming and pastoralism, but also includes small-scale industry and services. The middle income group is limited, and entrepreneurship is scarce. The central government plays an important economic role through direct participation, such as the Gezira Scheme, and fiscal policy. Traditionally, the government aimed at budgeting for a small surplus that was used, together with foreign assistance, to finance economic development. Since the mid-1960s, however, the government has engaged in deficit finance and has borrowed large sums from the banking system. This has resulted in a decline of private initiative in internal trade, exports, and medium-scale industry.

Little government revenue is raised by direct taxation, while indirect taxes, such as those on imports and excise and consumption duties, provide half the revenue. Other revenue is derived from government monopoly profits on sugar, tea, coffee, and salt and proprietary receipts from agricultural and other schemes.

The smallness of the industrial sector and the predominance of rural life have tended to constrain the development of workers' and employers' associations. In 1958 all trade unions were dissolved but were permitted to function again in 1961 within limits prescribed by legislation. There are trade unions representing the workers in government ministries, the Sudan Railways, the Central Electricity and Water Administration, and other bodies. Unions normally are affiliated to the three central federations of the Sudanese Workers' Union, the Federation of Workers' Trade Unions in the Private Sector, and the Federation of Workers' Trade Unions of the Public Sector. Political activity by trade unions is discouraged.

Leading businessmen are members of the Sudan Chamber of Commerce, and an important pressure group is the Gezira Tenants' Association, which attempts to promote the tenants' interests as opposed to those of the Sudan Gezira Board.

A five-year plan was declared in 1970. The plan did not make special provisions for the development of the south, but emphasized the development of agriculture and livestock as well as transport and communications. Instead of the average annual growth rate of the gross domestic product of 5 percent realized in the period between 1965 and 1970, the planned growth rate for 1970 to 1975 was set at 8 percent per annum. Development was to be funded both by government revenues and foreign loans.

Since 1969 the government has leaned heavily on Socialist principles, but its intentions to federate with Egypt, Syria, and Libya have been impeded by troubles in the southern Sudan. Government intervention in the economy is likely to grow, and the activities of the private sector and the trade unions is likely to be drastically curtailed. Given political stability, the immense resources with which the country is endowed are capable of being translated into considerable economic growth over the long term. (E.I.U.)

Transport. The transport system is underdeveloped and represents a serious constraint on economic growth. The country's vast area and the availability of only one outlet to the sea throw a heavy burden on the limited facilities and especially on the government-owned Sudan Railways, which handles almost all foreign trade and employs about one-fifth of all wage earners.

There are almost 3,400 track route miles of railways

The railway network

throughout the country. The main line runs north from al-Ubbayyiḍ (el-Obeid) via Khartoum to Lake Nasser and the submerged terminal of Wādī Ḥalfā. There are branch lines from Sannār and ʿAṭbarah to Port Sudan and from Sannār to ar-Ruṣayriṣ. There is also a westward extension from al-Ubbayyiḍ to Nyala with a branch line south to Wāw. In the early 1970s, extensions were planned to Jūbā, Aswān, Egypt, and al-Junaynah (in the extreme west of Darfur province); another line will eventually reach from al-Junaynah across Chad to northern Nigeria.

There are more than 6,500 miles of roads. In the north, roads are generally motorable, unimproved tracks except in the towns, and they are impassable after rain. There are several gravelled all-weather roads in the south, where other roads, including the through route from Jūbā to Khartoum, are impassable during the rainy season. In the early 1970s all-weather paved roads were planned to link The Sudan with the Red Sea (at Port Sudan), Ethiopia, Egypt, and Libya.

There are more than 2,300 miles of navigable waterways. The White Nile and the Baḥr al-Ghazal are navigable throughout the year. The Jur and Sobat rivers are seasonal. The Blue Nile is not navigable, and the Nile below Khartoum is only navigable in short stretches because it is broken by cataracts. The government operates steamer services on the White Nile between Kūstī and Jūbā and on the main Nile between Wādī Ḥalfā and Aswān and between Marawī and Kuraymah.

Port Sudan, 850 miles south of Suez, Egypt, is the country's main port on the Red Sea. Minor ports include Sawākin, Trinkitat, and ʿAqīq.

The government-owned Sudan Airways operates domestic and international services from the main airport at Khartoum.

ADMINISTRATION AND SOCIAL CONDITIONS

The government. By December 1972 The Sudan still had no formal constitution. After the military coup d'etat of 1969 the Constituent Assembly and Supreme Council were abolished and the provisional constitution suspended. In 1971 legislative, judicial, and executive powers were vested in the president, Major General Gaafar al-Nimeiry, who was also commander of the armed forces. In January 1972 the Sudanese Socialist Union approved the establishment of a Sudanese People's Assembly and approved a draft permanent constitution that was to be amended and endorsed by the People's Assembly upon its creation. The proposed Sudanese People's Assembly was to consist of 207 members, of whom 32 members were to be appointed by President al-Nimeiry and the rest elected by popular vote. The election of members of the Sudanese People's Assembly took place during September–October of that year. The new government, headed by Prime Minister (former President) al-Nimeiry, was announced in October 1972, and the Assembly opened later the same month. Their first task was the drafting of a new constitution embodying the agreements reached in the peace settlement of March 1972.

Local government

Local government was reorganized in 1971 to increase the power and functions of local councils. The country is divided into nine provinces, each headed by a Province Popular Executive Council. The provincial councils are chaired by the governor of the province, who is appointed by the Council of Ministers on recommendation of the Minister of Local Government. The membership is comprised of a two-thirds majority of members elected by the rural and town councils and of representatives of the central government. Beneath the provincial councils are subregional councils and rural and town councils. Their membership is also comprised of central government officials and members elected by functional organizations such as village development committees and trade unions. The smallest political units—village and block councils—are comprised only of directly elected members.

Coordination of local government activities is the responsibility of the provincial councils. The central government appropriates funds to the provincial councils, which then distribute the funds and powers to the local administrative organs.

In 1972 the Southern Region, comprised of Bahr el-Ghazal, Equatoria, and Upper Nile provinces, was established with its capital at Jūbā. It was granted limited self-government within the national structure. The People's Regional Assembly was created as the legislative body, its members elected by direct, secret ballot. The High Executive Council, appointed by the president, was formed as the administrative body and was charged with the establishment of a civil service in the south. Although the agreement establishing the southern government was ratified by representatives of both the north and south, some of its provisions were disputed by some southern guerrilla leaders.

All political parties were banned in 1969. Two years later, however, the Sudan Socialist Union was established as the country's only party. Its structure is comprised of a National Congress, Executive Committee, and Supreme Polit Bureau on the national level (all three chaired by the president); provincial assemblies; and basic units in the villages and towns. Ancillary organizations include the May Youth Corps and the Socialist Sudanese Women's Association. Membership to the union is open to all those over 18 years of age who are loyal to the revolutionary government.

Civil justice is administered through the High Court of Justice in Khartoum, province courts, and district judges. There is a body of civil law; where there is no special enactment, cases are decided according to "justice, equity, and good conscience." The criminal code is based upon the Indian Penal Code and is dispensed in major, minor, and magistrate's courts. There are also people's courts that try a substantial proportion of civil and criminal cases in accordance with popular custom. Muslims are subject to the Sharīʿah, the religious law of Islām in questions of inheritance, marriage, divorce, family relationship, and charitable trusts.

The armed forces have been greatly expanded since 1969, and the military's political role has been defined through the Sudan Socialist Union. In the early 1970s, the forces consisted of a 35,000-man army, a 600-man navy, and a 1,500-man air force. There were also 3,000 men in the paramilitary national guard and border police. As part of the agreement ending the civil war in 1972, a southern command of the army was to be formed; it would consist of 12,000 men, one-half of whom would be from the southern provinces.

Educational services

Administrative services. In the Muslim areas of the north, boys have long been instructed in religious subjects according to traditional methods. Primary education was begun in the northern Sudan after 1898, and secondary education commenced in 1913. Postsecondary schools in arts and science, agriculture, veterinary science, engineering, and law were established between 1938 and 1941. In 1947 these schools were brought together within Gordon Memorial College, which was linked in special relationship with the University of London until 1959. Education in medicine began in 1924 with the foundation of the Kitchener School of Medicine, which in 1951 was united with Gordon Memorial College in the University College of Khartoum. In 1956 University College became the University of Khartoum.

In the south, Christian missionaries were responsible for education until 1957, when the government assumed direct control. As a result, Arabic was given greater prominence in the curriculum, but education was to suffer severely from the civil war. There have been no formal schools since they were closed in 1962. During the war, education was offered in English and vernacular languages in bush schools that operated in areas controlled by the Anya-nya, the rebel army.

In 1970 the government instituted a new four-tiered educational system. It consists of a six-year primary level, a three-year general secondary level, a three-year level of either higher secondary or vocational, technical, and teacher-training programs, and three or more years of higher education. In addition, the government has instituted a special program to combat the country's high illiteracy rate of 81 percent in the early 1970s. The *maʿhad ʿilmī* in the mosque at Omdurman, attended by pupils from

Muslim areas, provides theological education and trains religious leaders (*'ulamā'*) and lawyers (*qāḍīs*). The principal centre for the training of intermediate school teachers is the Institute of Education at Bakht ar-Ruda near ad-Duwaym for men and at Omdurman for women. Secondary school teachers are trained at a Higher Institute for Teacher Training at Omdurman.

The University of Khartoum has faculties of agriculture, arts, science, economics and social studies, engineering and architecture, law, medicine, veterinary science, pharmacy, and extramural studies. English is the medium of instruction in the university and the secondary schools, but it is being replaced by Arabic in the latter. A branch of Cairo University in Khartoum provides evening classes in arts, law, commerce, and economy that are conducted in Arabic. The Khartoum Polytechnic Institute was founded in 1950.

Early in the 20th century The Sudan was reputed to be unhealthy, and epidemics of sleeping sickness, cerebrospinal meningitis, and yellow fever were frequent. The progress of medical and sanitary services under the Sudan Medical Service (later the Ministry of Health), supplemented in many places by missionary institutions, has reduced mortality. By the early 1970s there were almost 100 government hospitals of different grades and about 100 health centres located in all important areas. Rural areas were served by more than 1,600 dispensaries and dressing stations under medical assistants. There are doctors in private practice in the larger towns and a rural midwife service.

Towns are planned so that there are separate first-, second-, and third-class residential areas, as well as commercial and industrial zones. Buildings must be erected in conformity with regulations such as those governing the materials to be used and the number of stories. Outside the limits of towns are *deims* (Arabic: *admās*), where unregulated houses may be erected. In rural areas where the population is sedentary, housing conforms to tribal customs, while nomads occupy tents.

The Sudan Police Force, under the authority of the Ministry of the Interior, is responsible for the policing of the entire country. Its duties include internal security, criminal investigation, and the administration of passport migration, nationality, and alien registration. There are also several police reserve companies that are specially trained on quasi-military lines.

Social conditions. In 1964 more than half of the total labour force was engaged in agriculture, forestry, and fishing. Income is higher in urban and semi-urban areas than in the larger rural sector. In industry, commerce, and public administration there is legislation to cover employment exchanges, conditions of employment in factories and in domestic service, and workmen's compensation. Under legislation applying to cooperative societies, many such bodies have been registered, of which about 150 are agricultural and more than 100 are for marketing and credit.

Social and economic divisions

The greatest social and economic divisions are those between the north and the three southern provinces, which can be traced to British administrative policy under the Anglo-Egyptian Condominium of 1899 to 1955. Until 1946 the British government administered the southern provinces separately from the north because of the ethnic and linguistic differences between the peoples of the two areas. Because it was of easier access, the Islāmic north underwent economic and educational advances, while the south continued its traditional existence. Christian missionaries were allowed to operate in the south, where Arab traders and educators were banned. After 1946 this policy was amended and the two areas were treated as one unit; independence was granted in 1956 to the whole region as one nation.

The creation of one political state has not erased the historic differences between the regions. The southern peoples have long feared the Muslim north, and there was guerrilla activity against the national government from 1955 until the signing of a ceasefire in 1972. The war wreaked havoc in the south, and between 500,000 and 1,000,000 southerners were killed in the fighting. The rebel movement was divided between those who desired regional autonomy, federation, or independence, and it was feared that the agreements of 1972 would not be wholly acceptable to the rebel leaders.

CULTURAL LIFE

The Sudan is part of both Arab and black Africa and has a dual cultural heritage. The way of life is similar in both areas—most of the population in the north and the south are pastoralists—but history has exacerbated differences of race, religion, and language. The Islāmic Arabs were long slave traders who preyed upon the animist southern tribes. Fear of the northerners as slavers has been replaced by the fear of cultural assimilation. Although denied by the government, it is believed by many southerners that Islām and Arabic will be forced upon the southern tribes in a drive to create a wholly Arab state. If these suspicions can be ameliorated by the formation of the semi-independent Southern Region, it will be possible to create a nation in which both cultural traditions thrive.

Cultural institutions. Most cultural institutions are centred in Khartoum, where learned societies such as the Antiquities Service, the Educational Documentation Centre, and the Industrial Research Institute—as well as the British Council and the Soviet Cultural Centre—are located. Libraries in Khartoum are connected to educational institutes, and there is a public library in Omdurman and a research library of the Ministry of Agriculture in Wad Madanī. Museums include the Ethnographical Museum and the Sudan Museum in Khartoum, the Marawī Museum, with exhibits of antiquities in Marawī (Merowe), the archaeological Shaykhan Museum in al-Ubbayyiḍ, and the Sudan Natural History Museum, affiliated with the University of Khartoum.

Press and broadcasting. The government-controlled Sudan Broadcasting Service broadcasts daily radio programs in Arabic and English. Programs intended for the southern provinces are aired in the vernacular languages. A weekly half-hour program is also broadcast in Somali, and it is planned to greatly extend external broadcasting by 1975. The Sudan Television Service offers daily service to the Three Towns area from its station at Omdurman. In the early 1970s service was being extended north to 'Aṭbarah and south to the entire Gezira region.

The press was nationalized in 1970 and its ownership and supervision transferred to the Sudan Socialist Union. There are two Arabic daily newspapers, two Arabic weeklies, and one English weekly. The Ministry of Information publishes a weekly broadcasting magazine, a monthly cultural magazine, and daily bulletins for the press and embassies. There is also a weekly magazine aimed at youth movement.

PROSPECTS FOR THE FUTURE

The Sudan's future economic development is dependent upon cotton. The great extent of the country has also need for a resolution of internal political problems, which have diverted energies and resources needed for development, and the necessity for evolving a more balanced economy by reducing the degree of dependence upon cotton. The great extent of the country has also inhibited the rapid development of an effective transportation network. It is hoped, however, that in the years ahead the transportation problem will progressively be overcome. For example, if The Sudan's railway system should be linked with that of Nigeria through Chad, a trans-African railroad running from Lagos in Nigeria to Port Sudan on the Red Sea would come into existence.

Suez Canal

The Suez Canal (Qanāt as-Suways) a sea-level waterway across the Isthmus of Suez in the Arab Republic of Egypt connecting the Mediterranean and the Red seas, for almost 100 years until its closing by the Arab-Israeli War of June 1967, provided the shortest maritime route between Europe and the lands lying around the Indian and western Pacific oceans and was one of the world's most heavily used shipping lanes. The canal extends 100 miles (160 kilometres) between Port Said (Būr Saʿīd) in the north and Suez in the south, with dredged approach channels north of Port Said into the Mediterranean, and south of Suez. The canal does not take the shortest route across the Isthmus, which is only 75 miles, but utilizes three intervening lakes, from north to south, Buḥayrat al-Manzilah (Lake Menzala), Buḥayrat at-Timsāh (Lake Timseh), and al-Buḥayrāt al-Murrah (the Bitter Lakes). It is an open cut, without locks, and, though extensive straight lengths occur, there are eight major bends. To the west of the canal lies the low-lying delta of the Nile; to the east is the higher, rugged, and arid Sinai Peninsula. Prior to construction of the canal, completed in 1869, the only important pre-existing settlement was Suez, which in 1859 had about 3,000 inhabitants, the rest of the towns along its banks having grown up since, with the possible exception of al-Qanṭarah, which was a tiny village. The name Suez is held to derive from Qolzuom, the pharaonic name of the settlement. This became Arabicized into Suways, originally translated by the French as Souyès. Classical writers, Herodotus especially, rendered the original name as Clysma.

Physical description. *Geology.* The Isthmus of Suez, the sole land bridge between Africa and Asia, is of recent geological origin. Both continents, it would appear, once formed a single large continental mass, but during Tertiary times (about 2,500,000 to 65,000,000 years ago) the great fault structures of the Red Sea and Gulf of Aqaba developed, with the subsequent drowning of the Red Sea trough and its prolongation as far as the Gulf of Suez. In the succeeding Quaternary Era, there was considerable oscillation of sea level leading to marine erosion in the southeast Mediterranean and, finally, transgression by the Mediterranean far to the south, thus linking the two seas. Later uplift led to the emergence of a low-lying isthmus bounded to the east and southwest by higher plateau formations and narrow in the south but broadening northwards to a very low-lying open coastal plain. There, the Nile Delta once extended further east (as a result of periods of abundant rainfall coincident with the Pleistocene Epoch, or Ice Age), and two former river arms, or distributaries, crossed the northern isthmus, one branch reaching the Mediterranean at the narrowest

The Suez Canal.

point of the Isthmus and the other entering the sea some nine miles east of present Port Said. Topographically, the Isthmus is not uniform; there are three shallow, water-filled depressions—al-Manzilah, at-Timsāh, and the Bitter Lakes, these last distinguished as Great and Little though they form one continuous sheet of water. Between these lake depressions are east–west aligned ridges: Jisr al-Jīr north of at-Timsāh, Serapium between at-Timsāh and the Bitter Lakes, and Jabal ash-Shallūfah between Little Bitter Lake and the Gulf of Suez. A number of more resistant bands of limestone and gypsum obtrude in the south of the Isthmus, and another significant feature

is a narrow valley (aṭ-Ṭumaylāt) leading from Buḥayrat at-Timsāh southwestward toward the middle Nile Delta and Cairo. The Isthmus is composed of marine sediments, coarser sands, and gravels deposited in the early periods of abundant rainfall, Nile alluvium (especially to the north), and wind-blown sands.

Original size of the canal

The canal. When first opened in 1869, the canal consisted of a channel with a depth of barely 20 feet (six metres), 72 feet (22 metres) wide at the bottom, and 190 feet (58 metres) wide at the surface. Passing bays, 1,000 to 1,500 feet long and 16 feet wide were built, as far as possible, every 16 miles. Construction involved the excavation and dredging of 97,000,000 cubic yards of sediments. Between 1870 and 1884 some 3,000 groundings of ships had occurred as results of the narrowness and tortuousness of the channel. Major improvements began in 1876, and, after successive widenings and deepenings at the time the canal was closed by the Arab–Israeli war in June 1967, it had a minimum width of 179 feet and an uninterrupted depth of almost 40 feet at low tide; passing bays had been greatly enlarged and new bays constructed; bypasses were made in the Bitter Lakes and at al-Ballāḥ; stone or cement cladding and steel piling for bank protection had been almost entirely completed in areas particularly liable to erosion; tanker anchorages were deepened in Buḥayrat at-Timsāh; the new berths were dug at Port Said to facilitate grouping of ships in convoy. During 1964 plans had been made to deepen the canal to 60 feet and double its width by 1975, but these, never realized, have since been supplanted by further plans to accommodate supertankers (see below *Present situation and future prospects*).

Operation. In 1870, the canal's first full year of operation, there were 486 transits, or fewer than two per day. In 1966–67 there were 20,326, an average of 56 per day, with net tonnage increasing from 437,000 (1870) to 267,000,000. Originally, passing involved one ship entering a siding and stopping, but after 1947 a system of convoys was adopted. Transit time at first averaged 40 hours; by 1939 it was 13, but as traffic increased after 1942 it went up to 15 hours in 1967 despite convoying, suggesting that the canal was operating at near capacity. Convoys left twice daily, passing at Kabrit and al-Ballāḥ. On entering at Port Said or Suez a ship was assessed for tonnage and cargo (passengers were not charged for after 1950) and handled by three pilots, one for the approach roadstead and two for canal transit with changeover at al-Ismāʿīlīyah. Over 300 pilots of 15 to 20 nationalities were employed.

The nature of traffic greatly altered, the chief feature being the enormous growth of oil movement from the Persian Gulf after 1950. In 1913 oil and petroleum by-products in northbound traffic amounted to 291,000 tons; in 1966 to 166,000,000 tons. Passenger traffic, from an all time peak of 984,000 in 1945, declined considerably due to competition from aircraft. Northbound cargoes consisted of petroleum, ores and crude metals, bulk foodstuffs (chiefly grain), and textile fibres (cotton and wool). Southbound cargoes were chiefly manufactured goods, machinery, vehicles, and fertilizers. Of cargo shipped through the canal after 1960, 82 percent was northbound, 17 percent southbound (the rest going to Egypt), with oil accounting for over 70 percent of the total. Much southbound traffic was of empty tankers, and because less than half rates were charged for ships in ballast there were two problems—the obvious one of revenue, and the other of differing speeds as between empty and full vessels, which controlled convoy procedure. In 1913 exactly 60 percent of canal shipping was registered in Great Britain, followed by The Netherlands (6 percent) and France (5 percent). In 1966–67 the chief flags were United Kingdom (16 percent), Liberia (13 percent) Norway (11 percent), Greece (8 percent), and the Soviet Union (7 percent).

Traffic and cargoes

Communications and towns. Construction of the canal led to the growth of settlements in what had been, except for Suez, almost uninhabited arid territory. Over 70,000 acres have been brought under cultivation, and about 8 percent of the total population was engaged in agriculture, with approximately 10,000 commercial and industrial activities of various sizes. Settlements of importance are Port Said (population [1966 census] 283,000), with its east-bank counterpart, Būr Fu'ād; al-Ismāʿīlīyah (Ismailia) (population [1966 census] 144,000), on the north shore of Buḥayrat at-Timsāh with a westward extension, Muʿaskar (Moascar); and Suez (population [1966 census] 264,000), with its west-bank outport, Būr Tawfīq. Most of the population has been evacuated from the canal area since 1967.

There are two roads on the west bank: one, originally a company service road, follows closely the canal bank; the other, the Treaty Road, part of the state system, runs between Suez and al-Ismāʿīlīyah, then northward toward Port Said with ferries at al-Kūbrī and at al-Firdān to al-Qanṭarah. From this last, a road continues along the east bank to Būr Fu'ād, and another eastward through the Sinai to Israel. A major road runs westward from al-Ismāʿīlīyah through the aṭ-Ṭumaylāt valley, and there are direct routes from Suez to Cairo and from Port Said to Cairo via the delta. Military exigencies since 1967 have led to changes in the road pattern throughout the entire area. Rail connections, part of the Egyptian state system, existed on both banks of the canal. A swing bridge just south of al-Firdān carried the main line into Sinai.

History. *Construction.* The first canal in the region seems to have been dug *c.* 1800 BC, when an irrigation channel navigable at flood period was constructed into the Wadi Tumelat (Wādī aṭ-Ṭumaylāt). This was extended by the Ptolemys via the Bitter Lakes as far as the Red Sea. From the region of Buḥayrat at-Timsāh a northward arm appears to have reached a former branch of the Nile. Extended under the Romans, when it was known as Trajan's Canal, neglected by the Byzantines, and reopened by the early Arabs, this canal was deliberately filled in for military reasons during AD 775. Throughout, the aim appears to have been to facilitate trade from the delta lands to the Red Sea rather than to provide a passage to the Mediterranean.

Ideas for a direct Suez Canal were put forward by the Venetians in the 15th century and at subsequent intervals, but all encountered Ottoman hostility. In 1798 Napoleon personally investigated the remains of the ancient canal and ordered a survey for a direct canal, which was carried out in 1799. It was concluded that the level of the Red Sea was 33 feet above that of the Mediterranean, and, therefore, locks would be needed. Studies of a possible canal were made in 1834 and again in 1846. In 1854 Ferdinand de Lesseps received an Act of Concession from the viceroy (khedive) of Egypt, Muḥammad Saʿīd, to construct a canal; and in 1856 a second act conferred on the Compagnie Universelle du Canal Maritime de Suez (the Suez Canal Company) the right to operate a maritime canal for 99 years after completion of the work. Construction began in 1859 and took ten years instead of the six envisaged; climatic difficulties, a cholera epidemic in 1865, and early labour troubles all slowed down operations. An initial project was the cutting of a small canal from the delta along the Wadi Tumelat with a southern branch (the Turʿat as-Suways al-Ḥulwah [Sweet Water Canal]) to Suez and a northern one (al-ʿAbbāsīyah canal) to Port Said. This supplied drinking water in an otherwise arid area and was completed in 1863.

The Suez Canal Company

At first, hand digging with picks and baskets was used, fellahin being drafted as forced labour. Later, dredgers and steam shovels with European labour took over, and, as dredging proved cheaper than dry excavation, the terrain was artificially flooded and dredged wherever possible. Other than in the few areas where rock strata were met, the entire canal was driven through sand or alluvium. In August 1869 the waterway was complete and was officially opened with an elaborate ceremony in November 1869.

Finance. The Suez Canal Company had been incorporated as an Egyptian joint stock company with its head office in Paris. Despite much early official coolness, even hostility, on the part of Great Britain, de Lesseps was anxious for international participation and offered shares widely. Only the French responded, however, and the

remainder was largely taken up by the khedive, who came to own 44 percent as compared with 52 percent by French interests. The first board of directors included representatives of 14 countries.

In 1875 financial troubles compelled the khedive, Ismāʿīl, to sell his holding, which (at the instigation of the prime minister, Benjamin Disraeli) was at once bought by the British government. Until 1875 the shares remained below their issue price, but with the British purchase (at 568 francs for a Fr. 500 share) steady appreciation took place, from a low point of Fr. 215 in 1870 to over Fr. 3,600 in 1900.

By the 1950s the board of directors numbered 32, representing France, Great Britain, The Netherlands, the United States, and eventually Egypt. Originally allocated 15 percent of profits, Egypt later relinquished these and, after the sale of Ismāʿīl's 176,602 shares, remained unrepresented until 1949 when it was, in effect, reinstated as a board member and allotted 7 percent of gross profits. From 1936 onward Egyptian participation in the organization and working of the canal increased. Besides more directors it was agreed in 1949 that 90 percent of new clerical jobs and 80 percent of technical appointments would be offered to Egyptians. The Canal Company also providing hospitals, schools, and other amenities.

In 1956, 13 years before the concession was due to expire, the canal was nationalized by Pres. Gamal Abdel Nasser. Since that time the Egyptian government has exercised complete control, though the original company continues in Paris as a conglomerate.

International status. Although the canal was built to serve, and profit from, international trade, its international status remained undefined for many years. A convention was finally signed in 1888 making the canal open to all ships of all nations both in peace and war, acts of hostility in its waters being forbidden. Britain did not join the convention until 1904.

The history of international use of the canal during wartime included denial of passage by Spanish warships during the Spanish–American War of 1898; passage by a squadron of the Russian Navy during the Russo-Japanese War in 1905; and passage of Italian vessels during the Italo-Turkish War of 1911–12. Theoretically, the canal was open to all belligerents during World Wars I and II, but the naval and military superiority of the Allied forces denied effective use of the canal to enemy shipping.

Following the armistice between Israel and its Arab opponents in 1949, Egypt denied use of the canal to Israel and to all ships trading with Israel. The Arab–Israeli War in June 1967 closed the canal to all shipping.

Present situation and future prospects. Since June 1967 the canal has remained closed, and significant new trading patterns have emerged. Most precious cargoes of small bulk are now increasingly routed by air, as are a large majority of passengers, with the rest routed around Africa via the Cape of Good Hope. Containerization has partly offset the resultant higher costs. New sources of crude petroleum have been developed closer to the markets of Europe (Algeria, Libya, Nigeria), while Kuwait has increasingly close links with Japan, its principal trade partner. Much of the rerouted oil traffic is now by giant tanker; with the restraints of canal size removed, vessels of 200,000–300,000 tons are in operation, with supertankers of 500,000 tons planned. Enlargement of the canal will be a necessity, since 73 percent of revenues came from oil.

The challenge of containers, supertankers, and pipelines

Reopening would involve clearance, repairs, reinstallation of equipment, re-establishment of the operation teams (pilots and other personnel), and, inexorably, enlargement. Besides 15 ships trapped in the canal and now written off by their owners (but easily movable), ten more were sunk in the southern portion, and there is debris (shattered equipment) in the north. Repairs to portions of the banks damaged by military action will be necessary, although little silting is believed to have occurred. Plans in 1971 called for, in effect, the construction of a new canal by setting back the eastern bank by 328 feet and dredging to a depth of 66 feet. This could possibly be completed within four to five years, allowing vessels of 100,000 tons (the break-even point in competition with the Cape route) to use the canal within one year. Some regard these estimates as optimistic.

Another important factor is an oil pipeline between Suez and the Mediterranean at Alexandria, planned for completion in the 1970s with a capacity of 80,000,000 tons per annum. This, with the Israeli pipeline from Elat (now used by Iran to reach the markets of Europe), could provide formidable competition to an enlarged canal.

Nevertheless, the immense significance of the canal remains. In the 1960s it handled 15 percent of world sea traffic (up to 40 percent for India and Pakistan, 20 percent for Australia and Great Britain). Some 50 percent of total proved oil reserves occur in the three Persian Gulf states of Iran, Kuwait, and Saudi Arabia; and there would be a considerable political significance in a reopened canal allowing easier access by the Soviet Union to the Indian Ocean. The utility of the canal is also shown by the accompanying table.

Distances Between Selected Principal Ports

	by cape	by canal	saving (percentage)
London or Liverpool to			
Bombay	10,800	6,300	42
Kuwait	11,300	6,500	42
Melbourne	12,200	11,000	10
Calcutta	11,700	7,900	32
Singapore	11,800	8,300	30
Marseille to

Sugar Production

Sugar is a sweet, crystalline substance, white or colourless when pure, derived from the juices of various plants, chiefly the sugarcane and the sugar beet but also the date palm and the maple tree. It is an article of human food and a sweetener for other foods, especially beverages, confectioneries, and canned goods.

Chemically, sugar is the organic compound sucrose, one of the carbohydrates and the prime source of energy in the human diet. Sucrose furnishes 712 BTU (British thermal units) of energy per pound (394 kilocalories per kilogram) to maintain body temperature and activity. Though chemists designate a large group of related compounds as sugars, in this article sugar refers specifically to sucrose. (For details on physical and chemical properties of sucrose and other sugars, see the article CARBOHYDRATE.)

Early sugar making in India

Sugar making was known in India as early as 3000 BC. *Gaura*, an old Indian word for sugar, was apparently derived from the name *Gur*, an ancient monarchy in Bengal. Domestic noncentrifugal sugar, sugar that is made without centrifuging for home consumption, is now called *gur* in India and *goela* in Java. A crown made of sugarcane is described in the Atharvaveda, a sacred book of the Hindus, written about 800 BC or earlier, and the Greek general Nearchus, who accompanied Alexander the Great to India in the 4th century BC, tells of a reed that produced "honey" without the aid of bees.

Sugarcane is believed to have originated independently in the Solomon Islands, in the South Pacific, because of a local legend that the ancestors of the human race were generated from a cane stalk: one bud stretched and grew, abruptly changing into a man, while another bud stretched and grew, abruptly changing into a woman.

The methods of growing cane and making sugar were propagated from India east to Indochina and west to the Arabian countries and Europe. In Sanskrit, the ancient language of India, the word for sugar is *śārkara* or *śākkara*, originally sand or gravel. This became *sukkar* in Arabic, *sákharon* in Greek, *zucchero* in Italian, *sucre* in French, and sugar in English. The changes in the words suggest the route of the propagation of the art.

By the 8th century, sugarcane was grown and sugar made in Arabic Spain and southern France. Venice was long the chief centre of sugar refining in Europe, supplanted in the 16th century by Antwerp. In 1544 two refineries were established in London and in 1689 one in New York.

In 1493, on his second voyage, Christopher Columbus brought sugarcane to the New World. The success of sugar plantations in Santo Domingo led to its cultivation in other islands of the West Indies. In 1737 planting was begun in Louisiana, but not until 1791 did it succeed.

Discovery of beet sugar

The beet grew wild in parts of Asia and was cultivated at an early time in southern Europe as well as in Egypt. It was long used as a garden vegetable and cattle fodder. In 1747 Andreas Marggraf, a German chemist, proved that various kinds of beet root, which tasted sweet, contained sugar and that it could be extracted in crystalline form. No one, however, took particular interest in his announcement until Franz Karl Achard, one of his pupils, planted beets on his estate, Caulsdorf, near Berlin, in 1786, in the hope of finding a species especially rich in sugar. Frederick William III, the king of Prussia, interested himself in Achard's work and provided for the world's first beet-sugar factory, which began operations in 1802 at Cunern, Silesia. By 1810 it was evident that beet sugar could be the basis for a successful industry.

In France, Benjamin Delessert made a quantity of well-crystallized beet sugar in his small factory at Passy in 1811, for which he was awarded the Cross of the Legion of Honour by Napoleon.

In the United States, beet sugar was first produced in 1838 at Northampton, Massachusetts, by Edward Church and David Lee Child.

Sugar was initially dispensed medicinally as a sedative; as a food or food sweetener it was a scarce luxury until the 17th century. It remained expensive as late as 1736, when it was listed with precious stones among the wedding gifts of Maria Theresa, future queen of Hungary.

CANE-SUGAR PRODUCTION

Sugarcane. Sugarcane is a perennial grass of the genus *Saccharum*. Most of present-day commercial canes are the offsprings or hybrids of the species *Saccharum officinarum*, which was developed from a wild cane species *Saccharum robustom* and cultivated by natives of southern Pacific Islands.

Culture. The cane-growing areas of the world are located from 37° N (south Spain) to 30° S (Natal, South Africa), but most of the world's cane sugar is grown in subtropical and especially in tropical areas.

The sugarcane plant produces a number of stalks that reach from 10 to 24 feet high and bear sword-shaped, long leaves. The stalks are composed of many segments and at each joint there is a bud. When the cane becomes mature, a growing point at the upper end of the stalk develops into a slender arrow, bearing a tassel of tiny flowers.

Sugarcane is propagated primarily by the planting of cuttings. Sections of the stalk of immature cane used for planting are known as seed cane, or cane sets, and have two or more buds (eyes), usually three. Seed canes are planted in well-worked fields. Mechanical planters that open the furrow, fertilize, drop the seed cane, and cover it with soil, are widely used.

Seed canes are spaced from 4½ feet to 6 feet apart at densities from 4,000 to 10,000 per acre. Under favourable conditions, each bud germinates and produces a primary shoot. Root bands adjacent to each bud give rise to a large number of roots, and each young shoot develops its own root system. Tillering, or sprouting at the base of the plant, takes place; and each original seed cane develops into a number of growing canes, forming a stool. The plant crop is obtained from these stools.

Ratooning

Another method of cane propagation is by ratooning, in which, when the cane is harvested, a portion of stalk is left underground to give rise to a succeeding growth of cane, the ratoon or stubble crop. The ratooning process is usually repeated three times so that three economical crops are taken from one original planting. The yield of ratoon crops decreases after each cycle, and at the end of the last economical cycle all stumps are plowed out and the field is replanted.

Sugarcane is grown in various kinds of soils, such as red volcanic soils and alluvial soils of rivers. The ideal soil is a mixture of sand, silt, and clay particles, with a measure of organic material. The land is plowed and left to weather for a time, before subsoiling, (stirring up the subsoil) is carried out.

Sugarcane demands a well-drained soil, so that its roots have access to air and can absorb it. Drains, either surface, underground, or both are provided, according to the topographic conditions of cane fields.

To attain good yields, sugarcane requires 80 to 90 inches of rain (2,000–2,300 millimetres) during the growing period. When precipitation is deficient, irrigation, either by spraying or by applying water in furrows, can make up for the deficiency.

Fertilizers are applied to sugarcane from the beginning of planting through the whole growth cycle, but not during the ripening period. Optimum amounts of fertilizers (nitrogen, phosphorus, and potassium) vary greatly with soil types, climatic conditions, and the kind and length of the growing cycle.

To secure a good cane crop, weeds in the cane fields must be attacked until the cane stools develop a good canopy, which checks weed growth. Weeding, still largely manual, is done with a hoe, though mechanical cane weeders with attached rakes have been developed. Chemical weed killers and herbicides are widely used.

Maturation

The growth period for cane crops varies considerably according to the region: 8–9 months in Louisiana; 15 months in Australia and Taiwan; 18–22 months in Hawaii, South Africa, and Peru.

The lowest temperature for good cane-plant growth is about 68° F (20° C). Continuous cooler temperature promotes the maturation of cane, as does withholding water. Harvesting and milling begins in the dry, relatively cool season of the year and lasts for five to six months.

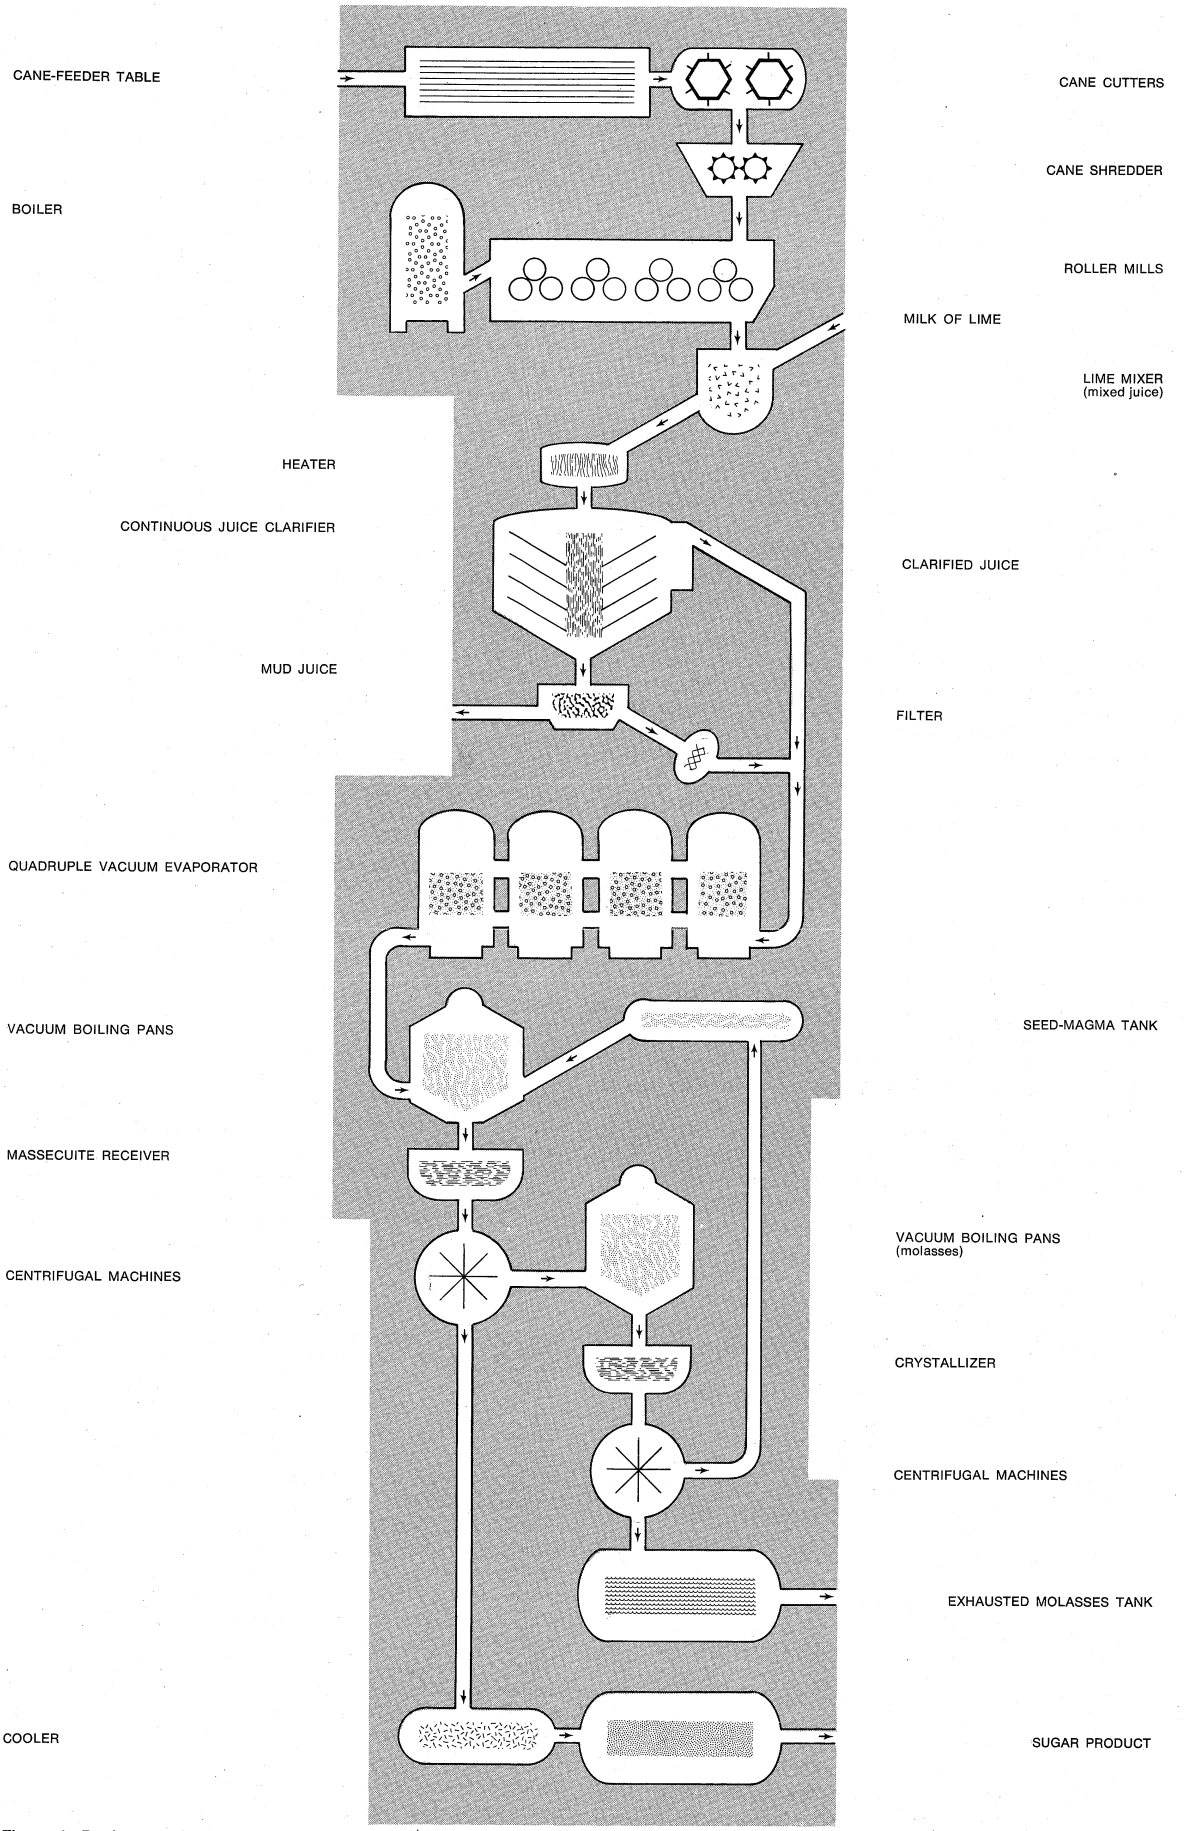

Figure 1: Basic steps in the raw-sugar manufacturing process.
Drawing by D. Meighan by courtesy of the Hatachi Zosen Co., Ltd., Tokyo

The mature cane is harvested by both manual and mechanical means. In Hawaii and Australia, mechanical harvesters are effectively used. Some are able to sever and discard the tops of erect crops and cut cane stalks, which are delivered into a bin trailer for transport to the mill by tractor or light railway wagon.

Diseases. The sugarcane plant is subject to many diseases. Sereh, a blackening and degeneration of the fanlike tops, is caused by an East Indian virus. Mosaic, mottling or spotting of foliage and sometimes curling, dwarfing, and narrowing of the leaves, may be caused by any of several viruses. Red rot (important in Java) is characterized by red patches within the canes, and is caused by the fungus *Physalospora tucumanensis.* Gumming disease (important in New South Wales, Australia) is characterized by gummosis, the pathological production of gummy exudates as a result of cell degeneration; it is caused by the bacterium *Xanthomonas vasculorum.* During the period 1880–93 the world's sugarcane production was severely damaged by these diseases, resulting in a temporary decline in the industry. In 1926 the spread of mosaic disease in Louisiana resulted in a drastic drop in sugar production to only one-quarter of the normal yearly average. Epidemics of these diseases have been checked by replacing the susceptible varieties of cane with varieties resistant to the disease.

Fiji disease

Fiji disease, a virus disease first reported from the Fiji islands, is characterized by elongated white to brown swellings on the underside of the leaves, followed by stunting and death. Early in the 20th century, Fiji disease caused such a severe loss as to menace the very existence of the industry in the Fiji islands. Leaf scald also caused serious damage in Australia and the Fijis during the first three decades of this century. Leaf scald is a vascular disease caused by the bacterium *Xanthomonas albilineans,* characterized by creamy or grayish streaking and later withering of the leaves. After World War II, ratoon-stunting disease was first recorded in Queensland as a specific virus disease of sugarcane, particularly ratoon crops. Recently the yield losses due to this disease in many cane-raising countries have been greater than those due to any other diseases.

Eyespot, characterized by yellowish oval lesions on leaves and stems, is a disease caused by the fungus *Helminthosporium sacchari.*

Pests. Sugarcane is attacked and damaged by various insect pests that bore into and feed on the different parts of the plant. Control measures include biological control by parasites or predators, chemical control by insecticides, and the introduction of resistant cane varieties.

The moth borer, *Diatraea saccharalis,* which is widely distributed throughout cane-growing areas, is capable of causing extensive damage when out of control. The sugarcane leafhopper and the anomala grub yielded to biological control in Hawaii when other measures were unsuccessful. Various predator animals live on insects destructive to the sugarcane. In Queensland the bandicoot, an insectivorous marsupial, is a most diligent destroyer of white grubs.

The insect pest responsible for the greatest crop losses in Queensland is the grayback beetle in its larval stage. The most effective grub control is obtained by applying the insecticide benzene hexachloride, after the young plant cane has germinated and stooled. Cane is also protected effectively against wireworms by applying insecticides when cane sets are planted. Rats, which destroy part of the stalk, are controlled by poisoning and trapping.

Breeding. The purpose of sugarcane breeding is to produce new hybrid varieties that will be immune, or resistant, to diseases and insect pests and will increase the production of sugar per unit area, yielding canes of higher sugar content and better fabrication qualities.

The first task of breeding is to obtain new cane seeds by crossing selected parent varieties, and then to select seedlings from the new seeds. The crossing is effected by enclosing in a cloth lantern two tassels from two different cane varieties selected as a male and a female parent. The commercially superior varieties are not necessarily ideal parents. Many of the best varieties were bred from parents unsuitable for commercial use. The production of such cane seeds and seedlings by crossbreeding has been established in Java and Barbados since the 1880s.

A selected seedling is planted and tested in the fields, and usually takes up to ten years before being released as a new commercial variety.

Most present-day hybrid commercial varieties are directly descended from the Cheribon cane, a Javan noble cane, species *Saccharum officinarium.* Noble canes, which represent the highest development of the species, are characterized by thick, barrel-shaped internodes, or segments, and large, soft-rinded, juicy stalks, and high sugar content. Original noble canes were susceptible to some serious cane diseases; their hybridization with wild canes was successful because, although wild cane *Saccharum spontaneum* contains little sugar, it is immune to most diseases.

Basic process

Raw cane-sugar manufacture. About 85 percent of the cane sugar produced in the cane-raising areas is raw sugar for further processing; the balance is plantation white sugar, for direct domestic consumption. The raw-sugar manufacturing process is illustrated in Figure 1.

Sugar juice in the cane is pressed out by means of a set of three-roll mills. The pressed juice, known as mixed juice, is purified by heating and adding milk of lime. This mixture is then sent to a continuous juice clarifier that separates the clarified juice and the muddy juice. The former is sent to an evaporator and the latter to a continuous-rotary vacuum filter. The filtrates are added to the clarified juice and the mixture concentrated in the evaporator. This raw-syrup mixture is further concentrated in vacuum boiling pans until sugar crystallizes out of the liquor, forming a mixture known as massecuite. The crystals (raw sugar) are separated from the massecuite by centrifugal machines.

Cane processing. Sugarcane is first weighed and then carried to cane-feeder tables.

Conventional milling of cane

The milling of cane by crushing and grinding is a highly developed process whose purpose is to rupture the plant cells by pressure to release the sugar-bearing juice. Machinery of massive construction is used because of the tough nature of the material to be ground. Multiple mills arranged in triangular form are universal. Rapidly revolving cane knives cut the cane into chips to level and compact the bed of cane on the carrier which delivers the cane to a two-roller or three-roller crusher that separates out about 60 percent of the juice by breaking and crushing the stalks or chips. Between the cane knives and the first mill, many factories use shredders with revolving and swinging hammers, to reduce the cane pieces to a fibrous structure, thus facilitating juice extraction by the mills. Shredders of the hammer-mill type shred the cane, and then pressurized rollers extract the juice in a process called maceration, imbibition, or saturation.

The conventional milling system is relatively inefficient, and continuous diffusers (such as are used to extract sugar from beets) have been successfully introduced to many cane-sugar factories. An example of such a cane-diffusion system is shown in Figure 2.

By courtesy of Hitachi Zosen Co., Ltd., Tokyo

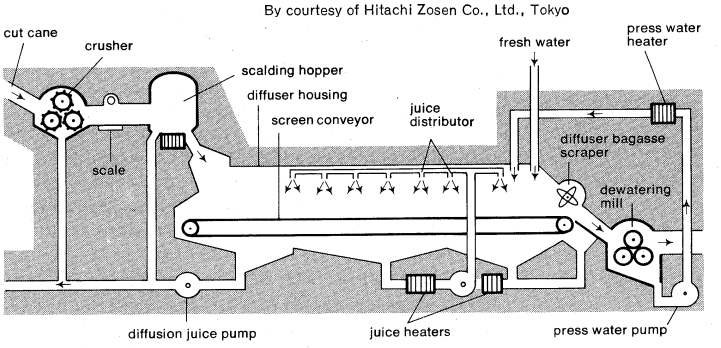

Figure 2: Cane-diffusion system.

The cane is cut in pieces as in a conventional milling plant by two sets of knives and is passed through a three-roller crusher, where about 60 percent of the juice is pressed out. The pressed cane, called crusher bagasse, is

conveyed into a continuous diffuser, in which sugar in the crusher bagasse is extracted in many stages by water percolation (lixiviation). Warm, fresh water is introduced at the bagasse outlet, and juice is drawn out after percolating through the bagasse at the bagasse inlet. This diffusion juice is mixed with crusher juice, and the mixture is sent to the clarification room. The diffuser bagasse contains much water, about 85 percent, and it is pressed by two sets of three-roller mills. The press water, after clarification, is used as lixiviation water for the diffuser, along with fresh water. The quantity of fresh water used in the diffuser is about 30 percent of the cane weight, and that of mixed juice, known as draft, is about equal to the cane weight. Lixiviation in the diffuser is carried out at close to 170° F (77° C) to inhibit bacterial growth.

Juice processing. The extracted, mixed juice is heated to about 220° F (105° C) and milk of lime (suspension of calcium hydroxide) added. The mixture then goes to a continuous juice clarifier. From here, clear juice is drawn off the surface of each tray and sent to the evaporator, while settled juice mud is scraped out and sent to mud receivers, continuous-rotary vacuum filters.

The invention of three basic machines in the 19th century made sugar a major industry; vacuum boiling pans (1813), centrifugal machines (1837), and effect evaporators (1843).

Effect evaporator

The effect evaporator shown in Figure 1 is a quadruple evaporator. Each of its four vessels has a set of heating tubes called calandrias. Heated in the tubes, the juice boils up with water vapour bubbles into the upper-vapour chamber. Only the juice comes down through a central downtake and goes again to the heating tubes, becoming more concentrated.

The calandria of the first evaporating vessel is heated with steam, that of the second with the vapour from the first. Vapour from the last vessel is drawn out by a vacuum pump and condensed in a water-cooled condenser. Pressure differences between the connecting vessels cause the juice to move to succeeding vessels when valves of the connecting tubes are opened.

Steam is supplied only to the first calandria and one pound of steam can produce about one pound of vapour by heating the juice to its boiling point; at the same time, one pound of vapour thus generated can also do the same work in the second vessel. If four evaporation vessels are used and one pound of steam is supplied, about four pounds of water can be evaporated from the juice. This is an effective and economical method of steam usage.

Raw-sugar factories may use triple, quadruple, or quintuple evaporators; quadruple evaporators are most usual.

The juice concentrated in the last vessel is drawn out by a syrup pump. This is raw syrup of about 65 percent solid and is sent to boiling pans.

Vacuum boiling pan

The structure of a vacuum boiling pan is shown in Figure 3. Near the bottom is a heating calandria. Modern pans have mechanical stirrers in the centre downtakes to insure good circulation of massecuite. A large vapour chamber above the calandria is connected to a vacuum pump via a cooling condenser so that a moderate vacuum can be maintained inside the pan during boiling.

To begin boiling, the pan is evacuated, raw syrup is drawn in up to the height of the upper tube-plate of the calandria, and steam is let in. The syrup begins to boil, becoming more and more concentrated. Seed crystals, small crystals of sugar, are added to the raw syrup as starters to help the crystallization of sugar from the syrup. Sucrose from the syrup begins to deposit on the seed crystals, causing them to grow. The growth of the seed crystals is maintained with continuous feeding of raw syrup until the massecuite volume reaches about 80 percent of the pan volume. During boiling, the sucrose crystals grow from about 0.012 inch (0.3 millimetre) to 0.039 inch (1.0 millimetre) in length. After the massecuite is made a little harder, the supply of steam is stopped and pan vacuum is cut off to the atmospheric pressure. The massecuite is then dropped into receivers for centrifugals.

In the centrifugal machine, the massecuite is separated into raw sugar and molasses; this molasses is boiled to produce a second massecuite, which is separated into a second raw sugar and a second molasses. The second molasses is also boiled and made to yield a third sugar, which is used as seed crystals for first and second massecuite boilings. The third molasses is exhausted molasses and is known as cane blackstrap.

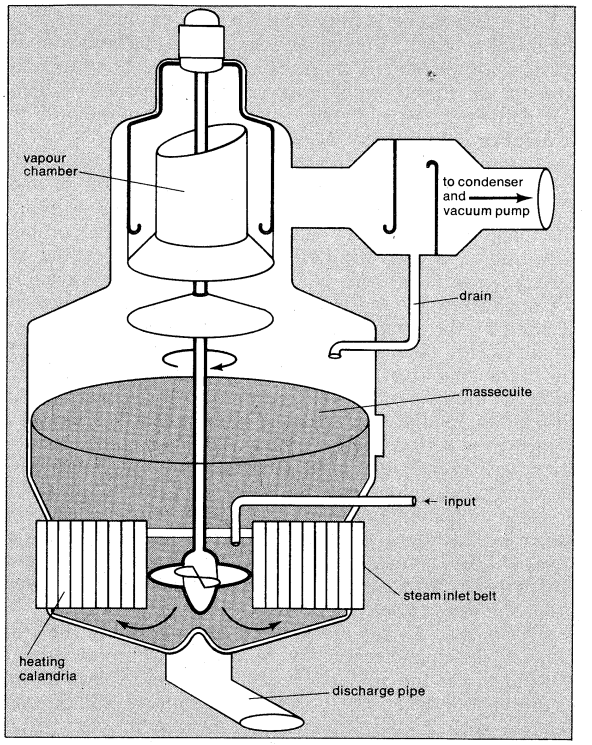

Figure 3: Principal structural features of the vacuum boiling pan with mechanical agitation.
By courtesy of Hitachi Zosen Co., Ltd., Tokyo

Discoloration of sugar products is far less in a vacuum pan, where the surface temperature of boiling massecuite is about 140° F (60° C), than in an open pan, where the temperature of the massecuite is over 250° F (121° C). For this reason, the invention of vacuum boiling pans was revolutionary in sugar manufacturing.

First and second massecuites are centrifuged immediately after discharge; the third massecuite is cooled to induce more dissolved sucrose to crystallize out.

Centrifugal machine

The centrifugal machine consists of a cylindrical basket to receive the massecuite; the basket is pierced with numerous holes to allow the molasses to escape and is lined with a screen of perforated sheet metal. An electric motor rotates the basket via a vertical shaft fixed at the bottom. The massecuite is fed into the slowly rotating basket until centrifugal action forces it to creep up to the edge, and then the basket is rotated at full speed (1,000–1,600 revolutions per minute). After a few minutes, the rotation is slowed almost to zero and the sugar inside the basket wall is scraped down onto a belt conveyer. After passing through coolers, where large conglomerates are removed by classifying screens, the raw sugar is stored in bulk.

In many modern cane-sugar factories, the operations are controlled automatically. At the milling station, the quantity of cane loaded to the mill is controlled by the motor speed of the cane carrier, which in turn is regulated according to the load change of the cane knives' motor and the depth of cane charged to the crusher. The control of evaporator work is effected by correspondence between the quantity of clarified juice and the steam supply and by the maintenance of a definite raw-syrup concentration.

Plantation white sugar (mill white sugar). Plantation white sugar is manufactured in south Asian countries for their own direct consumption. There are two methods of manufacture: impregnation with sulfur dioxide, sulfitation, and carbonation.

In sulfitation factories, mixed juice from the mill is heated to 165° F (74° C) and sent to tanks where the

gas is injected at the same time that milk of lime is added. After heating to 220° F (105° C), juice saturated with sulfur dioxide is sent to continuous clarifiers. The clarified juice is concentrated to raw syrup, which is further saturated with sulfur dioxide. The first massecuite is obtained from this syrup, and on centrifuging it yields white sugar.

In carbonation factories, mixed juice is heated to 131° F (55° C) and sent to carbonation tanks, where carbon dioxide is injected in the juice at the same time that milk of lime is added. Calcium carbonate precipitates are filtered off and the filtrate is further saturated with carbon dioxide and filtered again.

Sulfur dioxide is then injected into the carbonation juice, and the juice is concentrated to raw syrup; the syrup is further saturated with sulfur dioxide and filtered. White-sugar massecuite is obtained from this syrup.

BEET-SUGAR PRODUCTION

Sugar beet. Sugar beet, *Beta vulgaris, Saccharifera Alefeld* variety, is a biennial plant of the Chenopodiaceae family. It has long been grown as a summer crop in relatively cool northern parts of the temperate zones of the world, and recently, it has been grown as a winter crop in the southern parts of the temperate zones: South America, Africa, the Near and Middle East, and south Europe.

Culture. The growing period from sowing to harvesting is 170–200 days. A good yield of beet roots is obtained when the climate has been mild throughout the growing period. A good sucrose content in the beet roots is secured when the last period of growth has been cold. In the case of a winter crop, the ripening period is in the warm season; and ripening of the beet is promoted by withholding water to the beet.

Sugar beet requires a well-distributed precipitation of about 24 inches (610 millimetres) from January to October. If the precipitation is deficient, the crop must be irrigated.

Sugar beet is grown in various soils, ranging from sandy loam to heavy clay. An ideal soil is loam rich in humus, deep and homogeneous, having appropriate adhesion and mild moisture-holding capacity.

The seed bed is prepared by deep plowing after the preceding crop is harvested in autumn, and early the next spring it is shallow plowed, stamped, and harrowed.

Fertilizers are applied to sugar beets from the beginning of sowing through the entire growth period. Nitrogen fertilizer increases the weight of beet roots but delays ripening. Potash is well absorbed by sugar beet, increasing the root weight; but, again, if too much potash is absorbed, ripening is slowed down and, in addition, magnesium deficiency occurs. The absorption of phosphate is less than that of nitrogen and potash, but it increases beet-root weight and accelerates ripening.

Seed balls

Seed balls, or fruits, containing many seeds are formed at maturity by the sugar beet flowers. Balls containing single seeds were first obtained in the U.S.S.R. from atypical beets. Commercial production of single-seed balls has also been developed in the United States. Most beet seeds now used are from seed balls containing a single seed.

With single seeds, the quantity required has been reduced to less than three pounds (1.4 kilograms) per acre instead of the 20 pounds (9 kilograms) or more of whole-seed balls formerly required. When single seeds are planted with proper spacing, the seedlings grow at intervals that obviate the great labour expenditure for thinning and weeding required for seedlings from seed balls with many seeds. Recently, beet seeds have been grown in mild climates by the winter-annual method in which sowing is done in late summer or early autumn; the plants are dormant during the winter and produce seed the following season.

In most areas seeds may be sown during the latter part of March or in April. Before sowing, beet seeds are treated with disinfectants for black root disease. Precision drills sow monogerm seeds of well-classified sizes to a depth of ¾–1½ inches (2–4 centimetres) spaced 2½–3 inches (6–8 centimetres) apart. Rows are 20–22 inches (50–56 centimetres) apart. Fertilizers are applied simultaneously with seeds, and after covering, herbicides are applied by spray. The germination of the seeds occurs about ten days after sowing.

When weeds appear in the interrows they are removed so that fertilizers, air, and rainwater are more accessible to the beet roots.

Thinning is performed in the four- to six-leaf stage to keep the distance between plants at 8–10 inches (20–25 centimetres), leaving a final stand of seedlings averaging 100 to 150 per 100 feet (30 metres) of row.

Harvesting sugar beet

Sugar-beet harvesting usually starts late in September or early October and is performed rapidly so as to finish before the soil freezes. There are two methods of harvesting. In the Pommritzer method, the topping and the lifting of the roots are performed by two separate machines. In the other method, the two operations are carried out by one machine. The harvested beet roots are carried directly to the factories in trailer bins.

The sugar-beet crop is produced every four to six years; several other kinds of crops are also raised during this period. Sugar beet is usually planted after corn or wheat, in order to lessen the damage due to *Rhizoctonia* root rot or nematodes.

Diseases and pests. The beet plant is subject to many diseases and insect pests. Black root rot, a fungus disease characterized by lesions in the stem near the soil surface, and *cercospora* leaf spot, a fungus infection in which the leaves become greenish-yellow and root weight and sugar content are reduced, are most serious and can cause great damage if not controlled. Precautions must also be taken against damage by worms, beetles, and nematodes.

Breeding. Disease-resistant beets of higher sucrose content and heavier root weight are constantly sought. Sugar beet is a cross-pollinated plant and commercial varieties are hybrid plants. Superior polyploid varieties (varieties having multiple sets of chromosomes) have been developed in Europe. In the United States, breeding has been based on hybridization.

Beet-sugar manufacture. Harvested beets are carried as directly as possible to the factory yards where they are weighed and dropped into flumes to be carried by water to the factory. Dirt and extraneous matter adhering to the roots are removed during the fluming.

Washing and slicing

Preliminary processing. In the factory, beet roots are lifted by a wheel or pump to a beet washer, a tank overflowing with wash water and fitted with a horizontal shaft and propeller paddles. Washed beets are picked up from the tank and sent to a bunker over the beet slicer.

In Europe, suspended beet slicers with horizontally rotating slicing disks are widely used. They rotate at about 1,000–1,500 revolutions per minute. Washed beets are fed into a hopper and onto the rotating disk by gravity. Sliced-beet pieces, called cossettes, drop onto belt conveyors leading to the diffuser via a belt weigher.

The operating mechanism of a continuous beet diffuser is shown in Figure 4. Beet cossettes are fed to a hopper at the lower end of an inclined diffuser and carried upward by two scroll conveyors. Fresh hot water and press water from the diffuser-pulp press are added at the upper end of the apparatus. The cossettes are repeatedly squeezed lightly and loosened between two scrolls of the conveyors. Sucrose-rich juice accumulates at the lowest end of the apparatus, where it is drawn off, becoming diffusion juice, or raw juice.

The pulp is removed from the diffuser end and sent to presses, where pressed pulp and press water are obtained. The pressed pulp is then sent to dryers.

In order to inhibit bacterial growth in the diffusion apparatus, sucrose extraction is carried out at 160°–170° F 71°–77° C); and, usually, Formalin is added to the returned press water.

Preliming

The raw juice is sent to a tank where it is mixed with milk of lime which coagulates impurities. This process, called preliming, is indispensable for securing juice of good settling properties and filterability. The prelimed juice is then heated to 170°–180° F (76°–82° C) and again mixed with milk of lime in a main-liming tank. Preliming, main-liming, and carbonation are all continuous.

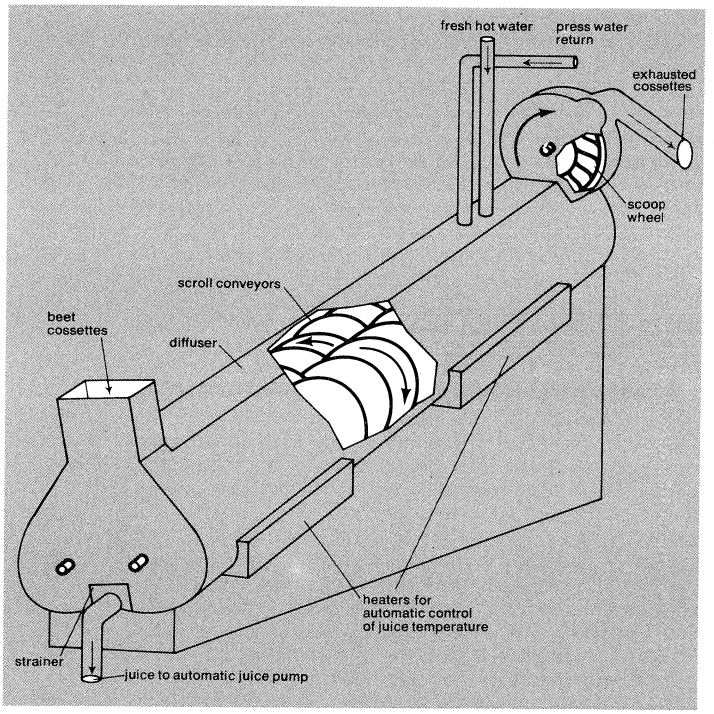

Figure 4: Continuous beet-diffusion system.
By courtesy of De Danske Sukkerfabrikker

The limed juice is further heated to 180°–190° F (82°–88° C) and carbonated in two or three tanks by the injection of carbon dioxide from the tank bottoms. Carbonated juice overflows to succeeding tanks. After the end point of carbon dioxide saturation is reached at the last tank outlet, the carbonated juice, along with the calcium carbonate that has precipitated out, is sent to a continuous mud-settling tank, or thickener, where clarified juice and muddy juice are separated. The thickened, muddy juice is filtered by continuous rotary vacuum filters, and the mixture of filtrate and clarified juice from the thickener is filtered, preferably by ceramic filters. The filtrate is heated to 210° F (99° C) and carbonated again.

The second carbonated juice is filtered by ceramic filters or pressure-leaf filters and the filtrate sent to a tank where sulfur dioxide is injected into it. This juice is then concentrated in a quadruple or triple-effect evaporator to a thick juice. Pressure evaporation is carried out in the first vessel of the effect at 15.5 pounds per square inch, and extra vapour is bled from the three vessels for heating and boiling. The thick juice is mixed with remelted liquors and filtered, the filtrate becoming the standard liquor.

Raw beet sugar. The thick juice is fed into boiling pans, and, after seeding, the seed crystals grow on the continuously fed juice and on the first molasses. As with cane sugar, the massecuite thus obtained is separated by centrifuge into raw sugar and molasses. This molasses is again boiled to produce the second massecuite, which is separated into the second raw sugar and molasses. The second molasses is considered exhausted.

White sugar manufacture. White sugar is produced by the three-boiling system from standard liquor, which consists of thick juice, the second sugar remelt, and the wash molasses from the first-massecuite centrifuging. The second massecuite is boiled from the first molasses, the third sugar remelt, and the wash molasses from the second-massecuite purging. The third massecuite is boiled from the second molasses to obtain the third sugar and exhausted molasses.

The Steffen process for recovering sucrose from exhausted molasses has been adopted in the U.S. and in Japan. This molasses contains about 50 percent sucrose. Finely powdered quicklime is added to diluted molasses, precipitating saccharate of lime that is used for liming beet juice in place of milk of lime. The disadvantage of this process is that raffinose is precipitated along with sucrose.

Use of ion-exchange resins

Many modern factories use ion-exchange resins that react chemically to de-ash and decolorize the thin juice, resulting in reduced quantity of molasses and improved quality of the sugar product.

The operations in modern beet-sugar factories are controlled automatically. At the diffusion station, variables are controlled according to the weight of the cossettes, as estimated at the belt weigher; at the liming station, the raw-juice quantity determines the quantity of lime added. Carbonation is controlled by setting the carbon dioxide valves according to the acidity of the juice at the last tank outlet. The evaporator control is effected by the correspondence between quantity of thin juice and the steam supply, which is adjusted according to the Brix, or percent by weight of sucrose in the thick juice. For sugar boiling, purging, and the boiler-house operations, controls are the same as for raw cane-sugar manufacture.

SUGAR REFINING

Most cane sugar is consumed in the form of refined sugars, and sugar refineries are located in or near big cities. Modern refineries are accessible to bulk, raw-sugar carriers.

Raw sugars. Of primary concern to the sugar processors is obtaining raw sugars of good refining qualities: (1) uniform grain sizes for ease of washing, called affining; (2) less colour and better filterability of washed, or affined, sugar; (3) lower ash content for higher sugar recovery.

Raw sugar is unloaded from sugar carriers at the factory storage house or sugar silos via an automatic weigher. The necessary quantity of raw sugar is carried to a continuous mingler, where it is mixed with warm syrup forming a continuous flow of magma, a thin, pasty mixture of raw sugar and syrup. The magma removes the molasses film that adheres around raw-sugar crystals and is fed into centrifugal machines for separation into affined sugar and affination syrup.

Affined sugar is dissolved at 150° F (66° C) in hot, sweet water with some fresh, hot water added to obtain raw liquor of about 65° Brix. Purification of raw liquor is most efficient and economical when a combination of liquor-carbonation and bone-ash decoloration methods are used. In the carbonation process, milk of lime is added to the continuous flow of raw liquor from the melter and the mixture fed into the carbonation tanks, where carbon dioxide is blown in from below. Carbonated liquor overflows to a succeeding carbonator tank where the reaction is completed. The liquor carbonation is carried out continuously. Carbonation produces decoloration of 50–60 percent, and the calcium carbonate precipitates that form are a good filter aid.

The carbonation slurry, or thin mixture, thus obtained is heated to 175° F (80° C) and filtered without added filter aid. The filtrate is further decolorized by percolation through deep beds of bone ash, tribasic calcium phosphate, which acts as a clarifying agent. A fine liquor is thus obtained and sent to the boiling house. The fine liquor is boiled to obtain sugar and molasses; then the molasses is boiled again to obtain the second sugar yield, and so on. The boiling system is complicated because the purity of fine liquor is higher than 98 percent, and at least six or seven stages of boiling are required until the molasses is exhausted; three stages of boiling are needed to desugar the affination syrup. A mixture of first, second, third, and sometimes fourth sugars is sold as white granulated sugar. Yellow or brown soft sugars are produced from low-grade massecuites. Refined products are dried, classified, and stored in sugar bins, from which they are drawn out for packaging or sending to the market in bulk.

Bone-ash decoloration

The installation for bone-ash decoloration is expensive, and many factories have adopted a combination method using carbonation and activated carbon for decoloration. Many Japanese refineries use ion-exchange resins for final decoloration of the liquor.

Automatic controls operate in the factory: the quantity of raw sugar fed into the mingler is measured continuously on a belt weigher and the required amount of affination syrup added according to the raw-sugar weight. Affined sugar is sent to the melter, where raw liquor of a constant

concentration is made automatically by adding controlled amounts of hot water. The liquor carbonation is controlled as for beet-sugar manufacture; the filtration end point of carbonation slurry is detected automatically by pressure measurements. Timers control the sequence of the bone-ash decoloration operation. Control of the boiling and purging operations is the same as for raw-cane-sugar manufacture.

Sugar types and grades. Most of the sugar consumed in the world is in the form of white granulated sugar from refineries, beet-sugar factories, or cane-mill white-sugar factories. These are classified according to grain size as extra-coarse, coarse, standard, fine, and extra-fine granulated. The grain size of extra-coarse granulated is larger than 0.04 inch (1.0 millimetre); that of extra-fine granulated is less than 0.01 inch (0.25 millimetre). Bakers' special (U.S.), or caster sugar (England), is produced by boiling very fine crystals; powdered sugar or icing sugar is produced by milling, with cornstarch added to prevent caking.

About 1,000,000 tons of soft white sugar is manufactured annually in Japanese refineries. White sugar massecuite of fine grain size, about 0.005 inch (0.125 millimetre), is purged, and the remaining sugar in the centrifugal baskets is sprayed with colourless inverted syrup. Soft yellow sugar and soft brown sugar are obtained from low-grade massecuites in the refineries. Low-grade sugars retain the reducing sugars (levulose and dextrose) of the massecuites.

Coffee sugar (England) consists of large brown crystals with characteristic flavour, produced as granulated sugar in several successive boilings from refinery liquor of appropriate colour. Candy sugar consists of very large white sugar crystals, obtained by slow crystallization from very high purity liquor; it is used mainly by the brewing industry.

Liquid sucrose and invert sugar

More than 2,000,000 tons of liquid sugar is produced in the U.S. chiefly for manufacturing purposes. There are two superior-grade liquid sugars: liquid sucrose and liquid invert. (Invert consists of equal parts of glucose and levulose obtained by the inversion of sucrose.) Liquid sucrose is manufactured by adjusting the concentration of fine liquor in refineries to 67.2 percent sucrose containing a maximum of 0.20 percent invert sugar. For liquid invert, the sucrose in the fine liquor is inverted more than half by passing through an ion-exchange resin column and adjusting the concentration to 77 percent solid.

Golden-coloured liquid sugar is produced for domestic use by processing selected refinery syrups, partially inverted.

Cube sugar in the form of regular hexahedrons or rectangles is produced by molding and pressing selected granulated sugar with sugar liquor for cementing the crystals and then drying.

In 1967, world production of noncentrifugal sugar in the form of brown lump sugar was 12,000,000 tons; most of this was produced in Asia.

About 170,000 tons of palm sugar in the form of lumps is produced in Asian tropical countries from the juice of coconut, palmyra, and date palm, obtained by tapping their trunks or inflorescences. Maple sugar, syrup or lumps, is produced in Canada and the northern U.S. from the juice of sugar-maple trees; the lower part of their trunks is tapped in early spring.

ECONOMICS

Production and consumption statistics. World production of raw sugar amounted to 73,710,000 metric tons, excluding noncentrifugal sugar, in 1968, of which cane sugar accounted for 40,960,000 and beet sugar 32,750,000 metric tons. World production of noncentrifugal sugar in 1966–67 amounted to 11,980,000 metric tons.

The principal cane-sugar producing countries are as follows (the figures in parentheses are tons of sugar produced in 1970): Cuba (8,530,000), Brazil (5,680,000), Australia (2,610,000), India 4,710,000), United States (2,440,000), Mexico (2,890,000), China (mainland) (2,400,000), South Africa (1,970,000), Philippines (2,200,000), and Argentina (1,160,000).

Main beet-sugar producing countries are as follows: U.S.S.R. (10,780,000), United States (3,060,000), France (2,530,000), West Germany (2,170,000), Poland (2,040,000), Italy (1,420,000), United Kingdom (1,040,000), Czechoslovakia (930,000), The Netherlands (780,000), and Turkey (771,400).

The world consumption of centrifugal sugar in 1968 amounted to 74,360,000 tons. Consumption is increasing yearly at a rate of 2–4 percent. The rate fluctuates because of the price. Per capita yearly consumption for the world was 43 pounds in 1968. Per capita consumption in pounds (0.454 kilogram) per year for ten countries are: The Netherlands (154), Ireland (141), Australia (126), Denmark (116), United Kingdom (114), Switzerland (114), United States (111), Israel (108), Soviet Union (105), and Canada (102).

World sugar trade. About 70 percent of world sugar production is consumed domestically. The balance is consumed in international trade: exports to the United States under its quota arrangement, exports under the Commonwealth Sugar Agreement, Cuban exports to socialist countries, exports from the U.S.S.R. to other socialist countries, and free-market sugar for trade. Except for free-market sugar, trades are carried out at preferential prices negotiated between the countries concerned.

The quantity of free-market sugar was about 9,400,000 tons in 1969; world production was about 68,000,000 tons. Free-market sugar is traded according to contracts between the countries concerned; the price is usually based on spot quotations on recognized exchanges, such as the New York Coffee and Sugar Exchange or the United Terminal Sugar Association (London).

The price of free-market sugar has fluctuated. In 1962 the price rose to 12.6 U.S. cents per pound because of the temporary depletion of sugar stock and sudden worsening of American-Cuban relations. In 1967 the price fell to 1.23 U.S. cents because of a surplus.

International Sugar Agreement

In order to stabilize sugar production and the free-market sugar price, the International Sugar Agreement was concluded in 1969, regulating the export quota for each member country and setting a floor price (3.25 U.S. cents per pound, or 0.454 kilogram) and a ceiling price (6.5 cents). This is the third post-World War II international agreement (1953, 1958, 1969) concluded under the auspices of the United Nations Conference on Trade and Development.

The retail price of refined sugar varies greatly in different countries, principally because of different amounts of custom levied on raw sugar and excise on refined sugar products. In 1969 the price was 3.8 U.S. cents per pound in Mauritius, 5.1 cents in Jordan, 7.6 cents in Singapore, 8.8 cents in Great Britain, 8.8 cents in Canada, 12.2 cents in the U.S., and 16.4 cents in Japan.

SUGAR BY-PRODUCTS AND SUGAR CHEMICALS

Sucrose esters

Methods of making useful sucrose derivatives have long been developed by the International Sugar Research Foundation, Incorporated, New York; sucrose esters are manufactured by a Japanese licensee for use as surface-active agents in food products.

Cane molasses. The world cane-molasses production was 14,000,000 tons in 1968–69. The major use is in livestock feed. Molasses contains 55 percent sugar and 2.8 percent protein and is a cheap source of readily available energy. Six to 10 percent by weight is added to dairy-cattle feeds. The second important use is for making alcoholic drinks, such as rum in Caribbean areas. A recently developed and interesting use for molasses is in manufacturing monosodium glutamate by fermentation in Japan and Taiwan; the diluted molasses, with urea added, is fermented by *Micrococcus glutamicus*.

Bagasse fibre. Bagasse, 24–27 percent of the cane, remains after the juice is pressed out. It is ordinarily burned as boiler fuel; but bagasse may be used for making soft or hard building board. Approximately 550,000 tons of bagasse pulp was manufactured in 1967 by 36 bagasse-pulp mills in the world; the bagasse is depithed; that is, the soft, centre tissue of the plant stems is removed. The pulp is made from such a depithed bagasse by sulfate process.

Cane wax. Cane wax is extracted from the dried filter cake of raw-sugar factories; naphtha, toluene, or alcohol is used as the extraction solvent. After decoloration, cane wax is used in manufacturing polishes, cosmetics, and paper coatings.

Beet pulp. Beet pulp is fed to livestock; wet pulp may be used soon after delivery from factories, but most of it is dried in oil-fired, direct-rotary driers and stored. Dried pulp contains about 9 percent protein.

Beet molasses. Beet molasses is also fed to livestock and may be added to beet pulp. Monosodium glutamate can be manufactured from beet molasses; it contains pyrrolidone carboxylic acid, which is easily hydrolyzed; that is, chemically split with water added, to form glutamic acid. In Europe beet molasses is used for manufacturing citric acid by fermentation.

SUGAR SUBSTITUTES AND NON-NUTRITIVE SWEETENERS

Sugar substitutes. Much corn syrup and honey are used as substitutes for sugar; in the United States a small quantity of sorghum syrup is used for the same purpose (see CEREALS AND OTHER STARCH PRODUCTS).

Corn syrup is a product of the hydrolysis of cornstarch; that is, the chemical splitting of cornstarch with addition of water.

Honey is inverted cane-sugar syrup with flower flavours, which is accumulated by bees during the blossom season.

Sorghum is the syrup made by concentrating sorghum-stalk juice.

Artificial, non-nutritive sweeteners. Artificial sweeteners were used originally as sugar substitutes for diabetics and others forced to restrict their intake of sugar, but recently they have been used for making soft drinks and other foods for people who wish to restrict their intake of calories to control their weight. Saccharin, cyclamates, and Dulcin, or Sucrol, are such artificial sweeteners.

Saccharin was discovered in 1879 by C. Fahlberg and Ira Remsen of Johns Hopkins University. It was first sold in 1884 in New York as sodium or calcium salt. It has hundreds of times the sweetening power of cane sugar.

Sodium cyclamate, or sodium cyclohexylsulfamate, was discovered in 1937 by L.F. Audrieth and M. Sveda at the University of Illinois. Many times sweeter than cane sugar, it was used as a sweetener from 1950 until 1969. Its general use has been prohibited in the United States, the United Kingdom, and Canada, because of evidence that it might cause cancer.

Dulcin, or Sucrol, is no longer used because of its toxic effects.

Austria has prohibited the use of artificial sweeteners in foods since 1939, with the exception of saccharin for certain products.

Suger of Saint-Denis

While the abbot Suger of Saint-Denis is important in the early history of France, it is for his role in the history of art that he is best remembered. Under his supervision and direction the abbey church of Saint-Denis (the patron saint of France) was rebuilt from a crumbling and decaying condition. It was a period that saw the emergence of new ideas in theology and philosophy, which the church of Saint-Denis fully reflects. It is believed that Suger was the inspiration behind many of the architectural innovations employed at Saint-Denis, which include an original use of the pointed (rather than round) arch and the ribbed vault and extensive use of stained glass, including a rose window in front. These features were instrumental in the development of a new style of architecture, which became known as Gothic.

Archives Photographiques, Paris

Suger, detail of a stained glass window, 12th century. In the abbey church of Saint-Denis, France.

Suger was born of peasant parents, probably somewhere near Paris, in 1081. As a child he showed unusual intelligence and was brought to the nearby abbey of Saint-Denis to be educated by the monks. His closest friend and schoolmate at the abbey was a boy his age, Louis Capet. This boy became King Louis VI in 1108. Suger became secretary to the abbot Adam of Saint-Denis and a close adviser to the king.

As secretary to the abbot Adam, Suger made various diplomatic missions to Henry Beauclerc of Normandy, who was also King Henry I of England and the son of William the Conqueror. Suger was greatly impressed by the strong, orderly administration of the Norman ruler, which contrasted with the chaotic feudalism in France.

The importance of Saint-Denis

Saint-Denis, shrine of the saint who had supposedly brought Christianity to Gaul, was an object of great veneration. Suger saw its destiny and that of the French crown as permanently related. He believed that by stressing and enlarging the king's role as vassal of Saint-Denis he could unite the king and his nobles under an idea they could mutually believe in. Suger also saw that the king could, and should be, protector of the peasants and the middle class.

In 1122 Suger was elected abbot of Saint-Denis. He had a chance shortly thereafter to test his idea of the cementing power of the symbolic idea of Saint-Denis. In 1124 the Holy Roman emperor Henry V invaded lands ruled by King Louis VI. The King rode into battle carrying the Oriflamme, the banner of Saint-Denis, which normally rested in the church, along with the relics of the saint. As a result of his (and Suger's) appeal to the nobility's veneration for the saint, he was followed by a larger army of nobles than had ever previously pledged their allegiance to him, or to his father. The army of Louis and the Oriflamme were so formidable that Henry V retreated without battle.

Although Suger was not an ascetic but a reasonable and humane man in a time of violent extremes, he guided the monks of Saint-Denis back into a life of greater piety and religious observation than they had known under the abbot Adam. In Adam's administration the monks had acquired a notorious reputation for behaving in an excessively secular fashion. Suger corrected this situation at the urging of Bernard, abbot of Clairvaux, later St. Bernard. Suger cooperated in this and many other matters with Bernard, who was a close adviser to the Pope and the greatest spiritual leader in Europe at the time. He could be a powerful enemy or ally, and Suger chose to be his ally.

After King Louis's death in 1137, his successor, Louis VII, rejected Suger's role as principal adviser, and Suger concentrated all of his efforts for the next five years on completing the rebuilding of the church of Saint-Denis. But in 1142 Louis seized lands belonging to his most powerful vassal, Thibaut, count of Champagne. Civil war resulted. The support of the powerful Thibaut had always been vital to the strength of the French monarchy, and the young king was making war ferociously and irrationally. Suger stepped in as an active adviser to Louis VII, as he had always done with his father, and negotiated a peace treaty between Thibaut and Louis. The treaty was signed at the dedication ceremony of the church of Saint-Denis, an architectural marvel.

As penance for the many lives that he had taken during the war with Thibaut, Bernard of Clairvaux urged Louis VII to lead a crusade to free the Holy Land from the Muslims. Suger was strongly opposed to this and tried unsuccessfully to change the King's mind. For the first time Suger stood in opposition to the wishes of the weak, young king as well as those of Bernard and the Pope.

Suger's regency

On June 11, 1147, Louis and Eleanor departed on the Second Crusade. Louis left his crown with Abbot Suger, who was appointed regent in his absence. The Crusade was a disastrous loss, but at home Suger governed well, despite the great financial drain on the funds at his disposal. He devised new and fairer means of taxation, passed laws preventing deforestation, and suppressed a revolt by a group of nobles who planned to make Robert, count of Dreux, brother of Louis VII, king in his absence. When, in 1149, Louis returned from the Crusade, many believed that Suger would not return the crown, but they were proved wrong.

In 1150 Suger himself, with Bernard, made plans for another crusade. But in 1150, before it was begun, Suger fell ill with malaria. He died on January 13, 1151.

Suicide

The term suicide means the act or instance of taking one's own life voluntarily and intentionally but the term can also be applied to any person who attempts to take, or has a tendency to take, his own life. It also refers to the behaviour of individuals and groups, even of nations, that may bring about their own self-destruction. The term partial suicide has been used for self-mutilation, and chronic suicide for habitual behaviour patterns injurious to life, such as alcohol and drug addiction. This article is concerned with suicide as the act of "taking one's own life." This definition needs further clarification, however, as it does not say anything about the outcome. It is now customary to distinguish between "suicide"—that is, the fatal suicide—and "attempted suicide," or the nonfatal suicidal act.

PROBLEMS OF DEFINITION AND CLASSIFICATION

Question of intention

The statement that a person has committed suicide is a judgment about the cause of death based on the inference of self-destructive intention. If the intention was clear and unambiguous, if it had been communicated to others in writing or in some other way, and if the method of self-destruction employed left no doubt about the suicidal nature of the act, it would be easy to judge a death as having been suicidal. But these conditions do not obtain for the majority of suicidal acts, fatal or nonfatal. Self-destructive intentions are often difficult to establish retrospectively; in case of survival they are often denied, either because they were not clear and unambiguous, or because the truth is deliberately withheld. Suicide notes are left behind in only a minority of cases. The method of self-damage preferred in many countries today—namely, self-poisoning—does not exclude the possibility of accidental death. In his classic study, *Suicide* (1897), Émile Durkheim, the French pioneer of sociological research on suicide, rejected ascertainment of self-destructive intention as the indispensable criterion. He put the emphasis on the anticipation of the outcome. He implied that no one would carry out an act he knew to be fatal unless he intended to die. Methods employed to achieve self-destruction have changed since Durkheim, but his views on the difficulty of establishing intention directly still hold true today.

The majority of suicidal acts are nonfatal and need to be differentiated from nonsuicidal acts of self-damage. The outcome of most suicidal acts, including many fatal ones, is uncertain. The following definition seems to be the most serviceable: "A suicidal act is any deliberate act of self-damage which the person committing the act cannot be sure to survive." The question is simply whether the person committing the act of self-damage was likely to be aware of its potential dangerousness. Thus, an act of self-poisoning carried out by a person with expert knowledge about the effects of poisons will be viewed differently from a similar act committed by a person without such knowledge.

The definition of what constitutes a suicidal act is fundamental to suicide statistics. Statistical data based on different concepts and definitions of suicide are not strictly comparable.

Medicolegal definitions of suicide. In almost all countries every death suspected of being due to violence, including suicide, is subject to a statutory procedure. Suicide can be defined operationally as a death declared suicidal by the legal authority entrusted with this judgment, but there are no generally accepted criteria on which it is based. In the past, suicide used to be a criminal offense in many countries. This applied to England and Wales until the Suicide Act of 1961 repealed this legislation, which still exists in some countries once under British sovereignty. The legal approach prevails in the ascertainment of suicide. This means that positive evidence of suicidal intention is usually insisted upon, unless the method employed makes a suicide verdict inescapable. As a result, many cases that from the medicopsychological point of view would be classed as suicide are registered either as undetermined or accidental deaths because the information available did not meet legal requirements.

Suicide and undetermined or accidental deaths

Classification of suicidal acts. The division of suicidal acts according to outcome is essential, if only because the nonfatal act—that is, the suicidal attempt—calls for preventive measures concerning individuals and gives rise to problems not posed by the fatal act.

The best known classification of suicides is the one that was proposed by Durkheim and that is still used by some sociologists and anthropologists. The criterion of this classification was the disturbance in the relationship between society and the individual. Durkheim distinguished three types: (1) Egoistic suicide resulted whenever abnormal individualism had weakened society's control and reduced the person's immunity against the "collective suicidal inclination"; in this instance, the individual lacked concern for the community with which he was inadequately involved. (2) Altruistic suicide was due to an excessive sense of duty to the community. (3) Anomic suicide was due to anomie; that is, to society's failure to control and regulate the behaviour of individuals. Egoism and anomie may reinforce each other. Durkheim's classification has not been found useful by doctors and others actually dealing with suicidal individuals, however.

A great variety of acts of self-damage are subsumed under the term suicidal attempts. Numerous proposals for their classification have been made, but none of them has found general acceptance. They have been divided into "serious" and "nonserious" from the medical and psychiatric points of view. Suicidal "gestures" have been distinguished from "genuine" attempts, the "impulsive" acts

from deliberate ones, "psychotic" from the "nonpsychotic," the "rational" from the nonrational, and so on. Suicidal attempts apparently aimed solely at influencing others have been described as "manipulative" and harmless to life. The conceptions of death and the orientation toward death held by the person committing the act have been made the basis of classification. The term suicidal attempt has been rejected by some authors, and new terms have been proposed instead. Rating scales for "dangerousness," "lethality," "suicidality" have been suggested. All of these proposals have remained tentative, and none of them has been adequately tested for its usefulness. Classifications based on psychological criteria have to take account of the complexity of motivations and the coexistence of conflicting tendencies underlying suicidal acts.

SUICIDE IN VARIOUS SOCIETIES

Premodern societies. There would seem to be no society in which suicides do not occur. Statements to the contrary were based on travellers' tales rather than on systematic observations. Attitudes toward suicide differ in various societies and are linked with ideologies of death and afterlife.

Taboos and beliefs relating to suicide

Recent anthropological studies carried out among African tribes have revealed that their frequency of suicide was about the same as that of European countries with rather low suicide rates and that suicide among them was regarded as evil. Physical contact with the body of a suicide is feared to have disastrous effects, such as illness or suicide among one's kin. The tree on which a person hanged himself is felled and burned. The ancestors have to be placated by sacrifices. The place where the suicide happened is believed to be a haunt of evil spirits. Suicide is dreaded in the community, and a threat of suicide is sometimes used to exert pressure on the family.

Motives underlying suicide in premodern Asian societies are complex and include self-punishment, revenge, and rehabilitation in the eyes of the community. Violation of taboos and loss of status are common motives. Loss of status played a part in suttee, the more or less voluntary suicide of the widow in India, now outlawed. For the Hindu, death is not final but, rather, one incident in a long series of existences. There are timely and untimely deaths, suicide usually belonging to the latter category and leading to an earthbound ghostly existence. Similar beliefs still exist in modern society.

In Tikopia, a small island in the western Pacific where pagan ideology still lingers, the attitude toward suicide is one of mild disapprobation. The gods are believed to receive the souls of the dead but not of those who hang themselves. Their souls wander about until their ancestral spirits have found them. The spirits do not object, however, if a man commits suicide by going off to sea in a canoe, or a woman by swimming out to sea. These methods of suicide are admired. The Christian Tikopians believe that the soul of a suicide does not go to paradise but to satan.

Whereas Brahminism tolerates suicide, the attitude of Buddhism is ambiguous, though it encourages suicide under certain conditions, such as in the service of religion and country.

Ancient and medieval European societies. In ancient Greece and Rome, attitudes toward suicide varied among tolerance, condemnation, and admiration. Some philosophers saw in suicide the ideal way of gaining freedom from suffering. Others, among whom were Pythagoras and Plato, disapproved of it for reasons similar to those later advanced by Christianity (see below). Condemnation of suicide in principle was not incompatible with admiration for special cases. Cicero, for instance, rejected suicide but expressed admiration for Cato, who killed himself rather than live under Caesar's dictatorship. The hardening of the attitude against suicide in the late Roman Empire was partly because of the high incidence of suicide among slaves, who thus deprived their owners of valuable property.

The Old Testament mentions only four cases of suicide, the best known being those of Samson and King Saul, both of whom killed themselves to avoid torture or death by the enemy. Neither the Old nor the New Testament condemns suicide explicitly, in contrast to the Qur'ān, which declares it a crime worse than homicide.

The Christian Church in the Middle Ages adopted a similar attitude and condemned suicide as a form of murder and as interference with the prerogative of God. It was declared to be an act inspired by diabolical possession. The body of the suicide was refused a Christian burial and sometimes exposed to humiliating indignities as a deterrent to others. Acts of this type were still perpetrated in Europe at the beginning of the 19th century.

The attitude of the Christian churches has remained one of condemnation, but the sanctions are not equally severe in all denominations. The funeral rites accorded to the suicide differ more or less from those who have died a natural death. Exemption from sanctions on the ground of mental disturbance is more readily granted than in the past. Orthodox Jewish law, too, condemns suicide.

Modern societies. Public attitudes toward suicide are still as ambivalent and divided as in ancient Greece and Rome. There have been apologists for suicide even among the clergy. Eminent philosophers and writers have proclaimed man's right to dispose of his own life, whereas others have maintained its condemnation with equal conviction.

Decline of punitive attitudes toward suicides

In the Middle Ages and in modern times up to the 20th century, society has used first the canonic and later the criminal law in its fight against suicide. Following the French Revolution of 1789, antisuicide legislation was repealed in European countries, England being the last to follow suit in 1961. The change in the legal status of suicide has had no adverse influence on the suicide rate.

The "permissiveness" of modern society, which implies greater tolerance of deviant behaviour, may be partly responsible for the increase in suicidal acts, especially of self-poisoning. Society's attitude toward suicidal behaviour is probably less moralistic and punitive today than it used to be a generation ago. There is a greater readiness to understand rather than to condemn. Nevertheless, the tendency to conceal suicidal acts still persists, but the reasons for this tendency may not be quite the same as they were when a suicidal act was looked upon as a crime. Today a sense of guilt felt by those who could have prevented it may be the main reason for hushing it up.

Suicide in Japan. The custom of seppuku (hara-kiri), or ritual self-embowelling, used to be reserved for the nobility and members of the military caste. It has been regarded as a form of altruistic suicide, but it probably was in the majority of cases a form of sanctioned punishment whereby the individual chose to die at his own hand rather than be beheaded. Compulsory hara-kiri was made illegal in 1868. Voluntary hara-kiri as expiation for defeat or as self-sacrifice was highly praised and occurs occasionally even today. Although it has always been statistically insignificant, it still reflects the attitude of part of Japanese society that suicide is a demonstrative act of self-sacrifice.

The methods of suicide used in Japan today are similar to those employed elsewhere. This was probably always the case. The Japanese suicide rate used to be high, though not the highest among those reported by the World Health Organization (see Table 1). Recently the Japanese rate has declined considerably, but the significance of this reduction remains to be explained. There has at this same time been a marked increase of the suicide rate in the age groups below 30. A similar, though less marked, increase among the young has been observed in other industrialized countries. The excessive increase in the incidence of suicide among Japanese youth has been attributed to peculiarities of Japanese society, which has a strong sense of hierarchy and makes it difficult to express aggression against authority. Japanese youth is believed to suffer more than other young people from conflicts arising from a need for dependence, the wish for self-assertion, and a profound sense of insecurity.

High-risk groups. The elderly, the sick, the mentally ill (especially those suffering from depressive illness), alcoholics, soldiers, and policemen present above-average suicidal risks. In modern society new high-risk groups

Table 1: Death Rates from Suicide*

Increases in young suicides

have come to the fore, the best known being physicians, students of universities and allied institutions, and drug addicts. The excessive suicide rates among students have been related to the general increase of aggressive behaviour among the young and to the special competitive position of the student in modern society.

Voluntary euthanasia and suicide. The steady increase in the number of the aged in modern society and the ability of medicine to prolong life have led to demands for legalization of voluntary euthanasia. A bill that would have enabled individuals suffering from incurable illness to have their lives terminated painlessly was introduced but defeated in the British Parliament in 1970. Its advocates argued that voluntary euthanasia was "suicide by proxy" and that it required only a modification of the English Suicide Act of 1961, which legalized suicide but made aiding and abetting suicide a criminal offense. The idea of legalized euthanasia has many adherents among the general public but is strongly opposed by the representatives of the religions and by the practitioners of medicine who refuse to accept the role of executioners. It has also been argued that the relationship of euthanasia to suicide is not as close as it seems because a degree of uncertainty of outcome is inherent in most suicidal acts.

STATISTICS

Suicide rates. The suicide rate is the number of suicides per 100,000 population from 15 years of age, suicide being extremely rare below that age. Table 1 illustrates the way in which suicide rates are tabulated and how their fluctuations are recorded. Yearly averages are compared because the data from a single year can be misleading. In all the countries listed in the Table the male suicide rate was higher than the female, but the degree of the difference varied greatly. In several countries it was smaller in the later than in the earlier of the two periods, a trend that has been observed since the beginning of this century.

Decline of overall suicide rates

The correlations between the suicide rates and certain social characteristics of populations have been studied by sociologists. The suicide rates have been found to be positively correlated with the following factors: male sex, increasing age, widowhood, single and divorced states, childlessness, high density of population, residence in big towns, a high standard of living, economic crisis, drug and alcohol consumption, history of a broken home in childhood, mental disorder, and physical illness. Among factors inversely related to the suicide rates are female sex, youth, rural occupation, religious devoutness, the marriage state, a large number of children, membership of the lower socioeconomic classes, war. These correlations are not ubiquitous nor are they immutable. In a study carried out in Nigeria, for instance, unmarried men were found to be less liable to suicide than married men. In the United States, the suicide rates among higher socioeconomic classes were not found to be in excess of those of the lower income groups, although blacks overall have lower rates than whites. The studies resulting in these findings, however, were made in limited areas of the countries concerned, and their results cannot be generalized.

Validity of statistical data

Recently, the validity of the statistical data concerning suicide and the comparability of national suicide rates have been questioned. A worldwide survey carried out with the help of a questionnaire revealed great differences in the methods and criteria of certification of suicide. For national suicide rates to be comparable, not only the methods of ascertainment ought to be equally reliable but also the population census. In England and Wales, for instance, an autopsy is obligatory in every case in which a coroner's inquest is carried out. The legal procedures in Scotland are different, and autopsy is not obligatory. This means that the suicide rates of those two parts of the United Kingdom are not strictly comparable. In any community the social pressures against the categorization of a death as suicide are considerable. Most families want to avoid such a declaration. The need for caution in the evaluation of national differences has now been officially recognized. The introduction to the suicide mortality statistics of the World Health Organization for 1968 contains the following warning:

> The true incidence of suicide is hard to ascertain. Varying methods of certifying causes of death, different registration and coding procedures, and other factors affect the extent and completeness of coverage, making international comparisons impracticable.

Recently, even the comparability of regional suicide rates in the same country has been called into question. A comparative study of drug deaths handled by 19 coroners' offices in the United States and Canada revealed striking differences in the proportions allocated to categories of suicidal, accidental, and undetermined deaths, respectively. Similar differences were found in England when the ratios between suicide verdicts and open verdicts given by coroners of four neighbouring large cities were compared. When a Los Angeles coroner was joined by behavioral scientists who carried out a "psychological autopsy," the proportion of "undetermined" deaths was reduced significantly.

It would be a mistake to dismiss the statistical method in suicide research out of hand. But it is in need of critical scrutiny, and the comparability of data ought to be checked before conclusions about the significance of differences are drawn. Uniformity of search procedures and of criteria of categorization will not be easy to achieve, but they are worth striving for.

Difficulty of measuring attempted suicides

Attempted suicide. Whereas the legal requirements concerning death by other than natural causes assure the registration of at least a large proportion of suicides, the incidence of attempted suicides is much more difficult to establish. Not only is there no machinery for their registration but there appears to be a collusion on the part of all the parties concerned—the survivors, their families, the community at large, and even medical people—to keep quiet about them whenever possible. Although in most countries attempted suicide is no longer a punishable offense, it is still frowned upon by society and causes guilt feelings to those closely involved.

To establish the approximate incidence of suicidal attempts, it is not enough to obtain the number of hospital admissions following acts of self-damage in a defined population because not all of the cases are admitted to hospital. For a survey to be comprehensive, the cooperation of doctors practicing in the area has to be sought. A study of this type carried out in Sheffield, Yorkshire (population 500,000), revealed that in 1960 and 1961 the number of attempted suicides was about ten times as high as the number of suicides registered in the same period. A survey carried out in Los Angeles had a similar result. A Swiss survey suggested a ratio of 15 to one of nonfatal to fatal suicidal acts. These surveys did not include suicidal attempts in which no doctors intervened. There is reason to believe that their number is not negligible.

Comparison of an unselected sample of suicides with one of attempted suicides shows remarkable differences with regard to sex and age. The peak age for suicides has been found to lie between 55 and 64, for attempted suicides between 24 and 44. More men than women kill themselves, but more women than men attempt suicide.

Methods of suicide and attempted suicide. Tables 2 and 3 show the differences in the methods preferred in England and Wales and the United States as well as the change in their use over a decade.

Table 2: Methods of Suicide, United States*

	male		female	
	1955	1965	1955	1965

In England and Wales, 53 percent of the men and 75 percent of the women had poisoned themselves in 1955; in 1965 the figures were 75 percent and 85 percent, respectively. Domestic coal gas claimed the highest number of victims. The shift from the latter to narcotic poisoning was very conspicuous. In the United States, the trend toward self-poisoning was only slight, firearms continuing to rule supreme. Domestic gas is not universally available in the United States, but firearms are.

Table 3: Methods of Suicide, England and Wales*

	male		female	
	1955	1965	1955	1965
Analgesics and narcotics	79	246	182	486
Other solid or liquid poison	29	24	22	19
Domestic gas	412	335	553	322
Other gases	13	48	1	7

Other agents	43	50	26	19

*Per 1,000 deaths.
Source: *World Health Statistics Report 21*, No. 6, Geneva: WHO (1968).

As is to be expected, the more lethal and violent methods are used less frequently in the nonfatal than in the fatal suicidal acts. In recent years hospital admissions for narcotic poisonings have increased steadily. In England and Wales their number trebled between 1957 and 1964. Similar developments have been reported from other European countries. At the same time, the suicide rates have not increased or have even declined. This apparent paradox can be explained by the very low lethality of narcotic poisoning under conditions of modern treatment. Also, coroners and their equivalents in other countries are more inclined to give an accident verdict or declare the cause of death undetermined in cases of narcotic poisoning than in other cases of self-inflicted death.

MEANINGS AND DYNAMICS OF SUICIDAL ACTS
