Cardinality of compact spaces. The Tikhonov theorem shows that the number of points in a compact topological space can be arbitrarily large. If one forms spaces by taking big Cartesian products, however, the first axiom of countability is not satisfied. Until the late 1960s, one of the unsolved questions in topology asked how many points there could be in a first-axiom topological space that was compact in the covering sense. In 1969 the Russian mathematician A.V. Arkhangelsky showed that no such space could have more points than there are real numbers.

Some kinds of spaces have been more widely studied than others. Metrizable spaces, decomposition spaces, Moore spaces, and uniform spaces, all to be covered below, are Hausdorff spaces with a particularly rich history.

Metrizable spaces. A topological space X is metrizable if one can assign a suitable distance $D(x, y)$ to each pair of its points x, y. This distance function is required to satisfy the following properties:

1. $D(x, y) \geq 0$, the equality holding if and only if $x = y$;
2. $D(x, y) = D(y, x)$ (symmetry condition);
3. $D(x, y) + D(y, z) \geq D(x, z)$ (triangle condition); and
4. D preserves the topology of X.

The fourth condition means that the open balls under the distance function form a basis for X.

One of the standard theorems in topology states: A necessary and sufficient condition that a separable, regular Hausdorff space be metrizable is that it have a countable basis. This theorem permits the supposition that any regular Hausdorff space satisfying the second axiom of countability is metrizable and shows, for example, that certain decomposition spaces are metrizable (even though it would be hard to assign them a metric) and that all theorems that hold in metrizable spaces are true in these spaces.

Not all metrizable spaces are separable. In the late 1940s, working independently in the Soviet Union, Japan, and the United States, three topologists—Y.M. Smirnov, J. Nagata, and R.H. Bing, respectively—came up with closely related sets of necessary and sufficient conditions that a Hausdorff space be metrizable. This work was probably triggered by that of another topologist, A.H. Stone, working in England.

Conditions that a Hausdorff space be metrizable

A topological space to which a distance function has already been assigned is called a metric space. Two spaces may be topologically equivalent even though they have been assigned quite different metrics. (The whole plane and the interior of a circle in the plane are examples of topologically equivalent spaces the ordinary metrics of which are quite different.) Any metric, however, is a handy tool to use in studying a space (though some may be better than others), so that it is of interest to determine which topological spaces are metrizable.

Decomposition spaces. Suppose a topological space X is decomposed into a disjoint collection G of closed sets, each compact in the limit-point sense such that if $g \in G$, and U is an open set in X containing g, then there is an open set U' in U containing g such that U' is the union of elements of G. Such a decomposition is called an upper semi-continuous decomposition. Breaking a square into vertical intervals gives an example of such a decomposition. One can build a topological space by regarding the elements of G as points and choosing certain subcollections of G as open sets. The usual selection defines a set of (generalized) points to be open in the decomposition space if and only if the union of the closed sets identified with these points is open in X. In the case of the decomposition of the square mentioned above, the decomposition space would be homeomorphic to an interval. In general, if X is regular, the decomposition space is regular, and if X satisfies the second axiom of countability, then the decomposition space does also. Hence it can be assigned a metric even though this metric might not be readily determined.

The study of collections of closed sets as points of a decomposition space is yet another illustration of how topology can be used to study collections other than ordinary point sets.

Collections other than point sets

One of the interesting properties of decomposition space is that if an upper semi-continuous decomposition of the plane is such that the elements of the decomposition are connected and do not separate the plane, then the decomposition space is topologically equivalent to the plane. Efforts to extend this result to higher dimensions have resulted in some interesting research and some unsolved problems.

Moore spaces. Robert Lee Moore introduced a kind of space that has been widely studied. Moore spaces are more restrictive than first-axiom regular Hausdorff spaces and more general than metrizable spaces. They share many of the properties of metrizable spaces, and many theorems that hold in metrizable spaces can be shown to hold in Moore spaces.

If X is a topological space, $x \in X$, and G is an open covering of X, Star (x, G) denotes the union of the elements of G containing x. A Moore space may be defined as a regular Hausdorff space X with a sequence of open coverings, $G_1, G_2, \cdots$ such that if $p \in X$ and U is an open set containing p, then there is an integer n (a function of p and U) such that Star $(p, G_n) \subset U$. It may be noted that a metric space is a Moore space because G_i can be taken to be the set of open sets with diameters less than $1/i$. The upper half-plane space, however, is a Moore space, but it is not normal and hence not metrizable.

For many years topologists tried to decide whether all normal Moore spaces are necessarily metrizable. It is now known that some of the same considerations that

prevent one from obtaining an affirmative answer to the Suslin problem by using the ordinary axioms of set theory make it impossible to show by using these axioms that even all separable normal Moore spaces are metrizable.

Uniform spaces. With each covering of a space X there may be associated a subset U of $X \times X$, in which U is the set of all points $(x, y) \in X \times X$, such that x and y lie in the same element of G. The set U is called a neighbourhood of the diagonal because it contains all points of $X \times X$ the two coordinates of which are equal. A collection of neighbourhoods of the diagonal is called a uniformity if it satisfies a certain set of requirements. These requirements, not listed here, were fashioned so as to be useful in studying functions defined on X. Any space for which a uniformity has been selected is called a uniform space.

Neighbourhoods of the diagonal

Some mathematicians are more interested in studying the continuous functions that can be defined on a space than they are in studying the space itself. Uniform spaces are particularly interesting to them because by using the uniformity they can consider functions on the uniform spaces that share many of the properties of uniformly continuous functions on metric spaces.

Problems of current interest. Many of the problems of research interest in topology are concerned with manifolds and involve an interplay between the methods of general topology and those of algebraic topology (see TOPOLOGY, ALGEBRAIC). An n-manifold $\mathfrak{M}^n$ is a separable metric space such that each point of $\mathfrak{M}^n$ lies in an open set homeomorphic with $\mathfrak{R}^n$. Some interesting results obtained after 1950 and some open questions are given below without defining all terms.

Planar fixed-point problem. The following has been called the most interesting unsolved problem in plane topology: Does each compact continuum that is the intersection of a decreasing sequence of disks have the fixed-point property?

Polyhedral Schoenflies problem. It was shown in 1960 by Morton Brown of the United States that an $(n-1)$-sphere in $\mathfrak{R}^n$ is tame under certain conditions. A set in $\mathfrak{R}^n$ is tame if there is a homeomorphism of $\mathfrak{R}^n$ onto itself that takes the set onto a polyhedron. The polyhedral Schoenflies question asks whether each polyhedral $(n-1)$-sphere in $\mathfrak{R}^n$ bounds a piecewise linear n-ball. The answer is known to be affirmative if $n = 1, 2, 3$, but the problem is unsolved in higher dimensions.

Triangulation problem. It was shown in 1952 by E.E. Moise of the United States that all three-dimensional manifolds can be triangulated, or divided into dimensional triangles (or tetrahedra). It was announced in 1969, however, that not all n-manifolds ($n \geq 6$) have a combinatorial triangulation. Which (if any) higher dimensional manifolds can be triangulated?

Triangulation

Free-surface problem. Is a two-dimensional sphere S^2 in $\mathfrak{R}^3$ tame if for each $\varepsilon > 0$, there are ε-maps f_1, f_2 of S^2 into opposite components of $\mathfrak{R}^3 - S^2$? It was shown in 1961 by the U.S. mathematician R.H. Bing that the answer is in the affirmative if f_1 and f_2 are homeomorphisms. It was shown that S^2 is tame if each component of $\mathfrak{R}^3 - S^2$ is locally 1-connected.

Approximating surfaces. It was shown in 1959 by R.H. Bing that if $\mathfrak{C}^2$ is a two-dimensional complex and h is a homeomorphism of $\mathfrak{C}^2$ into a combinatorial three-dimensional manifold $\mathfrak{M}^3$, then for each $\varepsilon > 0$ there is a piecewise linear homeomorphism h' of $\mathfrak{C}^2$ into $\mathfrak{M}^3$ such that h' is within ε of h. If $\mathfrak{C}^2$ is a connected two-dimensional manifold and $\mathfrak{M}^3$ is connected, it was shown that h' can be a side approximation in that if $h(\mathfrak{C}^2)$ separates $\mathfrak{M}^3$, and U is a component of $\mathfrak{M}^3 - h(\mathfrak{C}^2)$, h' could be selected so that each component of $h'(\mathfrak{C}^2) - U$ is of diameter less than ε. To what extent do these results extend to higher dimensions?

Poincaré conjecture. The axioms of plane geometry give a geometric characterization of the plane. It is known that a connected compact two-dimensional manifold is topologically a two-dimensional sphere if each topological circle in it separates it. It is natural to seek a nice characterization of a three-dimensional sphere. A conjecture rich in history is that a compact connected three-dimensional manifold $\mathfrak{M}^3$ is topologically a three-dimensional sphere if each map of the boundary of a disk into $\mathfrak{M}^3$ can be extended to send the whole disk into $\mathfrak{M}^3$. A variation of this conjecture that turned out to be false was proposed by the French mathematician Henri Poincaré in 1900. Numerous unsuccessful attempts have been made to answer the question. It is known that $\mathfrak{M}^3$ is a three-dimensional sphere if each simple closed curve in $\mathfrak{M}^3$ lies in a topological three-dimensional ball in $\mathfrak{M}^3$. Solutions by C.D. Papakyriakopoulos of the United States to Dehn's lemma and the loop theorem have facilitated the study of three-dimensional manifolds. Although the Poincaré problem still remains unsolved, it is of interest that in 1960 two U.S. mathematicians Stephen Smale and John Stallings gave independent solutions of a higher dimensional version of the Poincaré conjecture in $\mathfrak{M}^n$, $n \geq 5$.

Characterization of a three-dimensional sphere

BIBLIOGRAPHY. Among elementary treatments of topology with material understandable to those at the advanced high-school level are: B.H. ARNOLD, *Intuitive Concepts in Elementary Topology* (1962); R.H. BING, *Elementary Point Set Topology* (1960); RICHARD COURANT and HERBERT ROBBINS, *What Is Mathematics?* (1941); and L.A. STEEN and J.A. SEEBACH, JR., *Counterexamples in Topology* (1970). Although Arnold's approach is intuitive, some theorems are proved. Bing gives some topological examples and discusses the axiomatic approach to topology. Courant and Robbins' book discusses aspects of several branches of mathematics, and chapter 5 is devoted to interesting theorems and problems in topology. The book of Steen and Seebach contains examples prepared by teams of students working under the authors' direction.

Intermediate-level books suitable for those with the background of a course in calculus include: J.D. BAUM, *Elements of Point Set Topology* (1964); M.C. GEMIGNANI, *Elementary Topology* (1967); ROBERT H. KASRIEL, *Undergraduate Topology* (1971); KAZIMIERZ KURATOWSKI, *Wstęp do teorii mnogści i topologii* (Eng. trans., *Introduction to Set Theory and Topology*, 1962); and M.H. NEWMAN, *Elements of the Topology of Plane Sets of Points*, 2nd ed. (1951). The first three of these are especially suitable as texts for an undergraduate course in topology. Newman's book gives an elementary treatment of many of the topological properties of the Euclidean plane. WACLAW SIERPINSKI, *Topologia ogólna* (1928; Eng. trans., *General Topology*, 2nd ed., 1956), was the text that introduced many graduate students to the study of topology. JOHN L. KELLEY, *General Topology* (1955), followed as a widely used graduate text. It treated general topology in a way particularly useful to those working in analysis. Although DICK WICK HALL and GUILFORD L. SPENCER, *Elementary Topology* (1955), is labelled elementary, it has a careful treatment of some of the difficult properties of the plane not easy to understand. J.G. HOCKING and G.S. YOUNG, *Topology* (1961), has been widely used as a graduate text and not only treats general topology but also introduces many geometric ideas useful in the study of manifolds. More recent texts include JAMES DUGUNDJI, *Topology* (1965); RYSZARD ENGELKING, *Zarys topologii ogólnej* (1965; Eng. trans., *Outline of General Topology*, 1966); S.T. HU, *Introduction to General Topology* (1966); KAZIMIERZ KURATOWSKI, *Topologie*, 4th ed., vol. 1 (1958; Eng. trans., *Topology*, new ed., vol. 1, 1966); and STEPHEN WILLARD, *General Topology* (1970).

Tornadoes, Whirlwinds, and Waterspouts

Tornadoes, whirlwinds, and waterspouts are atmospheric vortices, or rotating funnel-cloud air masses of small diameter. They are differentiated from each other by the intensity of their rotation and by the surfaces that they traverse. Though tornadoes and whirlwinds both travel over landmasses, whirlwinds are atmospheric systems smaller than tornadoes. Waterspouts are tornadoes that form or pass over a water surface.

Tornadoes. The name tornado comes from the Spanish *tronada* ("thunderstorm"), which supposedly was derived from the Latin *tornare* ("to make round by turning"). The most violent of atmospheric storms, a tornado is a powerful vortex or "twister" whose rotational speeds are estimated to be near 300 miles (480 kilometres) per hour but may occasionally exceed 500 miles (800 kilometres) per hour. The direction of rotation in the North-

Definitions and general characteristics

Figure 1: *Tornadoes of the midwestern United States.*

(Right) Twin funnels, in one of the worst recorded tornado outbreaks, crossing a highway south of Elkhart, northern Indiana, on April 11, 1965; debris can be seen falling out of the left funnel.
(Left) Eric Lantz, (right) Paul Huffman

ern Hemisphere is usually, though not exclusively, counterclockwise.

The first visible indication of tornado development is usually a funnel cloud (Figure 1) or "tuba," which extends downward from the cumulonimbus cloud of a severe thunderstorm. As this funnel dips earthward, it becomes darker because of the debris that is forced into its intensifying vortex. Some tornadoes give no visible warning until their destruction strikes the unsuspecting victims.

Tornadoes often occur in groups or series, and several twisters sometimes descend from the same cloud base (Figure 1). An outbreak in the United States in the late afternoon and evening of April 11, 1965, is an example of such a series. This outbreak was the most destructive tornado disaster in the United States in 40 years. A system of at least 37 deadly whirls caused destruction in the states of Iowa, Wisconsin, Illinois, Indiana, Michigan, and Ohio; 271 persons were killed, and more than 3,000 were injured. Property damage was estimated at $300,000,000. The death total was surpassed only by that of a tornado on March 18, 1925, which killed 689 persons in Missouri, Illinois, and Indiana.

The forward speed of an individual tornado is normally 30 to 40 miles (48 to 64 kilometres) per hour but may range from nearly zero to 70 miles (zero to 112 kilometres) per hour. The direction of motion is usually from the southwest to the northeast, although tornadoes associated with hurricanes may move from the east. The paths of twisters average only several hundred yards in width and 16 miles (26 kilometres) in length, but large deviations from these averages may be expected; *e.g.*, the disastrous 1925 tornado was at times 1 mile (1.6 kilometres) wide, and its path length was 219 miles (352 kilometres).

In the short time that it takes to pass, a tornado causes fantastic destruction. There have been cases reported in which blades of straw were embedded in fence posts; a schoolhouse with 85 pupils inside was demolished and the pupils carried 150 yards (137 metres) with none killed; and five railway coaches, each weighing 70 tons, were lifted from their track and one coach was moved 80 feet (24 metres).

Although much remains to be learned about tornado formation and movement, remarkable advances have been made in the effectiveness of tornado detection and warning systems. These systems involve analyses of surface and upper-air weather, detection and tracking of atmosphere changes by radar, and spotting severe local storms.

Waterspouts. When a tornado forms or passes over a water surface it is called a waterspout. Like tornadoes, waterspouts may assume a variety of shapes and often occur in series or families. Measurements of their forward speeds are scarce, but estimates vary from a few miles an hour to speeds as high as 40 to 50 miles per hour. Contrary to popular opinion, a waterspout does not "suck up" water to great heights, though it may lift the water level a few feet. The main visible cloud consists mostly of freshwater clouds produced by condensation of water vapour; however, a sheath of spray often rotates around the lower portion of the vortex tube (Figure 2).

B.J. Oram

Figure 2: Waterspout in Tampa Bay, Florida, showing cloud and disturbed water surface. It was one of a series of spouts that occurred on June 25, 1964.

One of the largest and most famous waterspouts, observed near Massachusetts on August 19, 1896, was witnessed by thousands of vacationers and several scientists. Its height was estimated to be 3,600 feet (1,095 metres) and its width 840 feet (256 metres) at the crest, 140 feet (43 metres) at centre, and 240 feet (73 metres) at the base. The spray surrounding the vortex tube near the water surface was about 700 feet (200 metres) wide and 400 feet (120 metres) high. The spout lasted 35 minutes, disappearing and reappearing three times. Most waterspouts are smaller, with much shorter lives. This outstanding spout is an example of one that apparently was spawned by thunderstorm-squall conditions, similar to those that produce tornadoes over land.

There are few authentic cases of large ships ever being destroyed by a spout, although spouts are a dangerous hazard to small vessels; and a few intense waterspouts have caused deaths when they moved inland over popu-

lated areas. The belief that firing a cannonball or other projectile into a spout can "break it up" has no scientific foundation.

Whirlwinds. A whirlwind, in the general sense, is any rotating mass of air or atmospheric vortex. The term is, however, commonly restricted to atmospheric systems smaller than a tornado but larger than the eddies of microscale turbulence. The whirlwind is usually named after the visible phenomenon associated with it; thus there are dust whirls, or dust devils; sand whirls, or sand pillars; and fire, smoke, and even snow whirls, or spouts.

In contrast to the pendant form of the tornado funnel, a dust or sand devil develops from the ground upward, usually under hot, clear-sky conditions. The whirl shape is normally that of a cylindrical column or an inverted cone. The axis of rotation is usually vertical, but it may be inclined. The direction of rotation may be either clockwise or counterclockwise. Vortices with a horizontal axis of rotation are sometimes called rolls or rotors. Dust and sand whirls are not nearly as violent as tornadoes, although jackrabbits have been lifted by the more intense vortices. The whirls measure in diameter from a few inches to several hundred feet, and visible heights from a few feet to at least 5,000 feet (1,500 metres). This is probably not the upper limit, for sailplane pilots have used their spirally ascending currents to soar to above 15,000 feet. Like tornadoes and waterspouts, dust and sand devils often appear in groups or series. Eleven of them were simultaneously sighted in Ethiopia; and in the Mojave Desert a series of smaller whirls followed in the wake of a larger primary vortex. Such secondaries are sometimes referred to in India as "dancing devils."

Fire whirlwinds are a problem to the forest rangers who must cope with them. A historical example of a great fire vortex, produced by war, is that which formed over Hamburg, Germany, following a massive aerial bombing during the night of July 27–28, 1943. The fire fueled a counterclockwise rotation storm one to two miles in diameter and three miles high, with winds estimated to be more than 100 miles per hour in some sections.

Treated in this article are the occurrence, physical characteristics, and theories of formation of tornadoes and allied phenomena. For further information on atmospheric motions associated with severe storms, see WINDS AND STORMS; and CYCLONES AND ANTICYCLONES. See also, THUNDERSTORMS; and HURRICANES AND TYPHOONS.

OCCURRENCE AND DISTRIBUTION

Tornadoes. Tornadoes strike in many areas of the world, but nowhere are they as frequent or as fierce as in the U.S., where an average of 628 per year was reported during the period 1953–65. Direct comparisons of relative tornado frequencies in various countries are biased, because observational data are often lacking in sparsely settled regions. It appears, however, that Australia, where several hundred per year have been reported, has the dubious honour of second place. Other countries reporting tornadoes include, but are not limited to, Great Britain, Canada, China, France, Germany, The Netherlands, Hungary, India, Italy, Japan, the Soviet Union, and even Bermuda and the Fiji Islands.

Distribution and frequency of U.S. tornadoes

A total of 898 tornadoes were counted in the United States during the year 1965 alone. This peak may not be the all-time high, because in earlier years when the population density was less, the observational network was more crude. For the same period, 1953–65, the annual average number of days on which one or more tornadoes occurred (tornado days) was 158. A vast "tornado belt" embracing the Great Plains and the southeastern portion of the country is threatened by tornadoes every year (Figure 3). Every state in the nation, including Alaska and Hawaii, has experienced twisters. The average frequency varies from 109 in Texas to less than three in the far western and most of the northeastern states.

A more important criterion for gauging tornado severity is the average number of tornadoes in a unit area, such as a square mile or a two-degree square on a map. Computations of this tornado density for a 45-year period show that the greatest concentration of tornadoes per unit

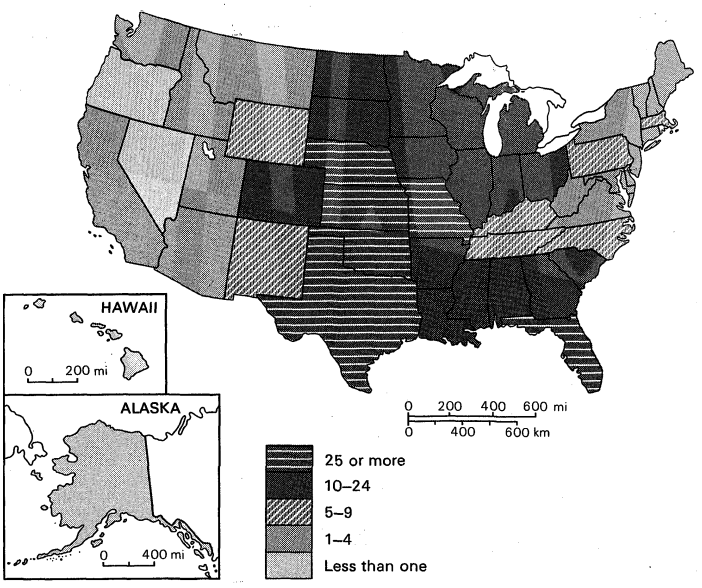

Figure 3: Annual frequency of tornadoes in the United States. (Based on 1953–65 data.)

area is found in the states of Oklahoma and Kansas. The area with the greatest potential for casualties is that which combines a high tornado incidence rate with a thick population concentration. Southwestern Oklahoma, for example, has the highest tornado incidence per unit area but because it is thinly populated, compared with the Chicago area, which has less than one-half its tornado incidence, casualty potential for Chicago is much greater. Over a 45-year period the potential casualties for Chicago are nine people per square mile, compared with one person per square mile in southwestern Oklahoma. Although the probability that a specific locality will be struck by a tornado in any one year is very small, this low probability does not mean that such an event will not happen. An extreme example of an apparent defiance of probability statistics took place in Codell, western Kansas, a small town hit by tornadoes on the same date, May 20, in three successive years, 1916, 1917, and 1918.

Seasonal and diurnal variation

Tornadoes may occur during any month of the year. Normally, for the United States as a whole, the month with the most tornadoes is May; and more than half the year's total occurs during the three months of April, May, and June (Figure 4). The lowest frequency is in December and January. No season of the year is free from tornadoes, but in spring and summer they are five times as numerous as in winter and fall.

By courtesy of U.S. Department of Commerce

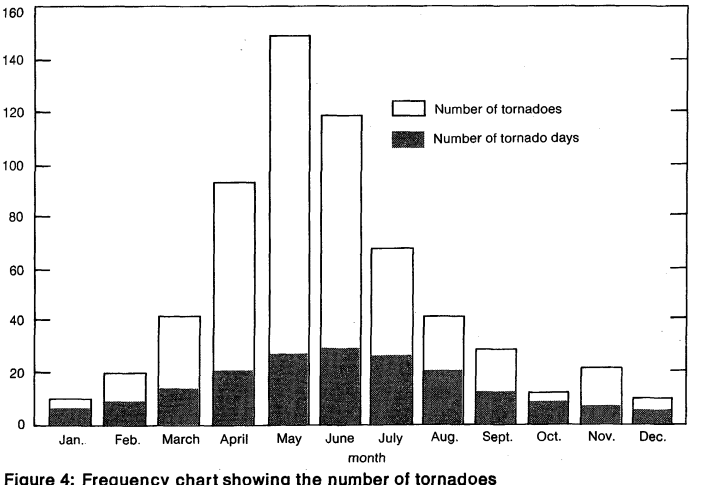

Figure 4: Frequency chart showing the number of tornadoes and the number of tornado days per month for the United States. (Based on 1953–65 figures.)

Tornadoes are generated from severe thunderstorms,

which form readily between warm, moist air from the south or southwest and contrasting cool, dry air from the west or northwest. A squall line of severe local storms often develops along this boundary, and sometimes a family of tornadoes is spawned. In February, warm, moist air from the Gulf of Mexico begins to penetrate the Gulf states. As it continues its northern and eastern penetration, tornado frequencies reach their peaks during April over the southern Atlantic states, during May over the southern Plains states, and during June over the area extending from the northern plains to western New York state. In the summer and fall the decreasing contrast between the air masses results in a reduction of tornado incidence in most sections, although they may develop from the severe thunderstorms associated with unstable air masses, especially in Florida, where tornadoes are often associated with hurricanes. During December and January, cold air dominates the country, and the moisture–temperature relationships required for tornado genesis are not usually present.

Although tornadoes may strike at any hour of the day or night, they generally form during the middle or late afternoon, between 3 to 7 PM, the period most favourable for the development of severe thunderstorms (*q.v.*), from which they are bred.

Waterspouts. The worldwide distribution of waterspouts is difficult to determine because most of them occur over oceans and their detection depends upon observations from coasts or from ships or airplanes. They are most frequent over tropical and subtropical waters; many of them have been observed over the Gulf of Mexico, off the coast of Florida and the Bahamas, and over the Gulf Stream. The spouts are common off the west coast of Africa near the Equator and off the coasts of China and Japan; but they may appear in unexpected places, such as the Grand Banks of Newfoundland and even near Seattle, Washington. As mentioned earlier, one of the largest observed waterspouts occurred off the coast of Massachusetts. A broad spout estimated to be 100 feet high and 700 feet thick appeared off the California coast in 1914, and one offshore from New South Wales, Australia, had a measured height of over 5,000 feet.

The most common season for waterspouts in the Northern Hemisphere is between May and October, but they may appear at any time of the year or of the day or night.

Whirlwinds. Every summer hundreds of thousands of dust and sand devils travel across the arid and semi-arid regions of the world. Only an extremely small fraction of such whirls are observed by man, however, because desert areas are sparsely settled. Observers report that whirlwinds are sighted almost daily during the hot season over the Sahara and the arid regions of Australia and southwestern United States. They are also common over sections of India and the Middle East. An extensive scientific census of dust devils near Tucson, Arizona, was taken from June 23 to July 28, 1962. A total of 1,663 whirls were spotted, and the daily average was near 80.

Dust devils may, at times, develop in more temperate weather and have even been observed as far north as the subarctic. The planet Mars, too, might have them, a theory having been proposed that the dust clouds in the Martian atmosphere may be produced by the action of dust devils.

Diurnal frequency and duration

Dust and sand devils are usually most active over desert areas in the early afternoon, 12:30 to 2:00 PM, local standard time. These times precede by several hours those at which the maximum air temperature is recorded in a standard, shaded instrument shelter five feet above the ground. One reason for this apparent anachronism is that the much hotter sand surface attains its peak temperature earlier than the air at the five-foot (1.5-metre) level.

The life of a dust or sand devil may be longer than visual observations indicate, because the vortex itself does not depend upon the visible material forced into it. Durations vary from several seconds to about seven hours, but most dust devils probably last less than five minutes, and few persist for more than an hour. The larger, more vigorous whirls have a longer lifetime than the smaller vortices. One large dust devil, with a height of about 2,500 feet (750 metres), lasted for seven hours as it travelled 40 miles (64 kilometres) on salt flats in western Utah. And in northwestern Mexico a large whirl formed at the end of an embankment and remained there for four hours.

PHYSICAL CHARACTERISTICS OF THE VORTICES

Although the visible characteristics of tornadoes, waterspouts, and other atmospheric vortices are well known, details regarding the distribution of velocity, pressure, energy, and particulate matter within them are lacking.

Tornadoes and waterspouts. Tornadoes destroy all standard measuring instruments; hence, most values given for velocity, pressure, and energy distribution have depended upon theory and engineering damage estimates. Since the 1940s, however, radar, instrumented aircraft, and photogrammetric techniques have provided some quantitative data for analysis of the vortex structure.

Velocity distribution

The first quantitative observation of the distribution of tangential and vertical speeds within a tornado was made from scaled movies of the debris and cloud fragments in a tornado in Dallas on April 2, 1957. The tornado was fairly stable and relatively small, with a spotty damage path. The variation of the tangential (rotational) velocity with radius at the 1,000-foot (300-metre) level is shown in Figure 5, in which the tangential velocity is seen to rise

Adapted from H. Kuo, *Journal of the Atmospheric Sciences*, vol. 23, no. 1 (January, 1966)

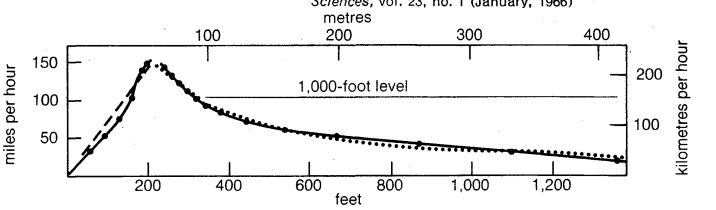

Figure 5: Variation of the tangential velocity with radius at the 1,000-ft. level in the Dallas tornado on April 2, 1957. Dashed and dotted line represents the theoretical values; solid line represents observed values.

steeply from zero at the centre of the vortex to 150 miles (240 kilometres) per hour at about 200 feet (60 metres) from the centre and then fall off more gradually. This type of velocity distribution closely resembles the Rankine (theoretical) combined vortex (dashed and dotted lines in the figure), in which the inner core is assumed to rotate with a constant angular speed, designated by the Greek omega (Ω), and corresponding to the rotation of a solid body. The tangential velocity is the product of the constant angular speed times the radius of the vortex. This is expressed in the equation $v_1 = \Omega r_1$, in which v_1 indicates tangential velocity and r_1 the radius distance. Hence, for this particular tornado, the tangential velocity in the inner core at the 1,000-foot level was almost directly proportional to the radius until the maximum speed (indicated by vm) was reached at the corresponding radius (rm). At this point, $vm = \Omega rm$.

The tangential velocity distribution in the outer portion of this two-celled vortex follows closely the relation $v_2 r_2 = C = \text{constant}$. Hence, $v_2 = C/r_2$, or the velocity is inversely proportional to the radius. The velocity profiles for the 300- and 100-foot levels showed somewhat greater deviation from the Rankine (theoretical) vortex, possibly because of frictional effects near the ground. The peak tangential speed for this tornado was 170 miles (274 kilometres) per hour, at a radius of 130 feet (40 metres) and elevation of 225 feet (69 metres).

Vertical speeds are measured by tracking debris in the air and correcting for free-fall velocities (which are not related to the tornado-derived speeds). Isotachs (lines of equal value of wind velocity) of these vertical speeds are depicted in Figure 6, in which distances are in metres and speeds in metres per second (one metre per second equals 2.24 miles per hour). A jet of strong vertical flow extends upward from a high-speed centre at 135 feet (41 metres), but the jet disappears near the 1,000-foot (300-metre) level. Above this altitude the line of zero velocity values at any one time appears to coincide with a zone of mois-

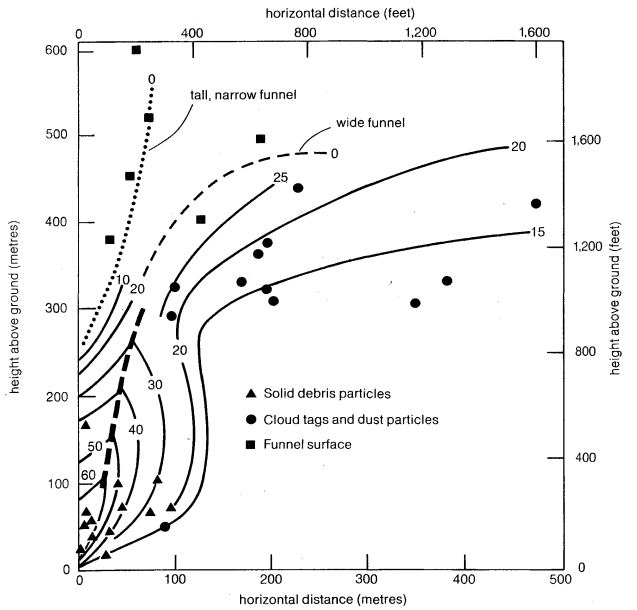

Figure 6: Distribution of the vertical wind velocities (in metres per second) in the Dallas tornado on April 2, 1957.

ture condensation around the funnel. This indicates that the upper portion of the funnel probably does not act as a sink mechanism, in which air condenses at high levels and then sinks to lower levels. Whether the horizontal and vertical velocity distributions presented for the Dallas tornado are typical of most other tornadoes is not known.

Pressure, heat flux, and energy

No direct measurements have been made of pressures within a tornado, although barographs outside the zone of destructive winds have recorded the sudden drops of pressure associated with the tornado passage. By the use of theoretical relationships between wind and pressure and evaluation of damage patterns, however, some estimate of the distribution of pressure may be obtained.

Although standard barographs are not designed to register the rapid changes of pressure produced by a tornado, there have been cases in which barographs or aneroid barometers on the fringes of the zones of maximum winds have done so. Pressure drops of 100 millibars, about 10 percent of normal atmospheric pressure, are not uncommon, and a fall of 200 millibars has been reported. Because these changes may occur within an interval of less than 30 seconds, the normal pressure inside a building does not have time to adjust to the fast reduction of pressure outside, causing explosive or "suction" effects. Roofs are lifted and walls are blown outward.

The heat flux and energy distribution within a tornado have never been measured directly. Calculated values for the kinetic energy of a typical tornado vary from 10^{10} to 10^{13} joules (10^4 to 10^7 kilowatt-hours). The energy input required to generate this organized motion is probably 10 to 100 times as great. For comparison, the total energy (including radiation) of the 20-kiloton nuclear bomb dropped upon Hiroshima was about 10^{13} joules (10^7 kilowatt-hours). Any theory of tornado development must explain how the potential energy of the environment is converted into the organized kinetic energy of the tornado vortex.

The lower portion of a tornado funnel often appears as a mass of dust and debris picked up by the vortex. The rim of the funnel is usually rendered visible by clouds produced by the condensation of water vapour. The inner core is almost cloudless. Heavy rains and hail are often associated with the severe thunderstorms from which tornadoes develop. Waterspouts sometimes draw fish and frogs into the vortex and then drop them onto land.

Velocity distribution

Dust devils and "fair-weather" waterspouts. Until quite recently few detailed measurements of horizontal and vertical velocities in dust devils had been made. Quantitative data on "fair-weather" waterspouts are still more sparse, but it is probable that the velocity distributions are similar to those of dust devils in many respects.

Recent measurements in dust devils indicate that the variation of the tangential velocity with radius corresponds closely to that of the Rankine vortex, as described earlier. Tangential speeds of 25 miles (40 kilometres) per hour have been measured and are probably common in moderately strong vortices. Velocities of over 50 miles (80 kilometres) per hour probably occur in some of the larger, more vigorous dust devils. Sailplane pilots have measured vertical speeds of 10 miles (16 kilometres) per hour in moderate whirls and 20–30 miles (32–48 kilometres) per hour in stronger vortices.

A recent study indicates that the mature dust devil may be divided into three vertical regions. Region 1 is a shallow frictional layer near the ground. It is here that the air and dust are entrained into the core of the whirl. Above this shallow boundary layer is Region 2, a stable vortex in which the pressure force and centrifugal force are in balance. Region 3 begins where the top of the vortex becomes unstabilized and the turbulent air diffuses radially with height.

Pressure drops of a few millibars are typical in dust devils. Details regarding the pressure distribution are not known, but there is good evidence that pressure in the well-defined vortex (Region 2) follows a radial distribution similar to that of the Rankine vortex.

The main energy source for a dust or sand devil is the heat flux from the hot surface, although, under certain circumstances, dust or sand devils can be formed in a moderate surface temperature environment, provided that other necessary meteorological conditions are fulfilled. A heat transport (flux) of 0.7 calories per square centimetre per minute was measured over a desert dry lake in California. For a circular area with a 10-metre (30-foot) diameter, this flux would correspond to a net upward heat transport of about 50,000 watts. A dust devil moving over a heated surface utilizes this energy to maintain itself. When dissipative forces, such as surface friction and eddy interaction with the environment, exceed the available energy, the whirlwind is destroyed.

THEORIES OF VORTEX FORMATION: THE GENERATION OF TORNADOES, WATERSPOUTS, AND WHIRLWINDS

At present, meteorologists have not generally agreed on any particular quantitative theory for complete explanation of the formation and maintenance of tornadoes, waterspouts, and other vortices. The literature on vortex theory is extensive; therefore this review will be concerned mainly with some of the more recent theories that seem to fit atmospheric observations and laboratory simulation experiments. Any theory of vortex formation must explain, quantitatively, how the potential energy of the environment is converted into the organized rotational motion of the vortex.

Downward development theory. One kind of tornado formation theory assumes that the tornado vortex develops downward from the parent thunderstorm cloud. It is known that the bases of cumulonimbus clouds associated with severe thunderstorms have stronger rotation than those of ordinary thunderstorms. Further, the visible funnel appears to work downward toward the ground. This visible aspect does not necessarily mean, however, that the tornado vortex itself must originate at upper levels since spirally rising air currents could produce a cloud sheath resulting from condensation of water vapour in the rising air.

Vortex-contraction theory. During the last 25 years radar has been extensively employed in the detailed analysis of severe storms. The use of radar in this area is based on the fact that clouds and precipitation "backscatter" the emitted radiation, producing an "echo" that is photographed on a radarscope. Areas of relatively clear air ("echo-free") are delineated by contrast. Radar meteorologists have contributed significantly to both theories of tornado development and methods of warning.

The "hook" echo

A photograph of a historically significant echo associated with an Illinois tornado is reproduced in Figure 7. A projection from the mother thunderstorm lengthened and

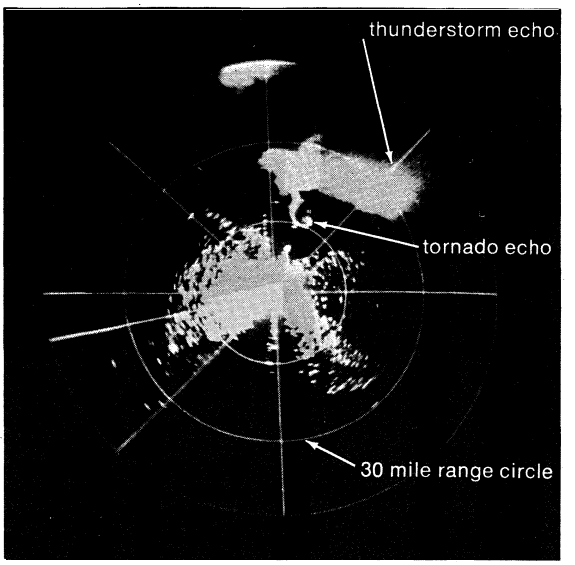

Figure 7: Hook echo of a tornado in Champaign, Illinois, photographed on a radar scope on April 9, 1953. This was the first occasion on which the hook echo, an important clue in the tornado warning system, was recognized and photographed.
By courtesy of the Illinois State Water Survey, Urbana, Illinois; photograph, Donald W. Staggs

curved in a counterclockwise manner to form an echo resembling a "figure 6" or "hook." The hook itself is not the tornado, but tornadoes are often associated with echoes of this shape. An analysis of echo alignments and motions and of surface pressure and wind distribution revealed that this distribution corresponded to that of a "tornado cyclone" detected in 1948. This kind of cyclone is a small low-pressure area of about 5 to 25 miles in cross section; the 1948 tornado funnel was one to two miles south of the cyclone centre, and it has been suggested that the contraction of this cyclone would result in an increase in angular momentum and a large upward motion, producing condensation within the tornado cyclone.

Severe local-storm theory. A model for severe local storms that may produce tornadoes is shown in Figure 8.

Adapted from K.A. Browning, *Journal of the Atmospheric Sciences*, vol. 21, no. 6 (November, 1964)

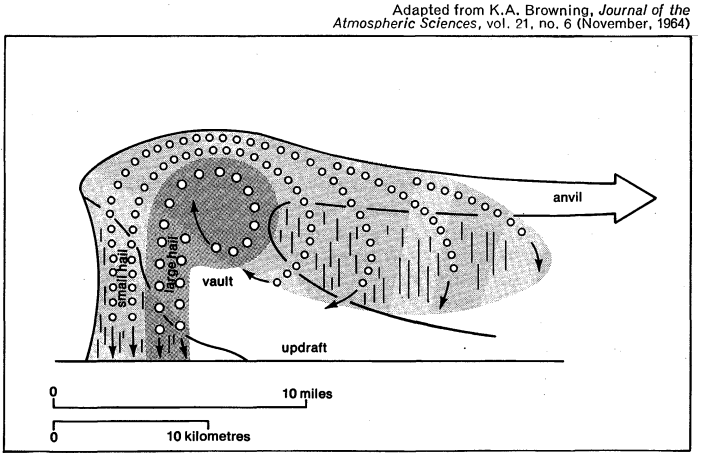

Figure 8: Vertical section illustrating precipitation trajectories in different parts of a severe storm travelling to the right of the prevailing winds in the middle troposphere.

This model includes a strong shearing of wind (scissor-like action) veering (turning, in clockwise sense) with height. It is based partly upon radar range-height scope photographs of a severe hailstorm in southeast England in July 1959 and of tornadoes in Oklahoma on May 4, 1961. Numerous surface observations were also utilized. The essential features of the model are the following:

1. An updraft of warm, moist air, in which most of the streamlines (lines following flow paths) turn counterclockwise (cyclonically) through about 270 degrees.
2. A downdraft within the precipitation areas ahead of the updraft.
3. An extensive overhanging radar echo ahead of the storm.
4. A region of low reflectivity or "vault" in which there is a persistent strong updraft. The largest hail usually falls in the area of intense echo surrounding the vault.
5. A hook-shaped echo that has a definite counterclockwise circulation. When a tornado forms, it is usually near the forward edges of the hook. It is believed that the hook-shaped echo results from rotation within the strong updraft. Large hail, frequently associated with tornado-breeding storms, requires a vigorous updraft for its formation. The development of a core of rotation within the updraft appears to be required for the genesis of severe storms moving to the right of the environmental winds in the troposphere. It has been suggested that the necessary core of rotation within the updraft could develop only when the updraft was strong enough to generate the growth of giant hail.

Electricity theory. It is known that lightning (*q.v.*), when it accompanies a tornado, has peculiar characteristics. The high-voltage discharges have been described as brighter and bluer than those from other storms. A farmer who had looked up into the core of a tornado later described the walls as constantly illuminated by lightning flashes that "zigzagged" from side to side. So it is not strange that lightning has been hypothesized as the source of energy for the genesis or maintenance of tornadoes. Electrical theories for tornado formation are not new, but have been revived in modern studies.

The lightning hypothesis

Electrical energy is assumed to be transferred to the vortex or the incipient vortex by mechanisms such as the electromagnetic acceleration of ions or heat released from lightning strokes. These electrical transfer mechanisms have been analyzed on the basis of theory and the use of simulated tornado vortex experiments. It has been concluded that the electrodynamic acceleration of ions is unimportant for either the genesis or maintenance of a tornado. Although the heat released from lightning could initiate updrafts, this lightning energy would have to persist for several minutes in order to generate a tornado. Laboratory experiments indicate that electrical discharges in the centre of an intense vortex inhibit, rather than strengthen, its circulation.

These negative results do not mean that electrical phenomena might not produce important indirect effects: the rate of release of latent heat from condensation and precipitation could be influenced by the electrodynamic acceleration of charged particles in the vortex.

General vortex theory. Because of the complex interrelationships of the meteorological factors that must operate together to develop a tornado, a quantitative dynamic theory for generation and maintenance of these twisters is very difficult to formulate.

A theory, nevertheless, has been formulated for the dynamics of atmospheric vortices, which applies not only to tornadoes but also to milder twisters, such as dust devils and other whirlwinds. This model is based on the preexistence of two atmospheric conditions considered to be essential for the genesis and maintenance of the vortices: (1) a thick layer of unstable stratification, either with or without the influence of the latent heat of condensation; and (2) existence of vorticity. The first factor produces sinking because vertical instability aids strong updrafts and the rising air mass is replaced by horizontally converging air. The second factor provides a source of momentum for the development of a stronger tangential velocity as the air converges into a smaller radius. Thus tornadoes and waterspouts, because they are basically convective in nature, are similar to dust devils and fire whirlwinds. For all of these vortices the ratio between horizontal extent and vertical extent (ranging from $\frac{1}{5}$ to $\frac{1}{50}$) is small in comparison to that for hurricanes and extratropical cyclones (from about 10 to 200). Because only the general mechanisms that govern the vortices were of concern, differences depending upon atmospheric structural details were disregarded and it was assumed that all of these small-scale vortices are governed by the same simple model.

From a set of equations for atmospheric vortex motions,

the effective radius of the innermost cell, assumed to be developing into a vortex, was found to be inversely proportional to the one-third power of the initial vorticity, and directly proportional to the one-third power of the product of the eddy viscosity coefficient and the effective depth of the unstable layer. When this layer is shallow, only relatively small and weak whirlwinds, such as dust devils, can be produced.

For a steady state (equilibrium) circular vortex, two solutions were derived. The first was a two-cell type, with descending motion in the centre and ascending motion in the outer part; the second was a one-cell type. The theoretical descending motion in the centre is compatible with the observed sparseness of particulate matter in the cores of tornadoes and dust whirls.

The two-cell solution also indicates that the pressure distribution in the outer portion of the vortex is the same as the flow in the outer part of the Rankine combined vortex described earlier.

Other solutions for a steady state vortex are possible, but it appears that all of them have the following common characteristics:

1. The maximum vertical speed is proportional to a stability factor and increases linearly with height in the unstable layer.
2. The maximum tangential speed is proportional to the angular momentum and the square root of the stability factor; it is inversely proportional to the square root of the coefficient of eddy viscosity, but it is almost independent of the height.
3. The radius of the maximum tangential wind is proportional to the square root of the eddy viscosity coefficient divided by the stability factor.
4. The tangential flow outside the radius of the maximum tangential wind closely approximates the relation in which the product of velocity and radius is a constant ($vr = C$).

The theoretical results of the dynamic–model theory agree quite well with observations of tornadoes and dust devils.

Res.*, vol. 69, no. 12, pp. 2435-2447 (1964), presents results of theoretical analyses and laboratory experiments to determine whether the unusual electrical phenomena associated with tornadoes might be important in the life cycle of the tornado; N.R. WILLIAMS, "Development of Dust Whirls and Similar Small-Scale Vortices," *Bull. Am. Met. Soc.*, vol. 29, no. 3, pp. 106-117 (1948), summarizes observations over Mojave Desert, California, presents theory for vorticity generation.

(N.R.W.)

Toronto

Character and location of the city

Situated on the northern shore of Lake Ontario, Toronto is Canada's second largest city, the seat of government of the Canadian province of Ontario, and the financial and commercial heart of Canada. It is little more than an hour's flying time from both New York and Chicago. During the 1950s and '60s Toronto grew phenomenally from a rather sedate provincial town—"Toronto the Good"—to a lively, thriving, cosmopolitan metropolitan area of over 2,600,000 persons, attracting some 50,000 newcomers every year from overseas, the U.S., and other parts of Canada. Although basically a large Anglo-Saxon community, its population now includes 250,000 Italians and a large number of German, Polish, and other European immigrants. The city has neither ghettos nor extensive slum areas. Its geographical situation on Lake Ontario modifies the climate somewhat, although winter temperatures may frequently drop below zero. Heavy snowfall, however, is rare even in January and February, the coldest months. July and August are humid, with temperatures in the 90s (°F; 30° C).

History. The first known settlement in the Toronto area, Teiaiagon, inhabited first by the Seneca and later by the Mississauge Indians, was on the east bank of the Humber River. In the 17th century it became a trading post, strategically situated at the crossing of ancient Indian trails going west to the Mississippi and north to Lake Simcoe and beyond into vast wilderness areas. These land and water routes were followed by explorers, fur traders, missionaries, and others intent upon opening up and exploiting the resources of the Great Lakes region.

By the mid-18th century the name Toronto had come to be commonly used for one of three tiny forts built (1720–50) in the area by the French to defend their trade with

the Indians against English and other European competitors. The French were defeated in 1759 and the forts were subsequently destroyed, but the settlement survived as a trading post.

At the end of the Seven Years' War with France (1763), Canada came under British sovereignty and during the next decade was a haven for those American colonists who, after the U.S. War of Independence, preferred British rule to that of the new Republic. Some 40,000 "Empire Loyalists" are said to have settled in the Great Lakes and St. Lawrence areas at this time, and during the 19th century large numbers of immigrants came from Britain.

In 1787 Lord Dorchester, governor in chief of Canada, opened negotiations with three Indian chiefs for the purchase of a site for the future capital of Ontario; about 250,000 acres fronting the lake were acquired in exchange for £1,700, bales of cloth, axes, and other trading goods.

Ontario's first parliament met in 1792 at Niagara, but in 1793 Col. John Simcoe, lieutenant governor of Upper Canada, selected the present site of Toronto for his capital because of its fine harbour, strategic location for defense and trade, and the rich potential of its wilderness hinterland. He changed its name from Toronto to York; two years later (1795) Ontario's capital consisted of only 12 cottages and a small military establishment on the edge of the wilderness.

Occupation by U.S. forces in 1813

While the British were engaged with France in Europe, the United States declared war on Britain; and York, with a population of 700 and practically defenseless, was taken (1813), pillaged and occupied by U.S. forces for 11 days before being retaken. The Speaker's Mace was carried off but was returned in 1934; the Royal Standard is still in the U.S. Naval Academy, Annapolis, Maryland.

Economic depression in Britain following the Napoleonic Wars drove many overseas, and York's population increased from 720 (1816) to about 9,000 in 1834, when the city was incorporated and the old name of Toronto restored. In 1849 there was a disastrous fire that destroyed some 15 acres of the downtown area, including St. James' Cathedral, St. Lawrence Market, and many offices, stores, and warehouses, but the city soon recovered.

Rapid development followed the coming of the Grand Trunk and Great Western railways in the 1850s, and for a decade prosperity was enhanced by a treaty with the United States (1854) that gave certain of Canada's products free entry to markets south of the border. The timber resources of the province were exploited, and large areas of land were converted to farming. Thus, Toronto grew rapidly as an industrial, trading, and distributing centre; its population was 45,000 in 1861, 208,000 in 1901, and 522,000 in 1921.

Prosperity and security were reflected in civic improvement, great building activity, and cultural progress. Between the city's incorporation (1834) and Canada's national confederation under the British North America Act of 1867, many of Toronto's buildings of historical and architectural importance were constructed, including the new St. James' Cathedral, St. Lawrence Hall, and University College, all of which are still extant. A Grand Opera House (since demolished) was opened in 1874, a stolid successor to the numerous small theatres of mid-century that were mostly converted barns. King's College (founded 1827), later to become the University of Toronto, was constructed in 1843 on the site of the present Ontario Parliament Buildings (1886).

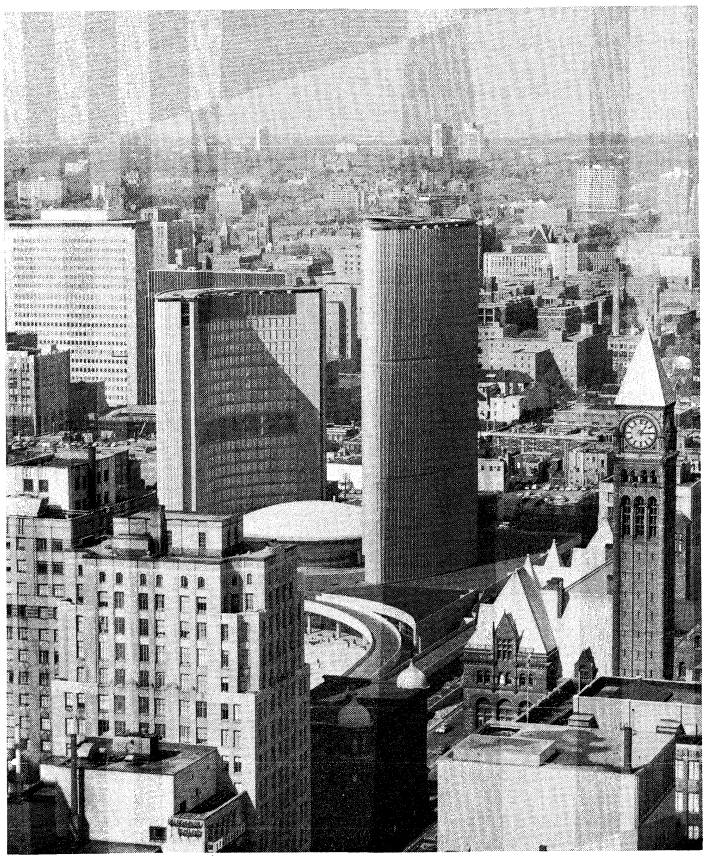
During the 50 years from 1834 to 1883, the city maintained its boundaries virtually unchanged. Some reclamation near the lake improved lakeshore properties and docking facilities. Largely by the annexation of adjacent villages and towns, the area of the city was doubled by 1900 and doubled again by 1920. In 1930 the metropolitan area included the central city, four towns (Leaside, Mimico, New Toronto, and Weston), three villages (Forest Hill, Longbranch, and Swansea), and five townships (Etobicoke, East York, North York, Scarborough, and York).

The depression years of the 1930s caused severe financial problems for suburban Toronto. Capital debt payments could not be met, and expenditure on public services—sewage and piped water supply in places remote from the lake, for example—had to be postponed. A rapid increase in population after World War II added to the municipal burden, and many solutions were investigated. In 1953 the Ontario Municipal Board recommended for the 13 municipalities the establishment of a federated form of government unique in North America. The Municipality of Metropolitan Toronto Act was passed, and a twenty-five-man Council of Metropolitan Toronto met for the first time on January 1, 1954. One of the first tasks of the council was to find ways and means of dealing with common major problems by united action, meanwhile permitting local matters to be handled independently. Since the joint credit of the combined municipalities was much greater than the sum of their credits as individual authorities, financing was greatly simplified. A common level of assessment and tax rate on property—the main source of revenue—was agreed upon by each municipality. A most significant feature of the system was that members of the Metropolitan Council were appointed by virtue of their election to office either as mayors, aldermen, or controllers of a particular municipality, thus ensuring a high degree of coordination and good communication between the central body and the local municipalities.

Uniting of the metropolitan area

The Metropolitan Council worked well: it resolved many of the difficult sewage and water problems; it greatly improved transportation by constructing expressways and roads, a new airport terminal building (1962), and an excellent subway; new schools were built and old ones improved; a regional parks system was introduced in an attempt to control future development.

Administrative reorganization of 1967



In 1967 the Metropolitan Toronto Corporation was reorganized. The 13 municipalities were reduced to six, and the council increased to 33 members—12 representing the city of Toronto, 20 for the five suburban boroughs, plus the chairman. The council considerably extended its responsibilities in education and the social services, adding, for example, urban renewal, waste disposal, and ambulance and library services.

The contemporary city. *Layout.* The site of the city is almost uniformly flat, although three to four miles inland there is a fairly sharp rise of some 40 feet—the shoreline elevation of the former glacial Lake Iroquois. Streets are laid out in a grid, although the pattern is modified to some extent by diagonal roads roughly following the shoreline. The central business areas are located around Bloor and Yonge streets and Yonge and Queen streets. The central financial district, with its numerous insurance and banking offices and the Toronto Stock Exchange, is on Bay Street south of the old City Hall (1899).

The skyline of the downtown area is dominated by the Toronto-Dominion Centre and Commerce Court, two major office and banking complexes rising over 50 stories. Other buildings of note are the new City Hall (1958) designed by the Finnish architect Viljo Revell; the Science Centre; Ontario Place; Scarborough College, Massey College, and several other university buildings; and many commercial and industrial buildings of high quality.

Toronto is a major Great Lakes port and, through the St. Lawrence Seaway, an ocean port as well. It handles over 6,000,000 tons of freight annually. The lakefront is separated from the downtown area by railway tracks and an expressway, but planned lakefront developments should radically change this situation. Ferry service connects the dock area and the Toronto Islands, about one-half mile from the shore, which contain yacht clubs, parks, and other recreational facilities.

To the north of the central business district is a fashionable shopping area. Immediately south of Bloor Street is a vestigial, park-like area, the site of the Ontario Parliament Buildings and the University of Toronto. Large expanses of grass and tall shade trees make this a pleasant central area, complementing the ravines that form so important an element in the metropolitan parks system. One of the most attractive residential areas is

Downtown Toronto, with the City Hall in the centre.
Dick Huffman—Pix

Rosedale, an older neighbourhood of dignified houses and winding, tree-lined streets quite close to the downtown area, which itself contains many residential streets of modest, well-designed houses.

Population. During part of the 1950s and 1960s Toronto became one of the fastest growing urban areas in North America, the metropolitan population expanding from 1,174,000 in 1953 to 2,628,000 in 1971. The influx of European immigrants transformed the character of the city: traditionally Protestant and largely of British origin, by 1961 less than half the inhabitants of the central city were of British extraction. The largest groups of immigrants came from Germany and Italy, but there were also substantial numbers from Greece, Portugal, and other countries.

Transportation. Policy for all means of public transportation—buses, tramcars, and subways—is coordinated by the Metropolitan Toronto Planning Board. Sophisticated computer models have been worked out to facilitate the flow of passenger and goods traffic in the metropolitan area, and the plan envisages a rapid transit network of commuter rail lines, extended subway and bus services, expressways, and arterial and collector roads. From 1953 to 1969 Metro Toronto expended some $377,000,000, and its road system alone totals 375 miles. Traffic signals at some 900 intersections are computer coordinated, and a 25 percent improvement in efficiency is claimed.

The modern, efficient subway consists of two lines running north–south and east–west. Seventeen miles west of the centre of the city is Toronto International Airport, Canada's busiest air terminal.

Economic life. Toronto enjoys the economic benefits of its position on the Great Lakes system, which makes it readily accessible to trade with major industrial centres in the United States and, via the St. Lawrence Seaway, to oceangoing shipping. As the capital of Canada's richest and most populous province, the city has a widely diversified economy. Ontario produces over 50 percent of Canada's manufactured goods and about 80 percent of its manufactured exports; it has immense resources of raw materials—minerals, timber, water, agricultural products, and hydroelectric power. In North America, the Toronto Stock Exchange stands fifth in value of trading.

Distribution of the labour force

In 1964 the city's labour force of 711,748 was distributed thus: manufacturing, 228,401; construction, 35,989; transportation, 54,901; wholesale trade, 45,412; retail trade, 104,917; financial services, 76,669; personal and recreational, 50,353; government and community, 108,357.

Culture and recreation. The city is an important cultural centre. The Toronto Symphony Orchestra and other musical groups have an international reputation. There are three major theatres, together with many small experimental theatres. The Art Gallery of Ontario and the Royal Ontario Museum have excellent collections, and there are numerous privately owned galleries. Two important recent additions are the Ontario Science Centre (1970), with its imaginative working exhibits, and Ontario Place (1971), a series of connected exhibition buildings on man-made islands in the lake that are an extension to the permanent Canadian National Exhibition. The city has two major universities—the University of Toronto with its colleges, Erindale and Scarborough, and York University with Glendon College. Ryerson Polytechnical Institute will shortly achieve university status, and the Ontario College of Art offers a wide diversity of excellent programs. Discotheques, coffeehouses, boutiques, movie theatres, night clubs, and the Toronto Maple Leafs ice hockey team all add to the colour and vitality of this vigorous community.

There is an active winter season of cultural activities, with a rich fare of concerts, theatre, opera, ballet, and films. Lectures, seminars, evening classes, and meetings of all kinds cover a multitude of subjects, and the religious life of the community is sustained by a variety of churches, synagogues, mosques, temples, and other meeting places. Many ethnic groups organize traditional festivals, balls, entertainments, and social activities, often in their own language.

In 1967 the Metropolitan Toronto Corporation assumed responsibility for the Canadian National Exhibition, claimed to be the world's largest annual exhibition, which was first launched in 1879 as the Toronto Industrial Exhibition. An international air show, agricultural, animal, and flower displays, theatrical and musical events, and a fairground attract over 3,000,000 visitors in the late summer each year. The permanent buildings are used for trade shows and other special events between seasons.

The Metropolitan Toronto Parks Department administers approximately 7,000 acres of parkland, and ambitious plans have been made for the development of Toronto's waterfront. The Metropolitan Toronto and Region Conservation Authority is an important joint provincial–municipal agency concerned with the development of recreational areas, flood control, and the conservation of existing woodlands and waterways. Established in 1957, it has jurisdiction over some 1,000 square miles and is responsible for the implementation of a large part of Toronto's waterfront-development plan. The authority also offers assistance and technical advice to rural land owners.

Local recreational areas

Toronto is the main regional tourist centre serving Muskoka, the Haliburton Highlands, and Georgian Bay, all magnificent lakeland and forest areas with fine hunting, fishing, and camping facilities. Recently there has been a remarkable increase in winter sports, and although Ontario's highest point is only 2,183 feet, good ski facilities are available within easy reach of the city. Algonquin Provincial Park is some 163 miles to the north, Niagara Falls is 80 miles south, and the city is surrounded by beautiful rolling farmland, with well-marked sites of historical and architectural interests. Camping, cottaging, boating, and fishing in summer and skiing, ice hockey, and curling in winter are the most popular forms of outdoor recreation.

(Th.Ho.)

Torts, Law of

Tort is a legal term used in both common- and civil-law systems to describe various wrongs that may give rise to civil proceedings, mainly in the form of an action for damages. The law of torts is concerned with the prevention of or compensation for harm sustained by a person through the unlawful or dangerous activity of others. The word tort has its origin in the Latin *tortus*, which means "twisted or crooked." It thus describes vividly the irregularity of the harmful conduct for which the law of torts provides a remedy.

The law of torts regulates a wide variety of unlawful behaviour, ranging from direct physical attack and dangerously negligent conduct to the most subtle forms of violation of values, such as social reputation or affection for next of kin. In modern times it has become one of the most important branches of the legal order, since scientific and technical progress, in, for example, the field of industrial processes or transport, has exacted an ever growing toll of life, limb, and property.

Civil- and common-law approaches to tort law

The common features of such a wide range of wrongs can be described only in general terms, which accounts for the vagueness of the statutory provisions dealing with tortious liability in many codified legal systems on the European continent and in Latin America. In contrast, the common-law countries have adhered to a system of special types of particular torts: "a set of pigeon-holes, each bearing a name, into which the act or omission of the defendant must be fitted before the law will take cognizance of it and afford a remedy," as one commentator has aptly described it.

THE NATURE OF TORT

Tort and crime. A tort is a species of civil wrong and must be distinguished from a criminal wrong giving rise to criminal proceedings, which have for their object the punishment of the wrongdoer. The function of criminal law is to protect the interests of the entire public by punishing an offender. The purpose of the law of torts is to protect the interests of individuals by granting compensation for damages they have suffered. Criminal proceedings are commenced and maintained by the state in the form of a criminal prosecution. Civil proceedings arising from a tort, on the other hand, are brought by the injured persons as private plaintiffs. The distinction between tort and crime thus lies in the interests at stake and the remedies afforded by the law. The same wrong, however, often constitutes a crime against the state and a tort against an individual. Thus, the thief who steals a piece of jewelry commits both the crime of larceny and the tort of conversion. Not infrequently, tort and crime even bear the same name, such as "trespass," "assault," "battery," or "libel"; and the same act can frequently be made the subject of proceedings of both kinds.

The distinction between crime and tort and punishment and compensation is in practice somewhat blurred by the fact that in many legal systems the idea of punishment is of some importance in the field of torts. This becomes particularly clear in the award of "punitive" or "exemplary" damages in addition to compensation under English or American law, in cases in which the wrongdoer has acted intentionally and deliberately. The same idea can be found in other legal systems—the German, Swiss, and Turkish, for example—with regard to serious violations of "personality rights," such as defamation (see below).

Concepts of the function of tort in Socialist legal systems

Closely linked to this punitive function of tort law is the ideological proposition of legal systems in Socialist countries that tortious liability must aim to deter and to educate the wrongdoer. The emphasis placed on the deterrent function of damages reflects the view that any violation of the rules of Socialist society can be explained as a relic of bourgeois-capitalist ideology that must be exterminated. In order to ensure the deterring effect of damages, Soviet law has gone as far as to prohibit liability insurance. This "educational" function of tortious liability might suggest that the amount of compensation, like the degree of punishment, should be proportionate to the wrongdoer's fault. Socialist legal systems, however, adhere expressly to the principle of full compensation irrespective of the degree of fault. The requirement of fault is completely abandoned with respect to certain particularly hazardous activities, such as the operation of automobiles. Socialist legal systems, like their Western counterparts, have thus retained the concept of liability without fault, although this would seem to be incompatible with the deterrent function of tort law.

Tort and breach of contract. A tort must be distinguished from a breach of contract. Whereas a contractual duty springs from an agreement of the parties, a tortious duty is imposed upon the parties by the law itself without regard to their consent. Every man, in principle, is free to enter into contractual relations with another. But he has no choice as to the obligations that the law imposes on him if he drives an automobile on a public highway. The purpose of contractual liability is to protect a specific interest in the performance of the promises of the contracting parties. The purpose of the law of torts on the other hand, is to protect very diverse legally recognized interests by providing compensation for losses suffered in respect of violation—by anyone—of such interests. The same facts, however, frequently may give rise to an action in tort and one for breach of contract. This situation may occur whenever a person voluntarily binds himself by a contract to perform some duty that is already imposed upon him by operation of law independently of any agreement. A surgeon, for example, who negligently treats his patient may be held liable for breach of an implied term in his contract to take reasonable care as well as for a tort of negligence committed by invasion of the interest in freedom from physical harm. Concurrent liability in tort and contract is not, however, universally recognized. Some legal systems—the French system for example—in principle restrict the injured person to an action for breach of contract when the wrongdoer was violating a contractual obligation.

Immunity from tortious liability. Under certain circumstances a civil wrong does not give rise to tortious liability because the wrongdoer is granted immunity. Such immunity from liability for conduct that would otherwise be tortious has in most legal systems traditionally been conferred upon the state. The general immunity of the state from liability for illegal conduct of its organs has been upheld with particular tenacity in the common-law countries. The judicial reluctance to impose vicarious liability upon governmental entities for the wrongs of their officers and employees can be explained as a result of the fear that tortious liability might unduly hamper or interfere with public administration and impose intolerable financial burdens upon the treasury. Modern developments, however, have proved that such fears were largely exaggerated. The threat of tortious liability, wherever it has been introduced, has not affected the smooth functioning of public entities. To a certain extent it may even be perceived as a stimulus to a more efficient and careful public administration. The ever growing use

of motor vehicles by government officials and the corresponding necessity of compensating accident victims has led to a further erosion of the immunity doctrine.

Tortious liability of public entities is thus now the rule, although certain exceptions are admitted. These are largely in the area of adverse effects on individuals of government policies, of judicial acts, of acts of state relating to other sovereign states, of certain military activities, and of malfunctions of postal services.

The erosion of the traditional-immunity doctrine is not restricted to Western countries: the same trend can be noted in Socialist legal systems. The civil code of a constituent republic of the Soviet Union (Russian Soviet Federated Socialist Republic [R.S.F.S.R.]) of 1922, for example, exempted state institutions from tortious liability unless contrary provision was established by law. The new civil code of the R.S.F.S.R. of 1964, however, has adopted the opposite position: article 446 expressly declares state institutions liable for injury caused to citizens by improper official acts in the sphere of administrative management unless otherwise provided by special statute.

Inasmuch as tortious liability is based on the requirement of fault, immunity is also conferred upon certain wrongdoers on account of their age or state of mind. Infants and insane persons under certain circumstances thus enjoy exemption from tortious liability. The extent to which such immunity is granted varies. Common law, on the whole, seems to be less reluctant than civil-law systems and the Socialist legal orders to recognize tortious liability of infants or lunatics.

THE HISTORICAL AND SOCIAL CONTEXT OF TORT-LAW DEVELOPMENT

Historical background. Problems of tortious liability have arisen ever since life in a common society led to the development of law. The law of torts in the earlier stage of its evolution usually consisted of a miscellaneous and more or less unconnected group of specific rules protecting a few particular interests against harmful interferences of a particular kind. Roman law, for example, knew three principal torts: *iniuria* (intentional interference with the person), *furtum* (intentional interference with property), and the rule of the *lex Aquilia* covering losses caused by negligence.

Tort law is more deeply imbedded in the past than any other branch of the common law. It abounds in historical curiosities, seemingly arbitrary distinctions, and strange inconsistencies. The reason for most of these anomalies lies in the ancient system of legal procedure with its "forms of action." Until comparatively recent times a plaintiff under common law could sue in tort only if he could fit his claim into one of the recognized forms of action for which some particular writ of summons was available (see PROCEDURAL LAW).

The earliest tortious actions in common law

The first writs that were available for tortious causes of action were those of trespass and of "trespass upon the case." The action of trespass, recognized about the year 1250, was restricted to direct and immediate injuries to land, goods, or persons, such as those occasioned by throwing a log that hits another man or his property. Indirect or consequential injuries, such as those suffered by someone who stumbles over the log, became remediable 100 years later by "actions of trespass upon the case." A considerable variety of injuries eventually became recoverable by applying for such a writ on the case, and it lay within the discretion of the judges whether they would consider the wrong concerned a good cause of action.

In striking contrast to the development in the common law, tort law in legal systems based on the civil law seems to have advanced much further from its historical roots. The great jurists of the law of nature in the 17th and 18th centuries enunciated the general principle that everybody shall be held liable for the damage caused by his fault, and this principle has been embodied in various forms in many civil codes. An example is presented by article 1382 of the French Code Napoléon or Code Civil of 1804.

Many other civil codes based on the French model have subsequently adopted similar provisions. Other legal systems in the civil-law sphere have chosen somewhat more restrictive solutions. The German Civil Code, for example, grants protection to various specifically mentioned interests.

Apart from general provisions dealing with liability for losses occasioned by one's fault, the civil codes usually contain specific rules imposing liability for the harmful acts of one's servants and for pursuing certain hazardous activities, such as keeping an animal or operating an automobile.

The difference between tort law in the common-law countries and in the civil-law sphere is not in practice as important as it may appear at first sight. Theoretically, the range of application of the abstract provisions in a civil code is much larger than the pigeonhole system of Anglo-American case law. It must be borne in mind, however, that behind the screen of the general terms of a civil code the courts develop a bulk of so-called case law that in many ways resembles its counterpart in the common law. Although the means by which a certain solution to a legal problem is reached may be strikingly different, the results tend to be very much the same under common- and civil-law influence.

Approaches to the problem of liability. The purpose of the law of torts is the adjustment of certain losses that are the inevitable result of living together in a common society. Such losses might, in principle, be borne by the individuals who suffer them. The law of torts, however, attributes liability for certain losses to persons other than the injured individuals. It enables the victims of harm resulting from the socially unreasonable conduct of others to demand compensation from the wrongdoers.

A major problem that has to be solved by the law of torts arises whenever a particular wrongdoer cannot be ascertained or when his fault cannot be proved. In such circumstances the victim of an accident might remain without compensation. The same situation might occur whenever the financial means of someone committing a tort are insufficient to compensate his victim. Two areas in which such problems of determining liability have been particularly acute are industrial and traffic accidents.

Industrial accidents. Traditional solutions to the social problems raised by contemporary accident rates lie within the scope of tort law that has been described above. Some countries, however, in regard to certain categories of risk, have increasingly adopted a scheme of compensation that is totally independent of any tortious liability of a particular wrongdoer. Modern systems of social insurance, for example, provide extensive protection against the harmful consequences of personal injuries. The pressing need for granting help to the victims of accidents irrespective of tortious claims was first felt with regard to industrial accidents. Under common law as well as under most other legal systems, by far the greater proportion of such accidents remained uncompensated. Among other factors, the difficulty of proving the employer's fault and the delay and expenses of litigation turned industrial accidents into personal disasters for the injured persons and their dependents. In order to provide a remedy for such blows of fate, the German legislature in 1884 introduced a system of social insurance for industrial accidents—an example that has been followed all over the world. In the Soviet Union as well as in other Socialist countries, the enactment of social-insurance laws was one of the first measures of the newly established governments. Despite considerable resistance, workmen's compensation acts have also been adopted by all United States jurisdictions. These acts usually charge the employer with the injuries attributed to the risks of the employment without regard to questions of the negligence of employer or employee. This form of strict liability is supplemented by a system of compulsory liability insurance, which distributes the losses over the entire industry. Although workmen's compensation acts rely on the employer's tortious liability in order to protect the employees, the system in its practical consequences results in a distribution of risks, which is the characteristic feature of insurance.

Extension of tortious liability by workmen's compensation acts

Contemporary trends all over the world show a tendency to widen the scope of social insurance beyond the field of industrial accidents. Many countries, especially in western Europe and in the Socialist sphere of influence, have adopted collective systems of health and general accident insurance. Under such systems the victims of personal injuries may obtain at least partial compensation for the losses they have suffered. Claims for compensation are directed against the social-insurance agency: the problem of tortious liability is thus irrelevant in this context. Some legal systems, however, provide that the social-insurance agency may take over the rights of the victim against the tort perpetrator in order to recover its payments.

Traffic accidents. Despite the progress of social-insurance systems, the regulation of traffic accidents in most countries has remained primarily the task of tort law. Due to the ever-increasing rate of traffic injuries, this function has turned into one of the heaviest burdens born by the legal system. The existing rules of tortious liability in some respects do not correspond to the needs of the times.

Common-law countries have generally adhered to the principle that liability for traffic injuries presupposes a wrongdoer's fault. This means in practice that victims of traffic accidents must prove that their injuries were the result of another's negligence. This and other obstacles have resulted in only a comparatively small proportion of traffic victims eventually obtaining compensation. By way of contrast, civil-law countries, including France, Germany, Italy, Switzerland, Scandinavia, Turkey, Spain, and Japan, as well as the Socialist countries, have adopted a rule of strict liability with regard to the operation of motor vehicles—that is, the driver of a motor vehicle is liable for compensation regardless of fault. Even this system leaves something to be desired from the point of view of the victim, since compensation is excluded when the accident is caused by an "act of God." It is at least reduced in cases of contributory negligence.

Tortious liability for traffic injuries—no matter whether founded on negligence or strict liability—also presents the problem that compensation can sometimes not be obtained because the person being sued (the tort-feasor) does not have sufficient financial means. With the strange exception of Soviet Russia and several states in the U.S., most countries have tried to minimize such risks by introducing compulsory liability insurance. Following the French example, many legal systems have gone so far as to grant to traffic victims a direct claim for compensation against the automobile operator's insurance company. Even compulsory third-party insurance, however, does not necessarily ensure full compensation to injured persons, for frequently the amount of damages recovered from the wrongdoer is limited by the extent of the offending party's insurance cover.

"No-fault" insurance as a substitute for tortious claims

The various deficiencies of the traditional principles of tortious liability with regard to the adjustment of traffic accidents have led to numerous reform projects in several countries. Strong criticism of the "forensic lottery" of tort liability as a system of personal-injury compensation in automobile accidents was first raised in the United States and has resulted in various plans aimed at the replacement of tort law by a system of compulsory automobile accident insurance. Such schemes provide for recovery of personal injuries for all victims of automobile accidents without regard to fault.

Redistribution of the burdens of tortious liability. The interplay of tort law and modern insurance practices has resulted in a socialization of the risks and losses that are inevitable in modern society. The ancient starting point of tort law—"the loss lies where it falls"—has largely been replaced by its modern counterpart—"the loss lies with the community." Judges and, above all, juries cannot be expected to remain indifferent to the question of which party to a lawsuit might best be able to bear the loss concerned: mere knowledge of the fact that one party is insured can influence their decisions considerably. In automobile-accident cases especially, this factor has led to a natural tendency to favour the plaintiff at the expense of the defendant, who is usually protected by liability insurance. In view of this, the jury in most parts of the United States may not be informed whether the defendant is insured or not.

The inclination of courts to consider the relative capacity of the respective parties to bear the loss has brought about a certain erosion of the traditional principles of tortious liability. The requirement of fault in automobile-accident cases under common law, for example, has largely been abolished in practice by overstraining the standards of care applied to the defendant's conduct. The result is that negligence is almost always found. The extension of the manufacturer's liability (see below) to the ultimate consumer of his product can equally be explained by the tendency to favour the poor against the rich.

Development of doctrines of strict liability

Another important change in tort law resulting from the social policy of shifting losses to defendants who might reasonably be expected to bear the burden without being ruined is the growth of "strict liability." During the course of the 19th century the principle "no liability without fault" had won worldwide recognition. One of the first exceptions to this doctrine related to the keeping of animals, and many legal systems, including the common law, contain a rule of strict liability for harm done by certain animals. Another exception was recognized by some civil-law countries with regard to the owner of a building that has collapsed.

One of the most important events in the development of the common law regarding strict liability was the English decision in the case of *Rylands* v. *Fletcher* (1868). According to the rule of this case, which has been recognized by most jurisdictions in the United States, a defendant, without regard to his fault, is strictly liable for the damage caused by abnormal and unduly dangerous things and activities, such as the storage of a large quantity of explosives or inflammable liquids. The doctrine of strict liability that developed from this case is confined to extraordinary risks and does not apply to such things as water in a cistern or gas or electricity in household pipes or wires. The principle of strict liability has further been extended by statute or modification of the common law to industrial accidents, to the manufacture or sale of food, and to aviation. Most civil-law countries have adopted the principle of strict liability for the operation of railways, motor vehicles, and nuclear plants.

A SURVEY OF MODERN TORT LAW

A basic distinction adopted by the common law in the course of the 19th century was based on the wrongdoer's will. Modern tort law distinguishes between intentional injuries and those that are merely negligent; that is, caused without the intent of the tort-feasor. Civil-law systems, on the other hand, usually treat intention and negligence alike, as two different kinds of fault for which tortious responsibility must be assumed. In practice, however, the rules relating to intentional, as opposed to negligent, wrongdoing reveal significant differences in civil law systems. Most of the wrongs falling under the various torts classified in their common-law form and described below give rise in civil-law countries to tortious liability according to the relevant provisions of particular civil codes.

Personal injury. Tort liability based on the wrongdoer's intent can arise from the interference with the person or the property of another. Intentional personal injuries under common law fall under several specific torts.

Battery. A defendant's conduct constitutes the tort of battery if he intentionally causes some physical contact with the person of the plaintiff without the latter's consent. The law relating to battery thus protects the interest in freedom from physical contact with another. The contact need not be directly with the plaintiff's body; contact with things attached to the person of another (throwing over a chair on which he is sitting, for example) will be sufficient. The contact need not entail actual physical harm: knocking off another's hat or spitting in his face amounts to battery, as does kissing a woman without her

consent. The last example illustrates one of the most important and intricate problems of the action for battery. In order to be liable for battery, the defendant must have acted without the plaintiff's consent. Consent may either be expressly declared, as when one agrees to a surgical operation, or it may be inferred from the circumstances of the case, as when one participates in a game of football. The plaintiff's consent is assumed for ordinary contacts that are common in social life, such as a friendly blow on the shoulder or a gentle touch to attract the attention of a stranger.

The problem of consent in surgical operations

The problem of the validity and the extent of a plaintiff's consent frequently arises in connection with surgical operations on patients who are unconscious or of unsound mind. If the plaintiff is incapable of giving valid consent because of a mental disturbance, for example, he will be able to bring an action for damages. If he has given valid consent to a particular operation, and the surgeon in the course of his treatment discovers the desirability of extending the operation to another area, the mere medical indication will not justify the surgeon in going ahead. Unless the consent given prior to the operation was sufficiently general in its terms, or unless an unforeseen emergency has arisen during the operation that allows the assumption that the patient would consent if he could be asked, the surgeon by extending the operation exceeds the express or implied consent of the patient and may be held liable for battery.

Assault. Closely related to the tort of battery is the tort commonly called assault. In contrast to battery, which protects the interest in freedom from physical contact with another, the action for assault is designed to protect the interest in freedom from a particular form of mental anxiety; that is, freedom from apprehension of harmful or offensive contact with another. The difference between assault and battery is, thus, that between threat and its realization. The apprehension of physical contact need not result in fear on the part of the plaintiff. Only the apprehension of an immediate contact, however, amounts to assault. There must thus usually be some threatening action, such as the shaking of a fist or wielding of a gun. Mere words—threats of future violence, for example—do not usually constitute an assault under common law.

Battery and assault in civil-law systems are not considered as special types of civil wrongs. Along with various other injuries, they fall within the range of application of the general provisions of civil codes on tortious liability. The different theoretical approach, however, does not in practice seem to entail substantially different results.

False imprisonment. The interest in freedom from confinement is protected by the tort of false imprisonment. There are many different ways in which this tort can be committed. An action for false imprisonment may arise from the plaintiff's confinement to a vehicle, to a house, a prison, or to an entire city. The barriers used for the confinement need not be physical. Restraint on movement in a street by a mere threat of force can constitute false imprisonment. There must, however, be a total restraint. If the plaintiff's movement is blocked in one direction only—by the closing of a bridge, for example—he has no remedy arising from a tort of false imprisonment. The tort can be committted by mere omission, such as failure to let a prisoner out of jail when he has served his sentence.

False imprisonment is, of course, excluded in cases of lawful arrest by police officers or, under certain circumstances, by private citizens who have witnessed the commission of a crime. Even if the confinement is authorized by the law, the prisoner may resort to an action for malicious prosecution; that is, for the groundless instigation of criminal proceedings. In order to obtain compensation the plaintiff must prove that the defendant maliciously and without probable cause had occasioned criminal proceedings that were terminated in favour of the plaintiff.

Mental suffering. As pointed out above, mere words do not constitute a cause of action for assault. And defamation (see below) does not provide protection from insults directed at the injured party that are not also communicated to a third person. It is quite possible, however, that a person might suffer a harm by being subjected to abuse that does not threaten physical violence and that is not heard by a third party. This gap in the common law has in more recent years been filled step by step by the recognition of a separate cause of action for the intentional infliction of mental or emotional disturbance. Tortious liability of this kind was first imposed on common carriers who had insulted their passengers and was subsequently extended to innkeepers and other persons offering their services to the general public. The new tort has further been applied to outrageous jokes, such as telling a woman facetiously that her husband has been killed. In other instances mishandling of dead bodies has been recognized as a valid cause of action for the survivors whose personal feelings were hurt. Under certain circumstances harms inflicted on a third person can amount to a tort of causing mental disturbance in those who have indirectly suffered fright or shock—at the sight of the mutilated corpse of a murdered sister, for example. Liability is restricted to mental suffering of a very serious kind and cannot be extended to trifling injuries.

Violations of property rights. Tort liability can arise from an intentional interference with another's property. There are various wrongs that fall under this category of the law of torts.

Trespass to land. A defendant is liable for trespass to land when he intentionally enters or remains on land in the possession of another without his permission. The same liability accrues from the intentionally caused intrusion of any physical matter into the plaintiff's land. It is not the function of tort law to protect ownership as such. The action for trespass to land purports to protect the interest in exclusive possession of land in its intact, physical condition. Thus, the tenant—not the landlord—sues if a third person enters land he occupies. Trespass to land can be committed by such acts as walking on the plaintiff's soil, flooding it with water, throwing rocks or rubbish on it, or by attracting a crowd of spectators eager to watch the landing of a balloon. Trespass to land can further be committed by invasion of that portion of the air space above the plaintiff's land that is requisite for its full use. The exact limits of this zone have been the subject of much discussion due to the rapid expansion of aviation. There can be no doubt, however, that the flight of an aircraft at a reasonable height above the ground does not constitute trespass to land. Similar problems as to the upward extent of the possessor's rights arise with regard to intrusions below the surface by mining or construction activities.

Nuisance. The enjoyment of land and the premises thereon is also protected by the tort of nuisance. Activities that produce excessive dust, noise, stenches, insects, fumes, seepage, gases, smoke, vibrations, or severe emotional disturbances—invasions more subtle and more persistent than those required for trespass—may give rise to an action for nuisance. The court may award damages, order the nuisance to be stopped by means of an injunction, or both.

Trespass to chattels. The counterpart to the tort of trespass to land, as far as movable property is concerned, is the tort of trespass to chattels. This action arises from any intentional, physical interference with a chattel in the possession of another—by damaging or removing it, for example. The plaintiff is entitled to compensation for the loss he has suffered. When he has been permanently deprived of his goods, he may recover their value by way of damages. The plaintiff will be entitled to something less than the full value of his property if, for example, his horse is beaten or his automobile is used without his consent.

Conversion. By far the most important action for intentional interference with the chattels of another arises from the tort of conversion. Conversion may be defined as an intentional dealing with a chattel in a manner that is seriously inconsistent with the right of the person entitled to it.

Conversion can be committed by acquiring possession

Various forms of conversion

of goods without legal justification and with the intention of exercising dominion over them. Stealing a chattel is conversion, as is its purchase from the thief or its seizure under legal process without justification. Merely to remove goods from one place to another may amount to trespass to chattels but is not necessarily conversion. Destroying or altering a chattel will constitute a conversion if done intentionally, as, for example, by shooting the annoying dog of a neighbour or by making wine from another's grapes. Even a mere erroneous delivery of a good to the wrong person can be conversion. Conversion can further be committed by a refusal to surrender a chattel upon lawful and reasonable demand, as in the case of a finder who refuses to hand over the property to the rightful owner. Furthermore, the mere use of a chattel without causing the least damage to it can amount to conversion if it is done in obvious defiance of the owners' rights.

The classification of torts relating to intentional interference with property under common law has no equivalent in civil-law systems. It should be noted that the range of application of the common-law action for conversion covers situations that in civil-law systems are regarded as partly nontortious.

Actions based on negligence. By far the greatest number of civil actions for tort and, possibly, the majority of civil actions as a whole are brought by injured persons to recover compensation for damage suffered through the negligent conduct of the defendant.

Negligence as a separate tort under common law was not recognized before the 19th century. Its development from the ancient action of trespass on the case coincided with the increasing use of dangerous machinery during the course of the Industrial Revolution. The growing rate of industrial and traffic accidents gave rise to social problems that the existing rules of tortious liability were unable to solve. The principle "no liability without fault," designed to further the interests of risk-taking entrepreneurs in the early capitalist economy, obstructed the evolution of strict liability as a means of providing compensation for the victims of such accidents. In order to meet the demands of social justice, lawyers directed their attention to the task of expanding the notion of fault from its traditional meaning. This led to a distinction between intentional and unintentional injuries and to an awareness of negligence as a separate basis of tort liability.

Civil-law approaches to negligence

Legal systems based on civil law have reacted to the same problems by recognizing strict liability for various ultrahazardous activities. Insofar as rules of liability without fault were not developed, stress was laid instead upon negligence as a ground for imposing tortious liability. The relevant general provisions of civil codes, expressly or implicitly, have admitted that negligence may give rise to tortious liability under the same conditions as intentional wrongdoing. Civil law, in contrast to common law, thus treats negligence as simply another kind of fault for which a defendant may be held liable. Many of the principles that have been developed under common law as specific rules relating to negligence as a separate tort, such as the rules of proximate cause or contributory negligence, are under civil law treated as general topics of tort law that bear on any kind of tort liability, no matter whether the wrongdoer's conduct was intentional or unintentional.

Definitions of negligence. Negligence may be described as a failure to comply with that standard of care that would correspond to the conduct expected of a reasonable man of ordinary prudence under similar circumstances. Any conduct that falls below that standard of behaviour is considered to be negligent. In order to find out whether the particular conduct of a particular person can be called negligent, his conduct must be compared with the supposed behaviour of a purely fictitious person who meets the requirements of an ideal citizen. This mythical person, who is always a model of prudence and care, can be found in most legal systems. He is extremely versatile: if the conduct of the driver of an automobile is to be considered, the reasonable man will be the motorist of ordinary sense using ordinary care and skill; if the fatal outcome of a surgical operation gave rise to the issue, he will be the prudent surgeon of the skill and knowledge commonly possessed by members of the surgical profession in good standing; and if the person who has caused injury to another lacks one of the physical attributes of ordinary people his behaviour will be compared with that of an ideal man who is equally physically disabled.

The mere failure to comply with the standard of care that has just been described is not sufficient to constitute the tort of negligence. As an English judge has put it: "In strict legal analysis, negligence means more than heedless or careless conduct, whether in omission or commission; it properly connotes the complex concept of duty, breach, and damage thereby suffered by the person to whom the duty was owing." (*Lochgelly Iron & Coal Co.* v. *M'Mullan* [1934].)

According to this definition, negligence requires a legal duty of care that is imposed on the wrongdoer and that is owed to the group of persons to which the plaintiff belongs. Liability for negligence, under common law, in other words, presupposes that the defendant was under an obligation to take reasonable care for the benefit of the plaintiff. "A man is entitled to be as negligent as he pleases towards the whole world if he owes no duty to them." (Lord Esher in *Le Lievre* v. *Gould,* [1893]). The requirement of a duty of care may be illustrated by a famous American case, *Palsgraf* v. *Long Island Railroad Co.* (1928): a railway passenger was trying to get into a train that had already begun to move. One of the defendant's employees assisted him, and a package containing fireworks fell from the passenger's arms upon the rails. The shock caused by the ensuing explosion upset some scales at the other end of the platform. The scales fell upon the plaintiff and injured her. The majority of the court held that there was no liability in negligence because, although the conduct of the defendant's servant was careless, no duty was owed to the plaintiff against this remote hazard. The decision in the Palsgraf case clearly reflects the view that common law does not recognize remote duties and that, therefore, no duty of care can be owed to the unforeseeable plaintiff. It must be noted, however, that the scope of duties recognized under common law is fairly wide. Any motorist, for example, is considered to be under an obligation to take reasonable care for the benefit of all other persons on the road.

Breach of duty

In order to support an action for damages based on negligence, the plaintiff further has also to show that the defendant failed to comply with his duty of care. A breach of duty can be assumed when the defendant failed to do what a reasonable man of ordinary prudence would do under the same or similar circumstances. A defendant cannot be held responsible for his passive inaction unless this was contrary to a specific duty to act. Common law seems on the whole reluctant to impose such duties. A motorist is thus not required to walk to a nearby telephone booth to summon medical aid for the victim of a road accident whom he sees lying on the ground in urgent need of help.

The third element necessary to an action based on negligence is causal connection between the defendant's carelessness and the damage suffered by the plaintiff. Legal problems relating to causation are among the most difficult and most controversial issues of the law of torts. There is no doubt that a person committing a tort can be held liable for the immediate consequences of his wrongdoing, such as fracture of the leg of a pedestrian who has been hit by his automobile. Great difficulties arise, however, when the injured person in the ensuing course of events suffers further damage—when the pedestrian catches an infectious disease during a stay in the hospital, for example. Although the fact of causation may be clearly established, the wrongdoer's liability must somehow be limited. This limitation of responsibility, under common law, is performed by the doctrine of "proximate cause." It excludes liability for those consequences of the defendant's conduct that are "too remote" to be attributed to him. A precise definition of this rule cannot be offered. Which consequences are deemed too

remote to be within the limits of a particular tort-feasor's liability must in practice be decided by means of a sense of justice rather than by means of logical reasoning.

Contributory negligence. Liability of a defendant arising from negligence can be excluded if the plaintiff was equally at fault—if he was reading a newspaper while he was crossing a street and was hit by an inattentive motorist, for example. Under common law, a plaintiff who fails to conform to the standard of care to which he is required to conform for his own protection is in principle denied recovery. This doctrine of "contributory negligence" can lead to highly unsatisfactory results when the negligence of both parties has been of equal importance in causing the harm or, even worse, where the defendant's negligence has been gross whereas the plaintiff's negligence has been relatively slight. Civil-law systems avoid such hardship by providing for an apportionment of damages according to the relative fault of the parties. A similar rule has been adopted in Great Britain by the Law Reform (Contributory Negligence) Act, 1945. Various statutes of similar effect operate in the United States. Where such "comparative negligence" statutes have not been enacted, the ancient common-law rule of contributory negligence has been modified considerably by the so-called doctrine of "last clear chance." This rule was developed by an English court in 1842 in the case of *Davies* v. *Mann* (1842). The plaintiff had negligently left his ass, fettered by its forefeet, in a highway. The defendant drove his wagon into it and killed it. It was held that, despite of his own negligence, the plaintiff could recover damages because the defendant could have avoided the harmful consequences of that negligence.

The defense of assumption of risk

Closely related to the doctrine of contributory negligence is the defense of assumption of risk. Liability for negligence, according to this rule, is excluded when the injured person expressly or implicitly agreed to assume the risk of the defendant's negligence. A spectator watching an ice-hockey match thus implicitly consents to the risk of being hurt by the puck, which may be hit out of the rink in the course of the game.

Effect of intervention of third parties. An intervening act of a *third party* in the production of damage does not necessarily relieve the defendant from liability. Inasmuch as such intervention could reasonably have been foreseen, it cannot be considered a superseding cause that will free the defendant from his responsibility. This is of considerable practical importance with regard to negligent medical treatment of an injured victim: the defendant is liable for all ordinary forms of professional negligence on the part of the doctor who treats the person he injured. He will be relieved from liability only if the intervening third person's conduct was so unusual that the defendant could not reasonably have foreseen it.

Negligence and industrial accidents. The working of the common-law rules on negligence caused considerable hardship with regard to industrial accidents. By far the greater proportion of injuries suffered in the course of employment remained uncompensated because the injured employees were unable to prove their employer's negligence. Even when negligence could be proved, the employer in many instances successfully raised the defenses of contributory negligence or assumption of risk on the part of the employee. The employer's liability was further restricted by the effect of the "fellow servant" rule, which relieved the employer from responsibility for injuries that had been caused by the negligence of a fellow servant. As described above, the social problems arising from these rules have largely been solved by the adoption of workmen's compensation acts.

The development of the rules of the manufacturer's liability to the consumer bears analogy to the evolution of tortious liability for the benefit of injured workmen. At first, the interests of consumers who had been injured by defective products did not find protection in the law of torts. In order to invoke the producer's liability based on negligence, the plaintiff would have to show that he had suffered harm by a breach of a duty owed to him by the defendant. But until the beginning of the 20th century, common-law courts failed to recognize the existence of a duty of care imposed on the manufacturer for the benefit of the consumer. This position has gradually been abandoned. Since the leading cases of *MacPherson* v. *Buick Motor Co.* (1916) in the United States and *Donoghue* v. *Stevenson* (1932) in Great Britain, the consumer, under certain circumstances, has had a direct claim based on negligence for compensation from the producer for injuries suffered as a result of defective goods. There is a growing tendency in American legal literature to hold the manufacturer more strictly liable for the harm caused by his products. If this trend prevails the plaintiff will be relieved from proving the defendant's negligence.

The development of manufacturer's liability in common law has exercised considerable influence on legal thinking and judicial practice in civil-law countries. The traditional position of many civil-law systems had failed to recognize special rules of tortious liability enabling the consumers who had been injured by defective products to obtain compensation from the producer. Following the example presented by the evolution of the common law, legal writing and judicial reasoning in civil-law countries have been building a system of manufacturer's liability that in its practical results in many respects resembles the solutions reached under common law.

Protection of intangible personal interests. *Defamation.* The interest in reputation and good name is covered by the law of defamation, which is made up of the torts of libel and slander. The distinction between libel and slander is based on the medium that is used to communicate a defamation. Libel, in general, is written, and slander, in general, is oral. Defamation by radio or television in common-law countries is increasingly regarded as libel. In contrast to slander, libel is always actionable per se; that is, without proof that damage has actually occurred. This difference may lead to strange results. Defamatory words in a letter regarding a third person but that have merely been read by the addressee make the sender liable for libel without proof of any actual damage to the plaintiff. A defamatory speech before an audience of 1,000 people, on the contrary, merely gives rise to an action based on slander, which, subject to certain exceptions, requires proof of actual damage. The distinction between both types of defamation is the result of a historical development peculiar to the common law. It has no equivalent in civil-law systems.

Distinction between libel and slander

Rights of privacy. Personal rights other than reputation have gained judicial protection in the United States by recognition of a so-called right of privacy.

The concept of a legal right to privacy had its origin in a review article by the American jurists Samuel D. Warren and Louis Brandeis, published in 1890. The authors postulated a "right to privacy"; that is, a legal principle

> which may be invoked to protect the privacy of the individual from invasion either by the too enterprising press, the photographer, or the possessor of any other modern device for recording or reproducing scenes or sounds.

This farsighted view today has gained support in most jurisdictions of the United States. English courts, however, up to the early 1970s have not followed the American example.

In practice, however, the different legal situation does not seem to have created any striking discrepancies between the extent of protection afforded to human personality on either side of the Atlantic. As far as civil-law systems are concerned, the French seem to have had the least difficulties in coping with modern menaces to intangible personal interests. Civil-law systems that are based on a more restrictive enunciation of tortious liability, such as the German system, on the other hand, have had some trouble in adjusting themselves to modern needs relating to protection of the integrity of personality. There has, however, been a recognition of a "general personality right" that may be regarded as a step toward safeguarding the individual from the intrusions of the mass media.

Tort law, to some extent at least, also provides protection for the interest of freedom from interference with family relations. A husband whose wife has been injured in an accident may thus claim compensation for the resulting loss of her household services and company. Simi-

larly, he may sue an adulterer who interfered with the marital relation.

BIBLIOGRAPHY. WILLIAM L. PROSSER, *Handbook of the Law of Torts*, 3rd ed. (1964); and FOWLER V. HARPER and FLEMING JAMES, JR., *The Law of Torts*, 3 vol. (1956), are among the best modern treatises on tort law. A concise survey of the present English law of torts is offered by HARRY STREET in *The Law of Torts*, 4th ed. (1968). *Clerk and Lindsell on Torts*, 13th ed. (1969); *Pollock's Law of Torts*, 15th ed. (1951); *Salmond on the Law of Torts*, 14th ed. (1965); and *Winfield on Tort*, 8th ed. (1967), are classic works that have appeared in numerous editions under the supervision of various successors to the original authors. The subject has been treated on a comparative basis by KONRAD ZWEIGERT and HEIN KOETZ in *Einführung in die Rechtsvergleichung auf dem Gebiete des Privatrechts*, vol. 2 (1969); and, with regard to tort law in the European Economic Community, by ANDREAS HELDRICH in *Die allgemeinen Rechtsgrundsätze der ausservertraglichen Schadenshaftung im Bereich der Europäischen Wirtschaftsgemeinschaft* (1961). As regards tort law in Socialist countries, see JOHN N. HAZARD, ISAAC SHAPIRO, and PETER B. MAGGS, *The Soviet Legal System*, rev. ed. (1969); GUYLA EORSI, "The Adaptation of Civil Liability to Modern Needs," *Review of Contemporary Law*, 10:11–24 (1963); and BERNHARD RUDDEN, "Soviet Tort Law," *New York University Law Review*, 42:583–630 (1967). Modern trends relating to the protection of traffic victims are reflected in ALFRED F. CONARD *et al.*, *Automobile Accidents Costs and Payments* (1964); LEON GREEN, *Traffic Victims: Tort Law and Insurance* (1958); and TERENCE G. ISON, *The Forensic Lottery: A Critique on Tort Liability As a System of Personal Injury Compensation* (1967).

Totemism

Totemism is a system of belief in which man is believed to have kinship with a totem or a mystical relationship is said to exist between a group or an individual and a totem. A totem is an object, such as an animal or plant that serves as the emblem or symbol of a kinship group or a person. The term totemism has been used to characterize a cluster of traits in the religion and in the social organization of many primitive peoples.

Totemism is manifested in various forms and types in different contexts, especially among populations with a mixed economy (farming and hunting) and among hunting communities (especially in Australia); it is also found among tribes who breed cattle. Totemism can in no way be viewed as a general stage in man's cultural development; but totemism has certainly had an effect on the psychological behaviour of ethnic groups, on the manner of their socialization, and on the formation of the human personality.

Origin of the term totem

The term totem is derived from *ototeman* from the language of the Algonkian tribe of the Ojibwa (in the area of the Great Lakes in eastern North America); it originally meant "his brother–sister kin." The grammatical root, *ote*, signifies a blood relationship between brothers and sisters who have the same mother and who may not marry each other. In English, the word totem was introduced in 1791 by a British merchant and translator who gave it a false meaning in the belief that it designated the guardian spirit of an individual, who appeared in the form of an animal—an idea which the Ojibwa clans do indeed portray by their wearing of animal skins. It was reported at the end of the 18th century that the Ojibwa name their clans after those animals that live in the area in which they live and appear to be either friendly or fearful. The first accurate report about totemism in North America was written by a Methodist missionary, Peter Jones, himself an Ojibwa chief, who died in 1856 and whose report was published posthumously. According to Jones, the Great Spirit had given *toodaims* ("totems") to their clans; and because of this act, it should never be forgotten that members of the group are related to one another and on this account may not marry among themselves.

Generally speaking, totemistic forms are based on the psychomental habits of the so-called primitives, on a distinctive "thought style" which is characterized, above all, by an "anthropopsychic" apprehension of nature and natural beings, for instance, ascribing to them a soul like man's. Beasts and the things of nature are again and again thought of as "persons," but mostly as persons with superhuman qualities.

THE NATURE OF TOTEMISM

It is advisable to define totemism as broadly as possible but concretely enough so that some justice can be done to its many forms. Totemism is, then, a complex of varied ideas and ways of behaviour based on a world view drawn from nature. There are ideological, mystical, emotional, reverential, and genealogical relationships of social groups or specific persons with animals or natural objects, the so-called totems. It is necessary to differentiate between group and individual totemism. These forms exhibit common basic characteristics, which occur with different emphases and not always in a complete form.

General characteristics

The general characteristics are essentially the following: (1) viewing the totem as a companion, relative, protector, progenitor, or helper—superhuman powers and abilities are ascribed to totems and totems are not only offered respect or occasional veneration but also can become objects of awe and fear; (2) use of special names and emblems to refer to the totem; (3) partial identification with the totem or symbolic assimilation to it; (4) prohibition against killing, eating, or touching the totem, even as a rule to shun it; and (5) totemistic rituals.

Though it is generally agreed that totemism is not a religion, in certain cases it can contain religious elements in varying degrees, just as totemism can appear conjoined with magic. Totemism is frequently mixed with different kinds of other beliefs—the cult of ancestors, ideas of the soul, beliefs in powers and the spirits. Such mixtures make the understanding of particular totemistic forms difficult. The cultic veneration of definite animals and natural things and powers by all those who belong to an ethnic unit do not belong to totemism itself.

Group totemism. Group (social or collective) totemism is the most widely disseminated form of totemism.

Characteristics of group totemism

Though the following characteristics can belong to it, they must not be taken to be part of a whole system: (1) mystic association of animal and plant species, natural phenomena, or created objects with unilineally related groups (lineages, clans, tribes, moieties, phratries) or with local groups and families; (2) hereditary transmission of the totems (patrilineal or matrilineal); (3) names of groups that can be based either directly or indirectly on the totem (the same holds true for personal names used within groups); (4) totemistic emblems, symbols, and taboo formulas are, as a rule, a concern of the entire group, but they can also belong to subdivisions of that group. Taboos and prohibitions can apply to the species itself or they can be limited to parts of animals and plants (partial taboos instead of partial totems). (5) Totems for groups are sometimes connected with a large number of animals and natural objects (multiplex totems) whereby a distinction can be made between principal totems and subsidiary ones (linked totems). Totems are associated or coordinated on the basis of analogies or on the basis of myth or ritual. (Just why particular animals or natural things—which sometimes possess absolutely no recognizable worth for the communities concerned—were selected as totems is often hard to fathom and may be based on eventful and decisive moments in a people's past which are no longer known.) (6) Accounts of the nature of totems and the origin of the societies in question are informative, even if they are sometimes valuable only as supplementary rationalizations; they are especially informative with regard to their presuppositions. If, for example, one group supposes that it is derived directly or indirectly from the totem, this may be recounted (as a rationalization) that an animal progenitor was changed into a human being who then became the founder of the group or that the ancestral lord of the group was descended from a conjugal union between a man and a representative of the animal species. Groups of men and species of animals and plants can also have progenitors in common. In other cases, there are traditions that the human progenitor of a kin group had certain favourable or unfavourable experiences with an

animal or natural object and then ordered that his descendants had to respect the whole species of that animal.

Group totemism is now found especially among peoples in Africa, India, Oceania (especially in Melanesia), North America, and parts of South America who farm rather than simply gather food from nature. Peoples with hunting and partly harvesting economies who exhibit this form of totemism include, among others, the Australian Aborigines (hunters who occupy a special position due to the many forms of totemism among them), the African Pygmies, and various tribes of North America—such as those on the northwest coast (predominantly fishermen), in parts of California, and in northeast North America. Moreover, group totemism is represented in a distinctive form among the Ugrians and west Siberians (hunters and fishermen who also breed reindeer) as well as among tribes of herdsmen in north and Central Asia.

Individual totemism. Individual totemism is expressed in an intimate relationship of friendship and protection between a person and a particular animal or a natural object (sometimes between a person and a species of animals); the natural object can grant special power to its owner. Frequently connected with individual totemism are definite ideas about the human soul (or souls) and conceptions derived from them, such as the idea of an alter ego and nagualism—from the Spanish form of the Aztec word *naualli*, "something hidden or veiled"—which means that a kind of simultaneous existence is assumed between an animal or a natural object and a person; *i.e.*, a mutual, close bond of life and fate exist in such a way that in case of the injury, sickness, or death of one partner, the same fate would befall the other member of the relationship. Consequently, such totems became most strongly tabooed; above all, they were connected with family or group leaders, chiefs, medicine men, shamans, and other socially significant persons. In shamanism, an earlier trait of individual totemism is often ascertained: the animalistic protective spirits can sometimes be derived from individual totems. To some extent, there also exists a tendency to pass on an individual totem as hereditary or to make taboo the entire species of animal to which the individual totem belongs. In this can perhaps be seen the beginning of the development of totems that belong to a group. Many tales about the origins of the group totem could, perhaps, point in this direction.

Nagualism

Individual totemism is widely disseminated. It is found not only among the tribes of hunters and harvesters but also among farmers and herdsmen. Individual totemism is especially emphasized among the Australian Aborigines.

SOME EXAMPLES OF TOTEMISM

Wiradjuri. (New South Wales, Australia) Totem clans are divided among two subgroups and corresponding matrilineal moieties. The group totem, named "flesh," is transmitted from the mother. In contrast to this, individual totems belong only to the medicine men and are passed on patrilineally. Such an individual totem is named *bala*, "spirit companion," or *jarawaijewa*, "the meat (totem) that is within him." There is a strict prohibition against eating the totem. Breach of the taboo carries with it sickness or death. It is said: "To eat your *jarawaijewa* is the same as if you were to eat your very own flesh or that of your father." The medicine man identifies himself with his personal totem. Every offense or injury against the totem has its automatic effect upon the man who commits it. It is a duty of the totem to guard the ritualist and the medicine man while he is asleep. In the case of danger or the arrival of strangers, the animal goes back into the body of the medicine man and informs him. After the death of the medicine man, the animal stands watch as a bright flickering light near the grave. The individual totem is also a helper of the medicine man. The medicine man emits the totem in his sleep or in a trance so that it can collect information for him. Finally, black magic (sorcery) is also practiced by the medicine man; by singing, for instance, the medicine man sends out his totem. To kill an enemy, the totem enters the chest of the enemy and devours his viscera. The transmission of the individual totem to novices is done through the father or the grandfather who, of course, himself is also a medicine man. While the candidate lies on his back, the totem is "sung into" him. The blood relative who is transmitting the totem takes a small animal and places it on the chest of the youngster. During the singing, the animal supposedly sinks slowly into his body and finally disappears into it. The candidate is then instructed on how he has to treat the animal that is his comrade, and he is further instructed in song and the ritual concentration that is necessary to dispatch the totem from his body.

Individual totems

By courtesy of the Australian News and Information Bureau, New York

Australian Aborigines dancing a corroboree. In dancing a corroboree the Australian natives imitate birds, animals, fish, and men, and also the movements of storms and floods.

Nor-Papua. (Murik Lakes, west of the mouth of the Sepik River, north New Guinea) Patrilineal, exogamous groups (consanguineous sibs) are spread over several villages and are associated with animals, especially fish. They believe that they are born from totems and they make them taboo. Children are able to decide during their initiation whether they will respect the paternal or maternal totem. Each group of relatives has a holy place to which the totem animal brings the souls of the dead and from which the souls of children also come. Totem animals are represented as spirit creatures in sacred flutes, in disguises, and in figures preserved in each man's house. At the end of initiation ceremonies, the totems are mimicked by the members of the group.

Iban. (Sungai Dayak, Sarawak, Malaysia) Among these peoples, individual totemism is clearly discernible. Particular persons dream of a spirit of an ancestor or a dead relative; this spirit appears in a human form, presents himself as a helper and protector, and names an animal (sometimes one of the natural objects) in which he is manifested. The Iban then observe the mannerisms of animals and recognize in the behaviour of the animals the embodiment of their protector spirit (*ngarong*). Sometimes, members of the tribe also carry with them a part of such an animal. Not only the particular animal, but the whole species of the animal is given due respect. Meals and blood offerings are also presented to the spirit animal. Young men, who wish to obtain such a protector spirit for themselves, sleep on the graves of prominent persons or seek out solitude and fast so that they may dream of a helper spirit. Actually, only a few persons can name such animals as their very own. Individuals with protector spirits have also attempted to require from their descendants the respect and the taboo given the animal representing the spirit. As a rule, such descendants do not expect special help from the protector spirit, but they observe the totemistic regulations anyway. Thus it can be concluded that particular families or groups of relatives of the Iban represent totem communities.

Birhor. (Munda-speaking hunter and harvester tribe that resides in the jungle of Chotanāgpur Plateau, north-

Group totems

east Deccan, India) The Birhor are organized into patrilineal, exogamous totem groups. According to one imperfect list of 37 clans, 12 are based on animals, ten on plants, eight on Hindu castes and localities, and the rest on objects. The totems are passed on within the group, but no account of their origin is available. From tales about the tribe's origins, it appears that the totem had a fortuitous connection with the birth of the ancestor of the clan. The Birhor think that there is a temperamental or physical similarity between the members of the clan and their totems. Prohibitions with regard to taboo are sometimes cultivated to an extreme degree. In regard to eating, killing, or destroying them, the clan totems are regarded as if they were human members of the group. Moreover, it is believed that an offense against the totems through a breach of taboo will produce a corresponding decrease in the size of the clan. If a person comes upon a dead totem animal, he must smear his forehead with oil or a red dye, but he must not actually mourn over it; he also does not bury it. The close and vital relationship between the totem and the clan is shown in a definite ceremony: the yearly offering to the chief spirit of the ancestral hill. Each Birhor has a tradition of an old settlement—thought to be located on a hill in the area. Once a year, the men of each clan come together at an open place. The elder of the clan functions as the priest who gives the offering. A diagram with four sections is drawn on the ground with rice flour. In one of these, the elder sits while gazing in the direction of the ancestral hill. The emblem of the particular totem is placed in one of the other places of the diagram; depending on the circumstances, this emblem could be a flower, a piece of horn or skin, a wing, or a twig. This emblem represents the clan as a whole. If an animal is needed for such a ceremony, it is provided by the members of another clan who do not hold it as a totem. The Birhor show great fear of the spirits of the ancestral hill and avoid these places as far as possible.

Kpelle. (Liberia, West Africa) In this society, there is not only group totemism but individual totemism as well. Both categories have the same designations, namely, "thing of possession," "thing of birth," "thing of the back of men." These phrases express the idea that the totem always accompanies man, belongs to him, and stands behind him as a guide and warner of dangers. The totem also punishes the breach of any taboo. The totems are animals, plants, and natural phenomena. The kin groups that live in several villages were matrilineal at an earlier time, but they are beginning to exhibit patrilineal tendencies. The group totems, especially the animal totems, are considered as the residence of the ancestors; they are respected and are given offerings. Moreover, a great role is played by individual totems that, in addition to being taboo, are also given offerings. Animal personal totems can be transmitted from father to son or from mother to daughter; on the other hand, individual plant totems are assigned at birth (plants of a tree of life for the child) or later. The totem also communicates magical powers. It is even believed possible to alter one's own totem animal; further, it is considered an alter ego. Persons with the same individual totem prefer to be united in communities. The well-known leopard confederation, a secret association, seems to have grown out of such desires. Entirely different groups produce patrilineal taboo communities which are supposedly related by blood; they comprise persons of several tribes. The animals, plants, and actions made taboo by these groups are not considered as totems. In a certain respect, the individual totems in this community seem to be the basis of group totemism.

A SHORT HISTORY OF TOTEMISTIC THEORY

From McLennan to Levi-Strauss. There are a number of theories or hypotheses concerning totemism. Many of them are marked by methodological deficiencies, preconceived ideas, and a prejudiced selection of source documents; nevertheless, some of these theories contain points of view that deserve consideration.

The first theory was proposed by the Scottish ethnologist John Ferguson McLennan. Following the vogue of 19th-century research, he wanted to comprehend totemism in a broad perspective, and in his study "The Worship of Animals and Plants" (1869, 1870) he did not seek to explain the specific origin of the totemistic phenomenon but sought to indicate that all of the human race had in ancient times gone through a totemistic stage.

Views of E.B. Tylor, Andrew Lang, and James G. Frazer

In 1899 McLennan's theories were criticized by E.B. Tylor, an English anthropologist who rejected the confusion of totemism with mere worship of animals and plants. Tylor claimed to find in totemism the tendency of the human spirit to classify the world and its things. He thus viewed totemism as a relationship between one type of animal and a clan. But he was opposed to the idea of seeing totems as the basis of religion.

Another Scottish scholar, Andrew Lang, early in the 20th century advocated a nominalistic meaning for totemism, namely that local groups, clans, or phratries, in selecting totem names from the realm of nature, were reacting to a need to be differentiated. If the origin of the names was forgotten, there followed a mystical relationship between the objects—from which the names were once derived—and the groups that bore these names. Lang wanted to explain the relationship through nature myths according to which animals and natural objects were considered as the relatives, patrons, or ancestors of the respective social units. Thoughts by the tribes on these matters led eventually to taboos. Group exogamy first originated in the formation of totemistic associations.

The first comprehensive work on totemism was *Totemism and Exogamy*, published in 1910 in four volumes by the British anthropologist Sir James George Frazer. It presented a meritorious compilation of the then known worldwide data on the subject.

Basing his view on research done among primitives in Australia and Melanesia, Frazer saw the origin of totemism as one possibility in the primitive interpretation of the conception and birth of children ("conceptionalism"). According to this primitive idea, women become impregnated when a spirit of an animal or a spiritual fruit enters into their wombs. Since the children therefore participate in the nature of the animal or plant, these plants or animals take on significance. These ideas were hereditary and resulted in the beginning of totem clans derived from a particular natural creature.

A Russian–American ethnologist, Alexander Goldenweiser, subjected totemistic phenomena to sharp criticism. This critical work had lasting importance, especially in the United States, where it engendered a skeptical attitude concerning totemism. Goldenweiser saw in totemism three phenomena that could exist singly and actually coincided only in the rarest of cases. These phenomena were: (1) clan organization; (2) clans taking animal or plant names or having "emblems" obtained from nature; and (3) belief in a relationship between groups and their totems. Goldenweiser did not perceive these phenomena as a unity, since any of them could exist apart from the others.

In another treatise published in 1910, a German ethnologist, Richard Thurnwald, claimed to recognize in totemism the expression of a specific way of thinking among the primitives. Primitives judge the natural environment according to its external appearance without analyzing it any closer and assume that there are sympathetic connections and combinations of natural things; from these ideas come lasting rules of behaviour (like taboos, respect, and social relationships). For the psychology of totemism, Thurnwald later (1917–18) put forth a detailed, systematic presentation; by means of concrete examples, he also raised questions about the connections of totemism with ancestor worship, notions of souls, belief in power, magic, offerings, and oracles.

Views of Émile Durkheim

The founder of a French school of sociology, Émile Durkheim, in a general work concerning the elementary forms of religion (1912), also examined totemism from a sociological and theological point of view. Durkheim hoped to discover a pure religion in very ancient forms and generally claimed to see the origin of religion in totemism. For Durkheim, the sphere of the sacred is a

reflection of the emotions that underlie social activities, and the totem was, in this view, a reflection of the group (or clan) consciousness, based on the conception of an impersonal power. The totemistic principle was then the clan itself, and it was permeated with sanctity. Such a religion reflects the collective consciousness that is manifested through the identification of the individuals of the group with an animal or plant species; it is expressed outwardly in taboos, symbols, and rituals that are based on this identification.

In further contributions, Goldenweiser in 1915–16 and 1918 criticized Lang, Frazer, and Durkheim and insisted that totemism had nothing to do with religion; that man in no way viewed his totem as superior to himself or as a deified being but viewed it as his friend and equal. Goldenweiser also rejected Frazer's thesis of "conceptionalism" as an explanation of totemism. On the other hand, Goldenweiser was of the opinion that all totemistic manifestations do have at least something of a kind of religion, but he was not inclined to include the guardian spirit conception within totemism.

In 1916, an American ethnologist, Franz Boas, posited a theory of totemism as an "artificial" unity, existing only in the thinking of ethnologists. For Boas, totemism exhibited no single psychological or historical origin; since totemistic features can be connected with individuals and all possible social organizations, and they appear in different cultural contexts, it would be impossible to fit totemistic phenomena into a single category. Boas was against systematizing and thought it senseless to ask questions about the origins of totemism.

Views of F. Graebner and B. Ankermann

The first theoretician of the Vienna school of Ethnology, Fritz Graebner, attempted to explain the forms of both individual totemism and group totemism and designated them as a moderately creedal or semireligious complex of ideas according to which individual members or subgroups of a society are thought to be in an especially close (but not cultic) relationship to natural objects. According to Graebner, with the help of the cultural–historical method, one can establish (1) the extent to which totemistic forms belong to one definite cultural complex, (2) which forms are "older" or "younger," and (3) the extent to which forms belong together genetically. Graebner tried to work out a "totemistic" complex (a "culture circle") for the South Seas. This complex entailed a patrilineal group totemism as well as the material, economic, and religious elements that, in his opinion, appear to be combined with the totemism in that area.

Another member of the same school, Bernhard Ankermann, in 1915–16 championed the view that all totemisms, regardless of where they are found, contained a common kernel around which new characteristics are built. As seen from the standpoint of what was found in Africa, this kernel appeared to him to be the belief in a specific relationship between social groups and natural things—in a feeling of unity between both—a relationship he believed to be spread throughout the world, even if only in a modified or diminished form. Magical and animalistic ideas and rites are merged with totemism in a strong inseparable unity. The genesis of this type of relationship presupposes a state of mind that makes no distinction between man and beast. Although magic can be closely connected with totemism, the feeling of unity between man and beast has nothing to do with magic, which was connected with it only later. According to Ankermann, the totems are not something perilous, something to be shunned, but, on the contrary, totems are something friendly; and since this is directly due to kinship, a totem is thought to be like a brother and is to be treated as such. The totemistic taboo is believed to be due to the fact that the totem is a relative. Ankermann was inclined to see the formation of totemism in a "lower" form of hunting, in an emotional animal–man relationship, in animalistic behaviour. Men of early times, he thought, might have imitated those animals that attracted their attention most of all. According to Ankermann, pretension and reality, however, for the "primitives" are blurred into one thing. Primitive man identifies himself with the animal while he is imitating it; the habit of so doing could lead to a continuing identification. Early man imitated all animals that interested him, but he imitated those that shared his place of habitation above all.

Views of Wilhelm Schmidt

In 1915–16 Wilhelm Schmidt, then the leader of the Vienna school of Ethnology, viewed totemism strictly according to the then-existing schemes of culture circles (today long abandoned); because totemism was disseminated throughout the world, he thought of it as a closed cultural complex in spite of local differences. He maintained that the differences in totemism shown by earlier theories are exaggerations and could, moreover, be due to the lack of particular elements of totemism, to the loss of certain forms of totemism, to incursions from the outside, or to different stages of the development of totemism, none of which would exclude a unified origin for all of totemism. Schmidt believed that the cultural–historical school of ethnology had produced proof that the older, genuine totemism occurred as an integral part of a culture located in a definite area and that it was "organically" connected with definite forms of technology, economy, art, and world view. From a "pure" totemism, Schmidt wanted to separate similar forms, such as sex and individual totemism. Moreover, though he did not designate totemism as a religion, he saw that it did have some sort of religious meaning. Schmidt (in opposition to Ankermann) wanted to regard the higher form of hunting as the economic basis for the totemistic "culture circle."

Views of A.R. Radcliffe-Brown and Bronisław Malinowski

The leading representative of British social anthropology, A.R. Radcliffe-Brown, took a totally different view on the totemistic problem. Like Boas, he was skeptical of the reality of totemism. In this he opposed the other pioneer of social anthropology in England, Bronisław Malinowski, who wanted to admit the reality of totemism in some way and looked at it more from a biological and psychological point of view than from an ethnological one. According to Malinowski, totemism was not a cultural phenomenon but was the result of trying to satisfy basic human needs within the natural world. As far as Radcliffe-Brown was concerned, totemism was composed of elements that were taken from different areas and institutions, and what they have in common is a general tendency to characterize segments of the community through a connection with a portion of nature. In opposition to Durkheim's theory of sacralization, Radcliffe-Brown took the point of view that nature is introduced into the social order rather than secondary to it. At first, he shared with Malinowski the opinion that an animal becomes totemistic when it is "good to eat." He later came to oppose the usefulness of this viewpoint since many totems—such as crocodiles and flies—are dangerous and unpleasant.

In 1952, when Radcliffe-Brown rethought the problem, he found that the similarities and differences between species of animals are to a certain degree translated into ideas of friendship and conflict, or close relationships and opposition among people. The natural world is represented in the form of social relationships to the extent that these social relationships become valid in primitive societies. The structural principle which Radcliffe-Brown believed he had discovered at the end of his comparative study is based on the fusion of the two contrary ideas of friendship and animosity. Thus totemism speaks in its own way of interrelationships and antitheses, ideas that are also found in moieties. So totemism is formulated as a general problem in which the contrasts in nature serve to create an integral whole. Thinking in terms of opposing things is, according to Radcliffe-Brown, an essential structural principle for evaluating totemism.

Views of Claude Lévi-Strauss

The most incisive critique of totemistic phenomena, one that denied the reality of totemism, was supplied by the French ethnologist Claude Lévi-Strauss in *Le Totémisme aujourd'hui* (English translation, *Totemism,* 1963). As a chief representative of modern structuralism, Lévi-Strauss was especially stimulated by Radcliffe-Brown, whose views he further attempted to expand. Lévi-Strauss believed that he was to approach the apparent, acknowledged difficulties in the study of totemism from the viewpoint of a study of structure. In order to study the structure of totemism, Lévi-Strauss devised a scheme to

illustrate the abstract polarities that he saw in totemism as a phenomenon in human culture. This scheme was implemented in a table of oppositions or polarities, or mutual relationships. The basic opposition, or relationship, was between nature and culture. On the one hand, there were in nature certain natural realities such as species of animals or plants and specific animals or plants. On the other hand, there were in culture various groups and individuals who identified themselves with particular species or with specific animals or plants. Lévi-Strauss distinguished four kinds of opposition, or relationship, between nature and culture within totemism: (1) a species of animal or plant identified with a particular group, (2) a species of animal or plant identified with an individual, (3) a particular animal or plant identified with an individual, and (4) a particular animal or plant identified with a group.

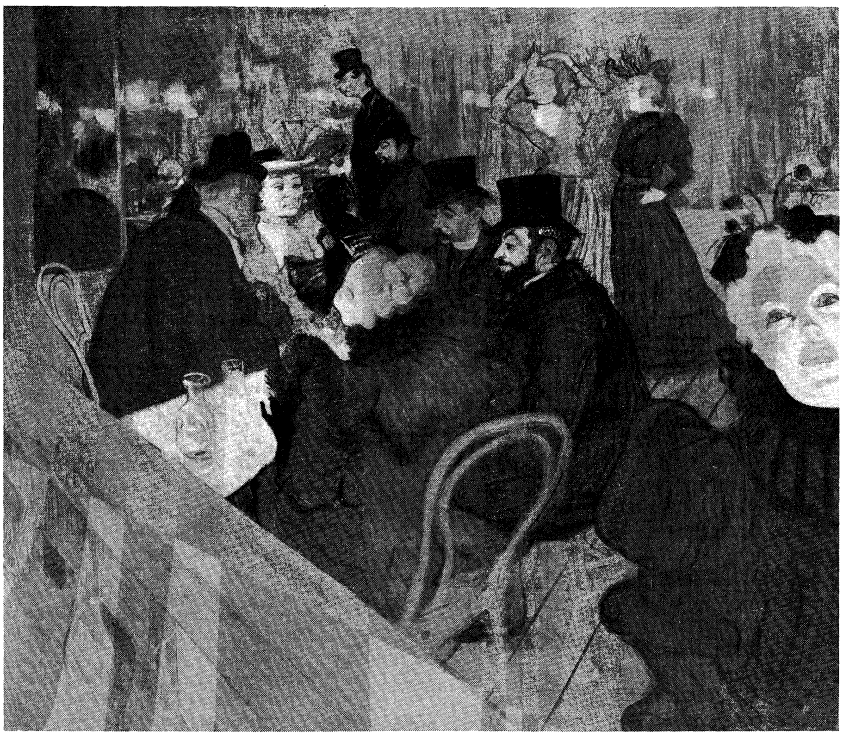
According to Lévi-Strauss, each of these four combinations corresponds to the phenomena that are to be observed in one people or another. The first antithesis holds good, for example, for the Australians, for whom natural things are associated with cultural groups (moieties, sections, subsections, phratries, clans, or the association of persons from the same sex). As an example of the second combination, there is the individual totemism of North American Indians, in which a person is correlated with a species of nature. For the third type of combination, Mota in the Banks Islands of Melanesia is cited: the individual child is thought of as the incarnation of a particular animal, plant, or natural creature that was found and consumed by the mother at the time that she was conscious of her pregnancy. For the fourth type of correlation, Lévi-Strauss cited examples from Polynesia and Africa where definite individual animals formed the object of group patronage and veneration.

Lévi-Strauss also critiqued the findings of A.P. Elkin, a specialist on Australia, where totemism had already played a special role in the formation of theories and where it exhibits an abundance of forms for expressing totemism. Elkin had differentiated the following forms: (1) individual totemism; (2) social totemism—*i.e.*, totemism that is in a family, moiety, section, subsection, patrilineal clan, or matrilineal clan; (3) cultic totemism with a religious content that is patrilineal and "conceptional" in form; (4) dream totemism—totemistic content in dreams—found in social or individual totemism. Elkin denied the unity of totemism, but (according to Lévi-Strauss) wanted to preserve its reality on the condition that he might trace it back to a multiplicity of types. For Elkin, there is no longer "one" totemism but many totemisms, each in itself a single irreducible whole.

In connection with the Australian material, Lévi-Strauss argued that matrilineal clan totemism—that passed on the "flesh" or "blood"—and the patrilineal clan totemism —based on dreaming—were in no way heterogeneous but were to be thought of as being mutually complementary. They were different means of connecting the material and spiritual world; they were two different, but correlative, types that express the relationship between nature and society.

Lévi-Strauss concluded that not the similarities but the dissimilarities correspond to the so-called totemism. Such a pattern was clearly expressed in the basic model of the contrasts of the natural with the cultural (that were outlined above). Depending on the ideas of Radcliffe-Brown, Lévi-Strauss claimed to perceive antithetical thinking as a crucial structural principle in totemism and believed that the similarity among totemistic ideas in various cultures lay in similarities between both systems of differences—those documented in the natural sphere and those in the culturally defined social groups. Lévi-Strauss concluded that the distinction between the classes of man and animal serves as the conceptual basis for social differences. For Lévi-Strauss, totemism is therefore an "illusion" reduced to a form of thinking, and this so-called totemism is connected with understanding the demands that it answers as well as the way in which it seeks to satisfy those demands. Since it is a "logic that classifies," totemism in this sense has nothing of the archaic itself. Its picture is projected onto the material (the natural phenomena), not taken from it. It does not take its substance from without.

Present situation and emerging trends. From the publications of Lévi-Strauss and the contributions of his predecessors, it is obvious that difficulties stand in the way of an adequate interpretation of the intricate profusion of totemistic phenomena. But it seems fair to many authorities to ask whether it is possible to dispose of totemism simply as an illusion, whether the very abstract structural interpretation of the facts is actually legitimate. To those who question the position, it seems clear that even though all totemistic forms of expression can hardly be seen under one common denominator, reality cannot be totally denied to totemism. A specific relationship between man and nature, one that serves as a basic scheme of classification, seems to be at the basis of all the various forms of totemism. Indeed, this can be regarded as the prevailing characteristic of totemism in the form in which it manifests itself. A special problem, however, must be taken into consideration: since totemism can be connected with different ideas and practices, of religious, magical, or ideological natures, it is difficult to decide what is "totemistic" and what is "nontotemistic."



BIBLIOGRAPHY. FRANZ BOAS, "The Origin of Totemism," *Am. Anthrop.*, 18:319–326 (1916), contains a variety of ideas and objects defined as totemism, and thus maintains little unity; A.P. ELKIN, "Studies in Australian Totemism: The Nature of Australian Totemism," *Oceania*, 4:113–131 (1933–34); E.E. EVANS-PRITCHARD, "Nuer Totemism," *Annali Lateran.*, 13:225–248 (1949), describes the manifestations of totemism combined with the conception of the spirit in the "Nilot" tribe; J.V. FERREIRA, *Totemism in India* (1965), a critical evaluation of hitherto existing works on totemism in general and that of India in particular; R. FIRTH, "Totemism in Polynesia," *Oceania*, 1:291–321, 377–398 vol. 1 (1930–31), a useful survey article; J.L. FISCHER, "Totemism on Truk and Ponape," *Am. Anthrop.*, 59:250–265 (1957), describes and interprets the highly contrasting forms of totemism found in Micronesia, using not only the unusual sociological–ideological organization but also containing psychological aspects; G. FOSTER, "Nagualism in Mexico and Guatemala," *Acta Am.*, 2:85–103 (1944), deals with important borderline cases of totemism with particular regard to the problem of personal totemism; J.G. FRAZER, *Totemism and Exogamy*, 4 vol. (1910) and *Totemica: A Supplement to "Totemism and Exogamy"* (1937), comprehensive and informative reference works although the hypotheses are now out of date; A.A. HAEKEL, "Der heutige Stand des Totemismusproblems," *Mitt. Anthrop. Ges. Wien*, 82:33–49 (1952), attempts to give a critical examination with concrete examples of the question, complex in its various forms; CLAUDE LEVI-STRAUSS, *Le Totémisme aujourd'hui* (1962; Eng. trans., *Totemism*, 1963), contains a detailed critical evaluation of existing hypotheses of Anglo-American and French authors; R. PIDDINGTON, *An Introduction to Social Anthropology* 1:200–206 (1950), offers a short but sufficient characterization of the totemic phenomena, the difficulty in defining it, its great variability, and some concrete examples.

(Jo.H.)

Toulouse-Lautrec, Henri de

Henri de Toulouse-Lautrec exerted a great influence on French art of the late 19th and early 20th centuries by his use of new kinds of subjects, his ability to capture the essence of an individual with economical means, and his stylistic innovations. Although his legs were severely deformed following two accidents in his youth, and his body was later weakened by alcoholism and mental collapse, Toulouse-Lautrec nonetheless helped set the course of avant-garde art well beyond his early and tragic death at the age of 36.

Childhood and education. Henri-Marie-Raymond de Toulouse-Lautrec-Monfa was born November 24, 1864, at Albi. His family was wealthy and had a lineage that extended without interruption back to the time of Charlemagne. Toulouse-Lautrec grew up amid his family's typically aristocratic love of sport and art. Most of the boy's time was spent at the Château du Bosc, one of the family estates located near Albi. Henri's grandfather, fa-

ther, and uncle were all talented draftsmen, and thus it was hardly surprising that Henri began sketching at the age of ten. His interest in art grew as a result of his being incapacitated in 1878 by an accident in which he broke his left thighbone. His right thighbone was fractured a little over a year later in a second mishap. These accidents, requiring extensive periods of convalescence and often painful treatments, left his legs atrophied and made walking most difficult. As a result, Toulouse-Lautrec devoted ever greater periods to art in order to pass away the frequently lonely hours.

Crippling accident

Toulouse-Lautrec's first visit to Paris occurred in 1872, when he enrolled in the Lycée Fontanes (now Lycée Condorcet). He gradually moved on to private tutors, and it was only after he had passed the baccalaureate examinations, in 1881, that he resolved to become an artist.

His first professional teacher in painting was René Princeteau, a friend of the Lautrec family. Princeteau's fame, such as it was, arose from his depiction of military and equestrian subjects, done in a 19th-century academic style. Though Toulouse-Lautrec got on well with Princeteau, he moved on to the atelier of Léon Bonnat at the end of 1882. In Bonnat, Toulouse-Lautrec encountered an artist who fought vehemently against deviation from academic rules, condemned the slapdash approach of the Impressionists, and judged Toulouse-Lautrec's drawing "atrocious." His work received a more positive reaction in 1883, when he joined the studio of Fernand Cormon.

Work in Cormon's studio

In the early 1880s, Cormon enjoyed a moment of celebrity, and his studio attracted such artists as Vincent van Gogh and the Symbolist painter Émile Bernard. Cormon gave Toulouse-Lautrec much freedom in developing a personal syle. That Cormon approved of his pupil's work is proved by his choosing Toulouse-Lautrec to assist him in illustrating the definitive edition of the works of Victor Hugo. In the end, however, Toulouse-Lautrec's drawings for this project were not used.

Despite this approval, Toulouse-Lautrec found the atmosphere at Cormon's studio increasingly restrictive. "Cormon's corrections are much kinder than Bonnat's were," he wrote his uncle Charles on February 18, 1883. "He looks at everything you show him and encourages one steadily. It might surprise you, but I don't like that so much. You see, the lashing of my former master pepped me up, and I didn't spare myself." The academic regimen of copying became insufferable. He made "a great effort to copy the model exactly," one of his friends later recalled, "but in spite of himself he exaggerated certain details, sometimes the general character, so that he distorted without trying or even wanting to." Soon Toulouse-Lautrec's attendance at the studio became infrequent at best. He then rented his own studio in the Montmartre district of Paris and concerned himself, for the most part, with doing portraits of his friends.

The documentor of Montmartre. Thus it was that in the mid-1880s Toulouse-Lautrec began his lifelong association with the bohemian life of Montmartre. The cafés, cabarets, entertainers, and artists of this area of Paris fascinated him and led to his first taste of public recognition. He focussed his attention on depicting popular entertainers such as Aristide Bruant, Jane Avril, Loie Fuller, May Belfort, May Milton, Valentin le Désossé, Louise Weber (known as La Goulue, or the Glutton), and clowns such as Cha-U-Kao and Chocolat.

In 1884 Toulouse-Lautrec made the acquaintance of Bruant, a singer and composer who owned a cabaret called the Mirliton. Impressed by his work, Bruant asked him to prepare illustrations for his songs and offered the Mirliton as a place where Toulouse-Lautrec could exhibit his works. By this means and through reproductions of his drawings in Bruant's magazine *Mirliton*, he became known in Montmartre and started to receive commissions.

Toulouse-Lautrec sought to capture the effect of the movement of the figure through wholly original means. For example, his contemporary Edgar Degas (whose works, along with Japanese prints, were a principal influence on him) expressed movement by carefully rendering the anatomical structure of several closely grouped figures, attempting in this way to depict but one figure, caught at successive moments in time. Toulouse-Lautrec, on the other hand, employed freely handled line and colour that in themselves conveyed the idea of movement. Lines were no longer bound to what was anatomically correct; colours were intense and in their juxtapositions generated a pulsating rhythm; laws of perspective were violated in order to place figures in an active,

Artistic originality

unstable relationship with their surroundings. A common device of Toulouse-Lautrec was to compose the figures so that their legs were not visible. Though this characteristic has been interpreted as the artist's reaction to his own stunted, almost worthless legs, in fact the treatment eliminated specific movement, which could then be replaced by the essence of movement. The result was an art throbbing with life and energy, that in its formal abstraction and overall two-dimensionality presaged the turn to schools of Fauvism and Cubism in the first decade of the 20th century.

The originality of Toulouse-Lautrec also emerged in his posters. Rejecting the notion of high art, done in the traditional medium of oil on canvas, Toulouse-Lautrec in 1891 did his first poster, "Moulin Rouge—La Goulue." This poster won Toulouse-Lautrec increasing fame. "My poster is pasted today on the walls of Paris," the artist proudly declared. It was one of more than 30 he would create in the 10 years before his death. Posters afforded Toulouse-Lautrec the possibility of a widespread impact for his art, no longer restricted by the limitations of easel painting; and they enhanced the success he had enjoyed in the preceding year when his works were shown in Brussels at the Exposition des XX (the Twenty), an avant-garde association, and in Paris at the Salon des Indépendants.

Toulouse-Lautrec is most important for his success in going beyond a representation of superficial reality to a profound insight into the psychological makeup of his subjects. He turned to the lithograph after 1892 as a medium well suited to this goal. Among more than 300 lithographs produced in the final decade of his life were an album of 11 prints entitled "Le Café Concert" (1893); 16 lithographs of the entertainer Yvette Guilbert (1894); and a series of 22 illustrations for Jules Renard's *Les Histoires naturelles* (1899). But none of these works is more significant than "Elles," a series done in 1896, presenting a sensitive portrayal of brothel life. Toulouse-Lautrec spent lengthy periods observing the actions and behaviour of prostitutes and their clients. The resulting 11 works revealed these individuals as human beings, with some of the same strengths and many of the weaknesses of other members of society. A masterpiece of this genre is "Au Salon de la rue des Moulins" ("At the Salon"). This painting evokes sympathy from the spectator as he observes the women's isolation and loneliness, qualities which the young Toulouse-Lautrec had so often experienced himself. "At the Salon" is a brilliant demonstration, therefore, of his stated desire to "depict the true and not the ideal," in which truth is based not on a careful representation of detail but rather on capturing, in a few brief brushstrokes, the essential nature of a subject.

Physical and mental decline

The appearance of "Elles" coincided with a growing deterioration in his physical and mental condition. Toulouse-Lautrec's figure, even among the great human diversity found in Montmartre, remained unmistakable. His fully developed torso rested on dwarfish legs. Not quite five feet one inch tall, his size seemed further diminished because of his practice of associating with unusually tall men, such as his fellow students Maxime Dethomas and Louis Anquetin and his cousin and close friend Gabriel Tapié de Céleyran. His frequently ironic tone failed to mask a fundamental dislike of his physical appearance, and his letters contain many derogatory remarks about his body and references to an increasing number of ailments, including syphilis. Drinking heavily in the late 1890s, when he reputedly helped popularize the cocktail, he suffered a mental collapse at the beginning of 1899. The immediate cause was the sudden, unexplained departure of his mother from Paris on January 3. He was always close to his family, particularly to his mother, who had always supported his ambitions; and he interpreted her leaving as a betrayal. The effect on his weakened system was severe, and he was committed shortly thereafter to a sanatorium in Neuilly-sur-Seine. This decision was made by the artist's mother, against the advice of relatives and friends of the artist, in the hope of avoiding a scandal.

Toulouse-Lautrec remained formally committed until March 31, 1899, though he chose to stay on at the sanatorium until mid-May. While there he was able to demonstrate his lucidity and power of memory by preparing a number of works on the theme of the circus. These works, however, lack the force and intensity of his earlier compositions. In the spring of 1900 he started drinking heavily again. On September 9, 1901, less than three months before his 37th birthday, he died at Château de Malromé.

Assessment. Toulouse-Lautrec was not a profound intellectual. Tapié de Céleyran wrote that he read little and when he did it was usually at night, because of insomnia. But he was a great satirist of pretense and convention. In typical fashion, he passed off his initial, unsuccessful attempt at the baccalaureate by having name cards printed "Henri de Toulouse-Lautrec, flunker of the arts." This iconoclasm surfaced also when he parodied Puvis de Chavannes' serious Symbolist work "The Sacred Grove" by turning it into a boisterous scene filled with rowdy friends (1884; Henry Pearlman Collection, New York City). Yet he also could push himself in pursuits like swimming and boating, and toward the end of his life he installed a rowing machine in his studio. In his enthusiasm for sports he once accompanied a French bicycling team on a trip through England. Toulouse-Lautrec was, as two observers have concluded, a "sensitive, deeply affectionate man, conscious of his infirmity but wearing a mask of joviality and irony."

Although recognized today as a major figure in late-19th-century art, Toulouse-Lautrec's status in his lifetime was disputed. Indeed, the artist's father, who took slight interest in his son after his disabling injuries, regarded his son's work as only "rough sketches" and could never accept the idea of a member of the aristocracy betraying his class by turning from a "gentleman" artist to a professional one. Stung by such criticism and hampered by his infirmities, Toulouse-Lautrec persevered to emerge as a prolific artist whose work would help shape the art of decades to come.

MAJOR WORKS

PAINTINGS: "Mme la Comtesse A. de Toulouse-Lautrec" (*c.* 1881–82; Musée Toulouse-Lautrec, Albi); "Au Salon de la Rue des Moulins" ("At the Salon," 1894; Musée Toulouse-Lautrec); "Portrait of Mrs. Suzanne V." (1885; Ny Carlsberg Glyptotek, Copenhagen); "Mme la Comtesse A. de Toulouse-Lautrec, mère de l'artiste" (1887; Musée Toulouse-Lautrec); "Girl in the Artist's Studio" (1888; Kunsthalle Bremen); "In Batignolles" (1888; Tate Gallery, London); "In the Circus Fernando: The Ringmaster" (1888; Art Institute of Chicago); "Monsieur Samary, de la Comédie-Française" (1889; private collection, Paris); "At the Nouveau Cirque: Five Stuffed Shirts" (1891; Philadelphia Museum of Art); "À la mie" (1891; Museum of Fine Arts, Boston); "At the Moulin de la Galette" (1891; Stedelijk Museum, Amsterdam); "La Goulue at the Moulin Rouge" (1891–92; Museum of Modern Art, New York); "At the Moulin Rouge" (1892; Art Institute of Chicago); "The Moulin Rouge" (1892; Národní Galerie, Prague); "Quadrille at the Moulin Rouge" (1892; National Gallery of Art, Washington, D.C.); "Jane Avril dansant" (1892; Louvre, Paris); "Jane Avril Leaving the Moulin Rouge" (1892; Wadsworth Atheneum, Hartford, Connecticut); "Portrait of L. Delaporte" (1893; Ny Carlsberg Glyptotek, Copenhagen); "Le Docteur Tapié de Céleyran dans un couloir de théâtre" (1894; Musée Toulouse-Lautrec); "Femme tirant son bas, ou femme de maison" (*c.* 1894; Louvre); "La Danse de la Goulue, ou les Almées" (1895; Louvre); "Women in a Brothel" (1895; Szépmüvészeti Múzeum, Budapest); "La Clownesse Cha-U-Kao" (1895; Louvre); "May Belfort" (1895; Cleveland Museum of Art); "Chilpéric" (1895–96; John Hay Whitney Collection, New York); "La Toilette" (1896; Louvre); "At the Bar" (1898; Kunsthaus, Zürich); "The Tête-à-Tête Supper" (1899; Courtauld Institute Galleries, London); "Aux courses" (1899; Musée Toulouse-Lautrec).

POSTERS: "Moulin Rouge—La Goulue" (1891); "Reine de joie" (1892); "Le Divan japonais" (1892); "Aristide Bruant dans son cabaret" (1893); "Confetti" (1894); "May Belfort" (1895).

BIBLIOGRAPHY. The definitive biographical study of Toulouse-Lautrec remains the French work by the artist's life-

long friend, MAURICE JOYANT, *Henri de Toulouse-Lautrec*, 2 vol. (1926–27, reprinted 1968). Other biographies of the artist, though often with romantic, exaggerated texts, are HANS TIETZE, *Toulouse-Lautrec* (1953); JACQUES LASSAIGNE, *Toulouse-Lautrec* (1939; Eng. trans., 1953); PHILIPPE HUISMAN and M.G. DORTU, *Lautrec par Lautrec* (Eng. trans. 1964); GERSTLE MACK, *Toulouse-Lautrec* (1938); LAWRENCE and ELIZABETH HANSON, *The Tragic Life of Toulouse-Lautrec* (1956); and EDOUARD JULIEN, *Lautrec* (Eng. trans. 1959). There is no catalogue raisonné. For valuable discussions of the artist's work, see the introduction by JEAN ADHEMAR and THEODORE REFF to LUCIEN GOLDSCHMIDT and HERBERT SCHIMMEL, *Unpublished Correspondence of Henri de Toulouse-Lautrec* (1969); DOUGLAS COOPER, *Henri de Toulouse-Lautrec* (1955); HANSPETER LANDOLT, *Henri de Toulouse-Lautrec: Drawings and Sketches in Colour* (1955); and L.F. JOHNSON, "Time and Motion in Toulouse-Lautrec," *College Art Journal*, 16:13–22 (1956).

(A.C.Bi.)

Toussaint-Louverture

An outstanding individual in black history, usually regarded as the greatest figure in the history of Haiti, François Dominique Toussaint began life as a slave. He became virtual dictator of the island of Hispaniola (now Haiti and the Dominican Republic) and displayed statesmanship, military and diplomatic genius, and an understanding of economics. His supreme goal was the termination of Negro slavery. He also stood for the reconciliation of whites, mulattoes, and blacks, for republican principles, for the adaptation of blacks to French culture, and for Haitian independence.

Toussaint was born on Bréda plantation near Cap Français (now Cap-Haïtien), capital of the French colony of Saint-Domingue (Haiti), probably in 1743. The son of an educated slave, he acquired through Jesuit contacts some knowledge of French, though he wrote and spoke it poorly, usually employing the Creole patois and African tribal language. Winning the favour of the plantation manager, he became a livestock handler, healer, coachman, and finally steward. Legally freed in 1777, he married a humble woman who bore him two sons. Toussaint was homely, short, and small framed. He was a fervent Catholic, opposed to voodoo. He dressed simply and was abstemious and a vegetarian. Although he slept little, his energy and capacity for work were astonishing. As a leader he inspired awe and adulation.

Participation in a slave revolt

A sudden slave revolt in the north province (August 1791) found him uncommitted. After hesitating a few weeks, he helped his former master escape and then joined the black forces who were burning plantations and killing many whites and mulattoes. He soon discerned the ineptitude of the rebel leaders and scorned their willingness to compromise with white radicals. Collecting an army of his own, Toussaint trained his followers in the tactics of guerrilla warfare. In 1793 he added the name of Louverture.

When France and Spain went to war in 1793, the black commanders joined the Spaniards of Santo Domingo, the eastern two-thirds of Hispaniola. Knighted and recognized as a general, Toussaint demonstrated extraordinary military ability and attracted such renowned warriors as his nephew Moïse and two future monarchs of Haiti, Jean-Jacques Dessalines and Henry Christophe. Toussaint's victories in the north, together with mulatto successes in the south and British occupation of the coasts, brought the French close to disaster. Yet, in May 1794, Toussaint went over to the French, giving as his reasons that the French National Convention had recently freed all slaves, while Spain and Britain refused, and that he had become a republican. He has been criticized for the duplicity of his dealings with his onetime allies and for a slaughter of Spaniards at a mass. His switch was decisive; the governor of Saint-Domingue, Etienne Laveaux, made Toussaint lieutenant governor, the British suffered severe reverses, and the Spaniards were expelled.

By 1795 Toussaint-Louverture was world famous. Adored by the blacks and appreciated by most whites and mulattoes, he did much to restore the economy. Defying French Revolutionary laws, he allowed many émigré planters to return, and he used military discipline to force the former slaves to work. Convinced that people were naturally corrupt, he felt that compulsion was needed to prevent idleness. Yet the labourers were no longer whipped: they were legally free and equal, and they shared the profits of the restored plantations. Racial tensions were eased because Toussaint preached reconciliation and believed that blacks, a majority of whom were African born, must learn from whites and Europeanized mulattoes.

Though he worked well with Laveaux, Toussaint eased him out in 1796. Léger-Félicité Sonthonax, a terrorist French commissioner, also allowed Toussaint to rule and made him governor general. But the ascetic black general was repelled by the proposals of this white radical to exterminate the Europeans, and he was offended by Sonthonax's atheism, coarseness, and immorality. After some devious manoeuvres, Toussaint forced Sonthonax out in 1797.

Elimination of rivals

Next to go were the British, whose losses caused them to negotiate secretly with Toussaint, notwithstanding the war with France. Treaties in 1798 and 1799 secured their complete withdrawal. Lucrative trade was begun with Britain and also with the United States. In return for arms and goods, Toussaint sold sugar and promised not to invade Jamaica and the American South. The British offered to recognize him as king of an independent Haiti; but, scornful of pompous titles, and distrustful of the British because they maintained slavery, he refused.

Toussaint soon rid himself of another nominal French superior, Gabriel Hédouville, who arrived in 1798 as representative of the Directory. Knowing that France had no chance of restoring colonialism as long as the war with England continued, Hédouville attempted to pit against Toussaint the mulatto leader André Rigaud, who ruled a semi-independent state in the south. Toussaint divined his purpose and forced Hédouville to flee. Succeeding Hédouville was Philippe Roume, who deferred to the black governor. Then a bloody campaign in 1799 eliminated another potential rival to Toussaint by driving Rigaud out and destroying his mulatto state. A purge that was carried out by Jean-Jacques Dessalines in the south was so brutal that reconciliation with the mulattoes was impossible.

Controlling all Saint-Domingue, Toussaint turned to Spanish Santo Domingo, where slavery persisted. Ignoring commands to the contrary by Roume and by Napoleon Bonaparte, who had become first consul of France, Toussaint overran it in January 1801, freed the slaves, and amazed the nonblacks with his magnanimity.

Command of Hispaniola

In command of the entire island, Toussaint dictated a constitution that made him governor general for life with near absolute powers. Catholicism was the state religion, and many revolutionary principles received ostensible sanction. There was no provision for a French official, however, because Toussaint professed himself a Frenchman and strove to convince Bonaparte of his loyalty. He also described his success in restoring order and prosperity in epistles that, like all his writings, were ungrammatical yet testify to the grasp, incisiveness, and depth of a formidable intellect.

Bonaparte had confirmed Toussaint-Louverture's position but saw him as an obstacle to the restoration of Saint-Domingue as a profitable colony. Toussaint knew Bonaparte despised Negroes and planned to reinstitute slavery; aware that Bonaparte would seek to intimidate the island upon making peace with England, he drilled a huge army and stored supplies. Yet Toussaint behaved ambiguously: venerating France, fearing Bonaparte, aging and growing weary, he trusted no one and failed to clarify his purposes. He desired above all to prevent a restoration of slavery while preserving the society he had built. Whites and mulattoes looked hopefully to France to repress the huge black majority; on the other side, many black leaders, like Moïse, wanted to expel all whites and divide the plantations. Some blacks were alienated by Toussaint's perfidies and equivocations, his mysteriousness, and the occasional atrocities he thought necessary amid such dangers.

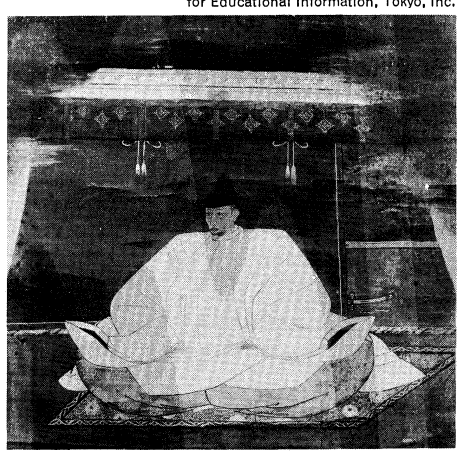
A French invasion under Gen. Charles Leclerc began in January 1802 in far greater force than expected. Most

whites and mulattoes defected to him; after a few weeks of furious fighting, so did the chief black leaders, even Christophe and Dessalines. In May Toussaint formally agreed to lay down his arms, in exchange for Leclerc's promise not to restore slavery. Perhaps he foresaw that yellow fever would destroy the French, as it did in the following year.

Leclerc gave Toussaint a spectacular welcome. The black leader retired in honour to a plantation. A few weeks later he attended a parley to discuss his personal situation. Suspected of plotting an uprising, he was seized and sent to Ft. de Joux in the French Alps, where he was confined and interrogated repeatedly, and where he died on April 7, 1803.

BIBLIOGRAPHY. Biographical accounts favourable to Louverture include: C.L.R. JAMES, *The Black Jacobins: Toussaint L'Ouverture and the San Domingo Revolution*, 2nd ed. rev. (1963), sound but with a Marxist bias; RALPH KORNGOLD, *Citizen Toussaint* (1944), a detailed study; and T. LOTHROP STODDARD, *The French Revolution in San Domingo* (1914), a classic work favourable despite its anti-Negro bias. A critical study is STEPHEN ALEXIS, *Toussaint Louverture, libérateur d'Haiti* (abridged Eng. trans., *Black Liberator: The Life of Toussaint Louverture*, 1949), a work that is credulous in places.

(J.E.F.)



Toyotomi Hideyoshi

Toyotomi Hideyoshi, a feudal lord of peasant origin, completed the unification of Japan begun by Oda Nobunaga; he did so by defeating the remaining powerful feudal barons (daimyo). He was born on February 6, 1537, in Nakamura, Owari Province (present-day Aichi Prefecture), the son of a peasant.

Early career

When he was still a boy, he left home for Tōtōmi Province (present-day Shizuoka Prefecture) and became page to a retainer of the Daimyo of Tōtōmi. After a short period, he returned home to become a foot soldier for the great Japanese leader Oda Nobunaga. His cheerful nature, tactful manner, and intelligence helped him to be promoted to samurai (a military retainer of a daimyo). When Nobunaga began his campaign to subjugate central Japan in 1568, Hideyoshi fought in many of the important battles.

Toyotomi Hideyoshi, detail of a portrait by an unknown artist, 1599. In a private collection.

In September 1573, by overthrowing two powerful daimyo, Hideyoshi became a lord of Nagahama, Ōmi Province, and subsequently took the name of Hashiba-chikuzen-no-kami.

From 1577, by order of Nobunaga, Hideyoshi embarked on the suppression of San-in and San-yo (Chugoku district), in the course of which he invaded Bitchū Province. Operating from a base at Himeji Castle in Harima Province, he besieged the daimyo Mōri Terumoto at Takamatsu. In 1582, Oda Nobunaga died after an attack by his retainer Akechi Mitsuhide; Hideyoshi immediately made peace with Mōri, and then moved east to avenge Nobunaga by killing Mitsuhide, which he accomplished at the Battle of Yamazaki.

At a conference of the Oda family's chief retainers, Hideyoshi insisted that Nobunaga's grandson succeed as head of the Oda family in opposition to two powerful vassals of their late leader who supported Nobunaga's third son. In 1583, Hideyoshi defeated one of these vassals in a battle and allowed him to commit suicide. After subduing a number of important strongholds, Hideyoshi in the same year built a castle in Ōsaka and embarked on his attempt to conquer the whole of Japan in an effort to complete Nobunaga's work of unifying the country after more than two centuries of feudal warfare. In the following year he fought a battle with Tokugawa Ieyasu, a powerful daimyo and a supporter of Nobunaga's second son. After an inconclusive fight, the two leaders concluded an alliance.

In 1585 Hideyoshi was appointed *kampaku* (chief adviser to the emperor) and later became *dajō-daijin* (chief minister). He was awarded the family name of Toyotomi by the Emperor, and he thus came to bear the name Toyotomi Hideyoshi. Shortly thereafter, he made peace with Mōri Terumoto, who had again become his antagonist, and then conquered the large islands of Shikoku and Kyushu, which constituted most of western Japan. He achieved some of his victories with Tokugawa Ieyasu's assistance. After subduing, with Ieyasu's aid, the Kantō and Ōu districts in the east in 1590, he became head of an alliance of daimyo that constituted a government of national unification.

Administrative innovations

At first he imposed such measures as *katana-kari* ("sword hunting") in order to enforce the prohibition of the use of arms by farmers, merchants, and monks and *shiro-wari* (destruction of castles or reducing the number of castles), to destroy unnecessary strongholds throughout Japan. He also introduced *shi-nō-kō-shō*, freezing class distinctions by rigidly separating warriors, farmers, artisans, and tradesmen, and by allowing each class to live in different areas of a town or village to promote the orderly establishment of a feudal society. In addition, he conducted *kenchi* (land surveys) and abolished road checkpoints in order to promote transportation. Development of mineral resources was encouraged so that the resulting coinage would help to further trade.

Upon conquering the whole of Japan, Hideyoshi entrusted the position of *kampaku* to his nephew, Toyotomi Hidetsugu, henceforth assuming the title of *taikō*, the designation of a retired *kampaku*. He then prepared to invade Korea. His ultimate purpose was reportedly the conquest of China, the Philippines, and India, but even control of the Korean peninsula, which he first invaded in 1592, was not possible because of Japan's entirely inadequate forces for an undertaking of such magnitude. After a temporary peace with China, which eventually broke down, Hideyoshi in 1597 staged a second invasion of Korea. He died at the age of 62 on August 18, 1598, deeply perturbed by the unfavourable results of the Korean war.

There were no children born to Hideyoshi by his formal wife, but he had a son by a concubine. At Hideyoshi's death, however, the son was only six years old, and Tokugawa Ieyasu took the reins of government, to become five years later the founder of the Tokugawa shogunate, or military government.

Assessment

Because of Hideyoshi's lowly beginnings, he was said to be illiterate and uncultured. He did, however, secretly attempt to educate himself, showing a facility for composing poetry. He performed well in Nō plays and avidly studied tea ceremony with a prominent master, frequently holding such ceremonies to demonstrate his skill. After his death his policies of national unification were followed by Tokugawa Ieyasu, and they became the basis of the peaceful Tokugawa era, which lasted until 1868.

(T.Ku.)

Track-and-Field Sports

Track-and-field sports consist of competitions in running, walking, jumping, and throwing events. Although

these contests are called track and field (or simply track) in the United States, they are generally designated as athletics in British Commonwealth countries and the equivalent of this term in non-English-speaking nations.

This article covers the history of track and field, the organization and administration of the sport at various levels, the conduct of competitions, and the rules and techniques of the individual events that comprise a track-and-field meet. The article also contains descriptions of the controversies surrounding the sport, and the recreational and fitness activities that are offshoots of the competitive sport.

For related articles, see ATHLETIC GAMES AND CONTESTS, including tables of Olympic events and champions in the section *Olympic record;* for world records, see also SPORTING RECORD in the *Ready Reference and Index.*

Track-and-field athletics are the oldest forms of organized sport, having developed out of man's most basic activities—running, walking, jumping, and throwing. Track and field has become the most truly international of sports, with nearly every country in the world engaging in some form of competition. Most nations now send representative teams both of men and women to the quadrennial Olympic Games, which have become the official world championships of track and field. There also are several continental and intercontinental championship meets held, including the European, British Commonwealth, African, Pan-American, and Asian.

Within the broad title of track and field come as many as two dozen distinct events, which have been standardized by national and international governing bodies of the sport. These events, generally held outdoors with running and walking events on a quarter-mile (440-yard) or 400-metre oval track, and field events (jumping and throwing) either inside the track's perimeter or in surrounding areas, make up a "meet," or "meeting" in British usage.

In many parts of the world, notably the U.S., Canada, and Europe, track and field moves indoors during the winter; because of limited space, some events are modified, and several are eliminated altogether.

Also within the general scope of track-and-field athletics come separate but related competitions that are not contested on the track. Cross-country running competition is carried out on various types of countryside and park land. Marathons (races of 26 miles 385 yards) and races of other long distances are run on roads, and many of the long-distance race walks are contested on measured road courses.

With rare exceptions, only amateur athletes (*i.e.,* those who compete for no financial gain) are allowed to enter track-and-field meets. The rules of amateurism and of competition are established and enforced by the International Amateur Athletic Federation (IAAF) and its member body from each nation. These bodies also maintain both the world and the national records in the standard events.

General considerations

HISTORY

Track-and-field sports can be traced back as far as man's evolution into an upright animal. The activities that make up the modern track-and-field events are as basic and simple, yet as essential to him as his instincts to move and to survive. Running, walking, jumping, and throwing are intimately tied in with his urge to ensure self-preservation. And long before any formal contests were staged, it is more than likely that young men matched their skills in these natural activities against each other—and employed them in play—as boys and girls will do without any urging or formal instruction.

Early history, decline. There is little in the way of definitive records of track and field's early days as an organized and formalized sport. Egyptians and several Asian civilizations, however, were known to have engaged in track and field contests many centuries before the Christian Era. As early as 1829 BC, Ireland was the scene of the Lugnasad or Tailteann Games involving various forms of track-and-field activity.

The sport's first big push came from the Greeks. Athletic contests were common features of their religious festivals. The Olympic Games traditionally date from 776 BC and continued through 11 centuries—finally ending in *c.* AD 393 on orders from the Roman emperor Theodosius. The earliest reported Olympic event was the "stade"—a run of a little over 200 yards. A long jumper named Chionis holds an important position in track-and-field history because he has the oldest known measured mark, having leaped 23 feet 1½ inches in the long jump at the Olympic Games of 656 BC. The ancient Olympics

These ancient Olympics were strictly men-only affairs. Greek women were reputed to have formed their own Games, the Heraea Games, which—like the Olympics—were held every four years. The events included foot races of about 165 yards. Numerous other athletic festivals included the Pythian, Isthmian, and Nemean games (see further ATHLETIC GAMES AND CONTESTS).

The imperial edict that ended the Olympics in the 4th century AD apparently left the world without organized track-and-field activity for hundreds of years. If there were any organized contests during the early Middle Ages, no reports of them have survived.

Revival in England. Track and field as it is practiced today was born and grew to maturity in England and, later, its colonies and former colonies. The first historical mention of the sport comes from England in 1154, when practice fields were established in London. Later, however, during the 1300s, King Edward III banned athletic events, claiming they interfered with the practice of archery. Not until the following century, when Henry VIII was the reigning monarch, was track and field given official approval. This king reputedly was an accomplished hammer thrower.

During the 17th century, English men of means entertained themselves by matching their footmen in distance races and wagering on the outcome. Outstanding distance running times arose from these competitions, known as "pedestrianism," as early as the 1600s and 1700s. In 1653 a man known only as "a butcher from Croydon" was said to have run 20 miles in 1½ hours. Considering the fact that this time exceeds the current world record by several minutes, there is considerable doubt as to the accuracy of the course measurement and timing. Another early mark of note was a 4½-minute mile reported by Horace Walpole in 1787.

Development of organized sport. This, however, was the prehistory of track-and-field athletics. The development of the modern sport has come only since the early 19th century. In 1825 amateur races were held at Uxbridge and also at Lord's Cricket Ground in London. The English public schools and universities played a big part in the organization of the sport. Eton College established a 100-yard hurdle race in 1837 and added sprints and a steeplechase six years later. These were interclass meetings limited to students at the school. Emergence of "gentleman amateurs"

The Royal Military Academy at Woolwich in 1849 promoted the first regularly organized track-and-field competition of modern times. Activity developed on many fronts in the decade to come, but it was the 1860s when track and field enjoyed its biggest surge to that date.

In 1862 the West London Rowing Club organized the first track-and-field meet that was open to all amateurs. Two years later, Oxford and Cambridge universities inaugurated their annual match. Then, in 1866, the Amateur Athletic Club was founded and conducted the first English championships. The emphasis in all these competitions was to provide a meeting place for "gentleman amateurs"—well-to-do athletes who received no financial compensation for their efforts. The rules of these meetings served as a basis of current regulations governing amateurism.

In 1880 the Amateur Athletic Club yielded governing power to the Amateur Athletic Association (AAA), which took charge of overseeing men's track-and-field athletics in England and Wales and conducting the annual national championships.

Track and field in North America. The development of track and field in North America came at about the same time but proceeded at a slower rate. The first meet-

ing on that continent took place near Toronto in 1839. The San Francisco Olympic Club became the first organized team when it was founded in 1860. It was, however, the New York Athletic Club (NYAC), formed in 1868, that gave the sport its major thrust in the Western Hemisphere. The NYAC put together the world's first indoor track-and-field meet, on Nov. 11, 1868, at the Empire City Skating Rink in New York City. Actually, it could barely qualify as an indoor affair. The floor had not yet been laid, and runners competed on an eight-laps-to-the-mile track that had been staked out on the firm ground. The building lacked a roof, and canvas provided temporary cover. By 1876 the NYAC was promoting what could be considered the first national track-and-field competitions, though participation was limited. The club started a movement that led to the formation in 1879 of the National Association of Amateur Athletes (NAAA), consisting of 14 clubs, mostly in the New York–New Jersey area but also including one from Boston and the San Francisco Olympic Club, to conduct national championships. Beginning in 1879, the NAAA meets, all in New York City, continued for ten years. As a result of accusations of laxity in enforcing amateur rules, the Amateur Athletic Union (AAU) took over as the national governing body and conducted its first championships, in Detroit, in 1888. The AAU has continued its outdoor meets annually, adding the yearly indoor championships in 1906.

Meanwhile, intercollegiate competition was thriving in the United States. College championships began in 1876 under the auspices of the Intercollegiate Association of Amateur Athletes of America (IC4A). Ten colleges and universities from the northeastern U.S. made up the charter membership. Collegiate track and field reached national stature in 1921 with the staging of the first National Collegiate Athletic Association (NCAA) championships.

Development of international sport. The first international meeting of consequence came a year before the revival of the Olympic Games when, in 1895, the NYAC faced the London AC. But not until the Olympic Games in Athens, Greece, in 1896 did track-and-field athletics have the focal point necessary to become an international sport. Although the Olympic rebirth was rather insignificant by today's standards, it provided the inspiration and standardizing influence that were to make track and field the most international of sports. The Games grew steadily and by the 1908 Olympics in London had a representative field of 22 nations.

Rebirth of Olympics and formation of IAAF

In 1913 athletic spokesmen from 16 countries met in Berlin to draw up the charter for the International Amateur Athletic Federation (IAAF). The main outcome of this meeting was the adoption of a set of standard rules for amateurism and conduct of competition and to approve the first set of world records. Membership in the international governing body now has grown to over 130 countries.

Women's track and field. The emphasis in track and field's early days was almost exclusively on men's athletics. Women have a considerably shorter modern athletic history, stretching back just over a half century. The first women's national governing body came into existence in 1917 with the formation of the French Women's Sports Federation. Two years later, organized women's competition began in England.

An international women's governing body called the Fédération Sportive Féminine Internationale (FSFI) got its start in 1921 with Britain, Czechoslovakia, France, Italy, Spain, and the U.S. as cofounders. The FSFI sponsored women's world championships at Paris in 1922; Göteborg, Sweden, in 1926; Prague, Czechoslovakia, in 1930; and London in 1934, following the inter-Olympic plan of the women's Games in ancient Greece. Meanwhile, the International Olympic Committee refused to consider adding women's events for the 1924 Olympic Games, but under an agreement providing for dual control by the FSFI and the IAAF five events for women were included in the Games in 1928. In 1936 the IAAF became the governing body of women's track and field and the FSFI was dissolved.

Growing interest and participation. International games other than the Olympics came into being before World War II, notably the British Empire Games (started in 1930 at Hamilton, Ontario), and the European Championships (first held at Turin, Italy, in 1934). Not until after the war, though, did track and field enjoy its greatest period of growth. Easier international travel and communications, increased emphasis on the sport, and improved equipment, facilities, and techniques have coupled with other factors to push both the scope and quality of the sport to unprecedented levels.

Performances have improved radically, with no modern world record surviving from before 1959. The 110-metre high hurdle time (13.2 seconds) set by Martin Lauer of West Germany that year (a mark that has since been tied several times) is the oldest one on the books.

Participation has increased on all levels. This is particularly evident among the newly emerging nations of the world. Whereas Europe, the United States, Australia, and New Zealand formerly monopolized world track-and-field power, Asians, Africans, and Latin Americans began producing world class athletes after World War II. African runners from newly independent nations, for instance, won five races in the 1968 Olympic Games. No black athlete representing an African nation ever had won an Olympic title before 1960.

In an age of jet travel and instant communications, interest in track-and-field competition has spread around the world. The effects on the sport have been profound.

ORGANIZATION AND ADMINISTRATION

The international governing body for track-and-field sports is the International Amateur Athletic Federation (IAAF). The IAAF defines an amateur athlete as "one who competes for the love of the sport and as a means of recreation, without any motive of securing any material gain from such competition." This definition is subject to various interpretations among member nations, and it has been the source of many controversies and conflicts. But in its broadest sense it means that athletes are to receive no direct monetary payment for their athletic efforts. Most of the individuals involved in the administration of the sport also are not paid for their work. The organization comprises "duly elected national governing associations or federations of countries, in control of amateur track and field athletics, cross-country running and walking, which agree to abide by the rules and regulations of the IAAF. Only one member from each country can be affiliated."

Amateur defined

National track-and-field groups such as the United States' Amateur Athletic Union (AAU) and the British Amateur Athletic Association (AAA), along with the governing bodies of about 130 other countries, are represented in the IAAF.

The primary functions of the international body are to adopt and enforce a set of rules that are uniform throughout the world, to promote international competition, and to maintain world records in the various events.

The IAAF has established regulations for the conduct of the Olympic Games, continental and group championships such as the Pan-American Games, British Commonwealth Games, and European Championships and matches involving two or more member nations. Other competitions are conducted under the auspices of the ruling body of the nation where the meet is held. The rules governing these competitions are in substance nearly identical to those set up by the IAAF. In other words, the international group sets the policies that its members (each being the sole ruler of the sport in its country) follow.

Each IAAF member nation has its own national set of rules and maintains its own set of records in line with international guidelines. The amateur athletic federations of individual countries conduct their own national championships—usually annually—in men's and women's track and field, cross-country, race walking, and events such as the marathon run. These national ruling bodies also have the obligation of selecting representatives for international meets.

The national groups delegate the power to conduct individual meets within their boundaries, assuring, however, that these competitions meet their rules and regulations.

In the United States, for example, the AAU alone has the power to select international teams (except for the Olympic team, which is under the jurisdiction of the United States Olympic Committee), to establish rules, and to accept or reject records. It also conducts the national championships and other competitions. The nonchampionship meets generally involve either nonschool athletes or a mixture of students and nonstudents.

Meets in which participation is restricted to college or university athletes usually are governed by the rules of the National Collegiate Athletic Association (NCAA), National Association of Intercollegiate Athletics (NAIA), or one of two junior (two-year) college groups. Most secondary or high schools of the United States come under the aegis of the National Federation of State High School Athletic Associations and its subordinate units in each state.

Unlike most other countries, where competition among athletic clubs predominates, the bulk of U.S. track-and-field meets involve high school, college, and university individuals and teams. The schools typically are the spawning ground of the vast majority of athletes. It is normally only after they leave school that they join club and military teams or participate in AAU competition as "unattached" individuals.

Questions of payments to amateurs

Under IAAF rules, athletes can receive no direct payment for competing. Most member nations, however, do provide considerable support to amateur athletes who are potential international competitors. This support may consist of special training facilities for top-flight athletes, expense-paid travel and lodging, military duty with special privileges and duty exemptions, favourable occupational arrangements in eastern European countries, and, in the United States, the so-called athletic scholarships for athletes attending colleges and universities.

As amateur athletes, all that winners may accept as material rewards are prizes that are "of lasting value, are intended for the athlete himself and shall not exceed the value of U.S. $100 (or its equivalent in other currencies)." Usually these awards consist of trophies, medallions, jewelry, or merchandise.

Truly professional track-and-field athletes, who were prominent when match footraces for stakes were popular, have become rare in the 20th century. A relatively few exist in Australia, where handicap running events involving wagering are held and runners are paid for their efforts. England also supports a few such races. In the late 1960s, several American and European businessmen attempted to form professional track-and-field leagues, or circuits, featuring high-level performers. But their efforts were not successful.

The best of the world's track-and-field athletes remain in the amateur ranks, as evidenced by the fact that only one professional record exceeds that of amateurs. That is the relatively unnoticed and rarely held 100-mile track run, in which the professional athlete George Perdon of Australia set the record of 12 hours 25 minutes and 9 seconds in 1970.

Conduct of competition

The details of conducting track-and-field competitions vary, depending on location and the level and type of meet. But the basic format of the sport has been standardized to a great degree by the rules of the IAAF and subordinate bodies, and by tradition. The purpose of this section is to discuss the general organization and conduct of track and field meets.

Facilities. Outdoor track-and-field meets take place on or around oval-shaped running tracks that to meet official specifications must be either 440 yards (one-quarter of a mile) or 400 metres in circumference. With the exceptions of marathon runs and road walks held in conjunction with track meets, all running and walking events occur on the track.

Track compositions vary greatly. Whereas they were formerly almost exclusively made up of natural materials dirt, clay, cinders, and crushed brick being the most common) many new surfaces have been developed since 1960. Many tracks now feature toppings of asphalt-rubber mixtures and of synthetic compounds. These new track materials provide a consistent, resilient surface that stays "fast" in all weather conditions and needs little maintenance.

All-weather tracks and runways

These tracks, generally with "all-weather" toppings, have helped athletes on all levels achieve faster times. One of these surfaces, having a plastic-resin base, got its first international test in the 1967 Pan-American Games at Winnipeg, Manitoba, and was later used at the Olympic Games in Mexico City. That was the first Olympics to be conducted on an artificial surface. Nearly a dozen world records fell during the men's and women's competition there.

Field event athletes also are getting the benefit of improved footing. In an earlier era, jumpers and throwers launched themselves and their implements from dirt, cinders, or similar soft surfaces. Now the jumpers and javelin throwers generally use all-weather surfaced runways for their approaches. Shot-putters and hammer and discus throwers lob their implements from a circle of concrete or similar solid, smooth materials. With the improvement in takeoff areas there has been a corresponding improvement in putting and throwing records.

The field events normally are held on the area inside or adjacent to the track. With jumping, throwing, and running events all taking place at the same time, the stadium often takes on the appearance of a multiring circus with all rings operating at once.

Indoor track-and-field meets adapt themselves to meet the specifications of the arena where the meet is held. Because of the space limitations, several events must be dropped, including the javelin, discus, and hammer throws. Indoor tracks have a wide variety of sizes, shapes, and surfaces. But generally none is as big as the outdoor 400-metre/440-yard type. For the big meets in the United States and Europe—where the indoor sport centres and flourishes—tracks are usually wooden, with raised (banked) turns that facilitate running the cramped curves. Track sizes generally range from 140 to 220 yards in circumference, or eight to 12 laps to the mile. The straightaway for the short races usually is in the middle of the arena, inside the boundaries of the track, and the jumping and throwing also is done inside this perimeter.

Cross-country running utilizes any terrain that is available in the area where it is being run. This ranges from parklands, to golf courses, to forests, to farming country. Runners follow a course laid out for them—generally covering from 2 to 10 miles—and take natural obstacles as they come to them.

Running across country and on roads

Road running, such as the marathon race, road races, and the long-distance walking events occur on city streets and country roads that have been measured and marked according to official specifications. Often these races start and finish on the track. This is particularly true when they accompany track-and-field meets; *e.g.*, in the Olympic Games.

Equipment. Every event has items of equipment that are essential to the conduct of the event. All athletes, for example, require shoes that give traction, protection, and minimum weight. The quality of shoes has improved steadily, becoming at the same time lighter, more colourful, and more specialized in purpose. Both the spiked shoes worn by runners and jumpers and the flat-soled shoes of throwers have contributed to record breaking.

Other items of equipment—which have been modified and improved as well—include the starting blocks used by sprinters and hurdlers, hurdles, vaulting poles, and the implements employed in the various throwing events.

Timing and measurements. Exacting timing and measurement of performances are a vital part of track and field, not only to determine winners at the meet in question but also to provide marks that can be compared for record purposes. Official timekeepers record the times in the running and walking races, using either hand-held stopwatches or more precise electrical timing devices. In races of one mile and less times are taken in tenth-second increments. Distances above one mile are recorded in

fifth-seconds (although they are published as .2, .4, etc., rather than ⅕, ⅖).

For a time to be accepted as a record, it must be clocked by three officials, or by an automatic timer, and must meet other specifications in regard to wind assistance, competitive conditions, and proper certification. In running events through 200 metres, as well as the long and triple jumps, the assisting wind may not exceed two metres per second (about 4.473 miles per hour) in the direction of the runners.

Accepted measurement standards

Metric measurements are the official standard in international competition. Field event performances are recorded to the centimetre in all events except the discus, javelin, and hammer throws; these are measured in even-numbered centimetres.

The United States is one of the last remaining countries to retain the "English" system of measurement, as Great Britain and most of the rest of the British Commonwealth nations in the early 1970s joined the world's majority on the metric system. But while the U.S. clings to the traditional feet, inches, yards, and miles for domestic track and field, it shifts to metres in the international arena. In the running and walking events, this means switching from events such as 100 yards to 100 metres, from three miles to its equivalent 5,000 metres, and so on. In the field events, the performer sees his marks measured in metres and centimetres rather than feet and inches.

The IAAF recognizes world records in the "English" running and walking events, but all field event records must be measured in metric terms.

Official world records are maintained only in men's and women's outdoor track-and-field events. Because competitive areas vary so much, there are no recognized marks for cross-country and road races or for indoor events. In the United States, however, the AAU keeps official American indoor records.

Basic rules. Track-and-field meets generally occur during one- or two-day periods, although major championships such as the Olympic Games may stretch out over a week or more.

In running events up to and often including 5,000 metres, preliminary competitions, called heats, often are necessary to eliminate all but the best individuals. Key championship meets, for instance, may include as many as three qualifying rounds to advance runners to the final race. Athletes are placed in these qualifying heats according to their best performances, and only the heat leaders advance to the next race. The number reaching the final race varies according to the size of the track and the distance of the race, but generally it ranges from 8 runners in the 100-metre sprint to 12 or 15 in the 5,000-metre run. Races above 5,000 metres seldom if ever require preliminaries.

Qualifying heats and trials

An official fires a gun to start all races. In those runs of up to one lap of the track athletes are required to stay within marked lanes throughout the race. In multilap races, after leaving the starting line, the runners and walkers string out in single file or run along side by side on the inside edge of the track. The runner or walker whose torso reaches the finish line first is the winner. Two or more athletes may have identical times and still be separated in the placings.

Field event participants have two types of qualifying competitions. In most meets, all but the high jumpers and pole-vaulters (who are eliminated as they progress from one height to the next) are allowed three preliminary jumps or throws if there are more than eight competitors. Then the leaders at that point are allowed three more attempts to improve themselves. High jumpers and pole-vaulters are eliminated after three successive failures at a given height.

In major championship meets, however, the number of entrants is often so large that qualifying throws and jumps are required to cut the field to a manageable size. These usually consist of each man or woman trying to meet a minimum requirement. The leaders advance to the finals, where they follow normal field event procedures just as if there hadn't been an earlier round.

All field events have rules for breaking ties. In the high jump and pole vault, the jumper requiring the fewest attempts wins. In all other field events, the victory goes to the athlete with the superior second effort.

The men's decathlon consisting of a combination of ten running, hurdling, jumping, vaulting, and throwing events and the women's pentathlon consisting of a combination of five running, hurdling, jumping, and throwing events are spread over two days each. Athletics in these events get only three attempts in each of the throws and in the long jump and are arbitrarily divided into heats for the running portions. They receive points for each performance—the better the mark, the higher the point total—and the winners are those scoring the highest total. The IAAF has charge of establishing standard scoring tables.

Team scoring. Although track and field is basically an individual sport, with each event being something of a separate entity, an offshoot of this is the team scoring aspect.

Much public attention is given to the national scores in the Olympic Games, but these totals are strictly unofficial. Team scoring comes into play primarily in matches between nations, clubs, and school teams. U.S. universities, colleges, and high schools give particular emphasis to these combined scores.

Point scoring

The points allotted to individual events and places vary from meet to meet. A national competition may give ten points for a first-place finish, eight for second, six for third, and so on down to one for sixth. Scoring in an international dual match is five points for first, three for second, two for third, and one for fourth. The points scored in all events are totalled, and the team with the highest total wins.

Cross-country, road running, and walking meets utilize an entirely different scoring method. In these races, the first-place finisher receives one point, second place gets two, etc. The team's leaders, three to five athletes depending on the meet, have their finish positions totalled, and the team with the lowest score wins.

Seasons. The outdoor track season in the Northern Hemisphere normally begins on a major scale in March and continues through September, making it a spring and summer sport. The bulk of activity in the United States concludes with the closing of high schools and colleges in June, while the European season starts and finishes later. In the Southern Hemisphere—notably Australia, New Zealand, and South Africa—the track-and-field season falls in the November to April period because of the reversal of seasons.

Indoor track and field is concentrated in the winter months, mainly January through March. This phase of the sport developed as a cold-weather alternative to outdoor track and field. As it has gained in popularity, however, it has spread to areas that could conduct outdoor meets at this time of year. California, scene of several of the world's major indoor meets, is a prime example of a warm climate with indoor meets.

Cross-country running occupies the fall and winter months. In the United States, the sport centres on the September to November period. European runners carry on their activity almost from the end of one track season, October or November, to the start of the next, in March or April of the following year. Southern Hemisphere athletes run cross-country during their fall and winter. Road runs and walks are year-round sports. Events are held in every month of the year, from the heat of summer to the cold and snow of winter.

CONFLICTS AND CONTROVERSIES

Track and field, a sport that occupies centre stage at all international games, generates its share of conflicts, some of which revolve around the struggle for national prestige among the countries involved. Some nations as well as individuals stake much on the outcome of these events, and emotions run high on such occasions. The temptation to break, or at least bend, rules exists.

Conflicts often centre on definitions of amateurism. Ostensibly, all track-and-field athletes are amateurs. They compete "for enjoyment" and are not allowed to profit

financially from the sport, according to the IAAF definition of an amateur.

Although athletes are not openly paid for their participation, many top-quality performers are supported in a variety of ways, some legal and some questionable. Eastern European nations have given rise since World War II to a class of competitor often referred to as the state amateur. World class athletes receive preferential treatment from their respective governments in return for their athletic performances. Such direct government subsidies are not given in other nations of the world, but nearly every country hoping to field Olympic contenders has a system that supports athletes. In the United States, the colleges and universities assume this role by granting so-called athletic scholarships to relieve the athlete of the financial burden of going to school, thereby allowing the track-and-field performer ample time for training and competing. To some extent, the branches of the military service also provide this support by providing athletes with choice duty assignments. In Japan, industries see to the needs of outstanding athletes. In Scandinavian countries, special training camps are offered.

Complaints about payment of athletes

The IAAF has placed limits on the amount of expense money an athlete may receive while competing in meets around the world, as well as defining the type and value of awards allowed. Several athletes have been penalized for overextending these limits. Celebrated cases have involved famed distance runners. The world record holders Paavo Nurmi (Finland) and Gunder Hägg (Sweden) were forced into early retirement for allegedly violating amateur rules, as was the miler Wes Santee (U.S.).

Rumours of others accepting "under-the-table" payments are heard regularly in track circles. One well-publicized case involved shoe companies offering large sums of money to Olympic athletes at the 1968 Games. In return, the athletes were expected to display conspicuously the company's products during competition.

Political bickering among nations also is part of international sport; so much so that an early four-minute miler and Olympian, Chris Chataway of Great Britain, wrote a book about it entitled *War Without Weapons*. That title aptly describes the situation that sometimes seems to exist on the worldwide track-and-field scene.

At its first Olympics in 1952, the Soviet Union insisted that its athletes be housed apart from other athletes and threatened to pull out of the Games if its demands were not met. In an extension of "Cold War" politics, the Soviets also cancelled a meet with the United States in 1966, blaming U.S. involvement in the Vietnamese war.

Arguments extend as well to which nations should be allowed to enter international competition and which should not. This has been a particular problem among countries split apart by wars and revolutions. Following World War II, East and West Germany competed as one combined unit until 1964, then each fielded a separate team in 1968, but only after an agreement that neither's national anthem would be played nor flag flown. South Korea competed in the Olympics, but not North Korea; South Vietnam, but not the North; Nationalist China (Taiwan), but not mainland China.

An explosive issue during the 1960s was the status of the Republic of South Africa. The nation was excluded from the 1964 Olympics because of apartheid racial practices existing in that country. The International Olympic Committee tentatively agreed to readmit the South Africans to the 1968 Olympics. But when a majority of black African nations threatened to boycott en masse, South Africa again was barred from competing.

Individual athletes also have participated in boycott activities. Many American Negroes claimed before the 1968 Games that they would refuse to compete in protest over racial discrimination they said existed in their home country. The boycott, however, failed to materialize. A boycott by the West Germans the next year went ahead. When a countryman was barred from competing in the 1969 European Championships, the West German contingent voted not to compete.

Several countries, particularly the U.S., have had lasting disputes over control of the sport by various governing bodies. In the United States, the conflict between the AAU and NCAA has attracted the attention of the federal government.

Drug use

Another area of considerable controversy has been the use of drugs. IAAF rules prohibit the use of any chemical substance that might aid an athlete in the performance of his event—be it a strength-building, relaxing, or "pep" drug. But despite the rules, and despite tests developed to detect certain types of drug use, all available evidence indicates that intake of such substances is increasing.

One of the most popular drugs is the anabolic steroid variety. "Steroids" reportedly materially increase an athlete's strength and weight within a rather short period of time, when combined with a wholesome diet and heavy training. This makes this type of drug, taken in pill or injection form, particularly in demand among athletes in the throwing events, where size and power are prime requisites. Use of the drug is almost impossible to detect through standard tests. Other types of drugs, however, leave obvious traces, and at the Olympics and other major meets athletes are tested for drug usage.

Another type of athletic testing has caused considerable comment among athletes and the sports public alike. This is the testing of women to determine if they indeed meet the requirements of their sex. Several cases of men posing as women have been uncovered, one involving a German high jump champion during the 1930s.

Determination of sex even on the basis of the highly sensitive and accurate chromosome test is not as clearcut as it might appear, and disputes have arisen over the verdicts of doctors assigned to the testing at international events. One side effect of the tests has been the ruination of the careers and reputations of several athletes involved in the testing. After failing a chromosome test, a Polish sprinter of the 1960s retired. Many other athletes who for one reason or another avoided taking the tests have become the subject of normally unfounded rumours and insinuations.

RECREATION AND FITNESS

Since the actions involved in track-and-field athletics are the basic ingredients in nearly all sports, it is to be expected that a number of related recreational and physical fitness activities should grow up around the sport. In themselves, running, walking, jumping, and throwing lead to excellent physical conditioning as well as providing enjoyable recreation.

Running—or jogging as slow running often is called—and walking enjoyed a considerable return to popularity during the 1960s both for their recreational and their fitness aspects. Numerous experts in the fields of exercise physiology and preventive and rehabilitative medicine proved there is a distinct correlation between the lack of endurance exercise (such as running, walking, and other continuous activities) and disease, particularly heart disease. They recommended jogging, walking, bicycling, and the like, both to prevent disabling illnesses and attacks and to recover from them.

The jogger

Perhaps the best known exponent of this type of exercise is Kenneth Cooper, a United States Air Force medical officer who tested his theories on nearly 1,000,000 airmen and other volunteers. In his best-selling book, *Aerobics*, he heartily endorsed moderate forms of distance running and walking for persons of all ages and both sexes.

One result of jogging's popularity has been a tremendous growth in low-level distance running competition. Evidence of this can be seen in the Boston Marathon race, which in the early 1960s had fields in the range of 200 runners and by the end of the decade was drawing nearly 1,200 persons.

Many of the runners at Boston and elsewhere are runners who started in the sport rather late in life, or persons who have remained active over a long period of time. In both the United States and Europe, competitions began to accommodate men beyond the age of 40. Plans were underway to organize an unofficial "Veterans' Olympics" for these athletes.

Accompanying the growth of running in the older age

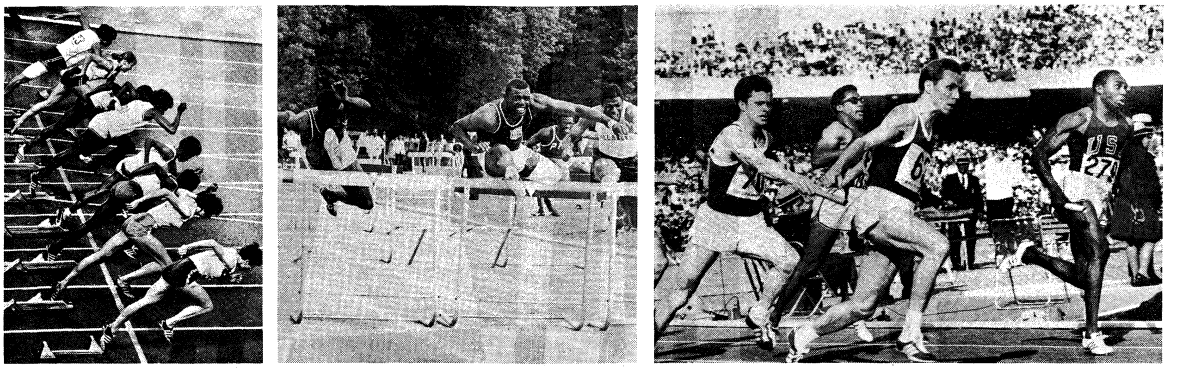

Figure 1: (Left) Start of the women's 100-m. final, 1968 Olympics, Mexico City. (Top to bottom) Chi Cheng (Taiwan), Raelene Boyle (Australia), Wyomia Tyus (U.S.), winner, Margaret Bailes (U.S.), Barbara Ferrell (U.S.), Miguelina Cobian (Cuba), Irene Kirszenstein Szewinska (Poland), Dianne Burge (Australia). (Centre) Willie Davenport (U.S.), first over the hurdle on his way to win the 110-m. race of the Dr. Martin Luther King Jr. International Freedom Games, 1969. (Right) Jim Hines (279), anchor man on U.S. 400-m. relay team, runs for a new world record of 38.2. East German anchor man Harold Eggers takes baton while speeding toward the finish during the 1968 Olympics.

groups is competition for the young athletes. This is particularly evident in the United States, where boys and girls as young as five years old compete regularly against athletes in their own age groups.

Another offshoot of competitive track is competition in extralong endurance runs. Athletic history is rich with reports of such feats of endurance. During the 1920s, a number of athletes twice attempted trans-United States runs known as Bunion Derbies. Interest in this sort of running revived in 1964 when the South African Don Shepherd ran unaccompanied across the U.S. in 173 days. Bruce Tulloh (Great Britain) broke that "record" in 1969 when he made the almost 3,000 miles in less than 65 days, accompanied by a small caravan of aides.

The Scandinavians devised a sport that employs elements of cross-country running, hiking, and land navigation. This increasingly popular sport called orienteering involves travelling an unmarked course through natural terrain. The runner–hiker checks in at various control points along the route, which he finds by using a map and compass. Thus, navigational skill takes on equal importance with running ability.

Track-and-field events

As many as 25 events may make up a men's track and field meet, and a women's competition may contain as many as 15 separate contests. A men's meet may include any of the following recognized events, with championship meets including most of them: 100-, 200-, 400-, 800-, 1,500-, 5,000-, and 10,000-metre runs (in the United States, 100-, 220-, 440-, 880-yard, and one-, three-, and six-mile runs); 110- and 400-metre (120- and 440-yard) hurdles; the 3,000-metre steeplechase; the 400- and 1,600-metre (440-yard and one-mile) relays with four members per team; the high jump, long jump (or broad jump), triple jump, and pole vault; the shot put, discus, hammer, and javelin throws; a race walk of from one mile to 50 kilometres; and a decathlon in which an individual competes in ten events. Women's competition may include the 60-metre (60-yard) run and 100- through 1,500-metre (100-yard through one-mile) runs; 80-, 100-, and 200-metre hurdles; 400- and 800-metre (400- and 880-yard) four-member team relays, and 2,400-metre three-member team relays; high jump and long jump; shot put, discus, and javelin throws; and the five-event pentathlon.

Recognized track-and-field events

This section will examine the basic technical facets and historical highlights of these running, race walking, jumping, and throwing events.

RUNNING

Running events range in distance from the 50-yard dash to continuous superendurance runs as long as 24 hours in duration. Some are on the track, others on roads and over the open countryside, and some require hurdling barriers.

Sprinting. The sprint, or dash, distances are those involving an all-out or nearly all-out burst of speed that is sustained throughout the event. Sprinting generally encompasses events from 50 to 440 yards and their metric equivalents. Races below 100 yards are limited mainly to indoor meets, and often to competitions involving younger athletes. Outdoors, both men and women sprint 100 yards or 100 metres, 220 yards or 200 metres, and 440 yards or 400 metres as their most common events. These distances are run in championship meets.

Until 1884, all sprinters started from a standing or leaning position. That year Bobby Macdonald, a Maori residing in Scotland, began a trend that was to become universal in sprinting by starting from a crouched position. This method, now used by nearly all sprinters, involves taking a preliminary position (on the starter's command, "On your marks") with one knee on the ground, one foot several inches in front of the other and both hands resting behind the starting line. On the command "Set," the runner raises his knee from the ground and leans forward. As the gun sounds, he drives powerfully from his mark and accelerates to full speed.

An athlete's start, and the quickness of his reaction time, can very well determine his result in races as short and exacting as these. The German sprinter Armin Hary, the 1960 Olympic 100-metre champion and first man to run 10.0 seconds for that distance, reputedly was one of the all-time best starters. He got off the line so quickly that he was widely accused of "beating the gun." Sprinters, all runners in fact, are allowed one false start. When one runner jumps the gun, a second shot sounds and all of the runners return to the starting line. Once an athlete is charged with his second false start, he is disqualified.

Another significant development in sprinting was the invention of starting blocks in 1927. The U.S. track coach George Bresnahan patented the blocks (adjustable metal or wood devices to support the feet at the starting line) that year and, using them, George Simpson ran the 100 yards in a world record time of 9.4 seconds in 1929. The record wasn't accepted, however, because the implement was not legal at that time. Most sprinters continued to start from holes dug in the track until starting blocks were legalized in the 1930s. Jesse Owens, the great sprinter and hurdler from the United States, set his many world records in that decade starting out of holes.

Use of starting blocks

Little distance separates sprinters at the end of high-quality races. To obtain the advantage at this crucial point they develop special techniques of finishing. In the 1920s, American world record-holding sprinter Charles Paddock was known to fling his arms wide and leave the ground in a flying leap at the end of races. Present-day sprinters rely on well-timed leaning finishes—which often leave them sprawled face down on the track later—to get their torsos to the line first.

Because of the shortness of these races in terms of time,

improvement is difficult to see and to measure. But improvement does come. For example, John Owen (U.S.) sprinted the first less than 10-second time for 100 yards in 1890, doing 9⅘ seconds (at that time, records were kept in fifth-seconds instead of current tenths). Not until 1929 did Simpson break through the 9½-second barrier with his unrecognized 9.4, which Frank Wykoff (U.S.) matched in 1930. It was another 33 years until Robert Hayes (U.S.) moved the record down another three-tenths-second to 9.1. At 100 metres, the case is similar. Luther Cary (U.S.) first broke 11 seconds in 1891, and the record didn't go below 10-flat until James Hines (U.S.) ran 9.9 in 1968. The slow, yet regular, improvement is more obvious as the distance increases.

Success at 100 and 200 metres (or 100 and 220 yards) often goes hand in hand, while 400-metre men and women are usually specialists at that distance.

Top short sprint men include Percy Williams (Canada), Eddie Tolan (U.S.), Jesse Owens (U.S.), and Bobby Morrow (U.S.): all won Olympic championships at both 100 and 200 metres. In the women's realm, Marjorie Jackson (Australia), Fanny Blankers-Koen (The Netherlands), Betty Cuthbert (Australia), Wilma Rudolph (U.S.), and Renate Stecher (East Germany) have accomplished a similar feat. Cuthbert also won at 400 metres in a later Olympiad.

The 400-metre dash, like the 200, is run around the track's turn(s) and in lanes all the way. This requires a start that is "staggered," all athletes starting progressively farther up the track with each line away from the inside, to equalize the total distances covered.

Staggered starts

All-time standouts in the one-lap (400-metre or 440-yard) sprint have been Ben Eastman (U.S.), who in 1932 improved the world record by a full second to 46.4; Otis Davis (U.S.) and Carl Kaufmann (Germany), the first men to break 45 seconds for 400 metres when they did 44.9 simultaneously at the 1960 Olympics; and Lee Evans (U.S.), 1968 Olympic champion who in Mexico City with 43.8 first broke 44-flat in the 400-metre run.

The women first ran 400 metres at the Olympics in 1964. Perhaps the greatest woman 400 runner ever, however, never ran in the Games. Sin Kim Dan (North Korea) tied or improved the world record five times during her career, to a low of 51.2 seconds in 1964, but her country was ineligible for the Olympics.

Middle-distance running. As distances exceed 400 metres, fatigue becomes an increasingly greater factor, and it becomes essential for the runner to regulate his pace. The aim is to take maximum advantage of his speed while harbouring strength for the final burst.

The middle-distance races—those in the range of 800 to 2,000 metres—are still run quite rapidly, but the factor that distinguishes them from the sprints is the controlled pace. The most common middle distances are 800 metres or 880 yards, and 1,500 metres or one mile, for both men and women. Olympic events are conducted at 800 and 1,500 metres for both men and women—women running the longer distance for the first time in 1972.

Undisputed focal point of middle-distance running has been the mile. Although this has long been the classic American and British Commonwealth distance, interest in the event has spread to countries that normally use only metric distances. The quest for the magic four-minute mile involved not only Americans, Englishmen, and Australians but also Swedes, Frenchmen, and others.

Even before World War II, speculation was beginning to grow about the possibilities of a runner breaking through the four-minute barrier. Glenn Cunningham (U.S.), who played a big role in the prewar flurry of interest, raced to a 4:04.4 effort indoors in 1938. Then came a series of war-years matches between the Swedes Gunder Hägg and Arne Andersson. They traded records several times, with Hägg finally bringing it down to 4:01.4 in 1945. The mark remained there for nine years.

The four-minute mile

May 6, 1954, was one of track-and-field's historic days. On a cool and blustery day at Oxford, England, medical student Roger Bannister (Great Britain) cracked the four-minute mark for the first time with 3:59.4. About six weeks later, Australia's John Landy knocked the record down further to 3:58.0, then lost to Bannister in a monumental match between the two at the British Empire Games later that summer.

Bannister and Landy opened the gates for a flood of sub-four-minute clockings. By the end of the 1960s, such runners as Derek Ibbotson (Great Britain), Herb Elliott (Australia), Michel Jazy (France), Peter Snell (New Zealand), and Jim Ryun (U.S.) had led a parade of almost 200 men who had broken the once seemingly impregnable barrier. The record has come down to Ryun's 3:51.1, yet four minutes remains an important landmark for all milers, and one indicating world class potential.

Perhaps because of this interest in the mile race, the equivalent 1,500 metres (or metric "mile") normally claims top billing in any Olympics or other international meet. Olympic 1,500-metre champions are numbered among the all-time greats of track and field; they include Paavo Nurmi (Finland), Jack Lovelock (New Zealand), Herb Elliott (Australia), Peter Snell (New Zealand), and Kipchoge Keino (Kenya).

Milers/1,500-metre runners show a tendency either to be fast in the shorter distances or to be strong in the longer ones. Among the first group are several athletes who have won Olympic titles at both 800 and 1,500 metres. They include Edwin Flack (Australia), James Lightbody (U.S.), Mel Sheppard (U.S.), and Albert Hill (Great Britain), all of whom accomplished it in 1920 or earlier, and Snell in the 1964 Games. Ryun also falls into the sprinter category, having held world records at 880 yards as well as 1,500 metres and the mile. Paavo Nurmi is the only athlete to have won the Olympic 1,500 and a longer distance. Other prominent examples of the endurance-type miler are Jazy and Keino, both of whom have held world records at distances up to 5,000 metres.

As indicated, some 800-metre men double in the 1,500 or mile. Others fall into the sprinter category, being quite proficient in the one-lap event as well as the two-lap. No athlete ever has won both the Olympic 400- and 800-metre titles, but 800 champions James Meredith, Mel Sheppard, Mal Whitfield, and Tom Courtney (all U.S.) have contributed to winning 4 × 400-metre relay teams.

World records in all middle-distance events have improved drastically in the 20th century, and particularly since World War II. The higher level of competition, better pacing, and improved tracks and running shoes can share in the credit for this. But the key reason is training techniques, which are of higher quality and quantity than ever before. In the 1930s and earlier, middle-distance runners seldom totalled more than 10 or 20 miles of training per week. Today's runners seldom do less than 50, and many go well beyond 100 miles a week.

Training techniques and improved records

Several athletes and coaches have made their unique contributions to training techniques. The Swedes Hägg and Andersson popularized the *fartlek* (or "speed play") method involving a mixture of slow and fast cross-country running. The Germans and eastern Europeans brought "interval" training into vogue during the late 1940s and 1950s. This method consists of a series of short (200- to 800-metre), timed runs on the track, broken up by periods of jogging or slow running and walking. Elliott brought "resistance" training, with running in soft sand and heavy weight lifting, into prominence. Finally, Snell used long and rather slow road running—100 miles a week—to get the basis for his record breaking. Athletes now use one or the other of these various methods, or a combination of them.

Pacing, as mentioned earlier, is crucial in middle-distance racing. An athlete must keep himself in a position where he can win, yet he must not squander his limited resources too soon. He also must avoid becoming trapped by other runners, since they all run as closely as possible to the inside lane and often in tight bunches.

Many runners prefer to get out in front at the start and dictate a pace. The majority, however, seem to prefer following the leader, conserving their strength, and relying on a fast finishing burst to win. Pacing styles have changed over the years, and this is particularly evident in mile running. The early style was to start fast, relax somewhat during the middle two laps, then finish as rap-

Pace and strategy

idly as possible. Walter George (Great Britain) ran this way during his record mile in 1886. Nurmi believed in evenly paced laps and ran this way during his 1923 record race of 4:10.4. Hägg, Bannister, and Landy all ran fastest on their first laps. But by the time Ryun got his record, the style had become even, conservative pacing over the first three-quarters, then a powerful finishing sprint. Ryun ran his last 440 yards in 53.5 seconds.

Comparative Records of Great Mile Runners

quarter	George (U.K.) 1886	Hägg (Sweden) 1945	Bannister (U.K.) May 1954	Landy (Australia) June 1954	Ryun (U.S.) 1967
1st 440	58.5	56.6	57.5	58.5	59.2
2nd 440	63.25	61.9	60.7	60.2	59.8
3rd 440	66.0	61.2	62.3	58.5	58.6
4th 440	65.0	61.7	58.9	60.7	53.5
Mile	4:12.75	4:01.4	3:59.4	3:58.0	3:51.1

The entry of women into international middle-distance running has come only recently on any kind of major scale. Women ran 800 metres at the 1928 Olympics, but the event wasn't revived until 1960. The 1,500-metre event for women was included for the first time at the 1972 Games. With the record for 800 metres standing at just under 2:00 (1:58.3, set in 1971; although Sin Kim Dan had run 1:58.0 in 1964, her marks were never accepted as records) and the 1,500 at about 4:05, two minutes and four minutes became significant barriers for women.

Long-distance running. The long distances are those from 3,000 metres to 30,000 metres (the longest event in which records are recognized by the IAAF) and the marathon. Runs at longer distances have been held and sometimes runs are held for distance covered in a specified time interval, ranging from 1 to 24 hours, but this discussion is concerned with the standard competitive events. Included here are flat-track races, the steeplechase, cross-country, and road runs. The most common of these events—which are almost exclusively the province of male athletes—are the 3,000-metre (or two-mile), 5,000-metre (or three-mile), 10,000-metre (or six-mile) runs, the 3,000-metre steeplechase, and the marathon road run of more than 26 miles. Olympic distances are the 5,000- and 10,000-metre runs, the steeplechase event, and the 26-mile 385-yard marathon.

Endurance and tactics

Pure, basic speed, although important to all running events, becomes progressively less a dominant factor as distance increases, while endurance training and tactics take on greater importance. The training techniques mentioned in the middle-distance section become all the more vital for athletes who run long distances. Training quantities increase accordingly; for instance, long-distance runners rarely average less than 100 training miles a week, and many go 200 or higher. Before the 1968 Olympic Games, Australian marathoner Derek Clayton reportedly averaged 210 miles a week. American Ted Corbitt indicated he was regularly logging 300 per week in preparation for a 100-mile race in 1969.

Pacing tends to level out in long distance races, with each mile or kilometre being covered in about the same time as all others. Track races of 3,000 to 10,000 metres still feature a fast burst on the later laps, but this begins to disappear with more distance until it becomes all but nonexistent in the marathon.

Accordingly, with improved training and techniques, times have improved startlingly. Using the 50 years from 1920 to 1970 as end points, the two-mile world record had dropped from above nine minutes to below 8:20; records at 5,000 metres and three miles were each more than a minute faster than they were in 1920, and the 10,000-metre and six-mile marks had come down more than three minutes.

The history of long-distance running is rich with stories of athletes who have held multiple world records. This is understandable for two reasons: (1) all track distance runs are closely related in terms of the abilities, techniques, and training required, and (2) long distance runners normally have careers of ten or more years, offering them many opportunities for fast times. Track runners who stand out most prominently in this respect are Walter George (Great Britain), Alfred Shrubb (Great Britain), Hannes Kolehmainen (Finland), Nurmi, Ville Ritola (Finland), Hägg, Emil Zátopek (Czechoslovakia), Vladimir Kuts (U.S.S.R.), Sandor Iharos (Hungary), and Ron Clarke (Australia). Although he never won an Olympic championship, Ron Clarke broke world records more than two dozen times during his long international career, he held marks at two, three, and six miles, and 5,000 and 10,000 metres when he retired in 1970.

One of the sport's unique events is the one-hour track run, the only official event whose object is running for distance within a set time rather than seeing how fast a man can go for a standard distance. Gaston Roelants (Belgium) averaged better than 4 minutes 42 seconds per mile when he covered 12 miles 1,478 yards—a world record—in the allotted time.

The steeplechase combines long-distance running with hurdling and negotiating a water hazard. Scattered over the 3,000 metres (slightly less than two miles) are 28 barriers and seven water jumps, or four barriers and one water clearance per lap. All barriers are three feet in height and are solidly constructed, allowing athletes either to hurdle the barrier or step on top. On the water obstacle, the barrier stands in front of a 12-foot-long pool that is 2½ feet deep immediately in front of the barrier and slopes up to ground level. Runners place one foot on top of the barrier, push off, then land—either beyond the pit or, usually, with one foot in the shallow end of it. Steeplechasing requires outstanding distance running ability as well as hurdling skill. Many of the top runners, notably Ritola and Roelants, have held world records for flat races as well as for the steeplechase.

Steeplechase and marathon

The marathon race commemorates the feat of a Greek soldier who in 490 BC supposedly ran from Marathon to Athens to bring news of his countrymen's victory over the Persians. The race between the same two Greek cities became part of the Olympic Games in 1896 and covered about 40 kilometres, or just under 25 miles. In 1908, the distance was standardized at its present 26 miles 385 yards. Traditionally, this long road race ends the track and field portion of the Olympics and is generally a highlight of the Games. Many athletes who have had success on the track attempt to make the big step upward from six to 26 miles, but only two have done it totally successfully. Kolehmainen won the 5,000- and 10,000-metre runs in the 1912 Games and won the marathon in the 1920 Games, eight years later. In 1952, Zátopek completed one of the greatest feats in long-distance-running history by winning all three events, the 5,000- and 10,000-metre runs and the marathon, in the same Games. Only one athlete has managed to win the Olympic marathon twice—Abebe Bikila of Ethiopia, in 1960 and 1964. And each time he ran the fastest time ever recorded for the distances.

Since marathon courses vary greatly in composition and terrain, no official record for the distance is maintained. For comparative purposes, however, statisticians have kept lists of the best performances. As with other track and field records, marathon times are continually being lowered. Jim Peters (Great Britain) in 1953 accounted for the first marathon under 2 hours and 20 minutes when he was timed at 2 hr 18 min 40.2 sec. Fourteen years later, Derek Clayton (Australia) brought the best time down below 2:10 with a clocking of 2:09:36.4. This represents 26.2 miles at less than five minutes each.

Many international marathons—as well as shorter and longer road races—are held annually throughout the world. The most famous are the Boston Athletic Association race, held each April since 1897, the Japanese Open at Fukuoka, and the Polytechnic, which covers a course from Windsor to Chiswick, England.

Cross-country running

Cross-country running varies according to locality of the race. In Great Britain, where races of this type are extremely popular and often bring together as many as 1,000 runners, runs are up to nine miles in length. Races cover whatever terrain is available, often involving cross-

ing creeks, running through plowed fields, and jumping fences. Europeans favour cross-country runs that resemble steeplechases. Races of several laps often are run over horse-racing courses, complete with barriers, and at shorter distances than those employed in England. Cross-country running in the United States typically is on golf courses and parklands, at distances up to 10,000 metres.

The sport of cross-country has its own championships, the International, held annually in March or April. Standard men's distance for this race is 12,000 metres or about 7½ miles. Women run 2½ miles or roughly 4,000 metres.

Except for cross-country, women compete in long-distance running only sporadically and never on a championship level. Women nevertheless have accomplished commendable long-distance feats. A 16-year-old American girl, Caroline Walker, in 1970 ran what is believed to be the fastest marathon ever recorded by a woman—3 hours 2 minutes and 53 seconds. Several women have completed the 54-mile Comrades Marathon in South Africa.

Hurdling. These events combine sprinting with negotiating a series of obstacles called hurdles. Men run the 110-metre (or 120-yard) high hurdles, over 10 barriers 106.7 centimetres (42 inches) high and 9.14 metres (10 yards) apart, and the 400-metre (or 440-yard) intermediate hurdles, also over 10 barriers but 91.4 centimetres (36 inches) in height, and 35 metres (38.25 yards) apart. The 110- and 400-metre distances are the standard international events. Low hurdling, over 30-inch (76.2-centimetre) barriers at distances of 220 yards and 200 metres, has all but disappeared as a standard event.

Women, through 1968, had only one hurdle race—80 metres over eight barriers about 76 centimetres (30 inches) high. Beginning in 1969, the hurdles were raised to about 84 centimetres (33 inches), the distance was lengthened to 100 metres, and an additional 200-metre race was added to the women's program. The 100- and 200-metre races both contain ten obstacles, the long race using 76-centimetre hurdles.

The object in hurdling is to spend the least possible time in the air, and to make the hurdling action smooth and rhythmic so as not to disrupt forward progress. Hurdling, therefore, is more a quick stepping action than a floating jump. A.C.M. Croome of Oxford University is credited with developing in about 1885 the economical hurdle clearance involving a straight front leg, forward lunge of the trunk, and snapping action of the trailing leg. This "step-over" action is the basis of modern hurdling technique.

Hurdle design

The modern L-head hurdle (which in the 1930s replaced the heavy, inverted T style) is designed so that a force of eight pounds (3.6 kilograms) on the top edge of the crossbar is required to overturn them. A hurdler may knock down an unlimited number of barriers without penalty. If, however, he trails a leg or foot alongside any hurdle instead of clearing it properly, or if he intentionally knocks down a hurdle with his hand, he is disqualified.

Leading hurdlers combine a sprinter's speed with suppleness and hurdling technique, since they must take the strides between barriers and then to clear the hurdles while travelling at an all-out pace. Starting and finishing techniques are as important here as in the flat sprints.

To support the claim that top hurdlers also must be top sprinters is the case of Harrison Dillard (U.S.). He was favoured to win the 1948 Olympic hurdle championship but he failed to qualify for the United States' team as a hurdler. Rather than be left out completely, he attempted the 100 metres and made the team. Dillard won the flat race at the London Olympic Games. Four years later, he returned to capture the Olympic high hurdles gold medal.

Strangely, in an era where records at all distances fall regularly, the high-hurdle mark recently has been the most stable in track and field. Martin Lauer (Germany) established the current record of 13.2 seconds in 1959, and Lee Calhoun (U.S.), the only man ever to win two Olympic titles in the event, tied it a year later. Though equalled several times since, Lauer still claims a share of the record.

The one-lap hurdle race places a premium on endurance and striding patterns as well as on speed and hurdling technique. Four-hundred-metre or 440-yard hurdlers require the speed of a quarter miler and the strength of a longer distance man. Specialists in this event tend to be high-quality long sprinters rather than top high hurdlers. The two-time Olympic champion Glenn Davis (U.S.) typifies this sort of athlete, having held the world record in the 440-yard flat race as well as in the hurdles.

Striding patterns

In the 400-metre hurdles, athletes normally take 15 strides between hurdles, but fatigue and varying track conditions often complicate this pattern and force improvisation. Running on the springy track in the high altitude of Mexico City, Dave Hemery (Great Britain) took only 13 steps between hurdles for most of the distance and ended up breaking the then existing world record by a full second with 48.1 seconds.

The roll of women's 80-metre hurdle Olympic champions and record holders includes many of the sport's outstanding athletes: Mildred Didrikson (U.S.), Blankers-Koen, Shirley Strickland De La Hunty (Australia), and Irina Press (U.S.S.R.).

Relay running. Standard relays usually involve four-man teams, each running equal and specified distances before passing a baton to a teammate. Most common of the relay events for men are the 440-yard, 880-yard, one-mile, two-mile, and four-mile as well as their metric equivalents. These are often referred to as the 4 × 110, 4 × 220, etc. In the Olympic Games and other international competitions, men and women run the 400- and 1,600-metre relays, women running the longer distance for the first time in the Olympics in 1972.

Except for the baton-passing and baton-carrying aspect, the running techniques in relays are identical to those of the comparable individual events. The baton is a hollow wooden, metal, or plastic implement about one foot in length. It must be handed from man to man within a specified take-over zone that extends 20 metres. In events of 880 yards and less, athletes may begin their run an additional 10 metres before the take-over zone but may not accept the baton until they reach the legal 20-metre area.

Baton passing

Baton passing is an exacting operation that decides the outcome of most races of 400 metres. Ideally, the incoming man hands off to the outgoing one while both are travelling at optimum speed and are a maximum distance apart. This requires constant practice and split-second timing so as to avoid losing momentum, running out of the exchange zone (which results in disqualification), or dropping the baton. Runners employ two basic passing methods—the blind pass (in which the outgoing runner does not look back) in the shorter events, and the safer visual pass (outgoing runner watches incoming one until pass is completed) at longer distances, where fatigue may lead to a costly drop.

Relays are primarily an outgrowth of the United States school system, which puts heavy emphasis on this sort of team competition. College and university teams on both coasts were running relay events before 1900. In 1895 a number of eastern schools competed in the first annual Pennsylvania Relay Carnival. That meet has expanded through the years to take in high school, club, and other athletes and now includes more than 3,000 athletes competing annually. Similar relay carnivals take place in other areas of the U.S., and the normal schedule has the 400- and 880-yard relays, the mile, two-mile, four-mile, and the sprint (legs of 440-, 220-, and 880-yards) and distance (440-yard, 880-yard, three-fourths mile, and one-mile) medleys. These all follow the rules and procedures described earlier. Another event, the 480-yard high-hurdle relay, is unique. This is run in "shuttle" fashion, with one runner travelling the normal direction on the track and his teammate returning the opposite way. No baton is carried; the outgoing runner simply starts when the incoming one crosses his finish line.

Because of its abundance of sprinting talent and emphasis on relay racing, the United States has dominated this phase of the men's sport in Olympic and other international competition.

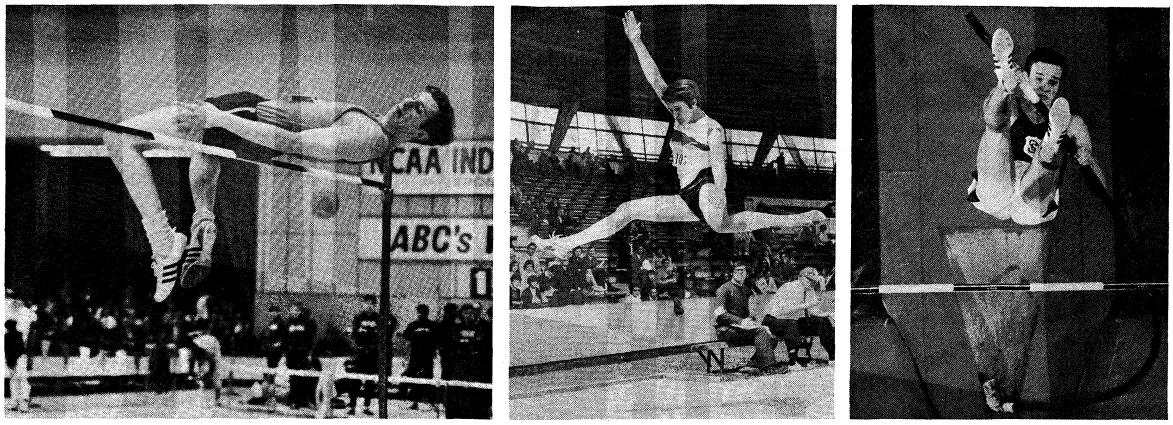

Figure 2: (Left) Dick Fosbury (U.S.), high jumping in style known as the "Fosbury flop," wins the event at the NCAA Indoor Track and Field Championships, 1968. (Centre) Barbara Inkpen (England) takes a spectacular leap in the senior long jump during the Women's Amateur Athletic Association Championship, Crystal Palace, 1969. Race walking. This facet of track and field bears little resemblance to the actions and speed of hiking or casual strolling. Top race walkers travel at a maximum rate of just over six minutes per mile, or ten miles per hour; *i.e.*, more than twice the speed of a hiker.

Walkers develop a special technique to carry them along at this rapid rate. Elements of the distinctive style are a rapid pulling motion with the legs, pronounced and rhythmic motion of the hips, and exaggerated arm and shoulder movement.

Rules of heel and toe racing

Race walking rules stipulate that (1) the walker must maintain unbroken contact with the ground (one foot always touching), and (2) the leg must be straightened (*i.e.*, the knees locked rather than bent) for an instant while it is in contact with the ground. When walkers are travelling at a high rate of speed, the temptation is strong to break contact with the ground or to make bent-legged contact. Both infractions are difficult to detect, since the steps occur within fractions of seconds, and make the judging of walking races both an important and exacting task. Walkers may receive one warning of impending violation and are disqualified for violation of the rules.

The IAAF and its member bodies recognize only marks made at selected distances: international race walking primarily follows the Olympic lead and uses the 20- and 50-kilometre distances as standard events in major competitions. Twenty kilometres equals roughly 12½ miles, and 50 kilometres is just over 31 miles. Both are relatively recent additions to the Olympic program, the "50" beginning in 1932, and the "20" in 1956.

Walking is primarily the domain of the Europeans, and only one athlete from outside that continent and Great Britain—Norman Read of New Zealand in the 1956 "50"—has managed to win an Olympic championship. Other 50-kilometre standouts have been the Olympic titlists Don Thompson (Great Britain), Abdon Pamich (Italy), and Christoph Hohne (East Germany). Among 20-kilometre walkers, Vladimir Golubnichy of the Soviet Union is outstanding, with a record of winning two Olympic races (in 1960 and 1968) contested at this distance.

Besides the Olympics, walkers compete in the Lugano Cup competition, which is the equivalent of the world walking championships. The team event contains walks of 20 and 50 kilometres. The cup goes to the nation with the best cumulative performance.

JUMPING

Men compete in four jumping events, the high jump, long jump, triple jump, and pole vault, while women compete only in the high jump and long jump.

High jumping. There is but one stipulation placed on the method an athlete chooses to get himself over the crossbar, which is perched atop two standards. He must leave the ground from one foot, not two.

The crossbar is raised progressively higher as athletes jump over it. High jumpers are allowed three attempts at clearing each height. On the third miss, they are out of the competition. They may enter the competition at any point. In fact, if they begin when the bar is at a higher level, this may work in their favour because of the "countback" rule for breaking ties. The rule works this way: (1) first officials check the athlete's number of attempts at the height where the tie occurred; (2) if two or more men are still tied, the total number of *failures* throughout the competition is computed; (3) if they remain tied, a count is made of the total number of *jumps* in the competition. In each of the three cases, the athlete with the lowest total is the winner. This puts a premium on taking as few jumps as possible.

Inflated or foam-rubber-cushion landing pads have replaced sawdust pits. These cushions are two or more feet thick and have both reduced the threat of injuries and made possible refinements of technique. Another boon to the high jumper has been the development of durable, all-weather takeoff areas that provide a consistent surface for the run-up and all-important foot placement preceding the jump.

Jumping styles

Jumping styles have evolved in the 20th century as records have progressed. One of the earliest and most basic techniques was the scissors, in which the jumper approached the bar from the right side and jumped off the left foot, with his torso upright when he crossed the bar. But neither this style nor its variants are employed to any appreciable extent in modern competition, and no athlete has topped seven feet using them. Another now rather rare jumping method is the western roll, sometimes called the belly roll, in which the jumper approaches the bar from the left and jumps off the left foot, "rolling" his torso over the bar. Its leading exponent, Gene Johnson (U.S.) has cleared 7 feet 1 inch (2.16 m).

The most common method employed is the straddle. With this style, the athlete approaches the bar at an angle, extends his lead leg upward toward the crossbar, drapes himself facedown and parallel to the bar at the height of his jump, then lands on his side or back in the pit. Charles Dumas (U.S.) used this technique in 1956 when he became the first man to break another of track and field's "magical barriers"—seven feet.

The straddle style's leading exponents include Valery Brumel (U.S.S.R.) and Ni Chihchin (China). Brumel, whose brilliant career was cut short in 1965 by a motorcycle accident that shattered his leg, accounted for six world record improvements and the 1964 Olympic championship. Ni never competed in the Games and his records are not officially recognized because his nation is not an IAAF member.

Brumel and Ni are examples of men who have taken maximum advantage of their size and leg power. Brumel is 1.85 m (6 feet ⅞ inch) tall, yet he has jumped 2.28 m (7 feet 5¾ inches). Ni is 1.84 m (6 feet ½ inch) in

height and has a high jump best of 2.29 m (7 feet 6¼ inches). Few jumpers have been able to exceed their own height by as much as Brumel's and Ni's 43 to 45 cm (17-inch-plus) differential. Pat Matzdorf (U.S.), 1.70 m (6 feet 3 inches) jumped 2.29 m (7 feet 6¼ inches) for a recognized world record in 1971.

Though straddle stylists claim the best marks, a more recent development in jumping technique has created more excitement. Dick Fosbury (U.S.) is credited with developing a style that involves approaching the standards from almost straight ahead, then twisting on takeoff and going over head first with the back to the bar, finally landing on the shoulders. The style, referred to as the "Fosbury flop," gained wide exposure and increasing acceptance when Fosbury used it to win the 1968 Olympic championship. Though many jumpers had successfully converted to this style by 1970, none had yet bettered Fosbury's best height of 2.24 m (7 feet 4¼ inches).

The "Fosbury flop"

Easily the leading female high jumper of all time is Iolanda Balas (Romania). Miss Balas, 1.71 metres (5 feet 7¼ inches) tall, used the complicated eastern cutoff style of jumping, characterized by bringing the trailing leg under the lead leg and down to the pit first. The shoulders and head are brought to the left (when the jumper leads with his right leg) and down, thus lifting the hips and buttocks up to clear the bar. Beginning in 1957, she tied or improved the world record 14 times, taking it from 1.75 m (5 feet 9 inches) to 1.91 (6 feet 3¼ inches). Her career included two Olympic championships. The "Fosbury flop" even came to the women's sport in the late 1960s. Debbie Brill (Canada), winner of the 1970 British Commonwealth Games, was the first to reach 1.83 m (6 feet)—still a rare feat for women—using her version of this technique.

The standing high jump went out with the 1912 Olympics, but mention should be made of Ray C. Ewry (U.S.). After being confined to a wheelchair as a youth, he developed the leg strength and spring to win eight Olympic championships in the standing jumps—three in the high jump, three in the long jump, and two in the triple jump.

Pole vaulting. The origins of this event can be traced back to the days when men used poles to assist them in clearing obstacles such as ditches, creeks, and fences. Present pole-vaulting competition is organized along the lines of the high jump—*i.e.*, vaulters attempt to get over a crossbar placed on uprights, they get three tries at each height, the "countback" rule is employed to break ties, and they land in a pit that now generally is of rubber composition or inflated.

IAAF rules state that pole-vaulting poles "may be of any material or combination of materials, and of any length or diameter." In the 1960s, fibre glass came into general use for vaulting poles because of the flexibility and catapulting action of that substance. The use of this pole revolutionized the event, as will be discussed later. Previously, more rigid bamboo and metal poles had been used.

Early in the history of pole vaulting, poles were equipped with spikes at one end. They dug into the ground as the vaulter planted his pole. Early in the 20th century, a slotlike box for pole placement became part of standard vaulting equipment. This box, which is sunk below ground level at the base of the uprights, is about eight inches deep and six inches wide at the point where the pole stops.

Pole-vaulting technique

Pole-vaulting technique involves the following. The vaulter takes an approach run of 30–45 metres (100–150 feet), carrying the pole with his hands about 0.75 m (2½ feet) apart and the pole roughly parallel to the ground. After planting the pole, he leaves the ground and pulls himself upward until he is almost doing a handstand on the pole. He twists as he approaches the bar and arches over feet first and facedown. The pole is released just before the flyover and is given a push backward to prevent its knocking off the bar; the athlete then lands on his back in the pit.

The fibre-glass vaulting pole brought revolutionary changes in the event, both in styles and performances. The new pole put more emphasis on gymnastic agility than the rigid types, where sheer speed and power were at a premium. Fibre-glass vaulters hang upside down early in their vaults, waiting for the right instant when the bowed pole recoils to give them their vital lift.

Before the advent of the fibre-glass pole it took 13 years (1927 to 1940) for the world record to progress from 14 to 15 feet (4.26 to 4.57 metres). John Uelses (U.S.), using fibre glass, accomplished the first outdoor 16-foot (4.88 metre) vault in March 1962. Just 18 months later, John Pennel (U.S.) surpassed 17 feet (5.18 metres). And in 1970, Christos Papanicolaou (Greece) pushed the world record over 18 feet (5.49 metres).

Cornelius Warmerdam (U.S.) was perhaps the leading pole vaulter of the pre-fibre-glass era, but he never competed in the Olympics because World War II intervened during his peak years. In 1940, Warmerdam achieved the world's first 15-foot vault. He improved that mark five more times in the next two years, reaching a height of 4.77 m (15 feet 7¾ inches) that no one bettered for 15 years. Warmerdam also went 15 feet 8½ inches indoors, but indoor marks are not counted as world records.

The next great vaulter, Bob Richards (U.S.), never bettered Warmerdam's marks. But Richards was the only man ever to win two Olympic pole-vault titles, his victories coming in 1952 and 1956. Others who excelled before the fibre-glass revolution of the early 1960s were Bob Gutowski (U.S.), who broke Warmerdam's world record, and Don Bragg (U.S.), the 1960 Olympic champion. Bragg won his Olympic title at 4.70 m (15 feet 5 inches). By 1964, fibre glass had taken over, and that year's champion Fred Hansen (U.S.) vaulted 5.10 m (16 feet 8¾ inches). Another Olympiad passed, and the 1968 Mexico City Olympic winner, Bob Seagren (U.S.), did almost a foot better than that.

Throughout the event's history, United States athletes have dominated—never losing an Olympic title and rarely being without a world record. The exceptions, since the 1920s, have been Charles Hoff (Norway), Pentti Nikula (Finland), Wolfgang Nordwig (East Germany), and Christos Papanicolaou (Greece), the first to top the 18-foot barrier with 18 feet ¼ inch (5.49 m) in 1970.

Long jumping. Formerly known in many areas as the broad jump and, for many years, as the running broad or long jump, this is competitive jumping for distance. An Englishman named J. Howard reportedly leaped 29 feet 7 inches (9.02 metres) in 1854—which is better than the existing record. But he employed aids that have since become illegal. Howard carried five-pound weights in each hand, and hurled them backward on takeoff to gain extra momentum, and he jumped from a slightly elevated block.

Long-jumping rules now state that an athlete can carry nothing in his hands and that the takeoff board must be level with the landing pit. The board marks the point where he breaks contact with the ground. He may step on the board, but he is charged with a foul if any part of his foot goes past the forward edge. The jumper lands in a sand-filled pit, and his distance is measured from the front of the takeoff board to the closest point of body contact in the pit.

The approach run in long jumping

A crucial part of long jumping, as with all jumping events, is the approach run. Not only is high speed required to achieve maximum momentum but the athlete also must arrive precisely at the takeoff point without breaking stride and on the proper foot. In the long and triple jumps, there is the additional problem of hitting the takeoff board. If the jumper starts too far back, he loses valuable distance; if he runs too far, he oversteps the board and has a foul charged against him. Athletes in these events normally measure their approaches carefully and place pegs alongside the runway as check points.

Long jumpers employ two basic styles. One is the "hang" (or "tuck") technique, where the knees simply are tucked under the body in midflight. The other is the more complicated "hitch-kick" style, which involves taking a long step in midair. The latter, which resembles walking on air, is the most popular among modern athletes.

Two distinct landmarks stand out in the history of long jumping. The first centres on the spectacular day Jesse

Owens (U.S.) ran and jumped through on May 25, 1935. Owens raised the world long-jump record to 26 feet 8¼ inches (8.13 m), and he also tied the world record for the 100-yard dash and set new world records for the 220-yard, and 200-metre runs on the flat, and for the 220-yard and 200-metre low hurdles. Not unil 25 years later did Owens—winner of four events at the 1936 Olympics—lose his long jump record.

During most of the 1960s, Ralph Boston (U.S.) led long jumpers. It was Boston who finally broke Owens' long-standing record and pushed the world record past 27 feet (8.23 metres). On Oct. 18, 1968, in the rarified atmosphere of Mexico City, Bob Beamon (U.S.) touched down at 8.90 metres (29 feet 2½ inches). No one had done better than 8.35 metres (27 feet 5 inches) previously. In 33 years, the world record had gone up less than nine inches (22.86 centimetres). Then, in one day, Beamon improved it by almost two feet (60.96 centimetres). Many track and field experts called this jump at the 1968 Olympics the greatest single performance in track and field history.

The event joined the women's Olympic program relatively recently, in 1948. Before that, the event's leader had been Blankers-Koen of The Netherlands, who had jumped 6.25 metres (20 feet 6 inches) in 1943.

Two ladies starred during the 1960s. Mary Rand (Great Britain), like Blankers-Koen a woman of many track-and-field talents, became the world's first female 22-foot jumper when she landed 6.76 metres (22 feet 2¼ inches) from the board to win the 1964 Olympics. Tatyana Shchelkanova (U.S.S.R.) never won the Olympic title but set numerous world records, with a best jump of 21 feet 11¾ inches (6.70 m) in 1964.

Triple jumping. In some quarters, this event has been known as the hop, step, and jump, which describes the combination of actions involved. A triple jumper takes an approach run similar to that in the long jump, although slightly slower because he must maintain control in order to execute the three phases of the leap. The first segment is a hop, in which the jumper must take off and land on the same foot. Then he goes into an elongated step, landing on the opposite foot. Both of these have been completed while still on the runway. The final phase is the jump into the pit, which resembles a long jump and ends with a two-footed landing. As an example of how far the triple jumper travels during each of the leaps, the longtime world record holder Józef Schmidt (Poland) had these marks during his 17.03-metre (55-foot 10½-inch) effort in 1960: hop—19 feet 8¼ inches; step—16 feet 5¾ inches; jump—19 feet 8½ inches (6.00, 5.02, and 6.01 metres).

Hop, step, and jump

Rules governing the triple jump are identical to those in the long jump in regard to the takeoff board, measurements, and number of efforts allowed. Early triple jumpers performed with two hops and a jump. James Connolly (U.S.) jumped in this manner when he won the 1896 Olympic championship, but rules prescribing the present method were adopted before the next Games.

Two athletes have stood out in the post-World War II period—Adhemar Ferreira da Silva (Brazil) and Schmidt. Da Silva was one of South America's rare world class track-and-field athletes (another has been Nelson Prudencio, also a triple jumper and also from Brazil). Da Silva's career included two Olympic titles, 1952 and 1956, and five world record performances. Between 1950 and 1955, he boosted the record from 52 feet 6 inches to 54 feet 3¾ inches (16.00 to 16.55 metres).

Schmidt won two Olympic—1960 and 1964—and two European championships. He placed only seventh in the 1968 Olympic Games, with a leg injury hampering him. Even at that, he nearly equalled his world record, which had stood for eight years.

The Games at Mexico City featured the greatest triple jumping in history, as five men—Victor Saneyev (U.S.S.R.), Prudencio, Giuseppe Gentile (Italy), Art Walker (U.S.) and Nikolay Dudkin (U.S.S.R.)—all went beyond Schmidt's former mark of 55 feet 10½ inches (17.03 metres). Olympic competitive pressure, the fast and springy artificial runway, and the lowered air resistance of Mexico City's 7,500-foot (2,300-metre) elevation all contributed to the onslaught. Within 24 hours, Gentile accounted for the first-ever 56-foot (17.07-metre) jump, and Saneyev—the winner—bounded over 57 feet with five-eighths inch to spare (17.39 metres).

THROWING

The four standard throwing events—shot put, discus, hammer, and javelin—all involve the use of implements of various weights and shapes hurled for distance. Women compete in only the shot, discus, and javelin.

Shot putting. This event, which evolved from stone putting, is not a "throwing" event strictly speaking. The action involved here is better described as shoving the weight, since the rules state that the arm may not extend behind the shoulders during the putting action.

The shot is spherical and has a smooth outer surface of metal (iron, brass, or a substance not softer than brass). In indoor competition, athletes may use a soft rubber-, plastic-, or leather-coated shot filled with metal pellets. The men's implement weighs 16 pounds (7.256 kg) and measures about five inches (12.7 cm) in diameter. Women put a 4-kilogram (8-lb 13-oz) shot, about 10 cm (4 in.) in diameter.

Shot-putters launch the ball from a ring 7 ft (2.134 m) across. The ring is equipped with a toeboard on the front. During competition, an athlete may not step on top of or over any portion of the circle (though he may touch the sides), or leave the ring before the shot hits ground. If he does so, or leaves from the front half of the circle at any time, he is charged with a foul. In present-day competition, the ring usually is mounted on concrete or a similar hard surface that provides solid, dependable footing. Athletes put into a sector with right and left boundaries that are approximately 65 degrees apart. Measurements are from the front of the ring to the point where the shot first touches ground.

Physical requirements of shot-putters

Shot-putters are among the largest athletes in track and field, usually well over 200 pounds (90 kg). And they have grown even bigger in recent years through the use of heavyweight lifting training, which adds both bulk and explosive strength. This form of training came into general usage during the 1950s, and combined with a new putting technique to revolutionize the event.

Before the early 1950s conventional shot-putting style involved making a 90-degree turn while crossing the ring. Parry O'Brien (U.S.) is credited with developing a style that included a full 180-degree turn. O'Brien began his put at the back of the ring, with his back to the toeboard. He crouched low, with the implement tucked near his chin, as he moved across the circle. Gathering momentum as he turned, he took full advantage of his speed and strength as legs and putting arm straightened explosively at the release. O'Brien officially improved the world record ten times between 1953 and 1959, won two Olympic championships, and was the first man to better 59, 60, 61, 62, and 63 feet (17.98, 18.29, 18.59, 18.90, and 19.20 m). His form, with minor variations, was adopted almost universally.

Before the O'Brien era, the key men in the event had been Ralph Rose (U.S.) and Jack Torrance (U.S.). Rose, an Olympic champion in 1904 and 1908, put the shot past 50 feet (15.24 m) for the first time a year after winning his second Olympics. It took 19 years for Rose's mark of 51 feet 0 inch to fall. Progress came slowly until the emergence of Torrance in the mid-1930s. Torrance, who weighed nearly 300 pounds (136 kg), improved the world record to 57 feet 1 inch (17.40 m), a mark that lasted 14 years.

Following O'Brien's exploits of the 1950s, Bill Nieder (U.S.) and Dallas Long (U.S.) each assumed the spotlight briefly. Nieder was the first man to better 65 feet (19.81 m) and won the 1960 Olympic crown, while Long, the 1964 Olympic king, first bettered 66 and 67 feet (20.12 and 20.42 m). They preceded another of the sport's supermen, Randy Matson (U.S.). Matson, nearly 6 feet 7 inches tall and weighing 270 pounds (122.5 kg), broke through the 70-foot (21.34-m) barrier in 1965, and two years later was able to surpass 71 feet (21.64 m).

(Left and centre) Don Chadez, (right) Tass—Sovfoto

Through the end of 1970, no other athlete had been able to exceed 69 feet.

Shot putting was not a part of the women's phase of the Olympic Games until 1948. A pioneer on a par with O'Brien in the women's shot was Tamara Press (U.S.S.R.). Press, 220 pounds (100 kg), thoroughly dominated the event while at her prime, winning the 1960 and 1964 Olympic titles and becoming the first woman to better both 55 and 60 feet (16.76 and 18.29 m). Even her records proved to be vulnerable, however. By 1968, Margitta Gummel (East Germany) had pushed the record out to 64 feet 4 inches (19.61 m) while winning the Olympic championship.

Discus throwing. This event, the throwing of a plate-like implement, is the classic event of track and field. In his writings, many centuries before the birth of Christ, the Greek poet Homer made numerous references to discus throwing, and a form of it was popular in the ancient Grecian Olympics.

The Greek technique of discus throwing

The Greek technique, as it was deduced from study of famous statues, consisted of throwing a four- to five-pound (1.8 to 2.3 kg) discus from a standing position on a pedestal and using a highly stylized form; a separate event using this style was part of the 1908 Olympics. But the style proved to be so artificial that it gave way completely to the modern technique. This involves starting by facing the back of the throwing circle and taking 1½ quick turns before releasing the discus. The circle is 8 feet 2½ inches (2½ metres) in diameter. Present rules stipulate that the sides and back of the ring must be surrounded by a cage for the protection of other athletes, officials, and spectators. The boundaries of the sector into which the discus is thrown are 60 degrees apart.

The discus for men is 4 pounds 6½ ounces (2 kg) in weight, about 8¾ inches (22.23 cm) in diameter, 1¾ inches (4.45 cm) thick in the centre tapering to one-half inch (1.27 cm) on the outer edges; the women's discus is 2 pounds 3¼ ounces (1 kg) in weight, about 7¼ inches (18.42 cm) in diameter, 1½ inches (3.81 cm) thick in the centre tapering to one-half inch (1.27 cm). The implement is constructed of wood "or other suitable materials" and has a metal rim around the outer edge. Rules of the competition, training techniques, and the physical dimensions of the athletes involved are similar to those in the shot put. In fact, many athletes double successfully in the two events. The discus places slightly more emphasis on speed and agility, however, and discus throwers tend to be a bit taller and leaner than shot-putters, though still normally weighing well above 200 pounds (90 kg).

The first great discus thrower of the 20th century was Martin Sheridan (U.S.), who won the Olympic championships in 1904 and 1908 (the former in a throwoff after tying with the shot-put champion Ralph Rose) and had improved the world record from 129 feet (39.30 m) to 144 feet (43.88 m) by 1909.

During and just after World War II, the record-setting task fell into the hands of a durable veteran, Adolfo Consolini (Italy). Consolini set his final world mark, 181 feet 6½ inches (55.32 m), in 1948, the same year he won the Olympic title and set a European record of 186 feet 11 inches (56.98 m) in 1955 when he was nearly 39.

The quest for 200 feet (60.96 m) began in earnest in the 1950s, by the Americans Fortune Gordien and Sim Inness. Gordien ended up with the highest mark of the two —194 feet 6 inches (59.28 m), but Inness won the 1952 Olympic title.

This was the background of one of the most spectacular stories in Olympic and track and field history—the career of Al Oerter (U.S.). Oerter's international competition began at the 1956 Olympics in Melbourne. He upset Gordien for the championship there. Four years later, he added a second Olympic title. He achieved a third gold medal at Tokyo, and finally a fourth at Mexico City. He is the only athlete ever to have won four consecutive titles in a single event. Also, in 1962, Oerter recorded the first 200-foot (60.96-m) performance.

Although Oerter beat him in Olympic competition, Ludvik Daněk (Czechoslovakia) exceeded Oerter's world record and became the first 210-foot (64.00-m) thrower. Daněk in turn surrendered the record to Jay Silvester (U.S.), first man to throw more than 220 feet (67.06 m).

Eastern Europeans—primarily athletes from the Soviet Union—have maintained almost complete dominance in women's discus throwing. From 1939 to 1952, the Soviet thrower Nina Dumbadze increased the world record from 158 feet 6 inches (48.30 m) to 187 feet 1¾ inches (57.04 m). Her countrywoman Nina Ponamanyeva twice won Olympic titles, in 1952 and 1960.

Tamara Press (U.S.S.R.), better known as a shot-putter, broke Nina Dumbadze's world record in 1960 and later extended the women's mark to 195 feet 10½ inches (59.70 m). The West German Liesel Westermann had the honour of making the first toss over 200 feet.

Hammer throwing. The so-called hammer actually is a ball similar to the shot, attached by a length of steel wires slightly under four feet (1.22 m) long to a handle that can be gripped with both hands. The hammer thrower takes several spins before letting the implement fly, and since it weighs 16 pounds (7.26 kg) its centrifugal force carries it a considerable distance.

Early precursors of the hammer throw

The event's predecessors are among the oldest events in track and field. Legends trace it back to the Tailteann Games, about 2000 BC. In those games, Celtic heroes were said to have gripped a chariot wheel held by its axle, whirled it around their heads and thrown it. Wheel hurling was replaced later by throwing a boulder attached to a wooden handle. During the 16th century,

King Henry VIII of England became proficient in an athletic event that involved throwing a blacksmith's hammer. The name remained, even though the nature of the implement changed.

Hammer throwing has been an Olympic Games event since 1900. Throwers compete from a circle that is the same size as the one used for shot putting—seven feet in diameter. They throw into a sector identical to that of the discus—60°. As with the discus throw, a wire-fence cage surrounds three sides of the hammer ring to protect observers. Hammer-throwing technique requires great strength combined with sure balance. Within the small ring, athletes make three turns. While spinning, the hammer is at arms' length and is creating a strong centrifugal pull that the athlete must counteract. Upon releasing the implement, he must guard against losing his balance and stepping out of the circle, which results in a foul.

Irish-bor athletes made this event their stronghold from the 1880s until almost 1950. Two enjoyed particular prominence. John Flanagan, a United States citizen, raised the world record 14 times from 1895 to 1909, and took it from 145 feet (44.20 m) to over 184 feet (56.08 m) during that period. He also won three consecutive Olympic championships—1900, 1904, 1908. Patrick O'Callaghan (Ireland) accounted for Olympic gold medals in 1928 and 1932 and was the first man over 190 feet (195 feet 4¾ inches [59.56 m] in 1937).

During the 1950s and 1960s, eastern Europeans displayed conspicuous strength in the event. But their dominance was not total. A Norwegian, Sverre Strandli, first broke 200 feet (60.96 m). Mikhail Krivonosov (U.S.S.R.) did much of the record breaking during the mid-1950s, improving the mark six times. In the 1956 Olympics, however, he lost to Harold Connolly (U.S.). Connolly, whose left arm was considerably smaller and weaker than his right arm because of a childhood injury, improved the world record seven times to a peak of 233 feet 9½ inches (71.26 m).

More recent hammer competition has featured the duels of Romuald Klim (U.S.S.R.) and Gyula Zsivótzky (Hungary). After finishing second in the 1960 Olympics, Zsivótzky repeated that placing 1964 as Klim won. The Hungarian, however, twice improved the world record before the 1968 Games and got his long-sought gold medal after a dramatic confrontation with Klim. Ironically, Zsivótzky lost the world record a short time later —to Klim.

Cramped indoor facilities do not allow for hammer throwing. But in the United States a similar weight event is substituted. In this event the athlete uses a 35-pound implement with a triangular handle attached directly to the weight. Leading throwers toss it in the range of 70 ft (21.34 m). A limited amount of outdoor competition also is conducted with a 56-pound weight, which is of similar construction; this competition was discontinued as an AAU event in 1959.

Javelin throwing. The art of spear throwing was introduced to the ancient Olympics in 708 BC as part of the pentathlon. Modern javelin throwing involves the use of a spearlike implement that is hurled with an over-the-shoulder motion at the end of an approach run. Javelins consist of three parts—the metal tip, which is weighted and pointed so that it will stick into the ground; the metal or wooden shaft; and the grip, which is the binding in the centre of the implement that the athlete holds while carrying out the throw. Men's javelins are about 8½ ft (260 cm) long and weigh roughly 1 lb 12 oz (800 g). The women's implement measures about 7½ ft (220 cm) and weighs 1 lb 5 oz (600 g).

The modern javelin

This event is the only one of the throws that uses a runway (about 100 ft or 30 m long) rather than a ring for the approach. On his approach the thrower runs down the runway carrying the javelin at about shoulder height. Just before reaching the foul line, he alters his step pattern and turns so that the nonthrowing side is in front of the one with the implement. He makes a half-turn back toward the throwing area and follows through as the throw is executed. The javelin is not required to stick in the ground as it comes back to earth, but the point must come down first. It must land within a 30-degree sector.

Throwers from Scandinavian countries have played a major role in this event as far back as the 19th century. Erik Lemming of Sweden established his first world record in 1899 and his final one—just under 200 ft (60.96 m) in 1912. Within this period, he captured two Olympic championships. The next two Olympic titles went to Jonni Myyrä (Finland), who did most of the record breaking through 1920. Myyrä's countryman, Matti Järvinen, 1932 Olympic titlist, improved the world record 10 times during his career to a peak of 253 ft 4½ in. (77.22 m) in 1936.

In the 1950s, Richard Held (U.S.) developed a javelin with improved glider-like aerodynamic qualities, with which his brother Franklin set world records of 263 ft 10 in. (80.40 m) in 1953 and 268 ft 2 in. (81.75 m) in 1955. The design principle came into general usage at the 1956 Olympics where Egil Danielsen (Norway) first surpassed 280 ft (85.34 m) with 85.71 m (281 ft 2½ in.). The design was formalized, with some changes, under specifications adopted by the IAAF in 1960 and, following minor improvements in performance by several athletes, Norwegian Terje Pedersen made a dramatic breakthrough by going from 285 ft 10 in. to 300 ft 11 in. (87.12 m to 91.72 m) within two months of 1964. Pedersen, however, never was a serious contender for Olympic honours. The 1964 title went to Pauli Nevala (Finland), and in 1968 the winner was Yanis Lusis (U.S.S.R.), one of the greatest competitors in the event's history. Nevala, Lusis, Jorma Kinnunen (Finland), and Mark Murro (U.S.) all joined Pedersen in the select 300-foot (91.44-m) category.

In the women's event, the all-around athlete Mildred ("Babe") Didrikson won the first Olympic championship in 1932. A later winner of the Olympic crown was Dana Zátopek, wife of four-time distance running champion Emil Zátopek of Czechoslovakia. Among women javelin throwers, 200 feet is on a par with 300 feet for men. Elvira Ozolina (U.S.S.R.) first bettered that barrier in 1964. Two months later, however, she lost the Olympic title to a 17-year-old Romanian, Mihaela Penes, who fell just shy of 200 feet.

DECATHLON AND PENTATHLON

Men and women both participate in multi-event competitions in which each of their performances earn points. The allotment of points is established by the IAAF and depends on the quality of the marks (*i.e.*, the better the mark the higher the point total). The men's ten-event decathlon and the women's five-event pentathlon are all-around tests involving running, hurdling, jumping, and throwing, and are part of the Olympic Games program.

Decathlon. Competition in the decathlon extends over two days and includes four running and six field events. Each day begins and ends with runs, and the field events come between them. The order is, on the first day: 100 metres, long jump, shot put, high jump, and 400 metres; on the second day: 110-metre high hurdles, discus throw, pole vault, javelin, and 1,500 metres.

Decathlon rules vary slightly from those in individual events. For instance, each athlete gets only three attempts in each of the throwing events and the long jump; he may make a false start twice rather than once before being disqualified from a run; aiding wind does not affect a mark for record purposes. The IAAF has revised its scoring tables three times since the event's inception, most recently in 1962. Top decathlon performers average at least 800 points per event.

Emphasis is on overall consistency and high point production in every event rather than concentration on individual event victories. In a very real sense, the athlete is competing against himself and the scoring tables as much as with the man beside him. It is possible for him to go through the ten events without having the best mark in any one, yet still to come out ahead in the combined scoring. In practice, the best decathlon athletes normally have an individual event or two in which they might be close to world class, plus no glaring weaknesses in the remainder. As an example, Bill Toomey, the world record

holder at the end of the 1960s, displayed the ability to win open 100-metre and 400-metre races and long jumping competitions, and he had more than adequate talent in the other seven events. An Olympic decathlon champion, because of his versatility, often is referred to as the world's greatest athlete. This title may have originated at the 1912 Olympics, where the King of Sweden reportedly said to decathlon winner Jim Thorpe (U.S.), "You, sir, are the world's greatest athlete."

Decathlon champions

Even though he later was relieved of his Olympic titles (pentathlon as well as decathlon) because he had played professional baseball, Thorpe earned recognition as the first great ten-event specialist. Others have been Harold Osborn (U.S.), Paavo Yrjölä (Finland), Glenn Morris (U.S.), Bob Mathias (U.S.), Rafer Johnson (U.S.), Toomey, and Nikolai Avilov (U.S.S.R.), all of whom achieved world records as well as won Olympic championships. Mathias is the only man to have won the Olympics twice, the first time in 1948, when he was 17 years old.

Pentathlon. The women's five-event contest, like the decathlon, is a two-day affair. The first day's competition includes the 100-metre hurdles (which replaced the 80-metre event following the 1968 Olympics), shot put, and high jump. The long jump and 200 metre come on the second day. On the IAAF scoring table for women, the leading performers score more than 5,000 points.

Pentathlon competition became part of the women's Olympic program in 1964, as the first championship went to Irina Press (U.S.S.R.). Press, also a world record hurdler, is part of the most famous family in women's track and field. Her sister, Tamara, held world records in the shot put and discus throw, and between them they won five Olympic titles.

Men's pentathlon and all-around

A five-event pentathlon for men was dropped from the Olympic Games program after 1924, but such competitions (not to be confused with the multisport Modern Pentathlon, which includes fencing, swimming, horseback riding, shooting, and running) still are held occasionally. All five events—the long jump, javelin throw, 200-metre, discus throw, and 1,500-metre—are held on the same day. Male pentathletes use the same table as in the decathlon; best performances are well over 4,000 points.

Another non-Olympic multi-event competition is the all-around, which is peculiar to the United States and conducted by the AAU. It is a one-day competition with ten events—100-yard dash, shot put, high jump, 880-yard walk, hammer throw, pole vault, 120-yard high hurdles, 56-pound weight throw, long jump, and mile run.

Trade, International

International trade transactions are extremely diverse and include the purchase and sale of consumer goods; consumer services, such as travel; industrial raw materials and services; producer and capital goods, such as plant and machinery; securities in such forms as promissory notes and stock-ownership certificates; and gold. The only distinguishing characteristic of an international trade transaction is that it reaches across a national boundary. In the typical exchange, an individual or business firm in one nation receives a foreign good, service, or security, in exchange for which some small part of that nation's domestic currency is allowed to pass into foreign hands. The other nation exports part of its production or assets, receiving in exchange what is to it a foreign currency. The transfer of money into foreign hands poses special problems, as does the export of goods or the import of goods. This article reviews the origin and function of such international transactions in the light of international trade theory, and it examines the principal issues and problems that are posed by international trade.

THE THEORY OF INTERNATIONAL TRADE

History. Accounts of barter of goods or of services among different peoples can be traced back almost as far as the record of human history. International trade, however, is specifically an exchange between members of different nations, and accounts and explanations of such trade begin (despite fragmentary earlier discussion) only with the rise of the modern nation-state at the close of the European Middle Ages. As political thinkers and philosophers began to examine the nature and function of the nation, trade with other nations became a particular subtopic of their inquiry. It is, accordingly, no surprise to find one of the earliest attempts to describe the function of international trade within that highly nationalistic body of thought now known as "mercantilism." Mercantilist analysis, which reached the peak of its influence upon European thought in the 16th and 17th centuries, focussed directly upon the welfare of the nation. It insisted that the acquisition of wealth, particularly wealth in the form of gold, was of paramount importance for national policy. Mercantilists took the virtues of gold almost as an article of faith; consequently, they never undertook to explain adequately why gold deserved such a high priority in their economic plans.

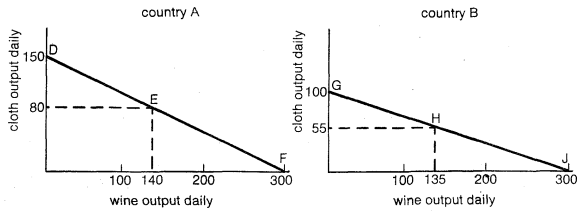
Mercantilism

The trade policy dictated by mercantilist philosophy was accordingly simple: encourage exports, discourage imports, and take the proceeds of the resulting export surplus in gold. Because of their nationalistic bent, mercantilist writers either brushed aside or else did not realize that, from an international viewpoint, this policy would necessarily prove self-defeating. The nation that successfully gains an export surplus must ordinarily do so at the expense of one or more other nations that record a matching import surplus. Mercantilists' ideas often were intellectually shallow, and indeed their trade policy may have been little more than a rationalization of the interests of a rising merchant class that wanted wider markets—hence the emphasis on expanding exports—coupled with protec-

tion against competition in the form of imported goods. Yet mercantilist policies, as will be noted later, are by no means completely dead today.

Comparative advantage analysis. The British school of "classical economics" began in no small measure as a reaction against the inconsistencies of mercantilist thought. Adam Smith (1723–90) was the founder of this school; his famous work, *The Wealth of Nations*, is in part an antimercantilist tract. In *The Wealth of Nations*, Smith emphasized the importance of specialization as a source of increased output, and he treated international trade as a particular instance of specialization: in a world where productive resources are scarce and human wants cannot be completely satisfied, each nation should specialize in the production of goods it is particularly well equipped to produce; it should export part of this production, taking in exchange other goods that it cannot so readily turn out. Smith did not expand these ideas at much length; but David Ricardo (1772–1823), the second great classical economist, developed them into the "principle of comparative advantage," a principle still to be found, much as Ricardo spelled it out, in every international trade text.

Simplified theory of comparative advantage. For clarity of exposition, the theory of comparative advantage is usually first outlined as though only two countries and only two commodities were involved, although it is by no means limited to such cases. Again for clarity, the cost of production is usually measured only in terms of labour time and effort; the cost of a unit of cloth, for example, might be given as two man-days. The two countries will here be A and B, and the two commodities wine and cloth. The labour time required to produce a unit of either commodity in either country is as follows:



Cost of Production (labour time)

	country A	country B
wine (1 unit)	1 man-day	2 man-days
cloth (1 unit)	2 man-days	6 man-days

As compared with country A, country B is productively inefficient. Its manpower needs more time to turn out a unit of wine or a unit of cloth. This relative inefficiency may result from differences in climate, in worker training or skill, or in the amount of available tools and equipment, or from numerous other possible reasons. Ricardo took it for granted that such differences do exist, and he was not concerned, for purposes of his comparative-advantage analysis, with their origins.

One's first inclination is to conclude that in such circumstances country B could not possibly compete with country A, and indeed that if trade were to be opened up between them, country B would be competitively overwhelmed. Ricardo insisted that this conclusion is false. The critical factor is that country B's disadvantage is less pronounced in wine production, in which its workers require only twice as much time for a single unit as do the workers in A, than it is in cloth production, in which the required time is three times as great. This means, Ricardo pointed out, that country B will have a *comparative* advantage in wine production. Both countries will profit, in terms of the real income they enjoy, if country B specializes in wine production, exporting part of its output to country A, and if country A specializes in cloth production, exporting part of its output to country B. Paradoxical though it may seem, it is preferable for country A to leave wine production to country B, despite the fact that A's workers can produce wine of equal quality in half the time that B's workers can do so.

To illustrate this conclusion, one might consider that country A's total labour force consists of 300 men. Disregarding the possibility of trade with B, A then has a choice of various daily outputs of cloth and of wine, depending on the number of men engaged in each of the two occupations. This range of choices is illustrated by the line DEF in the Figure. If all 300 men work on cloth production, total daily cloth output will be 150 units (point D in the diagram), since each such unit requires two days' labour. At the other extreme, if all labour works on wine production, daily wine output will be 300 units (point F). Any intermediate point on the line DEF is possible. Point E, for example, indicates 80 units of cloth produced daily (160 men so employed) and 140 units of wine (employing the other 140 men). DEF is country A's daily "production possibility" line. If it does not trade with country B and so can consume only what it produces itself, DEF will also be country A's "consumption possibility" line; it must choose some point thereon, depending on the preferences of its citizens for wine and cloth. DEF represents the limit of production and consumption possibilities; points above and to the right of DEF are unattainable.

Production possibilities for cloth and wine (see text).

In the right-hand diagram, the line GHJ has exactly the same production and consumption significance for country B—assuming its total force to be 600 men (so as to make it roughly equal to A in total output capacity). The position of the line GHJ reflects the fact that manpower in country B requires two days to produce a unit of wine, and six days for a unit of cloth.

One may consider that A and B are initially isolated from one another. Country A has chosen point E (80 cloth, 140 wine) as its production–consumption point. Country B has chosen point H (55 cloth, 135 wine). The opportunity of free trade between the two countries is now opened up. If both countries wish to attain the higher levels of production and consumption available to them through specializing on and trading of the product for which they have a comparative advantage, Country A will shift its entire labour force to cloth production, and Country B will shift its entire labour force to wine production. A possible barter rate (setting aside the detail of how this would be worked out) would be one cloth for two and one half wine. Country A might then choose to export 60 units of its total daily cloth output of 150, keeping the other 90 for domestic consumption. In exchange for this 60 cloth (at the 1-for-2½ exchange rate) it would receive 150 wine. A's real income position is thus improved in comparison with pretrade point E: cloth for domestic consumption has risen from 80 to 90, and wine consumption has risen from 140 to 150. Country B enjoys a similar gain. In comparison with pretrade point H, its daily cloth consumption has risen from 55 to 60, and wine consumption has risen from 135 to 150.

Price incentives to trade

The incentive to export and to import can be explained in price terms. In country A (before international trade), the price of cloth ought to be twice that of wine, since a unit of cloth requires twice as much labour effort. If this price ratio is not satisfied, one of the two commodities will be overpriced and the other underpriced. Labour will then move out of the underpriced occupation and into the other, until the resulting shortage of the underpriced commodity drives up its price. In country B (again, before trade), a cloth unit should cost three times as much as a wine unit, since a unit of cloth requires three times as much labour effort. Hence, a typical before-trade price relationship, matching the underlying real cost ratio in each country, might be as follows:

	country A	country B
Price of wine per unit	$5	£1
Price of cloth per unit	$10	£3

The absolute levels of price do not matter at all. All that is necessary is that in each country the ratio of the two prices should match the labour-cost ratio.

As soon as the opportunity of exchange between the two countries is opened up, the difference between the wine–cloth price ratio in country A (namely, 5:10, or 1:2) and that in country B (which is 1:3) provides the opportunity

of a trading profit. Cloth will begin to move from A to B, and wine from B to A. A trader in A, starting with a capital of $10 for example, would buy a unit of cloth, sell it in B for £3, buy 3 units of B's wine with the proceeds, and sell this in A for $15. (This example assumes, for simplicity, that costs of transporting goods are negligible or zero. The introduction of transport costs complicates the analysis somewhat, but it does not change the conclusions, unless these costs are so high as to make trade impossible.)

So long as the ratio of prices in country A differs from that in country B, the flow of goods between the two countries will steadily increase as traders become increasingly aware of the profit to be obtained by moving goods between the two countries. Prices, however, will be affected by these changing flows of goods. The wine price in country A, for example, can be expected to fall as larger and larger supplies of imported wine become available. Thus A's wine–cloth price ratio of 1:2 will fall. For comparable reasons, B's price ratio of 1:3 will rise. When the two ratios meet, at some intermediate level (in the example earlier, at 1:2½), the flow of goods will stabilize.

At a later stage in the history of comparative-advantage theory, the English philosopher and political economist John Stuart Mill showed that the determination of the exact after-trade price ratio was a supply-and-demand problem. At each possible intermediate ratio (within the range of 1:2 and 1:3), country A would want to import a particular quantity of wine and export a particular quantity of cloth. At that same possible ratio, country B would wish to import and export particular amounts of cloth and of wine. For any intermediate ratio taken at random, however, A's export–import quantities probably will not match those of B. Ordinarily, there will be just *one* intermediate ratio at which the quantities *do* correspond; that is the final trading ratio at which quantities exchanged will stabilize. (Once they have stabilized, there is no longer any profit in exchanging goods. Even with such profits eliminated, however, there is no reason why A producers should want to stop selling part of their cloth in B, since the return there is as good as that obtained from domestic sales. Any falloff in the amounts exported and imported would reintroduce profit opportunities.)

In the elementary labour-cost example used above, there will be *complete* specialization: country A's entire labour force will move to cloth production and country B's to wine production. More elaborate comparative-advantage models recognize "real" production costs other than labour (that is, the costs of land and of capital). In such models, part of country A's wine industry may survive and compete effectively against imports, as may also part of B's cloth industry. The models can be expanded in other ways: to take account of more than two countries, or more than two commodities, and of transport costs. The essential conclusions, however, remain those obtained from the elementary model used above, so that this model, despite its simplicity, still provides a workable outline of the theory. (It should be noted that even the most elaborate comparative-advantage models continue to rely on certain simplifying assumptions without which the basic conclusions do not necessarily hold. These assumptions are discussed below.)

As noted earlier, the effect of this analysis is to correct any false first impression that low-productivity countries are at a hopeless disadvantage in trading with high-productivity ones. The impression is false, that is, if one assumes, as comparative advantage theory does, that international trade is an *exchange* of goods between countries. It is pointless for country A to sell goods to country B, whatever its labour-cost advantages, if there is nothing that it can profitably take back in exchange for its sales. With one exception, there will always be at least one commodity that a low-productivity country such as B can successfully export. Country B must of course pay a price for its low productivity, as compared with A; but that price is a lower per capita domestic income and not a disadvantage in international trading. For trading purposes, absolute productivity levels are unimportant; country B will always find one or more commodities in which it enjoys a *comparative* advantage; that is, a commodity in the production of which its absolute disadvantage is *least*. The one exception is that case in which productivity ratios, and consequently pretrade price ratios, happen to match one another in two countries. Such would have been the case had country B required four man-days (instead of six) to produce a unit of cloth. In this particular circumstance, there would be no incentive for either country to engage in trade, and no gain from trading. In a two-commodity example such as that employed, it might not be unusual to find matching productivity and price ratios. But as soon as one moves on to cases of three and more commodities, the statistical probability of encountering precisely equal ratios becomes very small indeed.

The major argument derived from comparative-advantage analysis is that each country should specialize in those occupations in which it is relatively efficient; it should export part of that production and take in exchange those goods in whose production it is, for whatever reason, at a comparative disadvantage. The theory of comparative advantage thus provides a strong argument for free trade—and indeed for a laissez-faire attitude with respect to trade. The supporting argument is simple: specialization and free exchange among nations yield higher real income for the participants.

The fact that a country will enjoy higher real income as a consequence of the opening up of trade does not mean, of course, that every family or individual within the country must share in that benefit. Producer groups affected by import competition obviously will suffer, to at least some degree. Comparative-advantage theorists concede that free trade would affect the relative income position of such groups, and perhaps even their absolute income level. But they insist that the special interest of these groups clashes with the total national interest, and the most that they are usually willing to concede is the possible need for temporary protection against import competition, in order that the persons affected may have sufficient time to move to another occupation.

In actual fact, of course, nations often maintain permanent tariff and similar protectionist measures. The reasons for this clash between comparative-advantage reasoning and particular national policies are discussed below.

Sources of comparative advantage

As already noted, the British classical economists made no attempt to explain *which* commodities a country would export or import. They simply accepted the fact that productivity differences do exist between countries, and they explored the consequences of that fact. Thus far, the only systematic attempt to explain the background of relative productivity conditions has been that of the Swedish economists Eli Heckscher and Bertil Ohlin. Ohlin's book, *Interregional and International Trade*, built on the foundations of Heckscher's work, was first published in 1933.

According to the Heckscher–Ohlin theory, comparative-advantage positions derive primarily from differences in each nation's endowment of productive inputs—that is, land, labour, and capital. The United States, for example, possesses a relatively large quantity of capital goods—relative to its own stock of land and of labour and relative also to the proportions of land, labour, and capital possessed by other nations. Any given commodity, so it is asserted in Heckscher–Ohlin analysis, typically requires for efficient production a given "mix" of inputs. A country will have a comparative advantage in the production and sale of a commodity if and when its endowment of factors exists in the proportions needed for its production. Some commodities, for example, are considered to be "capital intensive"—that is, their manufacture demands the use of relatively large amounts of capital equipment. A country like the United States, possessing proportionately large quantities of capital (again, relative to other countries), can be expected to have a comparative advantage in such capital-intensive commodities. Other products will be labour intensive; still others, land intensive. Thus, comparative-advantage positions are parcelled out according to relative factor endowments. Ohlin suggested one or two other sources of trading advantages, but these he treated as being of minor importance.

Evaluation of international trade theory. International trade analysis, like the greater part of economic theory, is strongly deductive in its construction. Attempts to test the conclusions of this theory empirically are still in their infancy. Some attempts have been made to test Heckscher–Ohlin theory by examining the composition of actual exports and imports. The results (although far from conclusive) suggest that United States exports are more labour intensive than United States imports. This is in flat contradiction of the Heckscher–Ohlin theory, which says that the United States must export capital-intensive commodities and import labour-intensive ones, since it possesses a relatively large amount of capital and a relatively small amount of labour (as compared with the situation in most other countries). It has been suggested that differences in labour productivity might explain this contradiction. The productivity of U.S. labour is so much higher than elsewhere that its relative scarcity is more than compensated for.

If labour productivities vary markedly among countries, then the *size* of the labour force is not necessarily an important factor in evaluating its productive competence; that is, size is not really as important a factor in the distribution of comparative-advantage positions as the Heckscher–Ohlin theory suggests. There is, moreover, probably no room in Heckscher–Ohlin theory for any concept of "corrected size," size of the labour force adjusted up or down to allow for markedly high or low productivity. *Any* trade pattern, no matter how violently in opposition to Heckscher–Ohlin reasoning, could always be made to conform to that reasoning by making a suitable after-the-event "productivity correction." If *any* trade pattern is so explainable, then Heckscher–Ohlin analysis is reduced from a theory to a tautology, losing all predictive power.

Most international trade economists still cautiously recognize the Heckscher–Ohlin doctrine—possibly because of the lack of any coherent alternative—but it must be considered as a speculative and unverified hypothesis.

Simplifying assumptions of comparative-advantage analysis

The earlier comparative-advantage principle rests on a more secure analytic base. It cannot, however, be viewed as a comprehensive theory of international trade; it is instead an outline of some basic truths and a refutation of some elementary fallacies. To bring out these truths, the analysis makes some considerable simplifying assumptions. The more important of these assumptions are the following: (1) Full employment is assumed to prevail in both or all countries at all times; there are no problems of unemployment or recession. (2) Within each country, resources are assumed to be "occupationally mobile"; that is, in terms of the example earlier employed, the labour, capital, and land employed in wine production can move to cloth production or vice versa, if required to do so by competitive pressures. (3) The exchange of goods is treated as a *balanced* exchange—indeed, almost to the point that it might be a barter exchange. No consideration is given to the special problems arising out of balance-of-payments surpluses or deficits or out of the maintenance of a particular exchange rate. (4) Each country is assumed to have a *given* resource stock and a *given* technology.

The use of such assumptions is necessary but unfortunate. It is necessary because without them it would be impossible to bring out the fundamental truth of comparative-advantage positions. It is unfortunate because it conveys the impression that comparative-advantage theorists wish to brush aside as inconsequential many of the issues with which a nation must sometimes deal in its policies toward international trade. Nations have been known, for instance, to try to cope with unemployment by erecting barriers to international trade; or they have maintained such barriers because the occupational mobility of resources (their transfer to a different employment) is sometimes a slow and difficult process.

A more fundamental objection to comparative-advantage theory is its neglect of the fact that the composition and development of a nation's stock of productive resources may be changed by international trade. Comparative-advantage theory treats the resource stock as *given*. In point of fact, as a country becomes deeply involved in international trade, its resource stock (the size and nature of its capital stock, the training of its labour force) grows and changes in order to meet the particular demands of that trade. Comparative-advantage theory says that a nation's international trade situation—the pattern of its exports and imports—is what it is because of the nature of its resource supply, but sometimes one may say with equal truth that the nation's resource supply is what it is because of its involvement in international trade.

Insofar as the purpose of the analysis is to explain the gains in real income that accrue from the opening up of free international trade, the assumption of a given resource supply is convenient and defensible. If the intent, however, is the more ambitious one of furnishing a statement of the nature and consequences of international trade, the assumption is less satisfactory. Comparative-advantage theory is probably best viewed as simply an outline of some fundamental principles of international exchange. A more sophisticated theory of such exchanges remains to be built on this foundation.

STATE INTERFERENCE IN INTERNATIONAL TRADE

Methods of interference. Regardless of what comparative-advantage theory may say about the virtues of unrestricted trade, all nations interfere with international exchanges to at least some degree. Tariffs may be imposed on imports—in some instances making them so costly as to bar completely the entry of the good involved. Quotas may limit the permissible volume of imports. State subsidies may be offered to encourage exports. Money-capital exports may be restricted or prohibited. Investment by foreigners in domestic plant and equipment may be similarly restrained.

These interferences may be simply the result of special-interest pleading, for as already noted, particular groups suffer as a consequence of import competition. Or a government may impose restrictions because it feels impelled to take account of factors that comparative advantage sets aside. It is of interest to note that insofar as goods and services are concerned, the general pattern of interference follows the old mercantilist dictum of discouraging imports and encouraging exports.

Reasons for interference. The more important considerations that prompt governmental regulation are summarized below.

Revenue. Underdeveloped nations in particular often lack the institutional machinery needed for effective imposition of income or corporation taxes. The governments of such nations may then finance their activity by resort to tariffs on imported goods, since such levies are relatively easy to administer. The amount of tax revenue obtainable through tariffs, however, is always limited. If the government tries to increase its tariff income by imposing higher duty rates, this may choke off the flow of imports and so reduce tariff revenue instead of increasing it.

Protection of domestic industry. Probably the commonest argument for tariff imposition is that particular domestic industries need tariff protection for survival. Comparative-advantage theorists will of course argue that the industry in need of such protection ought not to survive and that the resources so employed ought to be transferred to occupations having greater comparative efficiency. The welfare gain of citizens taken as a whole would more than offset the welfare loss of those groups affected by import competition; that is, total real national income would increase. An opposing argument would be, however, that this welfare gain would be widely diffused, so that the individual beneficiaries might not be conscious of any great improvement. The welfare loss, in contrast, would be narrowly and acutely felt. Although resources *can* be transferred to other occupations, just as comparative-advantage theory says, the transfer process is sometimes slow and painful for those being transferred. For such reasons, comparative-advantage theorists rarely advocate the immediate removal of all existing tariffs. They argue instead against further tariff increases—since increases, if effective, attract still more resources into the wrong occupation—and they press for gradual reduction of import barriers.

Unemployment. A variant of the industry-protection argument is that tariffs or quotas are needed to maintain domestic employment—particularly in times of recession. Today, there is near-unanimity among economists that proposals to remedy unemployment by means of tariff increases are misguided. Insofar as a higher tariff is effective for this purpose, it simply "exports unemployment": the rise in domestic employment is matched by a drop in production in some foreign country. That other country, moreover, is likely to impose a retaliatory tariff increase. Finally, the tariff remedy for unemployment is a poor one because it is usually ineffective and because more suitable remedies are now available. Today it is recognized that unemployment is far more efficiently dealt with by the implementation of proper fiscal and monetary policies.

Economic development. The comparative-advantage principle supports, as indicated earlier, free-trade and laissez-faire policies. Ordinarily, a mature and developed country, with widely diversified and self-confident industries, has no great difficulty in accepting the validity of this principle, with the exception of those producers who are afflicted by import competition.

Considerations are quite different for an underdeveloped country—that is, a country with a low per capita income, with limited industry, and typically relying on the export of one or two agricultural or mineral primary products. Today, all such underdeveloped countries are forced to direct their policies toward growth and higher real living standards. Progress is commonly viewed in terms of industry growth and diversification. These countries, however, are unlikely to think in laissez-faire terms. The less privileged nations may vary in the extent of their belief that growth and development can and should be fostered by governmental action, but that some such action is needed is almost universally accepted. The leaders of such countries are thus inclined to regard laissez-faire comparative-advantage theory as an apology for the status quo devised by the more affluent countries. Many underdeveloped nations are thus in a painful position: they depend on their exchanges with richer countries for survival, and yet they suspect that this foreign trade is a form of exploitation, whether so intended or not, that keeps them in a subservient position as "hewers of wood and drawers of water" and that prevents the development of their domestic industries.

Weakness of comparative-advantage theory

Unfortunately, comparative-advantage theory is deficient on precisely this matter of the growth and expansion of resources. As noted earlier, the concern of this theory is with the best possible use of a *given* stock of industrial and other resources. It is thus difficult to resolve the issues involved. In general, the poorer nations have had limited success in the attempt to foster the development of their domestic industries by means of restrictions on foreign trade, and most economists are disdainful of the "infant industry" argument that tariffs and similar protection are effective means of generating industrial growth. A comprehensive evaluation of such attempts at development must await a more complete theory of the sources and effects of international trade.

National defense. A common appeal made by an industry seeking tariff or quota protection is that its survival is essential in the national interest: its product would be needed in wartime, when the supply of imports might well be cut off. The verdict of economists on this argument is fairly clear: the national-defense argument is frequently a red herring, an attempt to "wrap oneself in the flag," and insofar as an industry *is* essential, the tariff is a dubious means of ensuring its survival. Essential industries ought instead to be given a direct subsidy to enable them to meet foreign competition, with explicit recognition of the fact that the subsidy is a price paid by the nation in order to maintain the industry for defense purposes.

Autarky, or self-sufficiency. Many demands for protection, whatever their surface argument may be, are really appeals to the autarkic feelings that prompted mercantilist reasoning. (Autarky is defined as the state of being self-sufficient at the level of the nation.) A proposal for the restriction of free international trade can be described as "autarkic" if it appeals to those half-submerged feelings that "we" (citizens of the nation involved) form a community sharing a common welfare and common interests, whereas "they" (foreigners) have no regard for such welfare and interests and might even be actively opposed thereto. And it is quite true that a country that has become heavily involved in international trade has given hostages to fortune: a part of its industry has become dependent upon export markets for income and for employment. Any cutoff of these foreign markets (brought about by recession abroad, by the imposition of new tariffs by some foreign country, or by numerous other possible changes) would be acutely serious; and yet it would be a situation largely beyond the power of the domestic government involved to alter. Similarly, another part of domestic industry may rely on an inflow of imported raw materials, such as oil for fuel and power. Any restriction of this import inflow could have the most serious consequences. The vague threat implicit in such possibilities often results in a yearning for autarky, for national self-sufficiency, for a life free of dependence on the hazards of the outside world.

In point of fact, no nation in today's world, no matter how rich and varied its endowment of resources, could really practice self-sufficiency, and attempts in that direction could produce sharp drops in real income. Nevertheless, protectionist arguments—particularly those made "in the interests of national defense"—often draw heavily on the strength of such autarkic sentiments.

Balance-of-payments difficulties. Governments may interfere with the processes of foreign trade for a reason quite different from those thus far discussed: shortage of foreign exchange. Today, most governments try to maintain fixed exchange rates between their own currencies and those of other countries. Even if not absolutely fixed, the exchange rate is ordinarily allowed to fluctuate only within a narrow range of values. Fixed exchange rates are held to facilitate trade because they eliminate the uncertainty arising out of a fluctuating rate. If the rate fluctuates, either the exporter is uncertain as to the revenue he will earn from his sale or else the importer is uncertain as to what his purchase will cost him in terms of domestic currency.

The maintenance of a fixed exchange rate requires each government to keep a foreign exchange reserve, typically maintained in gold or in a major currency such as the United States dollar or the British pound sterling. This reserve is drawn upon whenever the country's total imports outrun its total exports in value. An import surplus means that the demand for foreign currencies (to pay for imports) outruns the supply of foreign currencies (earned through exports).

If balance-of-payments difficulties arise and persist, the government's foreign-exchange reserve will run low. In a crisis, this situation may force the government to devalue the nation's currency; that is, to give it a new and lower value in the foreign exchange markets. But typically, before being driven to this extremity, it will try to redress the balance by restricting imports or encouraging exports, in much the old mercantilist fashion.

The threat of trade restriction prompted by reserve shortages has grown more acute in recent years. The total volume of international transactions has risen steadily, but there has not been a corresponding increase in the supply of international reserves. International debate still goes on as to whether the needed reserve increase should be furnished by increasing the price of gold, which would increase the reserve power of any given physical quantity of gold; by the creation of "paper gold" through the International Monetary Fund or a similar agency; or by greater resort to the use of a national currency such as the pound sterling or the dollar. Meanwhile, nations are inclined to hoard their reserves: they regard any depletion with alarm while welcoming any increase. Thus they are drawn toward the old mercantilist policy of reserve accumulation, even though they know that it is not in the interest of expanded international trade that they do so. (For a more detailed discussion of this topic, see EXCHANGE AND PAYMENTS, INTERNATIONAL.)

"Paper gold" and other suggested remedies

Foreign ownership of domestic industry

A company that finds itself barred from an attractive foreign market by tariffs or quotas may be able to leapfrog the barrier simply by establishing a manufacturing plant within that foreign country. This policy of foreign plant investment has expanded enormously since the close of World War II. United States companies have taken the lead, investing particularly in western Europe, Canada, and South America. Industry in other developed countries has followed a similar pattern—some foreign companies establishing plants within the United States as well as in other areas of the world.

The governments of countries subject to this new investment find themselves in an ambivalent position. The establishment of new foreign-owned plants may mean more than simply the creation of new employment opportunities and new productive capacity; it may also mean the introduction of new technologies and superior business-control methods. But the government that welcomes such benefits must also expect complaints of "foreign control," an argument that will inevitably be pressed by domestic owners of older plants who fear a new competition that cannot be blocked by tariffs. Many governments are still wrestling with this problem, particularly insofar as investment by U.S. firms is involved. Countries such as Great Britain and Canada have been liberal in their admissions policy; others, notably Japan, impose tight restriction on foreign-owned plants.

PATTERNS OF TRADE

Degrees of national participation. Nations vary considerably in the extent of their foreign trade. As a very rough generalization, it may be said that the larger a country is in physical size and population, the less its involvement in foreign trade, mainly because of the greater diversity of raw materials available within its borders and the greater size of its internal market. Thus the participation of the United States is relatively low, its export and import totals each being just over 4 percent of its gross national product, and that of the U.S.S.R. even lower. The U.S. gross national product, however, is so immense by world standards that the United States still ranks as one of the world's most important trading countries. Some of the smaller countries of western Europe (such as The Netherlands) have export and import totals that approach 40 percent of their gross national products.

Trade among developed countries. The greatest volume of trade occurs among the developed, capital-rich countries of the world, especially among the industrial leaders known as the "Group of 10" (Belgium, Canada, France, Germany, Italy, Japan, The Netherlands, Sweden, the United Kingdom, and the U.S.). Generally, as a country matures economically its participation in foreign trade grows more rapidly than its gross national product.

Trade within the EEC

The European Economic Community (EEC, or Common Market) affords an impressive instance of the gains to be derived from freer trade. In economic terms, the EEC is simply a plan for unrestricted movement of goods, labour, and capital across the boundaries of its member countries (Belgium, France, Italy, Luxembourg, The Netherlands, and West Germany). A major part of the increases in real income in EEC countries is almost certainly attributable to the removal of trade barriers. The EEC's formation cannot, however, be interpreted as reflecting an unqualified dedication to the free-trade principle. EEC rules require member countries to maintain a common and often substantial tariff against goods from outside the Community.

Trade among developed and underdeveloped countries. Difficult problems frequently arise out of trade between developed and underdeveloped countries. Many less-developed countries are tropical, frequently relying heavily for income upon the proceeds from export of one or two crops, such as coffee, cocoa, sugar. Markets for such goods are highly competitive (in the sense in which economists use the term *competitive*)—that is, prices are extremely sensitive to every change in demand or in supply. Prices of manufactured goods, the typical exports of developed countries, are commonly much more stable. Hence, as the price of its export commodity fluctuates, the tropical country experiences large fluctuations in its "terms of trade," the ratio of export prices to import prices, often with painful effects on the domestic economy. With respect to almost all important primary commodities, efforts have been made at price stabilization and output control. These efforts have met with varied success.

Comparable problems arise when the underdeveloped country exports a mineral such as petroleum or copper. The initiative in developing such a resource is often taken by a foreign company from a developed country that owns (in part if not in full) the extracting capital facilities. Particularly since the mineral resource is exhaustible, charges of exploitation are common. The matter is a continuing source of political strife and may on occasion lead to expropriation of the mineral properties.

Several underdeveloped countries have joined in creating organizations for the promotion of trade between themselves. Notable examples include the Central American Common Market (1961), the Latin American Free Trade Association (1961), and the Common Afro-Malagasy-Mauritanian Organization.

Soviet foreign trade. The Soviet Union's involvement in foreign trade, measured as before by comparing exports or imports against gross national product, is even lower than that of the United States. The U.S.S.R. is not in general an important trader in world markets, but it has made occasional large-scale entries, such as its grain purchases during years of domestic crop shortage in the 1960s and early 1970s.

Since the 1917 Revolution, Soviet policy has clearly been influenced by autarkic feelings, further reinforced by its suspicions of the capitalist world and by its strong desire for centrally directed planning. Today, the U.S.S.R. appears to be showing a greater interest in expanded trade connections, doubtless because of growing industrial maturity.

The attitude of the U.S.S.R. toward foreign trade was forced to undergo some change when that country acquired influence over the eastern European countries after World War II. It established the Council for Mutual Economic Assistance (Comecon) to direct trade with and among its satellite neighbours. Comecon, however, appears to be primarily a device for implementing and integrating central development plans among member countries—unlike the European Common Market, which was planned to facilitate the unrestricted movement of goods and productive inputs. Exchanges among Comecon countries do not appear to be directed by the same considerations of price and quality that govern trade in the Western world; at any rate, the patterns of Comecon trade are often difficult for an outsider to interpret. Some satellite countries, it appears, would willingly trade more freely with the West, but they are restrained by demands that they first of all fulfill their obligations to the Comecon organization.

Comecon

(1776); DAVID RICARDO, *On the Principles of Political Economy and Taxation* (1817); JOHN STUART MILL, *Principles of Political Economy,* 2 vol. (1848); and BERTIL G. OHLIN, *Interregional and International Trade* (1933, rev. ed. 1967). Particularly useful international trade textbooks include: C.P. KINDLEBERGER, *International Economics,* 4th ed. (1968); D.A. SNIDER, *Introduction to International Economics,* 4th ed. (1967); and P.B. KENEN, *International Economics,* 2nd ed. (1967).

(R.R.)

Trademark Law

A trademark is a mark or a sign that distinguishes the goods of one manufacturer or trader from those of another. The sign must be one that can identify a product as originating from one source and, thus, distinguish it from those coming from another source. It may be a word or a device or combination of both. It may be an invented word like Kodak for cameras, a coined word like Coca-Cola for a soft drink, a fanciful word like Arpège ("arpeggio" in music) for a perfume, or a common word like Volkswagen ("people's car") for an automobile. And it may also

be a word that is originally a descriptive word but by continued and exclusive use by a manufacturer or trader becomes distinctive of his goods—for instance, Dry Ice.

What the law everywhere does require is that the mark must be "distinctive"; *i.e.*, that it allows the owner to communicate symbolically with the public in identifying his product and in assuring them that they are getting his product when the mark appears thereon. The concept of distinctiveness is not interpreted uniformly in the various parts of the world. Moreover, it has been expanded as a result of the evolution of the conditions of trade and new needs of protection. Particularly, there is now recognition and protection of so-called service marks, which identify and distinguish not products but services offered or performed by persons. The most familiar of these are marks used to identify transportation services, communication services, cleaning services, hotel services, and the like.

There are also collective or association marks, which are trade or service marks used by an association of producers or traders or by a cooperative or any other collective group. These serve to distinguish the products or services of the members of the group or to indicate membership in a union, association, or other organization.

In addition, there are the so-called certification marks used in connection with goods of persons other than the owner of the mark to certify regional or other origin, material, mode of manufacture, or other characteristics. The principles that apply to trademarks used on goods apply generally to the other kinds of marks as well.

An international definition

There has always been a felt need for an international definition that could be agreed upon by the various countries. One such was adopted in 1963 by the International Association for the Protection of Industrial Property, which describes the mark generally as "capable of distinguishing the products or services of a person or of a group of persons. The distinctive character of a mark, in respect of the goods or services designated by it, arises from the nature of the sign or of the use which has been made of it." What follows is an enumeration of a number of things that, if distinctive, can serve as trademarks: words or groups of words, letters, numerals, devices, names, the shape or other presentation of products or their packages, colour combinations with signs, combinations of colours, and combinations of any of the enumerated signs. The International Bureau for the Protection of Industrial Property established in Geneva has prepared a model trademark law for developing countries that defines a trademark in general terms as "any visible sign intended to distinguish the goods or services of one enterprise from those of another."

GENERAL CONSIDERATIONS

The purposes served by trademarks. The observation made by an American judge asserts that "it is not settled whether a trademark is to be primarily regarded as protecting the trademark owner's business from a species of unfair competition or as protecting the public from imitations." The truth, of course, is that a trademark purports to protect both, though often the law or the tribunals in interpreting and applying the law may appear to give primary weight to one or the other. Trademark law in fact looks upon four classes of interests and claims: the interest of the manufacturer or merchant who adopts and uses a trademark to identify or distinguish the goods he puts on the market to prevent the diversion of prospective customers; the interest of competitors who wish to prevent undue monopolization of effective symbols or signs or expressions giving information about the goods; the interest of the consumer not to be deceived or confused about the goods he wishes to buy; and the general public interest, which would be seriously affected if producers of goods could not ensure the benefit of their labour and investment and if consumer deception were tolerated.

The competing interests

Main characteristics of trademark. The primary function of a trademark is to identify the origin of the article to which it is affixed. This is the basic difference between a patent and a trademark. The purpose of the patent is not to indicate origin of the product but to protect a new product or a new process by which the product is made irrespective of the origin. A trademark is not necessarily an invention. It may sometimes be forced upon the producer by the public. A certain fortuitous sign may be liked by the public and eventually become a trademark, although it was not so intended at first. The trademark need not be novel. It may be in use in one industry and subsequently be adopted in another. A mark that has been a trademark in the past and abandoned may be readopted and used again as a trademark.

Guarantee of quality

Besides the primary function of indicating origin, the trademark has certain additional functions. One of these is to guarantee the quality of the products bearing the mark. The public may not know or care about the identity of the producer of a commodity but the mark identifies for them goods associated with certain experiences or assumed characteristics in composition, ingredients, quality, and the like. It gives assurance that goods bearing the same trademark at the next purchase will have the same characteristics. This is called the guarantee function of the trademark. It means also that the owner need not actually participate in the production of the goods. It is sufficient if he exercises control over the quality of the goods.

The source of products bearing a trademark is sometimes uncertain, varied, or fluid. Traders' trademarks may be affixed on products from divergent sources, and manufacturers' trademarks may be affixed on products made for the manufacturers in whole or in part by various suppliers or subcontractors.

The guarantee function of trademarks is particularly relevant when they are used in different territories since the owner of a trademark, to satisfy local requirements of the public's tastes or preferences, may not sell the identical goods in each area. Importation of the differing products of one country into the territory of another may interfere with the trademark's guarantee of quality and may injure the goodwill of the owner as well as deceive the expectations of the public. The same guarantee function is involved in cases of licensing trademarks where the law requires control and supervision by the owner of the trademark with respect to the methods of manufacture and the finished goods.

The mark also performs an advertising function. Once it has acquired goodwill and consumer response because it symbolizes real or assumed value of the product concerned, it constitutes a kind of advertisement. By constant repetition the mark is impressed on the consumer's mind to the point where its mere display suffices to remind the public of the standards or other properties of the product with which the owner has permeated the market.

Relationship of trademark to unfair competition. Trademarks have their origin in the rule that no man has the right to put up his goods for sale as the goods of another person, either by direct or indirect representation. By using the trademark of a rival person, even without making a direct false representation to the purchaser, the seller, in effect, tells him a lie and commits the tort of passing off, or unfair competition. A trademark is only one of the badges or indicia by which the trade of a person and the goods he deals in are identified with him and distinguished from the trade and goods of another. There are numerous other indicia, such as, the name under which one trades, the manner and packaging in which the goods appear on the market, the showing of prizes or medals that have been bestowed for the particular goods, and marketing or advertising devices.

How far the use of particular indicia, other than a trademark, does or does not amount to representing one's goods as those of someone else must always be a question of evidence before the courts. The growth and development of the concept of unfair competition rests upon notions of civil responsibility, principles of honest customs in trade, and disapproval of questionable practices. All such attitudes, of course, depend on the degree of community pressure for the suppression of unfair conduct in business.

Trademark law, while a part of the law of unfair competition deriving from the fundamental rule against passing off, has gradually crystallized in the recognition of trademarks as property. Since this law grants the trader, who

uses a mark to identify his goods and distinguish them from others, an exclusive right in the use of such mark, this right exists quite apart from a legal inquiry as to passing off. Legislation everywhere that defines and protects this property has given the trademark the characteristic of a special monopoly right in the sense that it prevents its use for another's similar goods in exactly the same way as it protects any other kind of private property. Thus the trademark law, within more or less fixed technical boundaries, prohibits acts that might not be calculated to deceive. Using the identical trademark of a registered proprietor of a trademark for identical or similar goods is prohibited regardless of whether such use is likely to deceive purchasers.

On the other hand, the security given by the law for the recognition and protection of trademark rights, is given in exchange for compliance with certain technical formalities, and failure to comply with such requirements deprives the claimant of the special protection of the trademark law. In such cases, the trademark owner may still be protected by the unfair competition law if the use of his trademark by another is likely to result in passing off by confusing the purchaser. The unfair competition law is an all-inclusive basic concept of which the law of trademarks is a particular branch. This is another way in which trademarks differ from patents. An inventor of a new product or a new process who has not obtained a patent cannot stop another person from making or using the same product or process, nor can he claim unfair competition against the second party. But the owner of a trademark who failed to register his mark may still be protected against its use by another under the conditions of a passing-off action.

This concept of the trademark law as a part of the law of unfair competition, while true of the United States, British-law countries, and a number of civil-law countries, is not universal. In many other countries, for example those of Latin America, there is either no unfair competition law at all or such law as there is exists apart from trademark law and is limited in application to specified acts of deception or fraud through other means. In such countries the one way to protect a trademark against unauthorized use by another is by registration as provided for by law.

THE SUBSTANTIVE LAW OF TRADEMARKS

Acquisition of trademarks. The value as well as the ownership of a trademark springs from its adoption and use with respect to the products it serves to distinguish and individualize. The law does not protect the material sign or mark itself as a creation or invention of the user but the value and the use of that sign or mark in connection with the business in the goods concerned. Because of this, the *right* in a trademark was, until recently, generally acquired by prior adoption and use, registration being only declaratory of *property* in a trademark. It followed that the registered proprietor of a trademark was only the prima-facie owner and anyone could show a prior use of such trademark and cause the cancellation of the registration. Generally speaking, this is no longer true. There remain comparatively few countries where registration of a trademark is merely declaratory of property therein.

In the United States the situation is a special one. Congress has no power to legislate generally on the subject of trademarks, and protection rests fundamentally on the common law. A trademark right is created by use of a trademark, and the common law protection attaches to such right, irrespective of registration. Federal registration gives the registrant only certain procedural advantages such as a presumption of ownership, a right to sue in the federal courts, a right to claim treble damages in case of willful infringement, and the right to claim protection in foreign countries in certain situations. The only other country where the law is the same is the Philippines, which derives its trademark law from the United States. In Canada, which has a legal position derived partly from British law and partly from American law, actual use of a mark is a condition of registration. In a few civil-law countries right in a trademark may be acquired by user apart from registration, but even in those countries this rule has been mitigated. In Belgium, Luxembourg, and The Netherlands, where, until recently, use alone was the source of ownership, the position is now changed under the unitary Benelux law, which establishes registration as the source of ownership. In Great Britain and the nearly 40 other jurisdictions that derive their trademark law from British law, the common law has been modified and registration gives substantive rights.

Use versus registration

Use alone as a basis of ownership in trademarks thus has been abandoned today in the vast majority of countries. This is explained by modern commercial conditions under which the market for any given industry or commercial enterprise is no longer confined within definite boundaries. An industry or trade may start with a mark extending over a small part of a country's territory, then extend to the whole territory of that country, and later reach any number of foreign countries. Under these circumstances the need has arisen for an enterprise adopting and using a new mark to give notice of its claim in a form that will protect its market beyond the boundaries in which notice is given by mere use of the mark. This not only provides protection for the person adopting a new mark but gives security to other manufacturers or traders who may consult the register to avoid adopting a trademark already in use. With prior use and adoption for the whole territory predicated on the registration of the trademark, registration may well be considered as the basis of ownership. The law may require the person who first adopts and uses the trademark in connection with his business to register it; unless he does so, he cannot complain of anyone else registering or using the same trademark since he failed to give notice to the public of his claim. Unless the later user of the mark acts fraudulently, he acquires a property right by registering the trademark himself. This is the law in a large number of countries today.

A position that entirely disregards rights created by use and grants ownership to the person who first applies for registration could result in injustice and in deception of the public. This has encouraged the development of a third system for acquisition of property in trademarks, which is particularly appropriate with respect to their international protection. In practice, the requirement of prompt registration in every country is nearly impossible in many cases. There must necessarily be a waiting period for a commercial or industrial enterprise to consider whether it will be able to do sufficient business with a certain trademark in a particular foreign country to require registration. The enterprise may have to consider what the prospects are of its exporting goods to a foreign country. It may have to test the market by trial shipments, engage in publicity, seek agents and distributors, etc. This is equally true in a single country, where the enterprise may adopt and use different trademarks in connection with several products. It may be preferable to test the market for a particular product before applying to register the mark. Or the trademark may not be registrable at first until it acquires distinctiveness by use. For these reasons a system has been developed under which registration gives ownership in a trademark only when uncontested for a stated period of time, during which the prior user may have his claim of ownership enforced.

A prior user has two remedies. He may file opposition against an application for registration of a mark by showing that he had a prior user right in the same or a similar mark. But in such cases he must generally show not only use, but that he has acquired a reputation as a user that would make the use of the applicant's mark deceptive or confusing and therefore disentitled to protection in a court of justice. Or else he must show that the mark applied for is his mark and that the applicant is therefore acting in defraud of his rights or that the applicant is not entitled to claim proprietorship of the mark. If the prior user fails to oppose registration in the name of another, he may still move to cancel the registration as an aggrieved person, but if he fails to do so within seven years from the date of registration, such registration becomes conclusive against him. This is the legal position today in all British-law countries, and, with some qualifications, represents the general principle elsewhere. In most other countries

the term within which a registration becomes incontestable as against a prior user is even shorter, between three and five years.

Even in the United States, the Lanham Trademark Act of 1946 introduced the principle of incontestability of registration after five years, although in practice there are many conditions and limitations. In France as well, where formerly ownership of a trademark was acquired by the user and an adverse registration could be cancelled at any time by a prior user, the law has changed in recent years. Ownership is now acquired by registration uncontested within five years, and it may be contested only by a person who has used his mark in France to such an extent that it has become well known to the public.

Distinctiveness of the mark

Registrability. A corollary to the importance of registration is that the mark must be such that it is entitled to valid registration. The primary requirement, of course, is that the mark must be distinctive, but in some countries certain subject matter cannot be registered as a trademark regardless of distinctiveness. In most important commercial countries, however, it is now provided that a mark that may not have been distinctive at the time of its adoption and first use may become distinctive if used exclusively for a sufficiently long time to have come to identify and distinguish the goods of the proprietor. This is particularly the case with respect to descriptive terms or subject matter that is not primarily distinctive, such as letters, numerals, colours, devices, and the general appearance of products or containers. The procedure for proving distinctiveness of such matters differs in the various countries, but the basic consideration is whether the mark has acquired what is called secondary meaning. This means that while the primary meaning of a certain trademark is, for instance, descriptive, the mark has developed a new secondary meaning designating and identifying certain goods as originating from a certain source.

In a number of countries the question of whether a trademark is distinctive or has acquired distinctiveness is not examined at the time application is filed for registration. The mark is registered and then it is up to the court to decide in a given case that may be brought before it whether the mark was validly registered. In many other countries the patent office examines the question of registrability both with regard to objective compliance with the legal requirements of registration, and with regard to prior registered marks of other persons. In most of these countries the decision of the patent office to allow the application for registration is published, allowing any interested person to oppose the application and ask that it be refused. This is the system that operates in the United States and in British-law countries.

Infringement. Ownership of a trademark confers both the positive right to use it and the negative right of precluding third parties from interfering with the proprietor's exclusive right. Interference with this exclusive right constitutes what is technically called infringement, which is one of the most important problems in the protection of trademarks. The issue as to whether or not there is infringement arises under various circumstances: (1) at the time of application by a newcomer to register a trademark and the registrar or the previous owner objects that such mark is infringing, (2) when an action is brought for cancellation of a registration, or rectification of the register to expunge a junior mark on the ground that it infringes a senior one, (3) in an infringement action when the plaintiff claims that the defendant is wrongfully using his mark.

In all of these instances the question is whether the resemblance to the plaintiff's mark is likely to deceive or confuse purchasers of the particular goods. Notwithstanding differences of law in the various countries, criteria for making such a judgment are generally alike. The general impression of the ordinary purchaser should serve as a guide. The mark should be looked at as a whole, since the ordinary purchaser will not stop to dissect it; the similarities rather than the differences should be considered. The two marks should not be viewed side by side, since the ordinary purchaser relies only upon his memory of the plaintiff's mark. Also the nature of the goods plays a role in the judgment; if the value of the goods concerned is high, the purchaser may be discriminating and cautious in looking at a mark, while in the case of common and inexpensive goods, no great thought is given. If purchasers are children or illiterate persons or foreign to the language of the mark, any doubt as to similarity should be resolved in favour of the owner of the old mark as against a newcomer. If a trademark is one combining a verbal and a figurative element, the verbal element is deemed more important because it is this that the public ordinarily recognizes and calls for. But there are exceptions to this rule when the figurative element dominates a trademark by its use, colour, etc.

The protection of famous marks

Infringement involves not only confusing similarity of trademarks but also similarity of the goods for which the two marks are used. There is considerable variety in the various countries as to the scope of protection of a trademark with respect to the type of goods. The general principle is that the goods of the two parties are deemed similar or conflicting if the public could attribute them to the same origin. The physical or essential characteristics of the goods as to form, composition, or quality is not necessarily the primary test. The fact that the goods are intended to satisfy the same need, are sold through the same channels, and are offered to the same class of customers is granted more importance. There has also been a recognition, both in theory and case law, that this general rule of similarity of goods is inadequate for the protection of certain marks enjoying a great reputation and that such marks should be protected against use by others even for quite dissimilar products. This view is based on several considerations.

In the first place, a mark that enjoys wide publicity in identifying certain products of outstanding quality becomes associated in the mind of the public with a certain origin. Use of the same trademark by another person even on dissimilar goods is likely to create an erroneous belief that the products of the newcomer come from the same origin, or that there is some relationship or connection between the two parties. Second, use by another person of such a mark for dissimilar products destroys the uniqueness and originality or distinctive power of the trademark, which is thus diluted and weakened, to the injury of the owner. Third, a newcomer who appropriates and uses a mark of great reputation is being permitted to obtain an unfair advantage or unjust enrichment from the efforts, expenses, and investment of the original owner.

In many countries the courts are granting protection to famous trademarks on any or all of the above mentioned grounds. But they are also conscious of the danger that they may be called upon to give this extended protection to marks that merely become widely known through unusually heavy advertising and publicity financed by owners with great resources. The courts are therefore leaning more and more on the extent to which the mark is known outside the relevant field of competition. The more memorable the mark is to members of the trade and the consuming public, the more likely its use may cause confusion as to origin or sponsorship, impair its economic value to the owner, and produce an unearned profit for the newcomer.

Transfer of rights in trademarks. A trademark is an asset of the proprietor, which may be disposed of as any other asset. If the proprietor is a human person, on his death the mark passes to his heirs. If a company, its trademark is transferred to the purchaser or liquidator with the rest of the assets of the business. For a long time it was thought that since a trademark is attached and owes its value to the goodwill and reputation of a business in which it is used, it cannot be transferred apart from the goodwill of the business; otherwise purchasers of the goods would be deceived. In fact, this theory is not true in many cases. Under modern conditions of trade a business is frequently built around a trademark, with the goodwill of the business inseparable from the trademark itself. In this situation the assignment of the trademark without the business in which it is used need not result in deception of the public. At any rate, in most of the world today, a trademark may be assigned without the goodwill of the

business, provided that the use of the mark by the assignee does not deceive the public. In most countries an assignment of a trademark must be recorded in the patent office in order to give legal notice to the public that there has been a change in the proprietorship of the mark.

Licensing arrangements

Even more important than the transfer of trademarks, particularly in the international field, is the licensing of trademarks. The proprietor generally finds it advantageous not to part with his trademark but rather to grant to another person the right or authorization to use the trademark in whole or in part on an exclusive or nonexclusive basis. In international trade, particularly, there are enterprises in various countries that seek licenses to use a mark enjoying an international reputation that would benefit the sale of their goods. This is a short cut to commercial success that saves investment and expense in promoting a new trademark. Manufacturers also find it advantageous to license their trademarks to foreign enterprises. This overcomes import restrictions, customs barriers, and foreign exchange difficulties, enables them to obtain royalties for the use of their mark from the licensee, and at the same time creates valuable goodwill for their trademarks through use by the licensee. In international arrangements this licensing frequently involves the sharing of secret know-how or special technological information and assistance that promotes economic development.

Here again, there once were objections to the licensing as unlawful, or at least improper, since the trademark was no longer associated with the proprietor's business, and its use by the licensee might result in deception of the public with regard to the origin of the goods. These objections have long since been overruled by practice and subsequently by law. As a result, in most countries today a trademark may be licensed, provided that the trademark proprietor controls and supervises the standards and specifications of the goods for which the mark is used so that they are equivalent to those under which the proprietor has used it. In many countries the law requires that the license be recorded in the patent office to provide notice to the public.

LOSS OF TRADEMARK RIGHTS

Just as a trademark right is acquired under conditions prescribed by law, it may also be lost under certain conditions. A registered trademark may be lost as a result of legal action annulling the registration either on objective grounds attacking the registrability of the mark or on grounds relating to prior rights of others. It may also be lost by renunciation or abandonment, affirmative or tacit, such as failure to renew the registration. More serious causes of loss of trademark rights come from failure to use a registered trademark and from the transformation of a trademark into a generic term.

In countries in which a trademark is acquired by use and the proprietor has not sought to obtain registration, the right continues so long as the mark has not been abandoned. Abandonment involves two elements: discontinuance of use of the mark and intention to abandon the mark. When the mark is registered, the obligation of the owner to use it is clear. The law has established a registration system and protects a registered trademark on the assumption that the proprietor has a bona-fide intention to use such a mark and that he does actually use it. Difficulties arise in the application of this principle, but generally the law does prescribe that the registration of a trademark may be forfeited if the mark is not used for a prescribed period of years. Usually this is between three to five years, with some countries requiring use even within a shorter time. In a number of countries, however, there is no requirement of use, and a few still retain old systems permitting registration of so-called defense and reserve marks, but these are gradually amending their law to require use.

The trademark lost by success

Loss of the right in a trademark also occurs when it is transformed, or degenerates, into a generic word. In this field there is considerable diversity in the law of various countries.

In the United States there have been spectacular cases of loss of trademark rights regarding such famous trademarks as Aspirin, Cellophane, Shredded Wheat, Thermos, and others. The position of U.S. courts, broadly speaking, is that a designation that is initially a trademark ceases to be such when it comes to be generally understood as a generic or descriptive designation of the type of goods in connection with which it is used. It makes no difference whether this transformation is made as a result of the action or negligence of the trademark owner or whether he has done everything possible to avoid this result. The courts consider only whether the public still recognizes the word as a trademark or whether it understands it as a description of the article. In difficult cases there may be a minority of the public or a substantial portion of the trade who still recognize the designation as a trademark indicating specific origin. In such cases the courts seek to balance the equities of the claimant for the mark, of his competitors, and of the public.

The law of British countries looks more to what the view of the mark is to the trade rather than to the general public. Once it has been established that there is a trade use of the mark in a generic or descriptive meaning, the mark may be declared lost.

In a contrary direction is the law of civil-law countries that generally considers the right in a trademark as equivalent to the right in movable property. It will not allow a mark to be expropriated for public and general use so long as the owner has not renounced his right, and any use of the mark by the trade or by the public without authorization of the owner is considered abusive. So long as the owner retains the registration of the mark and keeps it alive by renewal the mark cannot be lost.

A middle position is held by the Scandinavian countries, where, if the owner tolerates the use of his trademark in such a manner that it becomes a commonly used indication for goods of a certain kind, he loses his right in the mark.

Mention may also be made of the possible loss of trademark rights by confiscation—with or without the business to which they are attached—as a result of state action. The law of the state that has taken such action governs the legal position of the trademark within that country, but insofar as the confiscation purports to extend to trademarks registered in foreign countries, it generally meets the resistance of interested persons who claim that their business has been expropriated without proper indemnification. Many cases of such expropriation occurred after World War II in the Socialist states of eastern Europe. In many cases the owners of the business involved have emigrated to the West, where they have generally succeeded before the courts in preventing the state enterprise of such countries from claiming ownership of the trademarks registered in the countries of western Europe.

INTERNATIONAL INSTITUTIONS FOR THE PROTECTION OF TRADEMARK RIGHTS: THEIR PROVISIONS AND EFFECT

International Convention for the Protection of Industrial Property. During the 19th century, the increase of importance of trademarks in international trade led many countries to enter into bipartite conventions providing for the reciprocal protection of trademarks of their nationals. Such provisions also were included in various treaties of commerce, treaties of friendship, etc. The position under such treaties continued, however, to be insecure, varied, and fluid, especially since the protection of trademarks was bound up with the uncertain duration of such treaties. The great demand for stability and security in international trade finally led to the conclusion in Paris in 1883 of the International Convention for the Protection of Industrial Property, generally called the Paris Convention. This has been revised successively through the years, most recently at Lisbon in 1958. Many countries have acceded to this convention through the years with the result that at the present time nearly 80 countries are party to it, which makes it, in effect, an international charter for the protection of industrial property rights, and specifically of trademarks, in a large part of the world.

Basic principles of the convention

The convention establishes two basic principles. The first is the "national treatment" principle, which means that

the persons entitled to the benefits of the convention are treated in each country as that country treats its own nationals. They therefore have all the rights, advantages, and protection enjoyed by nationals, subject only to compliance with the conditions and formalities applicable to nationals. No discrimination is allowed between foreigners and nationals, and no reciprocity is required, which means that country A is bound to protect the trademarks of nationals of country B without being permitted to inquire whether country B does the same for the rights of the nationals of country A. This replaced the old system of reciprocity that created great uncertainty and variety in the international protection of trademarks.

The second principle of the convention is called the "unionist treatment." It provides that certain rights and benefits stipulated by the convention must be made available to persons entitled to its benefits, irrespective of whether or not these are provided for under the law of the country involved. Among the specific benefits and rights granted is the right of priority, under which an applicant for a trademark in one of the member countries may claim the priority of the filing date of his first application in his own country, provided he files for the same trademark in the other countries within six months from the first application. As a result of this important priority right, the claimant has time to protect his trademark in the other countries and prevails over an intervening applicant or any intervening user.

Another right is the so-called validation of trademarks, which means that a trademark registered in the country of origin must be accepted for registration and protected in the other countries, subject only to certain stated exceptions relating to prior rights or to marks that are devoid of any distinctive character or are generic or descriptive. The third important right provides that a member country must refuse or cancel the registration and prohibit the use of a trademark that infringes a foreign mark considered to be well known in the country where protection is sought. The complaining party is allowed up to three years to seek cancellation of an infringing mark.

Several other rights are provided, including a period of grace for the renewal of registration, the right to assign a foreign trademark without assignment of the trademark or the business in the home country, the right to contest the registration of a trademark by a foreign agent or representative of the owner, and the right to demand seizure on importation or prohibition of importation or seizure within the country of goods illegally bearing the trademark of another. Provisions for the protection of trade names and for protection against acts of unfair competition are also subjects of the convention.

The Paris Convention has a central organ for the administration and development of the international system of industrial property. This is the International Bureau, located in Geneva, which has been actively functioning for nearly a century in the interest of the Union for the Protection of Industrial Property established by the convention.

Pan-American trademark conventions. There have also been a series of Pan-American conventions for the protection of industrial property rights and particularly of trademarks, the most important of these being the General Inter-American Convention for Trademark and Commercial Protection concluded in Washington in 1929. This convention has been ratified and is now in effect among 10 of the 21 American republics. Some of these republics are still bound by the earlier Convention of Buenos Aires of 1910, to which five additional countries are a party. The convention of 1910 was a rather poor substitute for the Paris International Convention, whereas the Washington Convention of 1929 is an extensive document that contains the same two general principles as the Paris Convention; *i.e.*, the national treatment principle and the "unionist" principle. It does not provide for a right of priority but it does provide that a prior user of a trademark in any contracting country may contest the registration of the same or a confusingly similar mark in any other country if the newcomer had knowledge or ought to have had knowledge of the existence or use of the prior mark in its country of origin, if there has been prior use in the country where protection is sought, or if the newcomer failed to use the mark for a specified period after registration. The convention also provides for registration and protection of a mark already registered in the country of origin, subject to certain exceptions; and it contains full provisions for the protection of commercial names, for the suppression of acts of unfair competition, and for matters relating to false indications of origin.

Madrid arrangements. The other principal institution for the protection of trademark rights is the Madrid Arrangement for the International Registration of Trademarks. Originally concluded in Madrid in 1891, this arrangement has been revised through the years, and the present treaty is one adopted at Nice in 1957.

The main features of the arrangement revolve around a central filing system under which the owner of a trademark registration obtained in his country of origin may request his patent office to transmit an application for international registration to the International Bureau at Geneva. On receipt of this application the bureau registers the mark in the International Trademark Register and informs the countries that are party to the arrangement. These countries have a term of one year within which to declare whether they refuse protection to such a mark. If no such refusal is made, the mark is deemed registered in the particular countries as if the application were filed and the mark registered directly in each of them. If a country refuses protection to such a mark, the applicant may attempt to overcome the refusal by taking direct action in the particular country under the law of that country.

The membership of this arrangement includes 21 countries. Most of them are European, but also included are Morocco, Tunisia, Egypt, and South Vietnam. About two-thirds of all international marks registered are of French, German, and Swiss nationals.

The United States, British-law countries, Scandinavian countries, Latin-American countries, and the majority of non-European countries are not party to this arrangement.

Disadvantages of universal filing

While the advantages of a central filing for marks with a minimum of formalities and expense are obvious, there are a number of serious disadvantages. The basic objection to the whole system is the automatic extension of an international registration to twenty countries regardless of whether or not the applicant has a bona-fide intent, or indeed an interest, to have his mark protected in all of them. As a result of the multiplication of businesses and products in the present stage of international trade, there is a severe shortage of symbols, words, and devices available for adoption and registration as trademarks. Because of this, it is important that the trademark registers of the world be unencumbered by registrations for marks that are not really used or intended to be used. The contracting countries conscious of this disadvantage inherent in the automatic extension of international registrations, added a provision in 1957 that a supplemental fee be paid for each country, if the contracting countries should so provide. This fee, however, is so small that it has not had the result of reducing the encumbrance of the registers. Another disadvantage is that an applicant for an international registration is not limited to registering a mark for the goods for which he uses or intends to use the mark; he may cover any or even all classes of goods, which again narrows the field for subsequent bona-fide users of marks.

Finally, the requirement that the mark must have been first registered in the country of origin works to the disadvantage of nationals of countries where marks are submitted to very careful examination. In those countries the applicant may not obtain his registration for months or years before he can apply for an international registration, whereas in countries where there is no prior examination, a class including most of the members of the Madrid Arrangement, applicants may apply for an international registration promptly upon filing their marks at their national patent office.

Proposals are now underway for a new trademark arrangement that will avoid the disadvantages and pitfalls of the Madrid Arrangement.

There is a second Madrid Arrangement for the repression of false indications of origin. This particularly concerns the so-called appellations or origin—geographical names entitled to be used only by products whose quality and characteristics are due exclusively or essentially to natural or human factors of the particular geographical area. These include the well-known names of wine products, cheeses, beer, and other foodstuffs. An additional arrangement was concluded in Lisbon in 1958 to permit international registration or appellations of origin at the International Bureau under procedures analogous to those for the international registration of trademarks.

The European Economic Community and trademarks. The Rome treaty of 1958 establishing the European Economic Community, or what is generally called the Common Market, has no specific provisions on trademarks or trademark law. It does, however, touch upon the subject of trademarks indirectly in two ways. In the chapter dealing with the elimination of restrictions as between member states to ensure freedom of movement of goods between them, there is an exception in article 36 to the effect that prohibitions or restrictions of importation, exportation, and transit may be justified on certain grounds, including the protection of industrial and commercial property. Thus, if a certain trademark is owned in one of the member countries by one person and in another country by a different person, the goods bearing it cannot lawfully be imported from the one country to the other. This is reinforced by the general provision of Article 222 that the treaty shall in no way prejudice the system existing in member states in respect of property—and this, of course, includes property in trademarks.

The diversities of the trademark law in the member countries of the Common Market and the diverse ownership of trademarks in such countries do constitute legal barriers to the free movement of goods and to the economic integration that is the principal object of the Common Market. To prevent agreements and practices between enterprises that may have the effect of extending these legal barriers, the treaty has antitrust provisions in its chapter on Rules Governing Competition that affect agreements relating to trademarks.

Action on unification

Nevertheless, the treaty does aspire to eliminate the diversities of law and diverse rights in trademarks. Article 100 provides that the Council of Ministers of the Common Market "shall issue directives for the approximation of such legislative and administrative provisions of the member States as have a direct incidence on the establishment and functioning of the Common Market." And Article 235 provides that if action by the community appears necessary to achieve one of the aims of the community, the council shall enact the appropriate provisions. Thus the Council of Ministers of the Common Market may issue directives for the harmonization of trademark legislation and regulations of the Common Market countries, and eventually may enact a uniform law of trademark rights.

As a matter of practical fact, however, the council would not attempt to do this in such a technical field unless the member countries were really agreed that uniformity or unity of law is necessary and desirable. That is already being done with respect to patent law in the Common Market, by a special committee of experts from each of the six member countries, and will probably be followed by a similar effort for the adoption of a single trademark law.

BIBLIOGRAPHY. In the U.S., H.D. NIMS, *The Law of Unfair Competition and Trade-marks* (1917), was the basic work in the field until W.J. DERENBERG published his comprehensive book, *Trade-mark Protection and Unfair Trading* (1936). More recent information may be found in R. CALLMANN, *The Law of Unfair Competition, Trade-marks, and Monopolies*, 3rd ed. (1967). There is abundant analysis and critical exposition on many topics of trademark law in legal reviews, and particularly in the *Trademark Reporter* (monthly), published by the U.S. Trademark Association. In England, the standard reference is D.M. KERLY, *Law of Trade Marks and Trade Names*, 9th ed. (1966). In Germany, E. REIMER, *Wettbewerbs und Warenzeichenrecht*, 4th ed. (1966); and in France, E. POUILLET, *Traité des marques de fabrique et de commerce*, 6th ed. (1912), are standard reference books, P.ROUBIER, *Le Droit de la propriété industrielle*, 2 vol. (1952–54), has given a new dimension to juristic writing in France. A good book in Spanish is P.C. BREUER MORENO, *Tratado de marca de fábrica y comercio*, 2nd ed. (1953). S.P. LADAS, *The International Protection of Industrial Property* (1930), is a particularly useful work for a comparative view of the international protection of trademarks.

Trade Unionism

To be understood in its international context, trade unionism must be examined as part of a wider concept—the labour movement as a whole. That movement consists of several more or less intimately related organizations such as labour parties, workers' mutual insurance organizations, producers' or consumers' cooperatives, and workers' education and sports associations. All have the common objective of improving the material, cultural, and social status of their members.

What distinguishes one organization from another is the particular aspect of that broad objective it is endeavouring to pursue, and the particular method it employs. The relationship among the various parts of the labour movement varies from country to country and from period to period. Not all countries have produced the entire gamut of organizations referred to above; in some countries the term "labour movement" is virtually synonymous with "trade unionism."

ORIGINS AND BACKGROUND OF THE TRADE UNION MOVEMENT

Early forms of labour organizations. Unions originated, mainly in Great Britain and the U.S. in the late 18th and early 19th centuries, as associations of workers using the same skill. There is no connection between trade unions and medieval craft guilds, for the latter were composed of master craftsmen who owned capital and often employed several workers. The early unions were formed partly as social clubs but soon became increasingly concerned with improving wages and working conditions, primarily by the device of collective bargaining. Progressing from trade to trade within the same city or area, the clubs formed local associations, which, because they carried on their main activities on a purely local level, were almost self-sufficient. With industrial development, however, local associations sooner or later followed the expansion of production beyond the local market and developed into national unions of the same trade. These in turn formed national union federations.

Factors favouring unionism. The unions of the early 19th century were almost exclusively based upon a particular craft. But as mass production industries—which required large numbers of rapidly trained, semiskilled workers—developed, a trend toward large-scale union organization grew, and toward the end of the 19th century Great Britain was including unskilled workers. Unions that recruited members from such groups—whose ranks were expanding rapidly as a result of new technologies—emerged either as industrial unions or as general unions. Industrial unions attempted to organize all workers employed in producing a given product or service, sometimes including even the general office or white-collar workers. General unions included skilled workers and labourers of all grades from different industries, even though they usually started from a base in one particular industry. But changing technologies, union mergers, and ideological factors led to the development of various kinds of unions that would not fit easily into any of the above categories.

Labour unions as protest movements

Obstacles to union organization. In most Western countries, labour movements arose out of the protest of workers and intellectuals against a social and political system based upon discrimination according to ancestry, social status, income, and property. Such a system offered few avenues for individual or collective advancement. Discrimination in political franchise (restrictions on or outright denials of the vote) and a lack of educational opportunities, anti-union legislation, and the whole spirit

of a society founded upon acknowledged class distinctions were the main sources of the social protest at the root of modern labour movements.

Anti-union laws such as the Combination Laws in Britain, the French Loi Le Chapelier (forbidding combination), similar laws in most Germanic countries, and court decisions under common law in the United States in the 19th century made it inevitable that reformers would first turn their energies to the removal of those legal impediments. The demand for equal voting rights became an early preoccupation of the labour movements, partly because of a desire for recognition of the working man as a full citizen, and partly to give the worker political power to remove anti-union laws and to obtain legislation for improving working conditions, especially for children and women. At a much later stage, when democratic equality was substantially achieved, unification of unions that had been divided according to political or religious sympathies became the next goal of the labour movements, with less attention paid to anticapitalist ideologies.

UNION DEVELOPMENT IN INDUSTRIALIZED NATIONS

General differences. Among the various labour movements, the roles assigned to collective bargaining and to labour legislation vary substantially; such differences even occur within a single movement. In Great Britain and the United States the role of collective bargaining is stressed. Legislation is regarded primarily as a device to bring about, facilitate, and supplement orderly collective bargaining. Most continental European countries, though with considerable variations among them, rely on substantive labour legislation to a far higher degree than Great Britain or the U.S.

Collective agreements in Britain and many other Western countries, either traditionally or under the impact of tight labour markets, frequently designate the minimum wages allowable; the actual wage rates may be considerably above those listed in the contract. Prolonged full employment and high prosperity may tend to weaken the allegiance of workers to their union, because wages then tend to rise more from an increasing demand for labour than from union pressure. Such a weakening of allegiance to the union is particularly noticeable among younger members who did not live through the "heroic era" of a union's early struggles for recognition and improvements in low wages and poor working conditions.

Changes in the character of unions

The "generation problem" within the unions is complicated by rapid and substantial changes in the structure of the labour force in the industrial countries. The decline in agricultural jobs, the emergence of the semiskilled workers in the mass production industries, and the rise in the numbers of white-collar workers and employed women have changed not only the economic and social milieu within which the unions operate but also their recruiting potential and their character. White-collar workers have formed or joined unions in increasing numbers, though in lesser proportions than their blue-collar colleagues. A number of "quasi-unions" also have emerged—professional associations that, while often refusing to be classified as unions, increasingly behave as unions do and are sometimes prepared to cooperate with or even join confederations of manual workers.

Great Britain. *Early history.* Britain was a pioneer in the development of modern industry, and its unions are among the oldest in the world. They go back to the late 18th century when artisans, threatened by the establishment of mechanized factories, formed local clubs for their common defense. Their efforts soon met with government hostility, based at first upon the common law concept that unions were in "restraint of trade." Later, under the impact of the French Revolution, the Combination Acts of 1799 and 1800 declared unions to be criminal conspiracies against the public. Even after those laws were repealed in 1824, legal and administrative measures against unions continued for a long time.

In 1834, for example, six Dorsetshire labourers from the village of Tolpuddle (the "Tolpuddle Martyrs") were sentenced to seven years transportation to a penal colony in Australia for organizing trade union activities. It was only in 1871 that legislation was passed that exempted unions from prosecution because of "restraint of trade." Local trade clubs had survived intermittent prosecution, and in 1834 the reformer and socialist Robert Owen attempted, without lasting results, to organize them in a national movement—the Grand National Consolidated Trades Union.

In 1851 the Amalgamated Society of Engineers established the pattern for the "new model" unions—national associations of skilled workers who had passed through a regular apprenticeship. Their main economic weapon was their ability to restrict the number of apprentices, thereby limiting the supply of skilled labour. They also functioned as "friendly societies"; that is, they provided mutual assistance in case of sickness or for emigration.

During the same period, some of the leaders of the craft unions formed the so-called "Junta," which engaged in political action and joined Marx's International Workingmen's Association (the First International), even though most of them failed to understand—much less approve—the principles of Marxian socialism. This was not the first attempt of labour leaders to engage in political action. In the 1830s some unionists had joined a small group of radical members of Parliament in drawing up a petition for universal male suffrage, which became part of the platform of the Chartist reform movement. The Chartists were concerned mainly with electoral reform, but trade unions played an important part in their activities. Chartism was the first specifically working-class national movement in Britain. But the emergence of the working class as a major political force had to await the entrance of the miners into the political arena, the extension of the right to vote to large numbers of workers, and the organization of less skilled workers.

The legalization of unionism. After passage of the Trade-Union Act of 1871, which effectively legalized trade unions, unions of agricultural workers, seamen, gas workers, general and municipal workers, and dock workers were organized. This period of union activity culminated in the successful dock workers' strike of 1889. The new unions emphasized nation-wide collective bargaining and demanded a legal minimum wage and an eight-hour day. Socialist ideas entered the movement, and political organizations of the working class—such as the Independent Labour Party—came to play an increasing role. Shortly after the turn of the century, the Labour Party was born.

The legal status of unions became endangered by the Taff Vale court decision of 1901, which held that unions could be sued for losses incurred by employers as a result of union action. That decision was nullified by the Trade Disputes Act of 1906. Shortly before World War I financial support of the Labour Party by trade unions was legalized, provided that individual union members could "contract out." This meant that union members could choose not to pay the so-called political levy; that is, not make a contribution to the special fund that most unions established for support of the Labour Party. After the unsuccessful General Strike of 1926, that provision was changed into the "contracting in" system, which required union members to state expressly their wish to pay the political levy. As a result, a sizable proportion of union members failed to pay the levy, and in 1945 the newly elected Labour government once again established the "contracting out" principle.

"Contracting out" and "contracting in"

The growth of union membership. Between 1910 and 1920 trade union membership more than trebled, from 2,565,000 to 8,334,000. But the postwar slump of 1921 and the return to the gold standard in 1925 led to a great crisis in the history of British trade unionism—the General Strike of 1926. The failure of the strike resulted in widespread disillusionment, which was intensified by the start of the Great Depression in 1930. By 1933 union membership had fallen to 4,392,000, half of what it had been in 1920. Afterward union membership gradually increased until by 1969 it stood at more than 10,000,000, about 9,500,000 of whom were affiliated with the Trades Union Congress (TUC), the national organization representing British trade unions. The diversity in size

and organization of British unions is tremendous. They range from small local craft groups to giant general unions with memberships in excess of 1,400,000. A trend toward large-scale union mergers became apparent in the 1960s.

Dual system of bargaining. The basic institutional factor underlying problems of industrial relations in Britain is the existence of two bargaining systems: the industry-wide contract negotiated by the union and the employers' association, and the unofficial agreements arrived at in the various plants by managers, shop stewards, and individual workers. The terms reached under the unofficial system are consistently more favourable for the workers than those in the official contract. Such a dual system has its roots in the failure of most unions to control the shop stewards, and of the employers' associations to control the plant managers.

Union control over the shop stewards proved weak during World War I when the stewards assumed an authority that often brought them into conflict with the union leadership. World War II, and the long period of full employment that followed, reinforced that trend. The Industrial Relations Act of 1971 brought the first comprehensive legislation in this field in the country's history. It provided, among other things, for legally enforceable collective agreements between unions and employers.

Shop steward control of the going pay rates

Role of government. Caught between rising earnings, rising prices, and a great reluctance to permit a devaluation of the currency, the post-World War II governments embarked upon a series of experiments with methods of wage restraint. The first, undertaken in 1948–50, had ended in failure; and from 1951 to 1964 the Conservative governments made several attempts to limit wage and salary increases, but the unions refused to cooperate. When a Labour government was returned in 1964, some of the unions became more willing to accept an incomes policy. As a result, union (and business) representatives took their places on a Prices and Incomes Board empowered to investigate and suggest reforms, which were mainly related to enhancing productivity.

A searching investigation of the entire industrial relations system by the Donovan Commission (Royal Commission on Trade Unions and Employers' Associations) was also undertaken. Among other things, the commission recommended an obligatory 28-day conciliation period before any unofficial strike (any walkout not sanctioned by the official union leadership) could begin, and also a poll of the union's members if a major official strike was imminent and if the government doubted that the union leaders had rank-and-file support.

Various emergency measures were taken when the exchange rate of sterling was threatened in 1966 and again after sterling's devaluation in 1967. They included the suspension of all wage, price, and dividend increases for various periods. But in 1970 a government white paper admitted that "the use of a productivity, prices, and incomes policy for short-term purposes can only have a short-term effect. The long-term role of the policy is essentially an educational one."

The incomes policy put the responsibility for wage restraint on the unions. But, as mentioned above, effective earnings are determined not so much by the unions as by shop stewards, whose activities the union leaders do not entirely control. It was hardly surprising, therefore, that the incomes policy proved ineffective. Nor was it conceivable that the unions, created to improve their members' earnings, could for long be turned into devices for preventing their members from obtaining the wage increases that management was willing to concede. The creation of an Industrial Relations Commission and of a Commission for Industry and Manpower in 1969–70 indicated that new means were being sought to promote and preserve collective bargaining under conditions of full employment while at the same time keeping price increases at an acceptable rate.

United States. *The beginnings.* Unionism in the United States goes back to the early days of national independence when craftsman employees in various trades—carpenters, masons, shoemakers, and printers—formed local groups to obtain shorter hours and higher wages. The Mechanics' Union of Trade Associations formed in Philadelphia in 1827 represented an early attempt to combine unions of different crafts on a local level. The first steps toward extending the organization beyond the local area were made in the 1830s but were only temporarily successful. Much emphasis was placed on political action and the formation of labour parties. The main objectives included free education and the abolition of property restrictions on the right to vote, which had survived from Colonial times in some states down to the Jacksonian era (1828–36). Once those objectives were achieved in the Northern states, the labour parties disappeared. Most of the unions—including the National Trades Union formed in 1834—were dissolved in the depression of 1837.

First steps toward wider organization

In the 1850s a new departure occurred. With improvements in transport and the consequent expansion of markets beyond local areas, unions in the same trade began to expand their fields of operation and to establish regional or even national federations. The National Typographical Union was formed in 1852 and was followed by five others. Concentration on job-connected problems rather than on broad, ideological issues was characteristic of this period.

The Knights of Labor. The only large reform movement among the early labour organizations was backed by the Noble Order of the Knights of Labor, founded in 1869. Its objectives, many of them more political than industrial, were vague and moderate and included the eight-hour day and the abolition of child labour. Its rise was spectacular, especially after it won a strike against the Wabash Railroad, controlled by Jay Gould, a New York multimillionaire, in 1885. But after that victory, the organization soon declined—in part because of a growing anti-radical mood in the country. That mood was intensified by the Haymarket bomb episode in Chicago (1886), in which seven policemen were killed, and with which the Knights were quite unjustly associated. A more significant factor in their decline was the fact that the Knights combined skilled and unskilled workers in one organization. The mass immigration of unskilled workers weakened their economic power to the point that union victories could be won only with the assistance of skilled workers; and when they were no longer willing to give battle on behalf of the unskilled immigrants, the decline of the Knights became inevitable.

The American Federation of Labor. In the meantime, however, the American Federation of Labor began to supplant the Knights as a national federation of unions of skilled workers. Started with modest success as the Federation of Organized Trades and Labor Unions of the United States and Canada in 1881, it was transformed into the American Federation of Labor (AFL) five years later. Samuel Gompers, a cigar maker, was elected president, and his personality decisively shaped the AFL's evolution. It was to be a practical, non-ideological movement, accepting the existing social system but attempting to change it in favour of the organized skilled workers. The main instrument of change was to be collective bargaining. The affiliated organizations were to be autonomous within their "jurisdiction"; that is, the job territory over which their charter gave them full authority. Organization was limited to skilled workers, who alone were regarded as capable of forming effective unions.

Membership of the AFL grew only slowly until the turn of the century, partly because of a predominantly unfavourable economic situation and partly because of government hostility. Between 1900 and the outbreak of World War I, however, membership expanded from less than 600,000 to about 2,000,000. The war itself opened new opportunities for organized labour. Pres. Woodrow Wilson's administration gave Gompers semi-official status by making him a member of a small advisory commission to the Council of National Defense; and the President himself appeared at the 1917 AFL convention. By 1920 the membership of AFL-affiliated unions had doubled to 4,000,000.

The next decade was a period of crisis and stagnation

for unionism. Serious opposition to Gompers arose in 1921 in the person of John L. Lewis, newly elected head of the United Mine Workers. Gompers won, but his death in 1924 brought William Green, a member of the mine workers' union, to the presidency. The liquidation of the war industry, and a sharp anti-union offensive by many employers—who were supported by conservative U.S. presidents, hostile courts, and anti-labour sentiments of great sectors of the general public—combined to bring about a sharp decline in union membership. Under the slogan of the "open shop," by the use of so-called yellow dog contracts that required workers not to join unions, and by court injunctions against unions, employers staged a major offensive against organized labour. This not only kept the unions out of the steel industry but also reduced union membership to little more than its prewar level.

Rise of anti-union sentiment in the 1920s

The "Wobblies." The 1920s also saw the decline of an important union movement that had attempted to organize unskilled workers into industrial unions—the Industrial Workers of the World (IWW). The "Wobblies," as they were popularly known, had been founded in 1905 in Chicago in response to the AFL's opposition to unionism for unskilled workers. Consisting largely of itinerant industrial labourers, the IWW had concentrated on militant strike action, especially against employers hostile to unionism.

The movement included a considerable ideological element and eventually came under the control of anarchists and syndicalists. That fact, together with the IWW's strong opposition to World War I, led to the suppression of its press and to prosecutions under the Espionage and Sedition Acts of 1917 and 1918. After World War I, many states adopted legislation outlawing the IWW, thus driving it underground. It was further weakened by disputes with the Communists, so that by the mid-1920s it had ceased to be a significant force within the labour movement.

The Depression and New Deal. The Great Depression, which began in 1929, almost destroyed some of the unions, but it also gave unionism a new start. The reasons for this new turning point were several. With the depression and the shifting political climate, there came a radical change in labour legislation—the Norris-LaGuardia Act of 1932, which removed the legal basis for the use of court injunctions in labour disputes. (In a partial reinterpretation of that 1932 act, the U.S. Supreme Court in 1970 ruled that unions could be enjoined from permitting walkouts in violation of no-strike pledges contained in their contracts.)

The New Deal legislation that followed the victory of Franklin D. Roosevelt in the presidential election of 1932 guaranteed the right of workers to join unions of their own choosing and required management to engage in collective bargaining if the majority of the workers so desired. A National Labor Relations Board was set up to enforce the law. Although the law was revised later by the Taft-Hartley Act and the Landrum-Griffin Act, its basic principle that collective bargaining is the most desirable way of determining wages and working conditions was not changed. Even when strikes threaten national security, only delaying action is legally provided for; in some situations, however, governmental pressure to avoid or settle strikes has, in fact, come close to coercion. Minimum wage legislation was passed on both the federal and state levels, and government encouragement of unionism was manifested not only during the New Deal but repeatedly throughout the presidencies of Harry S. Truman, John F. Kennedy, and Lyndon B. Johnson.

A basic change in unionism itself

The change in the governmental attitude toward unionism was accompanied by a basic transformation of unionism itself. Adjusting itself to the new, enlarged role of the government in economic affairs, as well as to the catastrophic consequences of the Great Depression, the AFL abandoned its traditional distrust of government regulation of industrial relations. With some reluctance it accepted and finally supported a government-sponsored social security system providing for gradual expansion of old age pensions, unemployment benefits, and—much later—health insurance.

The Congress of Industrial Organizations. No less important was the belated adjustment of the structure of unions to accommodate the growing number of semiskilled workers in the mass production industries, whose employees the traditional craft unions of the AFL had failed to organize. Under the leadership of the United Mine Workers' president John L. Lewis, eight unions within the AFL promoted organizing drives to establish industrial unions in such industries as steel, automobiles, rubber, and chemicals. When endorsement of his plan was defeated at the AFL convention in 1935, Lewis set up a Committee for Industrial Organization, which three years later was transformed into the Congress of Industrial Organizations (CIO). For having formed a rival organization the unions of the CIO were expelled by the AFL.

The decisive battles of the new organization were fought in the steel and automobile industries. A favourite weapon of the organizers—mainly mine workers' leaders assisted by intellectuals and a few Communists—was the sit-down strike, a strike during which workers do not walk out of the plant but remain idle at their work positions, thus paralyzing the plant and making it necessary for management to make an immediate response to their demands. Victories in the largest steel and automobile companies in 1937 were finally crowned by the capitulation of the Ford Motor Company in 1941.

World War II and after. The new competition induced the AFL in turn to engage in organizing drives. Total union membership grew from 2,900,000 in 1933 to 9,000,000 in 1939. By the end of World War II it had risen to 15,000,000, more than one-third of total nonagricultural employment. Just as had World War I, World War II induced union expansion, partly because of government assistance offered in return for a no-strike pledge.

The World War II era also witnessed a growth in anti-union sentiment, though not quite as sharp as that following the first World War. The passage of the Smith-Connally (War Labor Disputes) Act of 1943 over President Roosevelt's veto, and of the Taft-Hartley Act four years later over President Truman's veto, both of which introduced new government controls over unions, was evidence of a changed public opinion. In spite of the postwar economic expansion, union membership stagnated—partly because of the shift toward white-collar employment that the unions found difficult to cope with. Jurisdictional disputes between unions affiliated to the two competitive federations led to a waste of union resources.

Merger of the AFL and CIO

On the other hand, the departure of the union leaders who had initiated and continued the AFL-CIO split removed some of the difficulties in the way of merging the two organizations. The expulsion of the Communist-dominated unions by the CIO in 1949 and the withdrawal of the United Mine Workers from the AFL also facilitated unification. In 1955 the AFL and CIO merged under the combined leadership of George Meany and Walter Reuther. The new organization (AFL-CIO) represented some 15,000,000 members at its birth. Not included in the new federation were the mine workers, some railroad unions, and various smaller organizations expelled for Communist domination; others were expelled later for corrupt practices—including the International Brotherhood of Teamsters with its more than 1,500,000 members.

The AFL and CIO had been instrumental, even before the merger, in setting up the International Confederation of Free Trade Unions (ICFTU) to combat the Communist-dominated World Federation of Trade Unions (WFTU). But issues of international policy soon caused sharp internal frictions between Meany and Reuther. While Meany criticized the ICFTU for failing to combat Communism with enough vigour, Reuther criticized Meany for complacency, for excessive concentration on a negative anti-Communist policy out of line with the thinking of most European unions, and for lack of imaginative leadership for social change. Personal rivalries intensified the conflict. In 1968 Reuther's United Automobile Workers left the AFL-CIO and combined with the Teamsters and two smaller unions and formed the Alliance for Labor Action (ALA) to engage in new organizing drives and to operate on a wider range of issues. The ALA had barely estab-

lished itself when it lost its main driving force with the death of Walter Reuther in an airplane accident in 1970.

Unions of public employees. By means of an executive order issued in 1962 the Kennedy administration gave federal public employees the right to organize and bargain collectively, though not to strike. That action, together with some legislation at the state level, led to a rapid expansion of unionism among public employees. But the problem of how bargaining could be conducted effectively without the ultimate sanction of the strike remained to be solved.

A number of professional associations, though refusing to regard themselves as unions, began in the late 1960s to engage in collective bargaining and even, occasionally, to go out on strikes. The outstanding example was the influential National Education Association, several of whose affiliates carried out successful strikes. A whole class of quasi-unions was thus developing outside the traditional labour movement.

Western Europe. Unionism on the Continent shares some features with unionism in Britain: early persecution by government and courts, reliance upon government intervention and mediation in disputes; a tendency for unions to carry on collective bargaining with employers' associations rather than with individual companies, and a general acceptance of the terms of agreements as a floor upon which higher effective earnings are achieved by various devices. A distinguishing characteristic of European trade unionism has been, and to a large extent still is, its tendency toward ideologically oriented unions, most of which were established by political parties or religious organizations in the 19th century. After World War II, a trend in the direction of unified trade unions, combining different ideological currents under one roof, manifested itself and has achieved considerable success.

Tendency toward ideological unions

Germany. Trade unionism began to gather momentum in Germany only after the fall of Otto von Bismarck in 1890. Under Socialist inspiration the bulk of the unions formed a national federation in that year. The Catholic Centre Party followed in 1894 with the establishment of a much smaller federation of Christian unions. Nationalist- and, for a brief period, Communist-led unions, as well as separate white-collar unions came into being at various times before World War I. There were some successes in collective bargaining, but unions remained fairly insignificant during this period.

After World War I, the Socialist-inspired unions organized in three main federations: the Allgemeiner Deutscher Gewerkschaftsbund, ADGB (General Confederation of German Trade Unions), for the manual workers, the AFA for white-collar employees, and the ADB for civil servants. Collective agreements for an industry or trade set minimum wages, which in turn were supplemented by the efforts of workers' councils in the plants. The council members were elected by all workers and white-collar employees, whether union members or not. Legally, and often in fact, councils were independent of the unions. Unionism flowered during the short period of prosperity in the 1920s but was destroyed by the Nazi takeover in 1933. The Labour Front, established and totally controlled by the National Socialist (Nazi) Party, was not a union by any definition of the term. Immediately after World War II, a powerful trade union movement came into being in West Germany. It was based on a merger of 16 Socialist and Christian industrial unions in a unified Deutscher Gewerkschaftsbund (DGB). Its membership, whose turnover is high, has levelled off at 6,500,000 workers in 1970 after a rapid rise. In addition, there are union federations for white-collar workers and civil servants. A small separate Catholic federation has had little success.

Under the slogan of "codetermination" the unions have acquired direct representation in management. Legislation enacted in 1951 provides that in the coal and steel industries stockholders shall elect five members of an 11-man supervisory board of the company, and workers another five. Two of the workers' representatives come from the enterprise, a third is appointed by the union, and two more by the union federation, usually the DGB. The 11th member is jointly elected by the ten others. In addition, one of the three members of the *Vorstand* (management), which actually runs the enterprise, must be selected with the approval of the workers' representatives; that member is in charge of labour relations. In other large firms, outside the coal and steel industries, labour holds one-third of the seats on the supervisory boards. The DGB has been campaigning for an extension of the coal and steel system to all large firms. A committee of social scientists appointed by the government to study the question in a 1970 report supported the DGB demand, though with some significant modification.

Union delegates on management boards

France. Ever since the merger in 1895 between syndicalist and Marxist trade unions, the French labour movement has suffered persistently from internal cleavages and organizational divisions. The main union federation, the Confédération Générale du Travail (CGT), was set up in that year. It represented a coalition of anarchists and syndicalists, who put their trust in a revolutionary general strike to destroy capitalism and the state, together with a group of Marxists, who aimed at obtaining control of the state by a revolution. The syndicalists organized local union federations, mostly of an industrial nature.

Syndicalism broke down in the World War I wave of patriotism that engulfed French workers; after 1918 the Communists inherited a large part of the syndicalist following. For most of the time ever since, the French labour movement has been divided into three main (and several smaller) ideologically inspired organizations: the CGT under Communist control, the mostly Socialist FO (Force Ouvrière, Workers' Strength), and the formerly Christian CFDT (Confédération Française Démocratique du Travail, French Democratic Confederation of Labour), which has been trying to overcome its religious origins and the limits those origins set to its expansion among the main body of French workers.

Although most French workers are not organized, and those who are union members pay their dues only irregularly, the elections of workers' councils and shop stewards (*délégués du personnel*) roughly indicate worker allegiances. It would thus appear that a small majority supports the CGT and somewhat fewer the CFDT and FO. White-collar workers are organized in the CGC (Confédération Générale des Cadres). Other unions remain outside all confederations.

In view of the fragmentation in the French labour movement, it is not surprising that collective bargaining developed late—after 1936. It is still less significant than labour legislation and administrative action in determining wages and working conditions. Workers' councils, to provide worker participation in management, and the shop steward system, to handle grievances in the plant, were both established by law. But by the early 1970s, dwindling union strength had weakened both institutions to the point that they were not functioning in large numbers of enterprises. The great strike movement of the late 1960s, which was organized more for political reasons than as a collective bargaining tactic, developed outside the unions. Later on, however, the unions finally succeeded in controlling it.

Collective bargaining a late and minor factor

Italy. In Italy, much the same as in France, the unions have remained weakened and divided by ideologies and religion. The late economic and political development of Italy directed labour's attention toward radical and political solutions. Soon after the resurgence of unions that followed the downfall of Mussolini's Fascist regime, the old tendency toward multiple and changing divisions within the movement reasserted itself.

Three major confederations emerged after World War II: the Confederazione Generale Italiana del Lavoro (CGIL), led by a coalition of Communists and left-wing II: the Confederazione Generale Italiana del Lavoro tori (CISL), representing the Catholic labour movement, but with some Socialists as well; and the Unione Italiana del Lavoro (UIL) under Social Democratic leadership. The CGIL claims some 3,500,000 members, the CISL 2,500,000, and the UIL 500,000, but usually such figures are exaggerated. In plant committee elections the CGIL usually obtains a slim majority of the votes, with the CISL getting 30 percent and the UIL about 15 percent. In the

wide-scale strikes of 1969–70, the unions persuaded far more than their members to join the so-called rolling strikes—short walkouts, one after the other, in different industries.

When labour agreements are reached, they usually are national in scope, and some cover benefits and conditions for all industries. In 1962 the unions obtained the additional right to conclude supplementary agreements at the plant level.

Scandinavia. The consolidation of local unions into national organizations paralleled the advance of industrialization in Norway, Sweden, and Denmark during the second half of the 19th century. That trend toward centralized unionism received support at the Scandinavian Labour Congress of 1897; and, by 1900, all three countries had small but firmly rooted federations of national trade unions. Employers' associations followed similar development from a local to national scale.

Agreement on basic principles

By the late 1930s the federations of workers and employers in the three countries had agreed on certain basic principles in the conduct of labour relations. Agreements between the labour and management federations, besides placing limitations on sympathetic lockouts and strikes, provide for orderly negotiations by upholding the right to organize for collective bargaining and by laying down procedures for discussion. The broad measure of understanding between labour and management and their common desire to keep government intervention at a minimum has facilitated responsible collective bargaining. Strikes and lockouts have not been entirely eliminated, but their occurrence has become less frequent, although a reversal of this trend manifested itself beginning in 1968. Full collective bargaining rights, including the right to strike, have been extended in Sweden to government employees of all kinds.

In Scandinavia collective bargaining is highly centralized in comparison with the United States or Great Britain. The influence of the federations of labour in conducting negotiations or determining national policy far surpasses that exerted by the AFL-CIO or the British TUC. The federations have the power to ensure that their basic decisions are implemented in the industry agreements. They have acquired an important role in political affairs through their close alliance with the Labour and Socialist parties. In Sweden, the federation has pursued a policy of establishing skill and industry differentials—the so-called solidarity policy—but effective wages have often departed from contract rates, thus counteracting the solidarity policy.

Norwegian and Swedish unions are organized chiefly on an industrial basis, whereas the Danish unions—comparable to the British in this respect—are both general and industrial. Although it is not compulsory, union membership is widespread, even among white-collar workers.

Yugoslavia. After its break with the Soviet Union in 1948, Yugoslavia commenced a program of economic reforms combining the profit motive, public ownership of most means of production, and a gradual decentralization of economic decision making.

The system of centrally directed state-managed enterprises has been progressively replaced by a workers' self-management system under which relatively free economic decisions are made. The concept of workers' self-management, recognizing the system's potential conflict of

Coproducer role for workers

interest between management and workers, stresses the role of workers as coproducers in the enterprise. Management is exercised by a director, who is under the supervision of a workers' council elected by the employees of the enterprise.

To the extent that workers' councils actually represent the workers' interests, they have superseded the role of the trade union within the enterprise. Union functions have consequently been reduced to such activities as assisting individual workers in personal matters, obtaining better training and education for workers, and exercising a modest participatory role in various enterprise deliberations.

The unions appear to be attempting to offset the decline in their traditional functions within an enterprise by enhancing their influence at provincial and national levels. There, the trade unions endeavour to participate in decisions on social and economic issues within the framework set by the political system.

Soviet Union. The Russian labour movement owes its origin to the strikes of the 1890s, in which revolutionary students and workers cooperated against the tsarist regime and capitalist business owners. Hampered by a hostile government, the trade union movement slowly developed on the general pattern of the German labour organizations. With the Russian Revolution in 1917, however, the entire basis of the developing labour movement changed. Under Lenin's strategy, the unions became one of the links connecting the Communist Party—a small, close-knit elite of professional revolutionaries—with the large mass of industrial workers on whose behalf the party would operate.

The role of unions under Communism. A key question arose after the Bolshevik takeover. What role would unions perform in a Socialist system in which capitalism had ceased to operate? A long and involved debate followed. The unions themselves endeavoured to fill the traditional role of trade unions: to maintain or improve the living standards of their members. Leon Trotsky argued, however, that the unions should be transformed into "production agents" so that they would serve the workers' interests by fostering increased productivity of labour, promoting economic reconstruction, and providing increased quantities of consumer goods. Unions were thus to be instruments of economic administration, with only a subsidiary role in setting wages and working conditions. Another more radical role was proposed by the Workers' Opposition, which urged that the trade unions should dominate the state and manage the economy.

The answer to the question of what role unions were to play in the new Communist state was, in fact, dictated by an overall economic policy that called for the commitment of all possible resources to industrialization. The destruction of much of the productive equipment of the country in World War I, the civil war, and the ensuing foreign intervention made it impossible for the shattered economy to satisfy even the most elementary needs of the population. Moreover, the failure of Germany to abolish capitalism, as the Bolsheviks had hoped, required a complete revision of Bolshevik strategy. In the absence of victorious revolutions in the industrially advanced nations, the "dictatorship of the proletariat" in the Soviet Union was doomed unless that country could be rapidly industrialized. Thus, the growth of a working class to build an industrial base in the Soviet Union became the main task of both party and unions.

Such a program, however, required that real wages be kept to a minimum so that all possible resources could be devoted to capital formation. Consequently, unions could not be permitted to assist workers in raising their living standards. Instead, they became instruments of the state

Unions as instruments of the state

to increase output and speed industrialization. That production-oriented role gave rise to a trade union structure appropriate to the machinery of Soviet economic administration and adaptable to its changes.

Pattern of unionism. Soviet trade unions are strictly industrial in nature. All persons employed in any one factory, state farm, or other undertaking belong to the same union; and that same union comprises all of the employees of similar factories, farms, or other enterprises everywhere else in the Soviet Union. Horizontal coordination occurs at the republic, regional, and local levels; but just as the economic administration has been closely centralized, so the national organs of the trade unions exercise effective authority over all lower levels of the union. More than 90 percent of industrial workers belong to unions, mainly because of the considerable advantages, such as social insurance benefits, available to members.

Other socio-economic functions. Soviet trade unions do not limit their activities to industry and plant matters alone. Their other functions include legislative initiative in labour matters; participation in national economic

planning and wages policy; the administration of social insurance; the organization of cultural and recreational facilities; and cooperation in the education and vocational training of workers.

Moves in the 1960s toward decentralization in economic planning and administration, the use of incentives, and the assignment of greater authority to local managers have given rise to an increase in union influence at the lower levels. Among the unions' new roles are greater participation in the settling of grievances and in application of the wage system at the plant level. Some observers have discerned a tendency for the Soviet industrial relations system to evolve in the direction of those of other advanced industrial nations. Nevertheless, like all other organizations in the Soviet Union, the trade unions remain in all essentials under the complete control of the Communist Party.

Japan. Japanese labour unions are mainly the product of the post-World War II period. With the support of the U.S. occupation forces, the Japanese government adopted a drastic labour-protection policy immediately after the war. Its constitution was amended in 1946 so that workers' rights "to organize and to bargain and act collectively" were guaranteed. The phenomenal postwar economic growth of Japan has resulted in a great increase in employment. Trade union membership in 1970 was estimated at 11,500,000, approximately one-third of its potential.

Unions enterprise-oriented. Union structure in Japan differs sharply from the Western pattern. The enterprise —not a craft or industry—provides the base of union organization. One of the main features of enterprise unionism is "lifetime" employment. Employers do not, as a rule, lay off workers either permanently or temporarily; on the other hand, workers are not expected to move from one company to another. Typically, the enterprise recruits and trains young workers immediately after their graduation from school, and continues to employ them until they reach retirement age, usually 55. Educational background and length of service in a given company are the key factors in wage determination. Under such a system collective bargaining naturally focusses on particular enterprises or companies.

"Lifetime" jobs for workers

National confederations. Most of the enterprise unions are combined in national unions or in federations that are affiliated with national confederations. Major confederations are Sōhyō (General Council of Trade Unions of Japan), with 4,200,000 members; Dōmei (Japanese Confederation of Labour), with 1,900,000; and Chūritsurōren (Liaison Council of Neutral Trade Unions), with 1,400,000 members. The national confederations participate very little in bargaining with employers; their major function is the guidance and coordination of their affiliated enterprise unions. Each spring, the national confederations form a special committee for Shunto (the spring offensive). The committee plans the amount of the wage increase to be demanded, the period of negotiations, and the dates of industry-wide strikes.

National unions and confederations play an even more important role in politics by allying themselves with one of the parties—Nippon Shakaitō (Socialist), Minshato (Democratic Socialist), and Kyosanto (Communist).

The new mobility. Some changes in the system seem to be resulting from Japan's high economic growth rates. Because the labour market, especially for young workers, has become extremely tight, and because labour mobility has increased, the lifetime employment system has begun to be eroded. Rapid technological changes have made obsolete the traditional system of basing wages on length of service. Young workers with a modern school education are more suitable for many of the new jobs. Partly because of the high rate of economic growth and partly because of the Shunto bargaining targets, the unions have been successful in obtaining high wage increases. Thus the main emphasis of the Japanese labour movement has begun to shift from politics to economics.

Australia and New Zealand. Early settlers, who had brought the ideal of unionism along with them from England, established the first workingmen's organizations in Australia and New Zealand in the 1830s in the form of small trade societies. The foundations of modern unionism in Australia were not laid until two or three decades later, however, when urban craft unions for skilled workers began to emerge in the 1850s and 1860s. During that period and until 1890 "mass" or "industrial" unions were formed, first by the coal miners and subsequently by others, including gold miners, seamen, and wool shearers. Economic growth and a labour shortage favoured union expansion. With manhood suffrage already a reality, the union movement devoted its attention to such essentially economic issues as the eight-hour day.

Miners among the first "mass" unions

Two distinctive features of present-day trade unionism, namely, political participation and compulsory arbitration, can be traced back to the serious strike setbacks and the economic depression of the 1890s. The Australian Labor Party, created and largely financed by the unions, has been a significant force on the Australian political scene since it first gained office in 1910. The Labour Party of New Zealand also derives much of its strength from trade union support.

Compulsory arbitration. Before 1890 unions had opposed the idea of compulsory arbitration. After losing a number of major strikes in which union recognition had been the main issue, the unions adopted a more favourable attitude toward arbitration, which would force employers to recognize them. Despite the retention of state arbitration systems in some form since passage of the first Commonwealth Conciliation and Arbitration Act of 1904, the focus of attention and activity has gradually shifted to the federal sphere. By the 1970s industrial relations were dominated by compulsory arbitration, yet collective bargaining continued, generally under close union control. Nor was strike action precluded by compulsory arbitration. Indeed, by international standards, the frequency of strikes in Australia has been relatively high, although with a short average duration.

In pre-Commonwealth days the need for close coordination for the successful pursuit of labour's objectives was expressed in successive Intercolonial Trade Union congresses, beginning in 1879. Their direct descendant is the Australian Council of Trade Unions (ACTU), founded in 1927.

Membership. In 1970 there were 305 unions in Australia with a total membership of 2,315,000, or 50 percent of the country's wage and salary earners. In 1969 119 unions with a total membership of 1,472,000 were affiliated with the ACTU, including all of the major unions. Two other central labour bodies, functioning on behalf of white-collar and professional unions, had an affiliated membership of 377,777. A much closer association has been developing between the ACTU and both of these bodies. A Council of Commonwealth Public Service Organizations claims a membership of about 100,000.

Half of all employees in unions

Later developments in New Zealand. Trade unions developed in Australia and New Zealand along broadly similar lines. In New Zealand, however, 1936 legislation provided for compulsory unionism. This took the form of providing that every employer bound by an award of the Court of Arbitration, or by any industrial agreement, could not employ a worker subject to the award or agreement unless that worker was a member of the union also bound by the award or agreement. This resulted in a considerable expansion and strengthening of the union movement. In 1961 the 1936 legislation was amended. Compulsory membership was made subject to agreement between employer and union or to a demand by more than 50 percent of the employees in an industry for compulsory unionism. Provision was made also to allow any worker conscientiously objecting to union membership to apply for a certificate of exemption. In the absence of a compulsory membership agreement, provision was made for the preferential hiring of unionists over non-unionists.

DEVELOPMENT OF TRADE UNIONS IN EMERGING NATIONS

The Indian subcontinent. *India.* According to a 1961 census, India's wage earners totalled 24,000,000, or 13 percent of its labour force, most of which was engaged in subsistence agriculture. Of the 24,000,000 wage earners,

about 4,000,000 (17 percent) were estimated to be organized in unions.

The weakness of Indian trade unionism is related to the country's slow industrialization. Historically, Indian unions were closely linked to the independence movement. The Indian National Congress Party took the initiative for the formation in 1920 of the first national body of trade unions, the All-India Trade Union Congress (AITUC), but this soon split into several factions.

The history of the trade union movement in India is one of conflicts and splits resulting mainly from ideological rivalries. Inter-union rivalry has hindered its development, and membership, which had increased rapidly after independence, stagnated during the 1960s and 1970s.

Collective bargaining is ineffective in India because the unions are not strong enough to force settlements; union rivalry makes the situation worse. As a result, unions tend to turn to the government for intervention. The Industrial Disputes Act of 1947 empowered the central or provincial governments to refer an industrial dispute for adjudication. In addition, wage boards have been set up for the determination of wages.

Pakistan. Though the nonagricultural sector of the Pakistan economy has expanded considerably since independence was achieved in 1947, some 20 years later (prior to separation from Bangladesh) approximately 68 percent of the total labour force of 40,000,000 was still engaged in agriculture. Of the approximately 14,000,000 wage earners, only 500,000 are organized; thus, the degree of unionization is only 3.5 percent, compared with India's 17 percent.

Low level of union membership

The All-Pakistan Confederation of Labour, established in 1950, has been recognized by the government as the sole representative of the workers in Pakistan. Many other trade union federations, however, have sprung up. Just as its Indian counterpart, the Pakistan labour movement is divided, and inter-union rivalry is a major handicap to its development. Collective bargaining is extremely difficult; when agreements are concluded they usually result from voluntary concessions made by progressive employers. Unilateral employer's decisions and government intervention play a dominant role in industrial relations.

Latin America. The highest rate of population increase of any area in the world not only has put a heavy strain on the educational systems of most Latin American countries but also has produced excess supplies of common labour. As a result, advances in wages and working conditions have been exceedingly difficult. Accordingly, one of the main objectives of Latin American trade unions has been to protect and insulate the employed labour force from the consequences of an excess supply of unemployed labour. Various job-protection devices have been developed, mainly based upon a system of severance pay proportionate to the length of an employee's service. Such a system makes dismissal expensive for the employer.

Ideological orientations. Labour movements in Latin America consistently have taken on an ideological colouring. In the early 1970s there were three main groupings of unions: those affiliated with the mildly progressive ORIT (Organización Regional Interamericana de Trabajadores), which in turn belongs to the International Confederation of Free Trade Unions (see below); the CLASC (Confederación Latinoamericana de Sindical Cristiana), a radical Christian movement strongly opposed to what is described as the American dominance of ORIT; and finally, the largely underground organizations, dominated by Communist parties or Communist sympathizers.

Mexico. Among the Latin American labour movements Mexico's is the most successful, partly as a result of the high growth rates of the Mexican economy during and after World War II. Although collective bargaining has been practiced for many years and is fairly well developed, the trade unions have succeeded in welding a close relationship to Mexico's governing party; the unions, in fact, constitute one of the three main divisions of the party organization. Thus, the success of the Mexican labour movement since about 1920 has depended mainly on relationship to the government party.

Elaborate labour legislation based on Article 123 of the Mexican Constitution gives labour courts powerful means to intervene in disputes. They may declare a strike lawful or unlawful, and by their decision the outcome of a strike is more or less settled. Unlawful strikes have few chances of success, but a lawful strike is almost certain to bring advances to the union.

Decisive role of labour courts

Africa. During most of the colonial period in sub-Saharan Africa, unionism, when it existed at all, was limited to white workers. Attempts of black workers to form unions—usually for the purpose of obtaining wages and working conditions similar to those of white workers—were frequently treated as rebellious political movements and suppressed. Black workers were thus compelled to engage in strikes and demonstrations without having a stable organization at their disposal. Violence often accompanied these short-lived movements.

In the late 1930s, and especially during and after World War II, colonial governments altered their policies and introduced trade unionism in their territories. Usually these unions were patterned after the model of the mother country, and in many cases they were simply branches of metropolitan unions. In some areas—as for instance Guinea and Kenya—close cooperation developed in due course between the unions and the national liberation movements. Political leaders were also often union leaders, or closely associated with them. In other parts of Africa—in Rhodesia, for example—the national liberation movements ignored the unions, the membership of which was rather small and which were therefore not in a position to offer financial or mass support to political movements.

After independence was achieved, unions consistently abandoned the patterns inherited from the former metropolitan territories. Western-style unionism was clearly inappropriate in sub-Saharan Africa with its low level of literacy, a labour force with a large migratory component, few educated working-class leaders, low living standards, and a poorly developed labour market. The unions, however, were rarely given an opportunity to develop new autonomous forms of organization and action. Almost everywhere the government party, by a combination of rewards and pressures, took over the unions under the slogan of "African socialism" and turned them into instruments to enhance production and restrict the wage demands of their members.

Only sporadically, mostly in North Africa, did autonomous unions survive. In most cases they formed the nucleus of the opposition to the government, as is the case in Morocco.

INTERNATIONAL ORGANIZATIONS

The large trade union movements of various countries for many years have maintained loose alliances by joining international organizations of labour; federations of unions, rather than individual unions, usually hold membership. In 1901, the International Federation of Trade Unions was established, chiefly under the guidance of German unions. It proved to be ineffective and disappeared during World War I. In 1919 it was revived at Amsterdam, but immediately came into collision with the Red International of Labour Unions, established by the new government of the Soviet Union. The Communist organization had a brief period of expansion but soon dwindled away and had disappeared before 1939.

Unity and division. At a 1945 conference in London a new organization came into being, the World Federation of Trade Unions (WFTU). Its principal organizers were the British Trades Union Congress, the U.S. Congress of Industrial Organizations, and the Soviet Russian Labour Federation. It made a vigorous but unsuccessful attempt to reconcile the differences between the Communist and non-Communist factions. The U.S. announcement of the Marshall Plan for economic aid to Europe, in which the Soviet Union and other Communist states declined to participate, provided the occasion for the withdrawal of the non-Communist faction.

Ideological cleavage of the international labour movement

In 1949, in London, the non-Communist groups created the International Confederation of Free Trade Unions

(ICFTU). At the first session, 70 labour organizations of 53 nations, claiming to represent 50,000,000 workers, became "founding members." The ICFTU was readily accepted by nearly all of the non-Communist-led labour organizations of the world; and after ten years it had grown to include 138 organizations located in 103 different countries, representing more than 57,000,000 workers.

The announced purposes of the ICFTU include: striving for world peace, the spreading of democratic institutions, increasing the standard of living for workers everywhere, a worldwide strengthening of free trade unions, and support to colonial people in their struggle for freedom. The ICFTU consistently opposed Fascist as well as Communist dictatorships, and implemented that policy by giving such aid as was possible to free labour in Spain and certain Latin American countries. It also furnished direct financial assistance to workers in Hungary and Tibet and campaigned against racialist policies in South Africa.

Failures and successes of the ICFTU. Lack of homogeneity among affiliates hindered the activity of the ICFTU in many fields, chiefly because of differences among its affiliates in the approach to unions in Communist-controlled countries. It found its work to be most effective in the area of international education. By 1960 it had created an International Solidarity Fund of $2,000,000 to aid workers who became victims of oppression and to promote democratic trade unionism in economically underdeveloped countries. Problems of union organization were discussed at ICFTU seminars in various parts of the world, with experienced labour leaders and labour spokesmen from the less industrialized countries participating.

To facilitate the functioning of its widespread activities, the ICFTU established headquarters in Brussels, Belgium, with regional or subregional offices in many other countries. From one or more of those centres it conducted numerous educational conferences, maintained a residential trade union training college in Calcutta, India, and assisted in founding an African Labour College in Kampala, Uganda. It provided assistance to inexperienced workers in areas in the first stages of industrialization and sent organizers to Lebanon, Okinawa, Cyprus, Cameroon, India, Indonesia, Nigeria, and elsewhere.

Worldwide program of training industrial workers

It has been the consistent policy of the ICFTU to cooperate with the United Nations Educational, Scientific, and Cultural Organization and with the International Labour Office in Geneva. It is wholly financed by contributions from its affiliates.

Communist and Catholic federations. The WFTU, meanwhile, has continued to be completely dominated by the Communists. It claimed to represent more than 90,000,000 workers by 1960, more than one-half in the Soviet Union and a large part of the remainder in Soviet satellite nations. It also has substantial affiliates in France and Italy. The WFTU has adhered strictly to the Communist Party line and has not cooperated with other organizations, serving more as a political instrument than as an economically oriented federation of unions.

A much smaller international organization, the International Federation of Christian Trade Unions (IFCTU), now called the WCL (World Confederation of Labour), is made up largely of Catholic labour unions in France, Italy, and Latin America. The ICFTU, at its founding congress in 1949, invited the affiliates of the IFCTU to join, but the invitation was rejected. On the international scene, the WCL has been a comparatively ineffective organization, its influence limited to a few countries in Europe and Latin America.

BIBLIOGRAPHY. The classic works on this subject are: SIDNEY and BEATRICE WEBB, *History of Trade Unionism*, rev. ed. (1920), *Industrial Democracy* (1920); JOSEPH SCHUMPETER, *Capitalism, Socialism, and Democracy*, 3rd ed. (1950); C. KERR *et al.*, *Industrialism and Industrial Man* (1960); S. PERLMAN, *A Theory of the Labor Movement* (1949); and J.T. DUNLOP, *Industrial Relations Systems* (1959).

The international labour movement is well presented (up to 1950) in L.L. LORWIN, *The International Labor Movement: History, Policies, Outlook* (1953).

Surveys of the literature may be found in A.M. ROSS (ed.), "Literature on Industrial Relations and Economic Development," in *Industrial Relations and Economic Development* (1967); and A. STURMTHAL, "The Labor Movement Abroad," in N.W. CHAMBERLAIN *et al.* (eds.), *A Decade of Industrial Relations Research, 1946–1956* (1958).

Larger areas are treated on a comparative basis in H.A. CLEGG, *A New Approach to Industrial Democracy* (1960); W. GALENSON (ed.), *Comparative Labor Movements* (1952); E.M. KASSALOW, *Trade Unions and Industrial Relations* (1969); A. STURMTHAL (ed.), *Contemporary Collective Bargaining in 7 Countries* (1957), *The Tragedy of European Labor, 1918–1939* (1951), and *Unity and Diversity in European Labor* (1953).

The bulk of the literature is devoted to individual countries. Among the outstanding works are: S.B. LEVINE, *Industrial Relations in Postwar Japan* (1958); V.R. LORWIN, *The French Labor Movement* (1955); KENNETH F. WALKER, *Australian Industrial Relations Systems* (1970); J.P. WINDMULLER, *Labor Relations in the Netherlands* (1969); I. BERNSTEIN, *The Lean Years: A History of the American Worker, 1920–1933*, and *The Turbulent Years: A History of the American Worker, 1933–1941* (both 1960); E.C. BROWN, *Soviet Trade Unions and Labor Relations* (1966); A. FLANDERS, *Trade Unions*, 7th rev. ed. (1968); D.L. HOROWITZ, *The Italian Labor Movement* (1963); INTERNATIONAL LABOUR OFFICE, *The Trade Union Situation in Sweden* (1961), *The Trade Union Situation in the United Kingdom* (1961), *The Trade Union Situation in the U.S.S.R.* (1960), *The Trade Union Situation in the United States* (1960); and T.L. JOHNSTON, *Collective Bargaining in Sweden* (1962).

Traffic Control

Traffic is the movement of people, goods, or vehicles between separated points, and traffic control involves the attempts to make these movements as fast, efficient, and safe as possible with minimum damage to the environment. Traffic control may thus involve planning automobile, truck, bus, and pedestrian movements through the congested streets of a large city; the design of navigation systems for aircraft takeoff, flight, and landing; and mechanized handling of freight for cargo ships. Inadequate control is characterized by congestion, pollution, and accidents.

The kinds of traffic present in a transportation system result from established patterns of activity. The principal land traffic systems, surface and underground, were over roads and railways, though other kinds are developing. Pipelines provide a unique continuous-flow means of moving an increasing variety of materials; though somewhat inflexible, often limited to single commodities, and directional in use, they have the important advantage of being practicable for almost any type of terrain. Cableway and conveyor systems are being developed for pedestrian use in high-density pedestrian traffic areas.

Sea and air transport are the other major types of transportation, but a number of hybrids are under development. Hovercraft (vehicles able to travel over land or water supported on a cushion of air), for example, have added a whole range of potential applications to vehicle technology since their development in 1955. Hovercraft control has aspects in common with both sea and land vehicles and, because of their high speeds, with air traffic (see AIR-CUSHION MACHINES).

The main recent changes in air transport relate to the possible development of supersonic transports and, as in the case of shipping, increasing vehicle size. An especially promising development is the potential reduction in size of airports. Now requiring thousands of acres, they may be reduced in size by vertical-takeoff and associated aircraft types. In shipping there is more specialization of carriers: in some, the cargo is divided up into individual shipping units, as in barges; others unload from a parent ship in small self-propelled units; and others carry cargoes in submarine plastic containers.

The more mixed the traffic to be controlled is, either by type or performance, the greater are the control problems in maximizing vehicle flow and assuring safety. Control is usually exercised by a particular supervising agency for specific types of traffic; problems of competition and regulation arise between these agencies.

ROAD TRAFFIC CONTROL

The following discussion is limited to questions affecting traffic control. For a complete treatment of road design, construction, and maintenance, see ROADS AND HIGHWAYS.

History. Traffic congestion, often bad enough to require drastic control measures, was a feature of city life at least as early as Roman times. A basic cause, then as now, was poor city planning, with roads laid out in such a way as to bring traffic from all quarters to a central crossing point. In the 1st century AD Julius Caesar banned wheeled traffic from Rome during the daytime, a measure gradually extended to cities in the provinces. Late in the 1st century AD the emperor Hadrian was forced to limit the total number of carts entering Rome.

The problem moderated with the decline of commerce in the early Middle Ages, but reappeared during the resurgence of city life in the high Middle Ages, when road maintenance and traveller safety were more paramount problems than traffic control. About 1500 Leonardo da Vinci, envisioning a revolutionary solution to urban traffic problems, then acute in the crowded and busy Italian cities, proposed separating wheeled and pedestrian traffic by creating routes at different levels. Except for the railways, however, very few segregated route systems were established before the 20th century.

Congestion was severe enough in European cities of the 17th century to require ordinances prohibiting parking on certain streets and establishing one-way traffic. The advent of the railroad brought temporary relief to the growing problem of road traffic control, though it created congestion at terminals inside cities. The automobile, with its increase, first in speed and then in numbers over horse-drawn transport, rapidly created a new situation that was to become one of the characteristic problems of urban industrialized society in the 20th century.

Traffic elements. Much motor traffic is still carried on roads that were conceived, if not used, for the horse-drawn vehicles of another age, though roads designed primarily and exclusively for motor traffic are not only easier, safer, and more efficient to drive on but facilitate the best form of traffic control. The essential features of major routes include separation of types of traffic and levels (grade separation), control of access, and design standards suited to the types of vehicle and drivers expected to use the routes. Most of these characteristics are included to permit "free-flowing" traffic on autobahns (Germany), autostradas (Italy), autoroutes (France), freeways and expressways (U.S.), and motorways (U.K.). Early examples of such motor roads were the Avus in Berlin opened in 1919, the Bronx River Parkway in New York opened between 1921 and 1924, Lake Shore Drive freeway in Chicago in 1933, Frankfurt-Darmstadt autobahn in 1935, and several privately financed motor routes built around Milan between 1922 and 1930. The U.S. interstate system, due for completion in the 1970s, is now the most comprehensive highway network in the world.

"Free-flowing" traffic

The elements of road traffic and their various functions are many and often conflicting. In all countries, the needs of pedestrians are quite different from those of vehicles. Vehicles themselves may wish to move at high speed, to manoeuvre and circulate through congested areas, to stop frequently for loading and unloading. Policy makers try to plan traffic-control systems to minimize such conflicts.

Problems. The principal problems associated with road traffic are those which relate to its impact on city dwellers and on commuters while in the city (see also TRANSPORTATION, URBAN). Individual mobility and the desire for travel in the developed countries are increasing at such a rate that demand for roads invariably outstrips supply. Congestion and a continuous worsening of public transport facilities is the result, and this in turn tends to affect urban land use. Cities spread out in patterns determined more by the motor car than by human social needs. New areas lack a cohesive structure. Administration of these huge urban-suburban areas is a continuing problem. Of more immediate significance is the worldwide toll in death and injury that results partly from the failure of road users or their vehicles and partly from improper road design. Furthermore, the growing public awareness of the noise, atmospheric, and visual pollution caused by road vehicles makes it imperative to review vehicles, roads, and their relationship.

Government regulation. All nations regulate vehicles and drivers on their highways. Drivers are regulated by age, types of vehicle driven, and financial provisions; vehicles are controlled by specifications pertaining to registration, ownership, mechanical worthiness, required accessories, sizes, and weights. Further regulations determine the manner of operation of vehicles on the public highways. Uniform Traffic Acts and Model Municipal Ordinances have been developed to guide traffic legislation throughout the U.S. The nations of western Europe have cooperated effectively in highway and driver regulation. A notable success is the European system of road signs, which employs symbols instead of words to overcome the language barrier. In the underdeveloped countries, where roads and highways are now considered to be critical to economic progress, government takes an even larger role.

Conventional control techniques. Among the principal types of highway control are rules limiting the use of streets. The one-way street was one of the earliest measures and is still in widespread use. Traffic flow can be thought of as possessing properties analogous to frictional materials. The capacity of an undivided street is thus increased if traffic is allowed to move in only one direction. Furthermore, if side streets are used to handle complementary flows, the capacity of the traffic network is further increased. Other general benefits include a reduction in accidents and shorter journey times. Similar considerations apply to the banning of turns, particularly those which require crossing major traffic streams.

The traffic engineer attempts to ensure a homogeneous traffic flow in order to encourage a greater degree of consistency in traffic behaviour. Speeds can be limited with maximum allowable speeds established for specific locations. Another set of restrictions involves loading and unloading, and parking. Curbside parking seriously reduces the potential flow in a street and thus limits its capacity, and often increases the accident rate. Further, parked cars may block the way of public safety vehicles such as fire trucks. Loading, unloading, and parking are controlled by the designation of parking areas, no parking zones, loading zones, time limits on parking, etc. Increasingly important are control measures aimed at improving the flow and regularity of public transit vehicles, particularly in downtown areas.

Traffic-control devices

Traffic-control devices are often used to inform the driver of various conditions affecting road use. These can be divided into categories. Regulatory devices may be either prohibitory (no entry, speed limit, no waiting) or mandatory (stop, keep left, yield). Warning devices are used to warn the road user of hazardous conditions, unusual traffic movements, or special local conditions (children playing, junctions, slippery road surfaces). A final group is that of guidance or informative devices giving route and other pertinent information (destinations, parking and service areas, information offices). The principal devices are road signs and carriageway markings. To ensure effectiveness, these must compel attention and quickly convey their meaning and adequate time must be allowed for driver response. Signs must furthermore command respect and be sited to minimize accidental collision. Ensuring maximum performance is related to uniformity of siting and layout, and the development of correct habitual responses is important. Uniform national standards have been adopted in most countries and an international system in western Europe as noted above. International standards have been drawn up in a United Nations Protocol on Road Signs.

Road traffic signals have improved in effectiveness since their introduction 100 years ago. Their purpose is to promote the orderly movement of traffic and reduce the frequency of accidents. In large cities it is necessary to synchronize street networks in order to maximize traffic flow. Traffic signal controllers are either pretimed or traffic-actuated. Pretimed controllers, widely used in Eu-

rope and the U.S., allocate a specific time interval to each stream of traffic in an orderly repeating sequence. Extensively used in Britain for many years, traffic-actuated signals vary the time allocation and sequence in response to actual traffic demands as measured by traffic detectors. Individual signal units have an illuminated red, yellow (amber) and green lens mounted in a signal head, directionally sited on poles or wires. At least two signal heads are visible to a traffic stream. Pedestrian signals which indicate when to walk are often added. Today's designers, however, prefer to segregate pedestrians and vehicles by constructing overhead or underground walkways.

Cycle length, that is the time required for a complete sequence of signal indications, normally varies between 30 and 150 seconds. A short cycle length reduces the overall capacity of the intersection. The alternative, a long cycle, may provoke some impatience but a driver is not concerned merely with the time lost at a single junction as much as with the speed and smoothness of his whole journey. Considerable research in recent years has been aimed toward limiting delay in traffic control systems. Early coordinated movement patterns were developed with fixed-time signals to allow compact groups of vehicles to progress along a street together. This simultaneous system required that all colour indications be alike at the same time, and had the unfortunate effect of causing drivers to exceed speed limits without achieving high overall journey speeds. This disadvantage was overcome to some extent by an alternate system in which all signals changed indication simultaneously, but adjacent signals showed opposite colours. Problems arose because, since the greens and reds must be of approximately equal duration, the system is suited only to uniformly spaced blocks with cross flows approximately equal to those progressing down the street. A better compromise is the limited progression system which uses a master controller to offset the start of each green phase to enable a speed progression to be maintained by vehicles. A more advanced master controller can operate the flexible progressive system which permits a variation of progression plans by remote control, for example to cover peak hour operation, or to favour directional movements of traffic at particular times of day.

Area traffic control

Digital computers have made possible more complete and more extensive forms of control. Computer control of large networks of roads is generally called area traffic control (Figure 1). Information is obtained by a variety

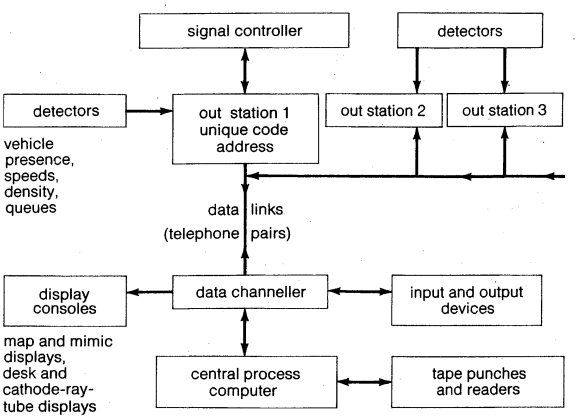

Figure 1: Relationship of elements in a road-traffic area-control system.

of traffic detectors installed in the street system, which measure the presence of vehicles, traffic flow rates, stopped time, speeds, and turning movements. The greater the number of detectors and measurements being made the more complex and expensive the system becomes as items of data are fed over special lines, or are coded and carried on standard telephone cables. Information is processed by the central computer which can then determine settings for all the traffic signals in the network based on some optimization of time, speed, or flow for all traffic or for a particular segment of the flow.

Ideally, such control is dynamically responsive to all changes in the state of traffic flow. Few, if any, systems operate at this level. The more usual arrangement is for a computer to scan the data inputs and compare what it deduces of the current situation with past experience and then select the nearest suitable set of control plans, built up by trial and error over a time period and stored. The selected plan may be modified by further computation to fit a current traffic situation more precisely. Thereafter the computer directly or indirectly operates the switching system that controls the signals.

In the control centres information is printed out on teleprinters; often display diagrams indicate the current state of all signal settings, flows, and journey speeds along routes. These displays may be further supplemented by tabular information on cathode-ray (television) tubes and by closed-circuit television surveillance. This latter facility enables the controllers to monitor the smooth operation of the system and simultaneously, to recognize situations such as accidents which the computer cannot understand.

Electronic control on important high capacity routes of a freeway or motorway is becoming a normal feature of such roads. Its essential purposes are to facilitate traffic merging from entrance ramps into the available gaps of the main stream and to redistribute traffic to adjacent streets if the capacity of the route is being impaired by too many vehicles entering. It is also necessary to warn drivers of hazards and of the consequences resulting from emergencies. Information about gaps in the traffic stream, breakdowns, or hazardous weather are collected by surveillance systems and relayed to a local or central processing point. Detectors coupled with auxiliary equipment are capable of deducing traffic flow and speed. Radio telephones and closed-circuit television may be used as supplementary aids, the latter sometimes being triggered and directed to locations in the system when other types of detectors indicate unusual outputs. New types of signals, capable of displaying various messages such as lane closures, accidents, fog warnings, and speed control, can be set automatically and remotely from integrated control centres which maintain emergency services and receive information continuously from surveillance equipment and both ground and air police patrols.

New concepts in control. Several experimental automatic road-vehicle systems have been built in the U.S. and Europe. While a standard of exceptional reliability is a basic requirement of a practical system, and while present costs are high, improvements in micro-electronics and in solid-state microwave sources indicate that costs might be more than offset, in the 1970s, by reduced accident rates and more efficient use of highways. The latter characteristic may be achieved by a high-speed electronic guidance system which could achieve a fivefold increase in present lane capacity, from 2,000 to 10,000 vehicles per hour, at speeds from 60 to 75 miles per hour (96–120 kilometres per hour). One concept, involving electronically coupled automobiles moving like the cars of a railroad train, could raise highway capacity to 40,000 vehicles per hour.

Steering systems

Steering systems are operated by mounting two magnetic field detectors at the front end of the vehicle equidistant from the centre of its longitudinal axis. A guidance cable, installed in the road, sets up a surrounding circular magnetic field. Any movement of the vehicle, from the travel axis, is measured as a transverse error causing corrective operation of the electrohydraulic steering mechanism. For further control purposes a speed signal is emitted from a buried cable; deviations from correct speed cause either acceleration or braking of the car. Particular difficulties with these systems involve the design of transitions from manual control areas to fully automatic areas and the achievement of technical reliability. In addition, difficulties of unlocking traffic jams in which vehicle densities are five times those at present, may be extraordinary.

Several semi-automatic systems offer stepping stones to full automation. One of the principal problems, which both limits driver performances and increases road acci-

dents, is the saturation of a driver's visual processes with a multiplicity of signs and signals. Improved methods of conveying the most important information have been developed in research programs. "Talking" signs for example, are activated by a signal from an approaching vehicle; their taped information is transmitted to the vehicle receiver for the driver's response. Receivers can be built so that they respond only to the roadside transmitters if the driver requires it but an override can be installed to permit the relay of important information such as traffic holdups ahead, accidents, changes in weather conditions, and information on parking.

Experiments have also been made with automatic routing systems. Traffic detectors linked to a computer measure flows and compute journey times on all parts of the road system. Control information is relayed to signs that display the most suitable routes to be used by approaching drivers to reach important destinations. One experimental project offers an individual route guidance system. The driver inserts a punched card, coded with destination and route requirements, into a transmitter which triggers a matching code transmitter at the approach to each intersection. A low-frequency response signal switch switches a visual display monitor on the vehicle's control panel indicating the turns required.

RAIL TRAFFIC CONTROL

History. The first slow and cumbersome horse-drawn rail traffic posed few control problems not resolved by follow-the-leader principles. It was only after the development of swifter steam-driven trains, in the early years of the nineteenth century, that more frequent trains and their proximity to each other created dangers of collisions. The smooth contact between tracks and iron wheels allowed higher speeds and greater loads to be hauled at the same time that the low friction necessitated long stopping distances. Engines were fitted with brakes and, later, manned brake vans, whose guard could apply the brakes when the engine driver signalled with a whistle.

Trackside control also developed slowly with the first signalman, or "railway policeman," located at passenger and goods depots, or stations, sited along the line. These men indicated, by means of hand signals, the state of the track ahead. Red taillights were mounted at the rear of trains at night to improve safety. Later, signal flags were often replaced by swivelling coloured boards, or disks, for daytime use and with coloured lights at night. Later, signals were located well ahead of stopping points, giving rise to the term "distant signal." As was the case with other modes of transport, the need for control increased with greater traffic movements and faster operating speeds; in the early period, elaborate signalling was unnecessary since the frequency of service was such as to still permit adequate train spacing. The first real method of control was the development of a time-interval system of train spacing. In the event of breakdown or accident, however, there were no means of delaying a following train from entering a section of track except by a physical check on entry and exit by sections; *e.g.*, a brakeman with a flag or lantern.

Telegraph communications

First introduced for railway use in England between Euston and Camden in 1837 the electric telegraph, permitted communication between fixed signal points. Each signalman was responsible for a portion of track known as a block section. Bell codes were used to describe the class and route of the train to be passed by the signalman to the next block section or to accept or reject a train from the preceding section. Generally, only one train was permitted in a section at one time; under poor visibility conditions a section was normally kept empty between every two trains. Many decisions of precedence were left to the individual signalman, and with only limited information at their disposal, signalmen often made incorrect decisions causing excessive delay. At the same time, standard codes and rules were established by most railway companies and safety was further improved by the introduction of Westinghouse air brakes about 1870.

Because concise and standardized information was needed by the engineer, mechanical semaphore arm signals, operated remotely by wires from a lever in a signal box, were developed in 1841 as a principal means of communication. The angle of the arm indicated stop, proceed with caution, or clear ahead. For night use coloured lenses, mounted near the pivot of the arm, are passed across a light source, thus displaying, for the different arm angles, either the familiar red for stop, yellow for caution (approach, reduce speed), and green for clear (proceed as authorized). Similarly the remote control and setting of points, in a block, was transferred from the trackside to the charge of the signalman. Interlocking devices were designed in the 1850s to prevent conflicting settings of points and signals. The time losses due to poor acceleration and deceleration characteristics of trains were obviated, to some extent, by the increasing use of presignals, informing the driver that the signal ahead might be at stop and requiring him to reduce speed or proceed slowly from a stop. Thus the more violent fluctuations were smoothed out; similar control arrangements have now been adopted for use in European cities to control road traffic.

Traffic elements. Railways in most countries are classified as either private or common carriers. Private carriers are in the minority, operating mostly in lumbering, industrial plants, and mining. Further operational classifications are made on the basis of the type of traffic carried. Principal subdivisions are intercity routes (line-haul), intracity route networks (commuter), switching services for warehousing and industrial plants, and general terminal operators.

Rail traffic is divided into passenger and freight, and, although both normally operate over the same system, there are special control problems particular to each. In recent years it has been clear that it is necessary to consider the total journey made by the rail passenger rather than simply the time he spends in the train. The integration of rail services with other forms of transport is essential, particularly in locating stopping points and in designing mainline terminals or commuter stations.

Freight is now a predominant factor in all rail operations. Although the heart of the freight control system is still the so-called marshalling yard, where individual wagons are collected for train makeup, recent years have seen the development of bulk trains, designed specifically for single train loads and running from a private siding to a similar destination siding. The rolling stock is often semipermanently coupled and the handling equipment at the terminals is usually designed for continuous operation of the system at a high capacity.

New systems management and control methods are still needed to improve the speed, regularity, and comfort of rail services while safeguarding established high standards of safe operation. The required resources are often beyond the capability of an outdated industry to provide; direct injection of capital, by national governments, is a worldwide phenomenon.

Conventional control techniques. Modern railway traffic-control techniques are principally automated developments of earlier systems based on timetabling, operating rules, and signals. The scheduling of trains in a working timetable predetermines the basic running patterns and the daily work pattern of personnel. Unscheduled operations require controllers to change the schedules. Minimum intervals between trains are determined, on the basis of track conditions. Time–distance diagrams are often used to compare running conditions with those in the timetable and to indicate when and what type of regulatory intervention is needed.

Colour light signals

Colour light signals have now largely superseded semaphore types. Because they are operated electrically, colour light signals can be sited at distances remote from the signal box. Combinations of light colours can be used to indicate different requirements to the driver. High intensity lights, visible over great distances, are particularly advantageous in poor weather. Searchlights use a single lens and bulb with different colours displayed by means of panels on colour filters rotated in front of the lamp. Lights can be more appropriately sited in relation to the driver's cab position and permit a greater variety of infor-

mation to be efficiently displayed. With the development of hydraulic, pneumatic, and electrical methods of switching, the problems of distance are overcome and the displacement of mechanical devices from the local signal box enables many more sets to be controlled from a central point.

The basic element in automatic control is an electric circuit built into the track which operates track signals. When a train enters a section of track it causes the current to detour through the locomotive's wheels and axles, instead of completing its normal circuit, altering signals ahead.

When a train has passed a section, the signal behind it is automatically switched by a track circuit immediately ahead to indicate danger. As the train advances to the next section, the first signal can automatically be changed to a lower state of warning and so on until a full clearance signal is set at a given number of sections behind the train. The number of intermediate sections left behind a train is determined by train speeds and section lengths, and influences the capacity of a track.

Today, manual signal boxes have generally been replaced by a few centralized boxes controlling large areas of track. All operations are performed with pushbuttons and the system is designed with full interlocking plant preventing any mis-setting of switches, points, and signals. Each movement can be made only in a predetermined and safe way, eliminating the setting of conflicting routes and signals. Operation of all devices is monitored and relayed from the trackside to an illuminated display on a track diagram. Newer systems also monitor all train movements with individual identity and location indicated by lights supplemented by cathode-ray tubes.

Additional automation has been carried to the cab. Relays, tuned to the transmission of a particular frequency, feed back an activating signal rearward. Similarly each track circuit is set to control the signals. Coded circuits operate other train-borne devices by the installation of suitable receiving coils mounted, above the track, at the front of the locomotive. In this way trackside signal displays are transferred to the cab, reducing the risk of a crew missing a signal. Greater safety margins are provided by the addition of audio signals. Various methods of providing coded impulses include systems in which drivers must respond to audio warnings with an acknowledgment signal. Automatic train stopping is provided by the same means, and in addition, the brakes may be automatically applied if a driver fails to respond to track restrictions. Another form of visual display makes use of a moving map continuously indicating a spot position.

Radio communications

The first recorded moving train two-way radio was used by the New York Central Railroad in 1928. Radio offers a number of advantages in improving communications between train crews and control dispatchers or maintenance gangs on the track. It also establishes a direct link between trains and obviates the need for crews to use wayside telephones. Equipment failures can be reported directly and because of this and other advantages, particularly in automated marshalling yards, delay is reduced. Most railways throughout the world are equipped to some extent with two-way train radios.

A further development is the automation of route-setting procedures. These enable a controller to notify the computer at the beginning and end of the required route; thereafter, all intervening signals and points are automatically established. Storage of a working timetable in program form can be used to initiate the route settings for each subsequent track movement and as each train clears appropriate sections of the track. At the same time identities of trains may be transmitted from one control to another in the form of unique labels, known as head codes. Thus, in addition to changing the signals behind it to red as it proceeds from section to section, a train can remotely generate complete new control sequences.

The development of computer-controlled freight transit is incomplete until a corresponding organizational and documentation process for the dispatch and receipt of goods has been integrated within the total system. A customer may, for example, transcribe orders to the transport system, specifying commodity type, consignment identity, consignor and consignee information, payment instructions, priorities, etc. Information can then be relayed to and from the computer and prices indicated for a particular consignment. In the next stage, trains are made up after each wagon has been loaded and, if required, part-load consignments can be allocated a space number in a specified wagon. Train makeup takes into account engine types, routing, overall weights and lengths, numbers and types of cars, and braking power for all trains leaving a siding. The information is then relayed to points down the line by telephone, telegraph, or teleprinter for the reverse process of train breakup. The grouping of consignments for common destinations into single cars reduces transshipment costs and time losses. Where placement lists of all loads are stored in a computer, optimization programs can be developed to minimize subsequent trucking distribution movements.

Sorting freight cars is a complex operation. Various control systems have been installed in marshalling yards enabling cars to be pushed over a raised track, known as a hump, so that the car travels freely down a grade and over switching points to its correct berth. Automatic humping includes sensors to detect car speed and weight, from which car rolling resistance is estimated. Once the uncoupled car has been allocated a train and siding, automatic switching sets the points along its predetermined path. Simultaneously the computer calculates the speed required for the car to reach the end of the train. Automatic braking devices or boosters reduce or increase the car's speed off the hump to that needed to reach its train coupling point in the siding.

Other, more refined, methods remotely control the pushing locomotive. The spacing of cars rolling off the hump, the automatic control of the pushing speed, and the control of retarders or speed boosters are all directly controlled by computer. Identification of car destinations is an essential part of the process. Manual checking in the yard with radio links to the yardmaster have been displaced by closed-circuit television checking off the train against the makeup list forwarded by teleprinter.

The final scheduling and control of the freight train is integrated into the comprehensive rail control system, and computers permit the computation of alternative strategies with an assessment of benefits. Controllers finally impose their selection of priorities. In the 1970s many of these systems were becoming universal.

Modern signalling systems

New concepts in control. Modern signalling systems have improved the safety, efficiency, and operating economies of railways by providing better track capacity and more flexibility. In West Germany alone more than 10,000 hand signal boxes in 1945 had been reduced to fewer than 3,500 in 1971, and the process is continuing throughout the world. Future control systems are largely developments of existing concepts, but wider area traffic control will be available as the reliability of components is improved and methods of optimizing large networks with multicommodity flows develop.

Difficulties occur when trains are run at different speeds under the same control system. The location of signals, for instance, is determined on the basis of the number of sections required for the fastest train to brake from full speed. This distance is excessive for slower moving trains and hence, because density cannot be maintained, line capacity is reduced. The greater the disparity, the more exaggerated the loss of efficiency will be. Because time is important to passengers, train speeds are rising; on the New Tōkaidō Line, a 500-kilometre section between Tokyo and Osaka carries 200 trains a day with more than 50 travelling at speeds up to 210 kilometres per hour.

A method of overcoming disadvantages of mixed traffic is the so-called moving block. In this system the fixed track block is replaced by a moving zone in the front and the rear of the train, the length of the zone determined by the speed of the train. If a train enters another train's zone, signals appear in the cab and at the same time automatically decelerate the train. The moving block system can be applied to express traffic while the conventional system is preserved for slower traffic.

Separating trains by an optimum minimum headway (distance between two trains moving in the same direction) requires the following train controller to have continuous information on the track ahead, including train positions and hazards. This information can be supplied by radar, overhead lines, and other methods.

These developments lead toward automation of the whole system, including driverless trains. A particularly interesting application of these principles is used in new urban rapid transit railways of which the Bay Area Rapid Transit railway in San Francisco is an example. A full system concept is being developed under complete surveillance, with computer processing and monitoring of all aspects ranging from automatic revenue collection to absolute traffic protection (insurance of no collisions) and automatic protection in case of computer failure. Operating speeds are up to 130 kilometres per hour at headways of 90 seconds.

Traffic control and communication is divided into three subsystems, line supervision, traffic protection, and automatic traffic operation. Unlike other control systems mentioned earlier, this system dispenses with central control and operates on the basis of car-carried traffic control, station and trackside control, central supervisory control, and the traffic telephone system.

Failure rates

Failure rates have been assessed for each subsystem based on component failure rates and, in turn, their failure consequences determined for the overall degradation of the system. Fail-safe operation and the minimization of delay were essential considerations. Maintainability has been the key to design of diagnostic apparatus. Other considerations have included a study of customer-created problems through the misuse of automatic ticket machinery (see also RAILROADS AND LOCOMOTIVES).

AIR TRAFFIC CONTROL

History. In the early days of flying, man depended mainly on his own senses aided by primitive controls borrowed from the mariner. The penalties of failure were severe. The first step toward improvement was to end the basic hazard of the aircraft pilot's isolation by installing a communication system. After World War I commercial aircraft were regularly equipped with radios for communication between ground and air. Positioned information and estimated times of arrival were relayed to the ground. Ground stations, in turn, transmitted weather and instructions to the aircraft. With the development of regular routes, networks of ground stations were established so that positions could be determined with known direction-finding techniques: the beaming of an aircraft's radio signal was simultaneously plotted on maps at two or more ground stations, and the resulting positional intersect of the bearings was relayed to the aircraft's radio operator. This technique permitted course corrections to be made when the ground was obscured by clouds. In the late 1920s, the development of radio beams enabled a pilot to follow a track to his destination. (For a detailed discussion of this subject, see NAVIGATION.)

With all these methods, however, control still depended largely on the pilot and, in those early days of aircraft radio, interference, topography, and weather often obliterated the transmissions. Terminal control was limited to the use of light signals by the ground control officers. Later the radio link was added to the system.

While air travel expanded steadily, it was not until World War II that the need to handle large numbers of aircraft brought the development of much more sophisticated types of control. Night bombing led to the development of so-called en route control in which pilots were given time checkpoints along the flight path and at the target point. The problem of returning to a darkened home base many hours later and perhaps, in very different weather conditions, led to the use of the standard beam approach in which the pilot located himself once his aircraft entered a signal beam emitted by a ground transmitter. The wide, fan-shaped beam, tapering to a point at the end of the runway, was divided into two halves, one of which was dots, the other dashes. The plane followed the path where dots and dashes overlapped, forming a continuous note. As an aid to the pilot in determining his position and the point at which to begin a descent, additional transmitters, emitting a vertically directed signal of different intensity, were provided.

Improved ground control methods were also necessary in wartime because of the large number of aircraft returning to a base at the same time. Aircraft and bases exchanged radio identities and sequences of landing were established, including stacking, directing returning aircraft to circle at 1,000-foot (300-metre) altitude intervals. The lowest aircraft was designated the next in turn to land, with each higher aircraft descending through a one-thousand-foot step to its next altitude until the last had been accommodated by the controller on a specified runway. Ground controllers also established "talk-down" methods. One such system developed at the time was called controlled descent through cloud and has led to a modern version, ground-controlled approach.

Traffic elements. Aircraft are flown today for numerous purposes ranging from scheduled airliners to unscheduled airliners, military aircraft, bulk cargo carriers, and such independents as private business and sport planes, crop sprayers, weather craft, and traffic controllers. Operational control of aircraft depends primarily on their service use, on whether they fly near the ground or in adverse climates away from bases, and whether they operate from land, water, or ice. Aircraft have high operating costs and, with increasing sophistication, represent larger investment problems and fly from complex and costly ground bases. Helicopters and the newer generation of vertical-takeoff aircraft have somewhat different characteristics and, therefore, individual control problems.

Lengths and widths of runways are classified according to the type of traffic they handle. Principal types include private, secondary, feeder, continental, and intercontinental airports.

Collision avoidance

Problems. Collision avoidance remains a critical traffic control problem. Systems are developed and can act as a supplementary aid in terminal areas, as well as the principal sensor in airways lacking ground surveillance equipment. Considering the high closing (approaching) speeds of modern aircraft (20 miles, or 30 kilometres, per minute) the somewhat lower ascent or descent rates (two miles, or three kilometres, per minute and four miles, or six kilometres, per minute, respectively) and aircraft capability for rapid acceleration, it is necessary to be able to specify required avoidance manoeuvres quickly from among available options. Simple proximity warning indicators detect aircraft presence, within certain ranges, in the surrounding airspace and warn the pilot, but avoidance ultimately depends on visual sighting of the intruder. Newer types of instruments, operating on a common frequency, transmit regular interrogation pulses; other aircraft respond with an identity "label." This is in a digital code form, presenting such information as altitude and rate of change in altitude, together with range-finding signals. Extremely accurate atomic clocks are synchronized in order to measure the time elapsed between the sending and receiving of signals and to deduce the interval of time separating the two aircraft. Without directional location, avoidance options are limited to a vertical plane of escape, but both aircraft must make the correct decision relative to the other; generally one moves up and the other down.

Thunderstorms ahead of aircraft are readily detected by airborne radar, but ice particles and other turbulences in the upper altitudes are not. While airports are usually sited to avoid frequent fog situations, as many as one in fifty landings must be aborted because of visibility conditions. New electronic automatic landing systems, using radio altimeters in conjunction with a computer, have been perfected, and it is likely in the future that fog will be more of a hazard on the journey to and from the airport. Accidents and pollution problems, including smoke, turbulence, and noise, have grown increasingly important. (See also TRANSPORTATION, AIR.)

Regulation. Late in World War II a number of Allied and neutral nations convened in Chicago to determine the

arrangements necessary for the safe and orderly development of international air transport. They established the International Civil Aviation Organization to study and report on customs facilities, traffic control, aircraft maintenance, and the important need for standardization. Air-transport terminals, unlike those of other transport modes, are likely to be used more frequently by the vehicles of another nation than those of the host country. Accordingly, standards have been laid down by member nations for all essential matters; factors of lesser import are subject to recommended practices. English has become the international language of control. The rules adopted are updated by regular conventions of the international organization.

Conventional control techniques. The purpose of air traffic control is to regulate flight movements, ensuring that collision courses are avoided and that safe distances are maintained between aircraft. The separation of aircraft is governed by International Civil Aviation Organization rules specifying lateral (angular distance), horizontal (distance or time interval), and vertical (different flight levels) intervals.

Airspace

Airspace is divided by flight levels into upper, middle, lower, and controlled airspace. Controlled airspace includes that surrounding airports and airways, which define the corridors of movement between them with minimum and maximum altitudes. The degree of control varies with the importance of the airway and may, for private light aircraft, be represented only by ground markings. Airways are usually divided by 1,000-foot (300-metre) and 500-foot (150-metre) levels with aircraft assigned specific operating levels, according to direction and performance. Normally all such movements are controlled by air traffic control centres. In upper airspace, above about 25,000 feet (7,500 metres) pilots may be allowed free route choices provided that flight tracks and profiles have been agreed on in advance. In middle airspace all pilots entering or crossing controlled airspace are obliged to accept control and notification must therefore be given to control in advance. Radar advisory services are often available in middle airspace but not generally below 5,000 feet (1,500 metres) in lower airspace. Besides vertical spacings, in airways, horizontal separations are important, usually taking the form of a minimum time interval of ten minutes between aircraft on the same track and elevation with a lateral spacing, typically, of ten miles (16 kilometres).

The simplest form of flight control is called the visual flight rule. Aircraft in controlled airspace must remain at least one nautical mile (1,852 metres) horizontally and 1,000 feet (300 metres) vertically away from all clouds and visibility must not be less than five nautical miles (9,260 metres). Outside controlled airspace, the aircraft must be flown clear of clouds and within sight of land or water. In congested airspace all pilots must obey the instrument flight rule; that is, they must depend principally on instruments for their safety. In poor visibility and at night instrument flight rules invariably apply. At airports, in control zones, all movements are subject to permission and instruction from Air Traffic Control when visibility is typically less than five nautical miles or the cloud ceiling is below 1,500 feet (450 metres).

Procedural control starts with the aircraft's captain receiving meteorological forecasts together with a briefing officer's listings of radio-frequency changes along the flight path and notices to airmen. Flight plans are checked and possible exit corridors from the flight path, in case of emergency, are determined. Flight plans are relayed to control towers and approach control centres. As the aircraft taxis out, under instructions from the ground-movement controller, the pilot awaits his turn to be fitted into the overall pattern of incoming and outgoing movements. Controllers allocate an outgoing track which enables aircraft separation to be maintained; this is determined from a check of the more recently used standard departure clearances. As the aircraft climbs to its initial altitude, on an instructed heading, the departure controller identifies the image caused by the aircraft on the radar screen before allowing any new takeoffs or landings. Further instructions clear the aircraft for its final climb to the en route portion of the flight and the pilots' first reporting point marked by radio devices. This portion of the flight may also be under radar surveillance.

Progress reports on the en route portion of the flight are required, and the aircraft may be tracked on radar. Pairs of transmitters define each leg of the airway. At several points along his route the captain reports altitude, time and the estimated time of arrival at the next listed reporting point. Flight progress strips are made up on boards from the filed flight plans and include all traffic on an airway under that centre's control. Information includes call signs, flight details, and estimated times of arrival at reporting points. As each report is received actual times are entered and the estimated times of arrival are adjusted for subsequent reporting points; altitudes are also checked. Each aircraft has a separate strip for each reporting point. The progress of all aircraft is thus adjusted as the flights proceed, and updating estimates are made of the future state enabling the controller, in direct communication with the flight by radio, to maintain separations and to permit pilots a safe change of course or altitude if these are required.

Flight progress strips

Since the introduction of long-range tracking radar, the flight progress board has been used as a backup system immediately available in the event of instrument failures. Whereas tabulating reported information only represents a succession of reports on an aircraft's position, radar gives continuous coverage of flight movements allowing safe reductions to be made in separations and, thus, increasing capacity (see also RADAR).

At a reporting point en route the receiving control centre takes over the flight from the departure centre, and all further reports and instructions are made to the new control centre. Descent instructions are relayed to arrange the incoming aircraft at separations of perhaps five miles (eight kilometres), in effect, on a slanting line. As the aircraft closes in speed adjustments or lengthening of flight paths may be necessary to maintain separations of three nautical miles over the airport boundary. Controllers determine the landing sequences and stacking instructions and may adjust takeoffs to handle surges in the incoming flights. The final stage is initiated by transfer of control to an approach controller. Under radar surveillance the final directions are given for landing. In the landing sequence, control passes to the control tower where precision radar is used to monitor the landing, and ground movement controllers issue taxiing instructions (Figure 2).

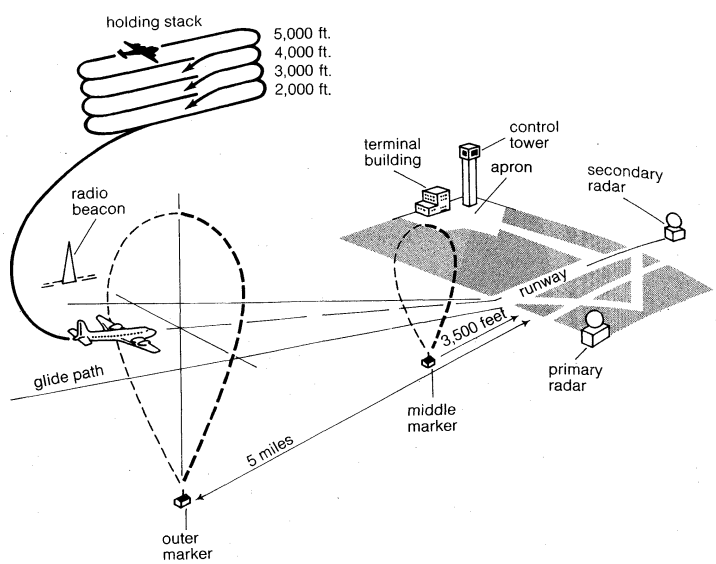

Figure 2: *Aircraft landing sequence.*
Control tower receives information on an airplane's approach via radar, allocates a runway, and issues final instructions so that the aircraft will intersect the glide-path beam of the instrument-landing system. Markers (dashed-line hoops) indicate to the pilot fixed distances from the runway.

The control tower handles the initial and terminal parts of the flight. Other tower functions include the operational control of high-intensity approach lights, emergency services, taxiing movements, and continuous broadcasts of airport information on runways in use and weather details. Besides a clear viewing position of the whole runway area, immediate and direct communication is an important requirement, particularly in coordinating activities with area and approach control centres. Smaller airport towers, with fewer traffic movements, may combine the functions of approach and final control.

New concepts in control. Air traffic control is still a manual operation controlled by humans. Semi-automatic systems are currently being installed, but if air travel is to continue its development, and effective airport and airway capacities with adequate safety are to be achieved, fully automatic systems will be required. Controllers are believed to be at, or near, the limit in the use of radar for aircraft surveillance and sequencing and voice communication for instructing aircrews and receiving information. Information is often limited and lacking in precision, both in terms of the ground controllers and the air crew and, furthermore, can be dangerously ambiguous. Because of this situation controllers and pilots may spend most of their time exchanging information. Decisions are thus in danger of being taken on the basis of incomplete data. The principal objective is to automate both the information and control systems, within a data-processing complex of specified reliability.

Flight data processing

The first essential component of an automated system is a means for processing flight data information. Flight plans, subsequent amendments, weather data, and notices to airmen may be entered directly into a central computer (Figure 3). Information from other centres is carried

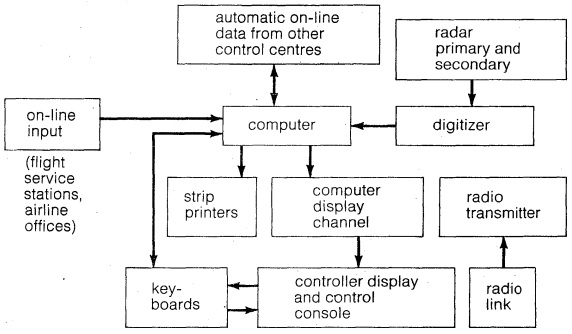

Figure 3: *Elements of an automated in-flight control system.* The information from other control centres and from radar is entered in the computer, which already contains flight plan and weather data.

via data links to remote input devices of the central computer. Operational data, from primary and secondary radar, is first processed into a digital form for onward transmission and subsequent computer processing. Data transfer and printout is available at equipped remote sites within a control centre or at other terminals. Target data and flight plan data can thus be correlated by developing suitable computer programs. Comprehensive information can be displayed to the controller giving automatic aircraft identity and tracking with flight information simultaneously displayed on the controller's consoles. Central computer processing eliminates the manual handling of information from one member of the air traffic control team to another and thus eliminates the use of manual marking. Pictorial displays of airways, obstacles, weather conditions, and boundary markers may also complete the comprehensive coverage. Ground-derived information is always available for positive identity, position, and altitude.

The ultimate development of this semi-automatic system will permit automatic computer ground-to-air control with simultaneous information and display to both ground controller and aircraft pilot for monitoring purposes. Full control will have passed from man to machine (see also TRANSPORTATION, AIR).

WATER TRAFFIC CONTROL

History. Navigation is still the principal means of controlling the paths of ships; direction measurements are made by a navigator using, as of old, a knowledge of the movements of the sun and stars and, since the Middle Ages, the magnetic compass or the later development, the gyroscopic compass (see also NAVIGATION; COMPASS; and TRANSPORTATION, WATER). From early times the need to exchange information between ships and with land stations, led to the development of visual and audible signal systems. Markers were carried by ships and also laid in channels, and the transmission of messages was accomplished through flag, semaphore, horn, bell, whistle, and light signals leading to the establishment of first national and later international codes. The invention and use of radio, at the beginning of this century, brought a marked improvement in ship communication.

Considerable advances in mapping were made over the centuries; modern navigation charts show all coasts, submerged obstacles, sea depths, and navigational aids such as lighthouses, lightships, buoys, and radio beacons (see also HYDROGRAPHIC CHARTING).

New forms of steam propulsion and the design of iron ships in the 19th century led to increased ship size. The growth in world trade brought to the fore the problem of establishing consistent avoiding action when vessels approached each other. International rules of the road at sea were laid down in 1863 and have since been periodically updated.

Traffic elements. Ships can be broadly divided into tramps, specialized vessels, and liners. Tramps are mostly conveyors of bulk cargo, trading internationally, and operating without fixed sailing schedules, generally committed on the basis of time, or for a specific voyage. Specialized carriers include tankers and a rapidly growing group of carriers designed for the movement of iron ore, sugar, and other bulk commodities. Container ships, ferries, and belships, capable of lifting awkward loads of up to 250 tons with large derricks, are among other specialized vessels. Liners are vessels operated as common carriers on scheduled services between ports.

Problems. A fundamental difference of scale exists between the potential size of vessels designed for operation on land and sea. Severe load limitations exist for land vehicles whereas at sea the million-ton ship is by no means unrealistic in the 1970s. The principal traffic problems of harbours and approaches are related to the increasing size of cargo ships and the growing numbers of small craft used for recreation. Many of these difficulties can be overcome by separating one type of operation and craft from another and by more rigorous demarcation of areas of use. Often the siting and establishment of new marinas, away from crowded shipping lanes and established ports, reduces the problems and permits the special needs of the leisure user to be fulfilled.

Water pollution

But a vast and urgent control problem has been created by the increasing pollution of the earth's water. At sea, improved sewage disposal methods and a reduction in air pollution can be effected by waste processing before discharge as required on land for other industrial operations. Reducing oil pollution is a more serious difficulty, long recognized by governments in legislation prohibiting oil discharge within 50 miles (80 kilometres) of land and in the designation and control of ocean dumping grounds. Such control is effected internationally through a United Nations agency, the Inter-Governmental Maritime Consultative Organization, and methods of instituting court proceedings against offenders have resulted from international conventions. Victims of pollution damage are also enabled to claim compensation from ship owners and insurers.

The redesign and development of control systems to prevent oil spillage are important in tanker design. Difficulties have arisen with some new systems due to the explosive dangers of residual vapour in the tanks. Apart from the "creeping" pollution arising from oil discharge during normal operations, the main problem is the danger of collision or shipwreck, in which massive quantities of crude oil or other harmful materials may be released

to pollute vast coastal areas. New methods of treatment are being investigated and disaster procedures laid down, enabling authorities to undertake swift clearing operations.

Regulations, international and national. International regulations control ship construction and use. All important routes are now governed by regional agreements. Shipowners have developed the liner conference system that regulates sailings and ports of call and establishes a common tariff for freight and passenger movements. Postal administrations also contract with shipping companies, through the shipping conferences, for mail handled as a commodity on a tonnage basis. Coastal shipping is usually subject to governmental control. Tramp shipping is based on market chartering of ships or space therein, for the carriage of all types of cargo to and from all ports. The largest of these markets is the Baltic Mercantile and Shipping Exchange in London.

Generally there are obligations for ship constructors and owners to comply with rules, established nationally and internationally, governing classification of ships. These affect ship design, particularly elements concerned with safety standards, including lifesaving equipment, waterproof and fireproof bulkheads, gangways, navigational aids, and construction standards. The maritime nations regularly hold international conventions to consider the problems of safety at sea, including all aspects of navigation. National regulations impose survey systems to check vessels for seaworthy conditions, and societies, such as Lloyd's Register of Shipping (U.K.), American Bureau of Shipping (U.S.), Registro Italiano (Italy), Germanischer Lloyd (West Germany), and Bureau Veritas (France), today classify and survey most of the world's mercantile fleet.

Conventional control techniques. Control of ships on the open sea still remains exclusively with the master of the vessel; when other ships are met established rules of steering are practiced. This ancient arrangement, primitive by comparison with the sophisticated and centralized air traffic-control system, has survived thanks to the expanse of sea and the relatively few ships sailing upon it. Communication between ships is, therefore, vital in their control, both at sea and with the confined channels of inland waterways. The principal methods of transmitting a signal are visual (that is, by flag, semaphore, or light) or audible (by means of horns or radio). The revised International Code of 1934 includes alphabetic, numeral, and answering flags. Urgent messages can be communicated by single flags while three-letter groups are used for compass points, bearings, and times. Semaphore signalling employs hand flags, while Morse can be transmitted visually by searchlights equipped with horizontal control slats, or by radio. Ships also use sirens for "in sight" conditions, to indicate impending course changes and, generally, for warning purposes in bad visibility.

Rules of steering

The control of ships near coasts is facilitated, both for warning and navigational purposes, by the use of lightships and lighthouses. Channels on the approach to ports are clearly marked by floating buoys, usually fitted with lights and equipped with sound signals (horns, bells, and whistles) for use in bad weather or at night. The proper provision of buoys and beacons, anchored in their correct position and their subsequent maintenance, is essential for control and safety purposes.

Buoys are classified by their functional role into categories denoted by shape, markings, and colour. The approach to an estuary for example, is marked by a landfall buoy and main channels by red can-shaped or black cone-shaped buoys. Where channels fork, at junctions, spherical buoys are used to indicate direction either to port or starboard. Other special buoys denote wreck positions, danger areas, and middle ground, the region near the centre of the channel where ships can safely move.

Marine and harbour radar was first developed during World War II in the United Kingdom. Subsequent developments have permitted much shorter wavelengths to be used, employing narrow beam scanners, that give an immediate measurement of bearing and range with accuracies better than 30 seconds and 20 yards (18 metres). Shipborne marine radar assists navigation and helps to reduce collisions at sea, providing map-type information both in darkness and fog of other objects, adjacent coastlines, icebergs, and some types of approaching storms. Harbour radar permits information to be radioed to ships to position themselves clear of channels in controlled anchorages and, entering or leaving port, allows determination of position relative to navigational markers. It also enables irregularities to be monitored by harbour masters and the movements of harbour vessels to be controlled by radio instructions to tug and other masters (see also RADAR).

Collisions occur at sea even in cases in which vessels have clearly sighted each other. This happens when, despite radio and radar equipment, erroneous deductions are made. Some collisions result from the slow response and poor manoeuvrability of ships; this is particularly true of the new supersized ships. Furthermore, because of their great size, new ships congest the few deep channels near coasts or leading to harbours. The mechanization of cargo handling and docks has concentrated the huge new ships into a few ports and their narrow approaches. Such natural shipping lanes as the English Channel, where nearly 1,000 ships a day pass through straits less than 25 miles (40 kilometres) wide, and other heavily used man-made systems such as the Kiel Canal in Germany, which passes some 90,000 ships a year, create the need for new control systems.

Collisions at sea

The first type of physical control system to be applied after the establishment of a basic set of rules for a given area is to segregate opposing directions of movement. A working party from the various navigational organizations of Europe has agreed on a sea-lane three miles (five kilometres) wide, separated by a safety zone two miles (three kilometres) wide, at several European locations. As in all international developments where the rights of nations, or even individuals, have become established over the centuries, the pace and manner of changes are usually exceedingly slow.

Whereas navigational control of a ship refers to its position relative to natural features, operational control refers to the governing of its movements in relation to that of other vehicles and along prescribed channels. A return echo, received from the emission of pulsed radio energy and transmitted by the rotating aerial of a marine radar, is displayed on a cathode-ray tube in a plan position indicator. Ships and channel markers are thus displayed at various selected ranges, from about 1 to 100 nautical miles (1 nautical mile = 1,852 metres), dependent on the power radiated by the installation and aerial characteristics. Newer equipment provides for an automatic plotting of the data aligned to standard charts.

New concepts in control. The development of a new navigation system was based on the principle that if two radio stations transmitted different signals, a receiver, equipped to pick them up simultaneously, could compare the differences and obtain an estimate of its range from the two stations. Such a system has been designed and manufactured using a master station, transmitting two or three slightly different signals at frequencies around 100,000 cycles per second (see NAVIGATION). Over 30 chains of stations are being erected throughout the world's most crowded shipping areas, covering approaches to western Europe, the U.S. and Canadian western seaboards, the Persian Gulf and Indian Ocean areas, and the waters around Japan and South Africa. Other systems, operating over much greater oceanic distances, are being developed from early versions of long-range navigators, but lack the precision of the closer, lower frequency chains.

While many of the problems of the control of inland waterways concern the maintenance of channels and locks, the increasing growth of traffic on major canals, inland seas, and lakes demands more advanced forms of traffic control than hitherto. Many of the most important waterways only offer single-lane operation for the larger ships, with carefully regulated speed control to inhibit erosion. An example of control is that maintained for the busy Kiel Canal, where a speed limit of 15 kilometres per

Control of lakes

hour permits about 180 ships to be accommodated at one time in the canal, with control exercised by stations at either end. The stations monitor and log data on ships' movements, coordinating a flow of information from visual observations made at locks and sidings along the canal's length. By constructing time–distance diagrams, controllers attempt to optimize the traffic flow by using the sidings to organize priorities.

Currently research is being undertaken to test a digital computer system for making the control decisions. Favoured is a simulation technique in which each ship's movements would be forecast in advance; if a conflict threatened between two ships, signals would automatically be set to stop one or the other vessel, according to a minimum delay criterion, in the previous siding.

With the advent of nuclear-powered vessels the avoidance of collision at sea has become even more paramount in control development. For the present, while the automation of crew operations by the provision of monitoring and control systems is growing, it is likely that ships will remain primarily self-controlled at sea. But the improvement of satellite communications, for the tracking and control of air traffic over the oceans, will probably lead in future years to a joint-use system shared with ships at sea.

BIBLIOGRAPHY. W.W. HAY, *Transportation Engineering* (1961), deals comprehensively with basic engineering principles; J.R. MEYER, J.F. KAIN, and M. WOHL, *The Urban Transportation Problem* (1965), covers many of the social and economic aspects controlling urban transport; M. WOHL and B.V. MARTIN, *Traffic Systems Analysis* (1967), describes the transportation process in depth; P.M. DANFORTH, *Transport Control* (1970), is a modern general review of the technology of control relating transport systems to the environment of man. General texts on railroad-traffic control include W.W. HAY, *Railroad Engineering* (1953); J.R. DAY and B.K. COOPER, *Railway Signalling Systems*, 2nd ed. (1963); and H. SAMUEL, *Railway Operating Practice* (1962). Air-traffic control is more subject to international requirements than either roads or railways. The principal publications are issued by the INTERNATIONAL CIVIL AVIATION ORGANIZATION (*Aeronautical Telecommunications* and *Communication Procedures, etc.*): and by the INTERNATIONAL AIR TRANSPORT ASSOCIATION: *e.g., Aviation's Role in Future Transportation* (1968). For a general descriptive text of the process of air-traffic control, see D.E. CHARLWOOD, *Take-Off to Touchdown* (1967); and on the regulatory aspects, J.L. GRUMBRIDGE, *Marketing Management in Air Transport* (1966); and S. WHEATCROFT, *Air Transport Policy* (1964). International aspects of shipping are covered in publications of the UNITED NATIONS CONFERENCE ON TRADE AND DEVELOPMENT (UNCTAD); the INTERNATIONAL CHAMBER OF SHIPPING; and the INTERNATIONAL SHIPPING FEDERATION. The INSTITUTE OF SHIPPING RESEARCH (BERGEN) publishes a wide range of shipping texts. General shipping texts include A.E. BRANCH, *The Elements of Shipping* (1964); and E.F. STEVENS, *Shipping Practice*, 8th ed. (1967). More specialized aspects of control include L. OUDET, *Emploi du radar pour prévenir les abordages* (1959; Eng. trans., *Radar and Collision*, 1960); F.J. WYLIE (ed.), *Use of Radar at Sea*, 4th rev. ed. (1968).

(F.D.H.)

Tragedy

Although the word tragedy is often used loosely to describe any sort of disaster or misfortune, it more precisely refers to a work of art, usually a play or novel, that probes with high seriousness questions concerning the role of man in the universe. The Greeks of Attica, the ancient state whose chief city was Athens, first used the word in the 5th century BC to describe a specific kind of play, which was presented at festivals in Greece. Sponsored by the local governments, these plays were attended by the entire community, a small admission fee being provided by the state for those who could not afford it themselves. The atmosphere surrounding the performances was more like that of a religious ceremony than entertainment. There were altars to the gods, with priests in attendance, and the subjects of the tragedies were the misfortunes of the heroes of legend, religious myth, and history. Most of the material was derived from the works of Homer and was common knowledge in the Greek communities. So powerful were the achievements of the three greatest Greek dramatists—Aeschylus (525–456 BC), Sophocles (*c.* 496–406 BC), and Euripides (*c.* 480–406 BC)—that the word they first used for their plays survived and came to describe a literary genre that, in spite of many transformations and lapses, has proved its viability through 25 centuries.

Four great periods of tragedy

Historically, tragedy of a high order has been created in only four periods and locales: Attica, in Greece, in the 5th century BC; England in the reigns of Elizabeth I and James I, from 1558 to 1625; 17th-century France; and Europe and America during the second half of the 19th century and the first half of the 20th. Each period saw the development of a special orientation and emphasis, a characteristic style of theatre. In the modern period, roughly from the middle of the 19th century, the idea of tragedy found embodiment in the collateral form of the novel.

This article focusses primarily on the development of tragedy as a literary genre. Further information on the relationship of tragedy to other types of drama will be found in the article DRAMATIC LITERATURE; its place in the development of literature in general is discussed in LITERATURE, WESTERN; and its role in the growth of theatre is discussed in THEATRE, WESTERN. Related material will also be found in the articles NOVEL and COMEDY.

THE DEVELOPMENT OF TRAGEDY

Origins in Greece. The questions of how and why tragedy came into being and of the bearing of its origins on its development in subsequent ages and cultures have been investigated by historians, philologists, archaeologists, and anthropologists with results that are suggestive but conjectural. Even the etymology of the word tragedy is far from established. The most generally accepted source is the Greek *tragōidia*, or "goat-song," from *tragos* ("goat") and *aeidein* ("to sing"). The word could have referred either to the prize, a goat, that was awarded to the dramatists whose plays won the earliest competitions or to the dress, goat skins of the performers, or to the goat that was sacrificed in the primitive rituals from which tragedy developed.

In these communal celebrations, a choric dance may have been the first formal element and perhaps for centuries was the principal element. A speaker was later introduced into the ritual, in all likelihood as an extension of the role of the priest, and dialogue was established between him and the dancers, who became the chorus in the Athenian drama. Aeschylus is usually regarded as the one who, realizing the dramatic possibilities of the dialogue, first added a second speaker and thus invented the form of tragedy. That so sophisticated a form could have been fully developed by a single artist, however, is scarcely credible. Hundreds of early tragedies have been lost, including some by Aeschylus himself. Of some 90 plays attributed to him, only seven have survived.

Four Dionysia, or feasts of the Greek God Dionysus, were held annually in Athens. Since Dionysus once held place as the god of vegetation and the vine, and the goat was believed sacred to him, it has been conjectured that tragedy originated in fertility feasts to commemorate the harvest and the vintage and the associated ideas of the death and renewal of life. The purpose of such rituals is to exercise some influence over these vital forces. Whatever the original religious connections of tragedy may have been, two elements have never entirely been lost: (1) its high seriousness, befitting matters in which survival is at issue and (2) its involvement of the entire community in matters of ultimate and common concern. When either of these elements diminishes, when the form is overmixed with satiric, comic, or sentimental elements, or when the theatre of concern succumbs to the theatre of entertainment, then tragedy falls from its high estate and is on its way to becoming something else.

Two vital elements

As the Greeks developed it, the tragic form, more than any other, raised questions about man's existence. Why must man suffer? Why must man be forever torn between the seeming irreconcilables of good and evil, freedom and necessity, truth and deceit? Are the causes of his suffering outside himself, in blind chance, in the evil designs of

others, in the malice of the gods? Are its causes within him, and does he bring suffering upon himself through arrogance, infatuation, or the tendency to overreach himself? Why is justice so elusive?

Aeschylus: the first great tragedian. It is this last question that Aeschylus asks most insistently in his two most famous works, the *Oresteia* (a trilogy comprising *Agamemnon, Choephoroi,* and *Eumenides*) and *Prometheus Bound* (the first part of a trilogy of which the last two parts have been lost): is it right that Orestes, a young man in no way responsible for his situation, should be commanded by a god, in the name of justice, to avenge his father by murdering his mother? Is there no other way out of his dilemma than through the ancient code of blood revenge, which will only compound the dilemma? Again: was it right that in befriending mankind with the gifts of fire and the arts, Prometheus should offend the presiding god Zeus and himself be horribly punished? Aeschylus opened questions whose answers in the Homeric stories had been taken for granted. In Homer, Orestes' patricide is regarded as an act of filial piety, and Prometheus' punishment is merely the inevitable consequence of defying the reigning deity. All of the materials of tragedy, all of its cruelty, loss, and suffering, are present in Homer and the ancient myths but are dealt with as absolutes—self-sufficient and without the questioning spirit that was necessary to raise them to the level of tragedy. It remained for Aeschylus and his fellow tragedians first to treat these "absolutes" critically and creatively in sustained dramatic form. They were true explorers of the human spirit.

In addition to their remarkable probing into the nature of existence, their achievements included a degree of psychological insight for which they are not generally given credit. Though such praise is usually reserved for Shakespeare and the moderns, the Athenian dramatists conveyed a vivid sense of the living reality of their characters' experience: of what it felt like to be caught, like Orestes, in desperately conflicting loyalties or to be subjected, like Prometheus, to prolonged and unjust punishment. The mood of the audience as it witnessed the acting out of these climactic experiences has been described as one of impassioned contemplation. From their myths and epics and from their history in the 6th century, the people of Athens learned that they could extend an empire and lay the foundations of a great culture. From their tragedies of the 5th century, they learned who they were, something of the possibilities and limitations of the spirit, and of what it meant, not merely what it felt like, to be alive in a world both beautiful and terrible.

Aeschylus has been called the most theological of the Greek tragedians. His *Prometheus* has been compared to the Book of Job of the Bible both in its structure (*i.e.*, the immobilized heroic figure maintaining his cause in dialogues with visitors) and in its preoccupation with the problem of suffering at the hands of a seemingly unjust deity. Aeschylus tended to resolve the dramatic problem into some degree of harmony, as scattered evidence suggests he did in the last two parts of the *Promethiad* and as he certainly did in the conclusion of the *Oresteia.* This tendency would conceivably lead him out of the realm of tragedy and into religious assurance. But his harmonies are never complete. In his plays evil is inescapable, loss is irretrievable, suffering is inevitable. What the plays say positively is that man can learn through suffering. The chorus in *Agamemnon,* the first play of the *Oresteia,* says this twice. The capacity to learn through suffering is a distinguishing characteristic of the tragic hero, pre-eminently of the Greek tragic hero. He has not merely courage, tenacity, and endurance but also the ability to grow, by means of these qualities, into an understanding of himself, of his fellows, and of the conditions of existence. Suffering, says Aeschylus, need not be embittering but can be a source of knowledge. The moral force of his plays and those of his fellow tragedians can hardly be exaggerated. They were shaping agents in the Greek notion of education. It has been said that from Homer the Greeks learned how to be good Greeks; from the tragedies they learned an enlarged humanity. If it cannot be proved that Aeschylus "invented" tragedy, it is clear that he at least set its tone and established a model that is still operative. Even in the 20th century, the *Oresteia* has been acclaimed as the greatest spiritual work of man, and dramatists such as T.S. Eliot, in *The Family Reunion* (1939), and Jean-Paul Sartre, in *The Flies* (1943), found modern relevance in its archetypal characters, situations, and themes.

Aeschylus' view of the problem of suffering

Sophocles: the purest artist. Sophocles' life spanned almost the whole of the 5th century. He is said to have written his last play, *Oedipus at Colonus,* at the age of 90. Only seven of his plays, of some 125 attributed to him, survive. He won the prize in the tragic competitions 20 times and never placed lower than second.

Sophocles has been called the great mediating figure between Aeschylus and Euripides. Of the three, it might be said that Aeschylus tended to resolve tragic tensions into higher truth, to look beyond, or above, tragedy; that Euripides' irony and bitterness led him the other way to fix on the disintegration of the individual; and that Sophocles, who is often called the "purest" artist of the three, was truest to the actual state of human experience. Unlike the others, Sophocles seems never to insinuate himself into his characters or situations, never to manipulate them into preconceived patterns. He sets them free on a course seemingly of their own choosing. He neither preaches nor rails. If life is hard and often destructive, the question Sophocles asks is not how did this come to be or why did such a misfortune have to happen but rather, given the circumstances, how must a man conduct himself, how should he act, what must he do?

His greatest play, *Oedipus the King,* may serve as a model of his total dramatic achievement. Embodied in it, and suggested with extraordinary dramatic tact, are all the basic questions of tragedy, which are presented in such a way as almost to define the form itself. It is not surprising that Aristotle, a century later, analyzed it for his definition of tragedy in the *Poetics.* It is the nuclear Greek tragedy, setting the norm in a way that cannot be claimed for any other work, not even the *Oresteia.*

Sophocles' emphasis on action

In *Oedipus,* as in Sophocles' other plays, the chorus is much less prominent than in Aeschylus' works. The action is swifter and more highly articulated; the dialogue is sharper, more staccato, and bears more of the meaning of the play. Though much has been made of the influence of fate on the action of the play, later critics emphasize the freedom with which Oedipus acts throughout. Even before the action of the play begins, the oracle's prediction that Oedipus was doomed to kill his father and marry his mother had long since come true, though he did not realize it. Though he was fated, he was also free throughout the course of the play—free to make decision after decision, to carry out his freely purposed action to its completion. In him, Sophocles achieved one of the enduring definitions of the tragic hero—that of a man for whom the liberation of the self is a necessity. The action of the play, the purpose of which is to discover the murderer of Oedipus' father and thereby to free the city from its curse, leads inevitably to Oedipus' suffering—the loss of his wife, his kingdom, his sight. The messenger who reports Oedipus' self-blinding might well have summarized the play with "All ills that there are names for, all are here." And the chorus' final summation deepens the note of despair: "Count no man happy," they say in essence, "until he is dead."

But these were not Sophocles' ultimate verdicts. The action is so presented that the final impression is not of human helplessness at the hands of malign gods nor of man as the pawn of fate. Steering his own course, with great courage, Oedipus has ferreted out the truth of his identity and administered his own punishment, and, in his suffering, learned a new humanity. The final impression of the *Oedipus,* far from being one of unmixed evil and nihilism, is of massive integrity, powerful will, and magnanimous acceptance of a horribly altered existence.

Some 50 years later, Sophocles wrote a sequel to *Oedipus the King.* In *Oedipus at Colonus,* the old Oedipus, further schooled in suffering, is seen during his last day on earth. He is still the same Oedipus in many ways: hot-

tempered, hating his enemies, contentious. Though he admits his "pollution" in the murder of his father and the marriage to his mother, he denies that he had sinned, since he had done both deeds unwittingly. Throughout the play, the theme of which has been described as the "heroization" of Oedipus, he grows steadily in nobility and awesomeness. Finally, sensing the approach of the end, he leaves the scene, to be elevated in death to a demigod, as the messenger describes the miraculous event. In such manner Sophocles leads his tragedy toward an ultimate assertion of values. His position has been described as "heroic humanism," as making a statement of belief in the human capacity to transcend evils, within and without, by means of the human condition itself.

Tragedy must maintain a balance between the higher optimisms of religion or philosophy, or any other beliefs that tend to explain away the enigmas and afflictions of existence, on the one hand, and the pessimism that would reject the whole human experiment as valueless and futile on the other. Thus the opposite of tragedy is not comedy but the literature of cynicism and despair, and the opposite of the tragic artist's stance, which is one of compassion and involvement, is that of the detached and cynical ironist.

Euripides: the dark tragedian. The tragedies of Euripides test the Sophoclean norm in this direction. His plays present in gruelling detail the wreck of human lives under the stresses that the gods often seem willfully to place upon them. Or, if the gods are not willfully involved through jealousy or spite, they sit idly by while man wrecks himself through passion or heedlessness. No Euripidean hero approaches Oedipus in stature. The margin of freedom is narrower, and the question of justice, so central and absolute an ideal for Aeschylus, becomes a subject for irony. In *Hippolytus,* the goddess Artemis never thinks of justice as she takes revenge on the young Hippolytus for neglecting her worship; she acts solely out of personal spite. In *Medea,* Medea's revenge on Jason through the slaughter of their children is so hideously unjust as to mock the very question. In the *Bacchae,* when the frenzied Agave tears her son, Pentheus, to pieces and marches into town with his head on a pike, the god Dionysus, who had engineered the situation, says merely that Pentheus should not have scorned him. The Euripidean gods, in short, cannot be appealed to in the name of justice. Euripides' tendency toward moral neutrality, his cool tacking between sides (*e.g.,* between Pentheus versus Dionysus and the bacchantes) leave the audience virtually unable to make a moral decision. In Aeschylus' *Eumenides* (the last play of the *Oresteia*) the morals of the gods improve. Athena is there, on the stage, helping to solve the problem of justice. In Sophocles, the gods are distant, but their moral governance is not questioned. *Oedipus* ends as if with a mighty "So be it." In Euripides the gods are destructive, wreaking their capricious wills on defenseless man. Aristotle called Euripides the most tragic of the three dramatists; surely his depiction of the arena of human life is the grimmest.

Euripides' view of justice

Many qualities, however, keep his tragedies from becoming literature of protest, of cynicism, or of despair. He reveals profound psychological insight, as in the delineation of such antipodal characters as Jason and Medea, or of the forces, often subconscious, at work in the group frenzy of the *Bacchae.* His Bacchic odes reveal remarkable lyric power. And he has a deep sense of human values, however external and self-conscious. Medea, even in the fury of her hatred for Jason and her lust for revenge, must steel herself to the murder of her children, realizing the evil of what she is about to do. In this realization, Euripides suggests a saving hope: here is a great nature gone wrong—but still a great nature.

Later Greek drama. After Euripides, Greek drama reveals little that is significant to the history of tragedy. Performances were given during the remainder of the pre-Christian era in theatres throughout the Mediterranean world, but with the decline of Athens as a city-state, the tradition of tragedy eroded. As external affairs deteriorated, the high idealism, the exalted sense of human capacities depicted in tragedy at its height yielded more and more to the complaints of the skeptics. The Euripidean assault on the gods ended in the debasement of the original lofty conceptions. A 20th-century British classical scholar, Gilbert Murray, used the phrase "the failure of nerve" to describe the late Greek world. It may, indeed, provide a clue to what happened. On the other hand, according to the 19th-century German philosopher Friedrich Nietzsche, in *The Birth of Tragedy* (1872), a quite different influence may have spelled the end of Greek tragedy: the so-called Socratic optimism, the notion underlying the dialogues of Plato that man could "know himself" through the exercise of his reason in patient, careful dialectic—a notion that diverted questions of man's existence away from drama and into philosophy. In any case, the balance for tragedy was upset, and the theatre of Aeschylus, Sophocles, and Euripides gave way to what seems to have been a theatre of diatribe, spectacle, and entertainment.

The long hiatus. The Roman world did not succeed in reviving tragedy. Seneca (4 BC–AD 65) wrote nine tragedies, mostly adaptations of Greek materials, such as the stories of Oedipus, Hippolytus, Medea, and Agamemnon, but with little of the Greek tragic feeling for character and theme. The emphasis is on sensation and rhetoric, tending toward melodrama and bombast. The plays are of interest in this context mainly as the not entirely healthy inspiration for the precursors of Elizabethan tragedy in England.

The long hiatus in the history of tragedy between the Greeks and the Elizabethans has been variously explained. In the Golden Age of Roman literature, roughly from the birth of Virgil in 70 BC to the death of Ovid in AD 17, the Roman poets followed the example of Greek literature; although they produced great lyric and epic verse, their tragic drama lacked the probing freshness and directness fundamental to tragedy.

With the collapse of the Roman world and the invasions of the barbarians came the beginnings of the long, slow development of the Christian Church. Churchmen and philosophers gradually forged a system, based on the Christian revelation, of the nature and destiny of man. The mass, with its daily re-enactment of the sacrifice of Jesus Christ, its music, and its dramatic structure, may have provided something comparable to tragic drama in the lives of the people.

Tragedy and the Christian mass

With the coming of the Renaissance, the visual arts more and more came to represent the afflictive aspects of life, and the word tragedy again came into currency. Chaucer (1340–1400) used the word in *Troilus and Criseyde,* and in *The Canterbury Tales* it is applied to a series of stories in the medieval style of *de casibus virorum illustrium,* meaning "the downfalls" (more or less inevitable) "of princes." Chaucer used the word to signify little more than the turn of the wheel of fortune, against whose force no meaningful effort of man is possible. It remained for the Elizabethans to develop a theatre and a dramatic literature that reinstated the term on a level comparable to that of the Greeks.

Elizabethan tragedy. The long beginning of the Elizabethan popular theatre, like that of the Greek theatre, lay in religious ceremonials, probably in the drama in the liturgy of the two greatest events in the Christian year, Christmas and Easter. In the Early Church, exchanges between two groups of choristers, or between the choir and a solo voice, led to the idea of dialogue, just as it had in the development of Greek tragedy. The parts became increasingly elaborate, and costumes were introduced to individualize the characters. Dramatic gestures and actions were a natural development. More and more of the biblical stories were dramatized, much as the material of Homer was used by the Greek tragedians, although piously in this instance, with none of the tragic skepticism of the Greeks. In the course of generations, the popularity of the performances grew to such an extent that, to accommodate the crowds, they were moved, from inside the church to the porch, or square, in front of the church. The next step was the secularization of the management of the productions, as the towns and cities took them over. Day-long festivals were instituted, involving, as in

Cycles of miracle and mystery plays

the Greek theatre, the whole community. Cycles of plays were performed at York, Chester, and other English religious centres, depicting in sequences of short dramatic episodes the whole human story, from the Fall of Lucifer and the Creation to the Day of Doom. Each play was assigned to an appropriate trade guild (the story of Noah and the Ark, for example, went to the shipwrights), which took over complete responsibility for the production. Hundreds of actors and long preparation went into the festivals. These "miracle" and "mystery" plays, however crude they may now seem, dealt with the loftiest of subjects in simple but often powerful eloquence. Although the audience must have been a motley throng, it may well have been as involved and concerned as those of the Greek theatre.

Once the drama became a part of the secular life of the communities, popular tastes affected its religious orientation. Comic scenes, like those involving Noah's nagging wife, a purely secular creation who does not appear in the Bible, became broader. The "tragic" scenes—anything involving the Devil or Doomsday—became more and more melodramatic. With the Renaissance came the rediscovery of the Greek and Roman cultures and the consequent development of a world view that led away from moral and spiritual absolutes and toward an increasingly skeptical individualism. The high poetic spirits of the mid-16th century began to turn the old medieval forms of the miracles and mysteries to new uses and to look to the ancient plays, particularly the lurid tragedies of Seneca, for their models. A bloody play, *Gorboduc*, by Thomas Sackville and Thomas Norton, first acted in 1561, is now known as the first formal tragedy in English, though it is far from fulfilling the high offices of the form in tone, characterization, and theme. Thomas Kyd's *Spanish Tragedie* (*c.* 1589) continued the Senecan tradition of the "tragedy of blood" with somewhat more sophistication than *Gorboduc* but even more bloodletting. Elizabethan tragedy never freed itself completely from certain melodramatic aspects of the influence of Seneca.

Marlowe and the first Christian tragedy. The first tragedian worthy of the tradition of the Greeks was Christopher Marlowe (1564–93). Of Marlowe's tragedies, *Tamburlaine* (1587), *Doctor Faustus* (*c.* 1588), *The Jew of Malta* (1589), and *Edward II* (*c.* 1593), the first two are the most famous and most significant. In *Tamburlaine*, the material was highly melodramatic—Tamburlaine's popular image was that of the most ruthless and bloody of conquerors. In a verse prologue, when Marlowe invites the audience to "View but his [Tamburlaine's] picture in this tragic glass," he had in mind little more, perhaps, than the trappings and tone of tragedy: "the stately tent of war," which is to be his scene, and "the high astounding terms," which will be his rhetoric. But he brought such imaginative vigour and sensitivity to bear that melodrama is transcended, in terms reminiscent of high tragedy. Tamburlaine, a Scythian shepherd of the 14th century, becomes the spokesman, curiously enough, for the new world of the Renaissance—iconoclastic, independent, stridently ambitious. Just as the Greek tragedians challenged tradition, Tamburlaine shouts defiance at all the norms, religious and moral, that Marlowe's generation inherited. But Tamburlaine, although he is an iconoclast, is also a poet. No one before him on the English stage had talked with such magnificent lyric power as he does, whether it be on the glories of conquest or on the beauties of Zenocrate, his beloved. When, still unconquered by any enemy, he sickens and dies, he leaves the feeling that something great, however ruthless, has gone. Here once again is the ambiguity that was so much a part of the Greek tragic imagination—the combination of awe, pity, and fear that Aristotle defined.

Conflict between tradition and individualism

In *Doctor Faustus* the sense of conflict between the tradition and the new Renaissance individualism is much greater. The claims of revealed Christianity are presented in the orthodox spirit of the morality and mystery plays, but Faustus' yearnings for power over space and time are also presented with a sympathy that cannot be denied. Here is modern man, tragic modern man, torn between the faith of tradition and faith in himself. Faustus takes the risk in the end and is bundled off to hell in true mystery-play fashion. But the final scene does not convey that justice has been done, even though Faustus admits that his fate is just. Rather, the scene suggests that the transcendent human individual has been caught in the consequences of a dilemma that he might have avoided but that no imaginative man *could* have avoided. The sense of the interplay of fate and freedom is not unlike that of *Oedipus*. The sense of tragic ambiguity is more poignant in Faustus than in *Oedipus* or *Tamburlaine* because Faustus is far more introspective than either of the other heroes. The conflict is inner; the battle is for Faustus' soul, a kind of conflict that neither the Greeks nor Tamburlaine had to contend with. For this reason, and not because it advocates Christian doctrine, the play has been called the first Christian tragedy.

Shakespearean tragedy. Shakespeare was a long time coming to his tragic phase, the six or seven years that produced his five greatest tragedies, *Hamlet* (*c.* 1601), *Othello* (*c.* 1602), *King Lear* (*c.* 1605), *Macbeth* (*c.* 1605), and *Antony and Cleopatra* (*c.* 1606). These were not the only plays written during those years. *Troilus and Cressida* may have come about the same time as *Hamlet; All's Well That Ends Well*, shortly after *Othello;* and *Measure for Measure*, shortly before *King Lear*. But the concentration of tragedies is sufficient to distinguish this period from that of the comedies and history plays before and of the so-called romances afterward. Although the tragic period cannot entirely be accounted for in terms of biography, social history, or current stage fashions, all of which have been adduced as causes, certain questions should be answered, at least tentatively: What is Shakespeare's major tragic theme and method? How do they relate to classical, medieval, and Renaissance traditions? In attempting to answer these questions, this proviso must be kept in mind: the degree to which he was consciously working in these traditions, consciously shaping his plays on early models, adapting Greek and Roman themes to his own purpose, or following the precepts of Aristotle must always remain conjectural. On the one hand, there is the comment by Ben Jonson that Shakespeare had "small Latin and less Greek," and Milton in "L'Allegro" speaks of him as "fancy's child" warbling "his native wood-notes wild," as if he were unique, a sport of nature. On the other hand, Shakespeare knew Jonson, who knew a great deal of Latin and Greek, and is said to have acted in Jonson's *Sejanus* in 1603, a very classical play, published in 1605 with a learned essay on Aristotle as preface. It can be assumed that Shakespeare knew the tradition. Certainly the Elizabethan theatre could not have existed without the Greek and Roman prototype. For all of its mixed nature—with comic and melodramatic elements jostling the tragic—the Elizabethan theatre retained some of the high concern, the sense of involvement, and even the ceremonial atmosphere of the Greek theatre. When tragedies were performed, the stage was draped in black. Modern studies have shown that the Elizabethan theatre retained many ties with both the Middle Ages and the tradition of the Greeks.

Tragic elements in Shakespeare's comedies and histories

Shakespeare's earliest and most lighthearted plays reveal a sense of the individual, his innerness, his reality, his difference from every other individual, and, at times, his *plight*. Certain stock characters, to be sure, appear in the early comedies. Even Falstaff, that triumphant individual, has a prototype in the braggadocio of Roman comedy, and even Falstaff has his tragic side. As Shakespeare's art developed, his concern for the plight or predicament or dilemma seems to have grown. His earliest history plays, for instance (*Henry VI*, Parts I, II, III), are little more than chronicles of the great pageant figures—kingship in all its colour and potency. *Richard III*, which follows them, focusses with an intensity traditionally reserved for the tragic hero on one man and on the sinister forces, within and without, that bring him to destruction. From kingship, that is, Shakespeare turned to the king, the symbolic individual, the focal man, to whom whole societies look for their values and meanings. Thus Richard III is almost wholly sinister, though there exists a fascination about him, an all but tragic ambiguity.

Although Shakespeare's developing sense of the tragic cannot be summed up adequately in any formula, one might hazard the following: he progressed from the *individual* of the early comedies; to the *burdened* individual, such as, in *Henry IV*, Prince Hal, the future Henry V, who manipulates, rather than suffers, the tragic ambiguities of the world; and, finally, in the great tragedies, to (in one critic's phrase) the *overburdened* individual, Lear being generally regarded as the greatest example. In these last plays, man is at the limits of his sovereignty as a human being, where everything that he has lived by, stood for, or loved is put to the test. Like Prometheus on the crag, or Oedipus as he learns who he is, or Medea deserted by Jason, the Shakespearean tragic heroes are at the extremities of their natures. Hamlet and Macbeth are thrust to the very edge of sanity; Lear and, momentarily, Othello are thrust beyond it. In every case, as in the Greek plays, the destructive forces seem to combine inner inadequacies or evils, such as Lear's temper or Macbeth's ambition, with external pressures, such as Lear's "tiger daughters," the witches in *Macbeth*, or Lady Macbeth's importunity. Once the destructive course is set going, these forces operate with the relentlessness the Greeks called Moira, or Fate.

Total vision of Shakespeare's tragedies

At the height of his powers, Shakespeare's tragic vision comprehended the totality of possibilities for good and evil as nearly as the human imagination ever has. His heroes are the vehicles of psychological, societal, and cosmic forces that tend to ennoble and glorify humanity or infect it and destroy it. The logic of tragedy that possessed him demanded an insistence upon the latter. Initially, his heroes make free choices and are free time after time to turn back, but they move toward their doom as relentlessly as did Oedipus. The total tragic statement, however, is not limited to the fate of the hero. He is but the centre of an action that takes place in a context involving many other characters, each contributing a point of view, a set of values or antivalues to the complex dialectic of the play. In Macbeth's demon-ridden Scotland, where weird things happen to men and horses turn cannibal, there is the virtuous Malcolm, and society survives. Hamlet had the trustworthy friend Horatio, and, for all the bloodletting, what was "rotten" was purged. In the tragedies, most notably *Lear*, the Aeschylean notion of "knowledge through suffering" is powerfully dramatized; it is most obvious in the hero, but it is also shared by the society of which he is the focal figure. The flaw in the hero may be a *moral* failing or, sometimes, an excess of virtue; the flaw in society may be the rottenness of the Danish court in *Hamlet* or the corruption of the Roman world in *Antony and Cleopatra;* the flaw or fault or dislocation may be in the very universe itself, as dramatized by Lear's raving at the heavens or the ghosts that walk the plays or the witches that prophesy. All these faults, Shakespeare seems to be saying, are inevitabilities of the human condition. But they do not spell rejection, nihilism, or despair. The hero may die, but in the words of the novelist E.M. Forster to describe the redeeming power of tragedy, "he has given us life."

Such is the precarious balance a tragedian must maintain: the cold, clear vision that sees the evil but is not maddened by it, a sense of the good that is equally clear but refuses the blandishments of optimism or sentimentalism. Few have ever sustained the balance for long. Aeschylus tended to slide off to the right, Euripides to the left, and even Sophocles had his hero transfigured at Colonus. Marlowe's early death should perhaps spare him the criticism his first plays warrant. Shakespeare's last two tragedies, *Macbeth* and *Antony and Cleopatra*, are close to the edge of a valueless void. The atmosphere of *Macbeth* is murky with evil; the action moves with almost melodramatic speed from horror to horror. The forces for good rally at last, but Macbeth himself steadily deteriorates into the most nihilistic of all Shakespeare's tragic heroes, saved in nothing except the sense of a great nature, like Medea, gone wrong. *Antony*, in its ambiguities and irony, has been considered close to the Euripidean line of bitterness and detachment. Shakespeare himself soon modulated into another mood in his last plays, *Cymbeline* (*c.* 1609), *The Winter's Tale* (*c.* 1610), and *The Tempest* (*c.* 1611). Each is based on a situation that could have been developed into major tragedy had Shakespeare followed out its logic as he had done with earlier plays. For whatever reason, however, he chose not to. The great tragic questions are not pressed. *The Tempest*, especially, for all Prospero's charm and magnanimity, gives a sense of brooding melancholy over the ineradicable evil in mankind, a patient but sad acquiescence. All of these plays end in varying degrees of harmony and reconciliation. Shakespeare willed it so.

Decline in 17th-century England. From Shakespeare's tragedies to the closing of the theatres in England by the Puritans in 1642, the quality of tragedy is steadily worse, if the best of the Greek and Shakespearean tragedies are taken as a standard. Among the leading dramatists of the period—John Webster, Thomas Middleton, Francis Beaumont, John Fletcher, Cyril Tourneur, and John Ford—there were some excellent craftsmen and brilliant poets. Though each of them has a rightful place in the history of English drama, tragedy suffered a transmutation in their hands.

The Jacobean transmutation

The Jacobean dramatists—those who flourished in England during the reign of James I—failed to transcend the negative tendencies they inherited from Elizabethan tragedy: a sense of defeat, a mood of spiritual despair implicit in Marlowe's tragic thought; in the nihilistic broodings of some of Shakespeare's characters in their worst moods—Hamlet, Gloucester in *Lear*, Macbeth; in the metaphoric implication of the theme of insanity, of man pressed beyond the limit of endurance, that runs through many of these tragedies; most importantly, perhaps, in the moral confusion ("fair is foul and foul is fair") that threatens to unbalance even the staunchest of Shakespeare's tragic heroes. This sinister tendency came to a climax about 1605 and was in part a consequence of the anxiety surrounding the death of Queen Elizabeth I and the accession of James I. Despite their negative tendencies, the Elizabethans, in general, had affirmed life and celebrated it; Shakespeare's moral balance, throughout even his darkest plays, remained firm. The Jacobeans, on the other hand, were possessed by death. They became superb analysts of moral confusion and of the darkened vision of humanity at cross purposes, preying upon itself; of lust, hate, and intrigue engulfing what is left of beauty, love, and integrity. There is little that is redemptive or that suggests, as had Aeschylus, that evil might be resolved by the enlightenment gained from suffering. As in the tragedies of Euripides, the protagonist's margin of freedom grows ever smaller. "You are the deed's creature," cries a murderer to his unwitting lady accomplice in Middleton's *Changeling* (1622), and a prisoner of her deed she remains. Many of the plays maintained a pose of ironic, detached reportage, without the sense of sympathetic involvement that the greatest tragedians have conveyed from the beginning.

Some of the qualities of the highest tragedians have been claimed for John Webster. One critic points to his search for a moral order as a link to Shakespeare and sees in his moral vision a basis for renewal. Webster's *Duchess of Malfi* (*c.* 1613) has been interpreted as a final triumph of life over death. Overwhelmed by final unleashed terror, the Duchess affirms the essential dignity of man. Despite such vestiges of greatness, however, the trend of tragedy was downward. High moral sensitivity and steady conviction are required to resist the temptation to resolve the intolerable tensions of tragedy into either the comfort of optimism or the relaxed apathy of despair. Periods of the creation of high tragedy are therefore few and short-lived. The demands on artist and audience alike are very great. Forms wear out, and public taste seems destined to go through inevitable cycles of health and disease. What is to one generation powerful and persuasive rhetoric becomes bombast and bathos to the next. The inevitable materials of tragedy—violence, madness, hate, and lust—soon lose their symbolic role and become perverted to the uses of melodrama and sensationalism, mixed, for relief, with the broadest comedy or farce.

These corruptions had gone too far when John Milton,

29 years after the closing of the theatres, attempted to bring back the true spirit and tone of tragedy, which he called "the gravest, moralest, and most profitable of all other Poems." His *Samson Agonistes* (1671), however, is magnificent "closet tragedy"—drama more suitable for reading than for popular performance. Modelled on the *Prometheus*, it recalls Aeschylus' tragedy both in its form, in which the immobilized hero receives a sequence of visitors, and in its theme, in which there is a resurgence of the hero's spirit under stress. With Restoration comedy in full swing, however, and with the "heroic play" (an overly moralized version of tragedy) about to reach its crowning achievement in John Dryden's *All for Love* only seven years later (published 1678), *Samson Agonistes* was an anachronism.

Neoclassical tragedy. *Corneille and Racine.* Another attempt to bring back the ancient form had been going on for some time across the English Channel, in France. The French Classical tragedy, whose monuments are Pierre Corneille's *Cid* (1637) and Jean Racine's *Bérénice* (1670) and *Phèdre* (1677), made no attempt to be popular in the way of the Elizabethan theatre. The plays were written by and for intellectual aristocrats, who came together in an elite theatre, patronized by royalty and nobility. Gone were the bustle and pageantry of the Elizabethan tragedies, with their admixtures of whatever modes and moods the dramatists thought would work. The French playwrights submitted themselves to the severe discipline they derived from the Greek models and especially the "rules," as they interpreted them, laid down by Aristotle. The unities of place, time, and action were strictly observed. One theme, the conflict between Passion and Reason, was uppermost. The path of Reason was the path of Duty and Obligation (noblesse oblige), and that path had been clearly plotted by moralists and philosophers, both ancient and modern. In this sense there was nothing exploratory in the French tragedy; existing moral and spiritual norms were insisted upon. The norms are never criticized or tested as Aeschylus challenged the Olympians or as Marlowe presented, with startling sympathy, the Renaissance overreacher. Corneille's *Cid* shows Duty triumphant over Passion, and, as a reward, hero and heroine are happily united. By the time of *Phèdre*, Corneille's proud affirmation of the power of the will and the reason over passion had given way to what Racine called "stately sorrow," with which he asks the audience to contemplate Phèdre's heroic, but losing, moral struggle. Her passion for her stepson, Hippolyte, bears her down relentlessly. Her fine principles and heroic will are of no avail. Both she and Hippolyte are destroyed. The action is limited to one terrible day; there is no change of scene; there is neither comic digression nor relief—the focus on the process by which a great nature goes down is sharp and intense. Such is the power of Racine's poetry (it is untranslatable), his conception of character, and his penetrating analysis of it, that it suggests the presence of Sophoclean "heroic humanism." In this sense it could be said that Racine tested the norms, that he uncovered a cruel injustice in the nature of a code that could destroy such a person as Phèdre. Once again, here is a world of tragic ambiguity, in which no precept or prescription can answer complicated human questions.

The return to Greek models

The English "heroic play." This ambiguity was all but eliminated in the "heroic play" that vied with the comedy of the Restoration stage in England in the latter part of the 17th century. After the vicissitudes of the Civil War, the age was hungry for heroism. An English philosopher of the time, Thomas Hobbes, defined the purpose of the type: "The work of an heroic poem is to raise admiration, principally for three virtues, valor, beauty, and love." Moral concern, beginning with Aeschylus, has always been central in tragedy, but in the works of the great tragedians this concern was exploratory and inductive. The moral concern of the heroic play is the reverse. It is deductive and dogmatic. The first rule, writes Dryden (following the contemporary French critic, René Le Bossu) in his preface to his *Troilus and Cressida* (1679), is "to make the moral of the work; that is, to lay down to yourself what that precept of morality shall be, which you would insinuate into the people. . . ." In *All for Love* the moral is all too clear: Antony must choose between the path of honour and his illicit passion for Cleopatra. He chooses Cleopatra, and they are both destroyed. Only Dryden's poetry, with its air of emotional argumentation, manages to convey human complexities in spite of his moral bias and saves the play from artificiality—makes it, in fact, the finest near-tragic production of its age.

Inductive and deductive morality

The eclipse of tragedy. Although the annals of the drama from Dryden onward are filled with plays called tragedies by their authors, the form as it has been defined here went into an eclipse during the late 17th, the 18th, and the early 19th centuries. Reasons that have been suggested for the decline include the politics of the Restoration in England; the rise of science and, with it, the optimism of the Enlightenment throughout Europe; the developing middle class economy; the trend toward reassuring deism in theology; and, in literature, the rise of the novel and the vogue of satire. The genius of the age was discursive and rationalistic. In France and later in England, belief in Evil was reduced to the perception of evils, which were looked upon as institutional and therefore remediable. The nature of man was no longer the problem; rather, it was the better organization and management of men. The old haunting fear and mystery, the sense of ambiguity at the centre of man's nature and of dark forces working against him in the universe, were replaced by a new and confident dogma. Tragedy never lost its high prestige in the minds of the leading spirits. Theorizing upon it were men of letters as diverse as Dr. Samuel Johnson, David Hume, Samuel Taylor Coleridge, and Percy Bysshe Shelley and German philosophers from Gotthold Lessing in the 18th century to Friedrich Nietzsche in the 19th. Revivals of Shakespeare's tragedies were often bowdlerized or altered, as in the happy ending for *Lear* in a production of 1681. Those who felt themselves called upon to write tragedies produced little but weak imitations. Shelley tried it once, in *The Cenci* (1819), but, as his wife wrote, "the bent of his mind went the other way"—which way may be seen in his *Prometheus Unbound* (1820), in which Zeus is overthrown and man enters upon a golden age, ruled by the power of love. Goethe had the sense to stay away from tragedy: "The mere attempt to write tragedy," he said, "might be my undoing." He concluded his two-part *Faust* (1808, 1832) in the spirit of the 19th-century optimistic humanitarianism. It was not until the latter part of the 19th century, with the plays of a Norwegian, Henrik Ibsen, a Russian, Anton Chekhov, a Swede, August Strindberg, and, later, an American, Eugene O'Neill, that something of the original vision returned to inspire the tragic theatre.

A new vehicle: the novel. The theme and spirit of tragedy, meanwhile, found a new vehicle in the novel. This development is important, however far afield it may seem from the work of the formal dramatists. The English novelist Emily Brontë's *Wuthering Heights* (1847), in its grim Yorkshire setting, reflects the original concerns of tragedy: *i.e.*, the terrifying divisions in nature and human nature, love that creates and destroys, character at once fierce and pitiable, destructive actions that are willed yet seemingly destined, as if by a malicious fate, yet the whole controlled by an imagination that learns as it goes. Another English novelist, Thomas Hardy, in the preface to his *Woodlanders* (1887), speaks of the rural setting of this and other of his novels as being comparable to the stark and simple setting of the Greek theatre, giving his novels something of that drama's intensity and sharpness of focus. His grimly pessimistic view of man's nature and destiny and of the futility of human striving, as reflected in his novels *The Return of the Native* (1878), *Tess of the D'Urbervilles* (1891), and *Jude the Obscure* (1895), is barely redeemed for tragedy by his sense of the beauty of nature and of the beauty and dignity of human character and effort, however unavailing.

Thomas Hardy's pessimism

The work of the Polish-born English novelist Joseph Conrad (1857–1924) provides another kind of setting for novels used as vehicles of the tragic sense. *Lord Jim* (1900), originally conceived as a short story, grew to a full-length novel as Conrad found himself exploring in

ever greater depth the perplexing, ambiguous problem of lost honour and guilt, expiation and heroism. Darkness and doubt brood over the tale, as they do over his long story *The Heart of Darkness* (1899), in which Conrad's narrator, Marlow, again leads his listeners into the shadowy recesses of the human heart, with its forever unresolved and unpredictable capacities for good and evil.

Dostoyevsky's tragic view. In Russia, the novels of Fyodor Dostoyevsky, particularly *Crime and Punishment* (1866) and *The Brothers Karamazov* (1880), revealed a world of paradox, alienation, and loss of identity, prophetic of the major tragic themes of the 20th century. More than any earlier novelist, Dostoyevsky appropriated to his fictions the realm of the subconscious and explored in depth its shocking antinomies and discontinuities. Sigmund Freud, the founder of psychoanalysis, frequently acknowledged his indebtedness to Dostoyevsky's psychological insights. Dostoyevsky's protagonists are reminiscent of Marlowe's Doctor Faustus, caught between the old world of orthodox belief and the new world of intense individualism, each with its insistent claims and justifications. The battleground is once more the soul of man, and the stakes are survival. Each of his major heroes —Raskolnikov in *Crime and Punishment* and the three Karamazovs—wins a victory, but it is in each case morally qualified, partial, or transient. The harmonious resolutions of the novels seem forced and are neither decisive of the action nor definitive of Dostoyevsky's total tragic view.

Paradox, alienation, loss of identity in Dostoyevsky

The American tragic novel. In America, Nathaniel Hawthorne's novel *The Scarlet Letter* (1850) and Herman Melville's *Moby Dick* (1851) are surprisingly complete embodiments of the tragic form, written as they were at a time of booming American optimism, materialistic expansion, and sentimentalism in fiction—and no tragic theatre whatever. In *The Scarlet Letter*, a story of adultery set in colonial New England, the heroine's sense of sin is incomplete; her spirited individualism insists (as she tells her lover) that "what we did had a consecration of its own." The resulting conflict in her heart and mind is never resolved, and, although it does not destroy her, she lives out her life in gray and tragic isolation. Melville said that he was encouraged by Hawthorne's exploration of "a certain tragic phase of humanity," by his deep broodings and by the "blackness of darkness" in him, to proceed with similar explorations of his own in *Moby Dick*, which he dedicated to Hawthorne. Its protagonist, Captain Ahab, represents a return to what Melville called (defending Ahab's status as tragic hero) a "mighty pageant creature, formed for noble tragedies," whose "ponderous heart," "globular brain," and "nervous lofty language" prove that even an old Nantucket sea captain can take his place with kings and princes of the ancient drama. Shakespearean echoes abound in the novel; some of its chapters are written in dramatic form. Its theme and central figure, reminiscent of Job and Lear in their search for justice and of Oedipus in his search for the truth, all show what Melville might have been—a great tragic dramatist had there been a tragic theatre in America.

Some American novelists of the 20th century carried on, however partially, the tragic tradition. Theodore Dreiser's *American Tragedy* (1925) is typical of the naturalistic novel, which is also represented by the work of Stephen Crane, James T. Farrell, John Steinbeck. Though showing great sensitivity to environmental or sociological evils, such works fail to embody the high conception of character (as Melville describes it above) and are concerned mainly with externals, or reportage. The protagonists are generally "good" (or weak) and beaten down by society. The novels of Henry James, which span the period from 1876 to 1904, are concerned with what has been called the tragedy of manners. The society James projects is sophisticated, subtle, and sinister. The innocent and the good are destroyed, like Milly Theale in *The Wings of the Dove* (1902), who in the end "turns her face to the wall" and dies but in her death brings new vision and new values to those whose betrayals had driven her to her death.

The trend in American fiction, as in the drama, continued in the 20th century, toward the pathos of the victim —the somehow inadequate, the sometimes insignificant figure destroyed by such vastly unequal forces that the struggle is scarcely significant. F. Scott Fitzgerald's Gatsby in his novel *The Great Gatsby* (1925) is betrayed by his own meretricious dream, nurtured by a meretricious society. The hero of Ernest Hemingway's novel *A Farewell to Arms* (1929), disillusioned by war, makes a separate peace, deserts, and joins his beloved in neutral Switzerland. When she dies in childbirth, he sees it as still another example of how "they"—society, the politicians who run the war, or the mysterious forces destroying Catherine—get you in the end. The tone is lyric and pathetic rather than tragic (though Hemingway called the novel his *Romeo and Juliet*). Grief turns the hero away from, rather than toward, a deeper examination of life.

Only the novels of William Faulkner, in their range and depth and in their powerful assault on the basic tragic themes, recall unmistakably the values of the tragic tradition. His "saga of the South," as recounted in a series of novels (notably *Sartoris*, 1929; *The Sound and the Fury*, 1929; *As I Lay Dying*, 1930; *Sanctuary*, 1931; *Light in August*, 1932; *Absalom, Absalom!* 1936; *Intruder in the Dust*, 1948; *Requiem for a Nun*, 1951), incorporates some 300 years of Southern history from Indian days to the present. At first regarded as a mere exploiter of decadence, he can now be seen as gradually working beyond reportage and toward meaning. His sociology became more and more the "sin" of the South—the rape of the land, slavery, the catastrophe of the Civil War and its legacy of a cynical and devitalized materialism. Increasingly he saw the conflict as internal. The subject of art, Faulkner said in his 1949 Nobel Prize speech, is "the human heart in conflict with itself." His insistence is on guilt as the evidence of man's fate, and on the possibility of expiation as the assertion of man's freedom. Compassion, endurance, and the capacity to learn are seen to be increasingly effective in his characters. In the veiled analogies to Christ as outcast and redeemer in *Light in August* and in the more explicit Christology of *A Fable* (1954), in the pastoral serenity following the anguish and horror in *Light in August*, and in the high comedy of the last scene of *Intruder in the Dust*, Faulkner puts into tragic fiction the belief he stated in his Nobel speech: "I decline to accept the end of man."

Guilt and expiation in Faulkner

TRAGEDY AND MODERN DRAMA

Tragic themes in Ibsen, Strindberg, and Chekhov. The movement toward naturalism in fiction in the latter decades of the 19th century did much to purge both the novel and the drama of the sentimentality and evasiveness that had so long emasculated them. In Norway Henrik Ibsen incorporated in his plays the smug and narrow ambitiousness of his society. The hypocrisy of overbearing men and women replace, in their fashion, the higher powers of the old tragedy. His major tragic theme is the futility, leading to catastrophe, of the idealist's effort to create a new and better social order. The "problem play" —one devoted to a particular social issue—is saved in his hand from the flatness of a sociological treatise by a sense of doom, a pattern of retribution, reminiscent of the ancient Greeks. In *Pillars of Society* (1877), *The Wild Duck* (published 1884), *Rosmersholm* (published 1886), and *The Master Builder* (published 1892), for example, one sacrifice is expiated by another.

In Sweden, August Strindberg, influenced by Ibsen, was a powerful force in the movement. *The Father* (1887) and *Miss Julie* (published 1888) recall Ibsen's attacks on religious, moral, and political orthodoxies. Strindberg's main concern, however, is with the destructive effects of sexual maladjustment and psychic imbalance. Not since Euripides' *Medea* or Racine's *Phèdre* had the tragic aspects of sex come under such powerful analysis. In this respect, his plays look forward to O'Neill's.

Anton Chekhov, the most prominent Russian dramatist of the period, wrote plays about the humdrum life of inconspicuous, sensitive people (*Uncle Vanya*, 1899; *The Three Sisters*, 1901; and *The Cherry Orchard*, 1904, are

typical), whose lives fall prey to the hollowness and tedium of a disintegrating social order. They are a brood of lesser Hamlets without his compensating vision of a potential greatness. As in the plays of the Scandinavian dramatists, Chekhov's vision of this social evil is penetrating and acute, but the powerful, resistant counterthrust that makes for tragedy is lacking. It is a world of victims.

American tragic dramatists. In little of the formal drama between the time of Ibsen, Strindberg, and Chekhov and the present are the full dimensions of tragedy presented. Some critics suggested that it was too late for tragedy, that modern man no longer valued himself highly enough, that too many sociological and ideological factors were working against the tragic temperament. The long and successful career of Eugene O'Neill may be a partial answer to this criticism. He has been called the first American to succeed in writing tragedy for the theatre, a fulfillment of his avowed purpose, for he had declared that in the tragic, alone, lay the meaning of life —and the hope. He sought in Freud's concept of the subconscious the equivalent of the Greek idea of fate and modelled his great trilogy, *Mourning Becomes Electra* (1931), on Aeschylus' *Oresteia*. Although the hovering sense of an ancient evil is powerful, the psychological conditioning controls the characters too nakedly. They themselves declare forces that determine their behaviour, so that they seem almost to connive in their own manipulation. *Desire Under the Elms* (1924) presents a harsh analysis of decadence in the sexual and avaricious intrigues of a New England farmer's family, unrelieved by manifestations of the transcendent human spirit. *The Great God Brown* (1926) and *Long Day's Journey into Night* (1939–41; first performance, 1956) come closer to true tragedy. In the latter, the capacity for self-knowledge is demonstrated by each member of the wrangling Tyrone family (actually, O'Neill's own; the play is frankly autobiographical). The insistent theme of the "death wish" (another example of Freud's influence), however, indicates too radical a pessimism for tragedy; even the character of Edmund Tyrone, O'Neill's own counterpart, confesses that he has always been a little in love with death, and in another late play, *The Iceman Cometh* (1939), the death wish is more strongly expressed. Although he never succeeded in establishing a tragic theatre comparable to the great theatres of the past, O'Neill made a significant contribution in his sustained concentration on subjects at least worthy of such a theatre. He made possible the significant, if slighter, contributions of Arthur Miller, whose *Death of a Salesman* (1949) and *A View from the Bridge* (1955) contain material of tragic potential that is not fully realized. Tennessee Williams' *Streetcar Named Desire* (1947) is a sensitive study of the breakdown of a character under social and psychological stress. As with Miller's plays, however, it remains in the area of pathos rather than tragedy.

O'Neill: pessimism too radical for tragedy

Other serious drama. The 20th century has produced much serious and excellent drama, which, though not in the main line of the tragic tradition, deserves mention. In British theatre, George Bernard Shaw's *Saint Joan* (1923) and T.S. Eliot's *Murder in the Cathedral* (1935) dramatized with great power both doubt and affirmation, the ambiguity of human motives, and the possibility of fruitless suffering that are true of the human condition as reflected by tragedy. During the Irish literary revival, the work of J.M. Synge (*Riders to the Sea*, 1904) and Sean O'Casey (*Shadow of a Gunman*, 1923), like Faulkner's work, sought a tragic theme in the destiny of a whole people. The masterpiece of this movement, however, is not a tragedy but a comic inversion of the ancient tragedy of *Oedipus*—Synge's *Playboy of the Western World* (1907).

Tragedy in works of social protest

The drama of social protest—exemplified in such works as the Russian Maksim Gorky's *Lower Depths* (1902), the German Bertolt Brecht's *Threepenny Opera* (1928) and *Mother Courage* (1941), and the American Clifford Odets' *Waiting for Lefty* (1935)—shares the tragedians' concern for evils that frustrate or destroy human values. The evils, however, are largely external, identifiable, and, with certain recommended changes in the social order, remediable. The type shows how vulnerable tragedy is to dogma or programs of any sort. A British author, George Orwell, suggested in *Nineteen Eighty-four* that tragedy would cease to exist under pure Marxist statism. Brecht's fine sense of irony and moral paradox redeem him from absolute dogmatism but give his work a hard satiric thrust that is inimical to tragedy. Traditional values and moral imperatives are all but neutralized in the existentialist worlds of the dramas and novels of Jean-Paul Sartre and Albert Camus, two outstanding philosopher-dramatists of the post World War II era. In their works, the protagonist is called upon to forge his own values, if he can, in a world in which the disparity between the ideal (what man longs for) and the real (what he gets) is so great as to reduce the human condition to incoherence and absurdity. Plays that led to the coinage of the term the theatre of the absurd are exemplified by *Waiting for Godot* (1952) and *The Killer* (1959), respectively by the Irish writer Samuel Beckett and the Romanian Eugène Ionesco, both of whom pursued their careers in Paris. Here, the theme of victimization is at its extreme, the despair and defeat almost absolute.

A coherent and affirmative view of man, society, and the cosmos is vital to tragedy—however tentative the affirmation may be. Unresolved questions remain at the end of every tragedy. There is always an irrational factor, disturbing, foreboding, not to be resolved by the sometime consolations of philosophy and religion or by any science of the mind or body; there is irretrievable loss, usually though not necessarily symbolized by the death of the hero. In the course of the action, however, in the development of character, theme, and situation and in the conceptual suggestiveness of language, tragedy presents the positive terms in which these questions might be answered. The human qualities are manifest, however limited; man's freedom is real, however marginal. The forces that bear him down may be mysterious but actual—fate, the gods, chance, the power of his own or the race's past working through his soul. Though never mastered, they can be contended with, defied, and, at least in spirit, transcended. The process is cognitive; man can learn.

Absence of tragedy in Oriental drama. In no way can the importance of a conceptual basis for tragedy be better illustrated than by a look at other drama-producing cultures with radically different ideas of the individual, his nature, and his destiny. While the cultures of India, China, and Japan have produced significant and highly artistic drama, there is little here to compare in magnitude, intensity, and freedom of form to the tragedies of the West.

In Buddhist teaching, the aim of the individual is to suppress and regulate all those questioning, recalcitrant, rebellious impulses that first impel the Western hero toward his tragic course. The goal of Nirvāṇa is the extinction of those impulses, the quieting of the passions, a kind of *quietus* in which worldly existence ceases. Western tragedy celebrates life, and the tragic hero clings to it: to him, it is never "sweet to die" for his country or for anything else, and the fascination for Western audiences is to follow the hero—as it were, *from the inside*—as he struggles to assert himself and his values against whatever would deny them. In Oriental drama, there is no such intense focus on the individual. In the Japanese Nō plays, for instance, the hero may be seen in moments of weariness and despair, of anger or confusion, but the mood is lyric, and the structure of the plays is ritualistic, with a great deal of choral intoning, dancing, and stylized action. Although a number of Nō plays can be produced together to fill a day's performance, the individual plays are very short, hardly the length of a Western one-act play. Nō plays affirm orthodoxy, rather than probing and questioning it, as Western tragedies do.

The drama in India has a long history, but there too the individual is subordinated to the mood of the idyll or romance or epic adventure. Perhaps one reason why the drama of India never developed the tragic orientation of the West is its removal from the people; it has never known the communal involvement of the Greek and Eliz-

abethan theatres. Produced mainly for court audiences, an upper class elite, it never reflected the sufferings of common (or uncommon) humanity. Only recently has the drama in China embraced the vigour and realism of the common people, but the drama is in the service not of the individual but of a political ideology, which replaces the traditional themes of ancestor worship and filial piety. In all this, the mighty pageant figure—Oedipus, Prometheus, Lear, or Ahab standing for the individual as he alone sees and feels the workings of an unjust universe—is absent.

Tragedy in Nō drama

An example from the Nō plays will illustrate these generalizations. In *The Hoka Priests,* by Zenchiku Ujinobu (1414–99), a son is confronted with Hamlet's problem—*i.e.*, that of avenging the death of his father. He is uncertain how to proceed, since his father's murderer has many bold fellows to stand by him, while he is all alone. He persuades his brother, a priest, to help him, and disguising themselves as priests, they concoct a little plot to engage the murderer in religious conversation. There are a few words of lament—"Oh why,/ Why back to the bitter World/ Are we borne by our intent?"—and the Chorus sings lyrically about the uncertainties of life. The theme of the conversation is the unreality of the World and the reality of Thought. At an appropriate moment, the brothers cry, "Enough! Why longer hide our plot?" The murderer places his hat on the floor and exits. The brothers mime the killing of the murderer in a stylized attack upon the hat, while the Chorus describes and comments on the action: "So when the hour was come/ Did these two brothers/ By sudden resolution/ Destroy their father's foe./ For valour and piety are their names remembered/ Even in this aftertime" (translated by Arthur Waley, *The Nō Plays of Japan*, 1921).

Thus the Nō avoids directly involving the audience in the emotions implicit in the events portrayed on the stage. It gives only a slight hint of the spiritual struggle in the heart of the protagonist—a struggle that is always speedily resolved in favour of traditional teaching. In play after play the action does not take place before our eyes but is re-enacted by the ghost of one of the participants. Thus, the events presented are tinged with memory or longing—hardly the primary emotions that surge through and invigorate Western tragedy at its best.

Loss of viability in the West. The absence, even in the West, of a great tragic theatre in the 20th century may be explained by the pantheon of panaceas to which modern man has subscribed. Politics, psychology, social sciences, physical sciences, nationalism, the occult—each offered a context in terms of which he might act out his destiny, were it not crowded out by the others. Modern man is not tested but harried and not by gods but, too often, by demons. In the dramas of Athens and England, tragedy was born of the impossibility of a clear-cut victory in man's struggle with powers greater than himself. In the modern drama, the struggle itself seems impossible.

The would-be hero is saved from a meaningful death by being condemned to a meaningless life. This, too, however, has its tragic dimension, in its illustration of the power of evil to survive from millennium to millennium in the presence or the absence of the gods.

Tragedy is a means of coming to terms with that evil. To assume that tragedy has lost viability is to forget that this viability was seriously questioned by the first Western philosopher to address himself to the problem. An account of the development of the theory of tragedy will reveal a resourcefulness in man's critical powers that can help to compensate, or occasionally even supersede, his lapsing creative powers. (R.B.S.)

THEORY OF TRAGEDY

Classical theories of tragedy. As the great period of Athenian drama drew to an end at the beginning of the 4th century BC, Athenian philosophers began to analyze its content and formulate its structure. In the thought of Plato (*c.* 427–347 BC), the history of the criticism of tragedy began with speculation on the role of censorship. To Plato (in the dialogue on the *Laws*) the state was the noblest work of art, a representation (*mimēsis*) of the fairest and best life. He feared the tragedians' command of the expressive resources of language, which might be used to the detriment of worthwhile institutions. He feared, too, the emotive effect of poetry, the Dionysian element that is at the very basis of tragedy. Therefore, he recommended that the tragedians submit their works to the rulers, for approval, without which they could not be performed. It is clear that tragedy, by nature exploratory, critical, independent, could not live under such a regimen.

Ethics and art—Plato and Aristotle

Plato is answered, in effect and perhaps intentionally, by Aristotle's *Poetics.* Aristotle (384–322 BC) defends the purgative power of tragedy and, in direct contradiction to Plato, makes moral ambiguity the essence of tragedy. The tragic hero must be neither a villain nor a virtuous man but a "character between these two extremes, . . . a man who is not eminently good and just, yet whose misfortune is brought about not by vice or depravity, but by some error or frailty [*hamartia*]." The effect on the audience will be similarly ambiguous. A perfect tragedy, he says, should imitate actions that excite "pity and fear." He uses Sophocles' *Oedipus the King* as a paradigm. Near the beginning of the play, Oedipus asks how his stricken city (the counterpart of Plato's state) may cleanse itself, and the word he uses for the purifying action is a form of the word catharsis. The concept of catharsis provides Aristotle with his reconciliation with Plato, a means by which to satisfy the claims of both ethics and art. "Tragedy," says Aristotle, "is an imitation [*mimēsis*] of an action that is serious, complete and of a certain magnitude . . . through pity and fear effecting the proper purgation [catharsis] of these emotions." Ambiguous means may be employed, Aristotle maintains in contrast to Plato, to a virtuous and purifying end.

To establish the basis for a reconciliation between ethical and artistic demands, Aristotle insists that the principal element in the structure of tragedy is not character but plot. Since the erring protagonist is always in at least partial opposition to the state, the importance of tragedy lies not in him but in the enlightening event. "Most important of all," Aristotle said, "is the structure of the incidents. For tragedy is an imitation not of men but of an action and of life, and life consists in action, and its end is a mode of action, not a quality. . . ." Aristotle considered the plot to be the soul of a tragedy, with character in second place. The goal of tragedy is not suffering but the knowledge that issues from it, as the denouement issues from a plot. The most powerful elements of emotional interest in tragedy, according to Aristotle, are reversal of intention or situation (*peripeteia*) and recognition scenes (*anagnōrisis*), and each is most effective when it is coincident with the other. In *Oedipus,* for example, the messenger who brings Oedipus news of his real parentage, intending to allay his fears, brings about a sudden reversal of his fortune, from happiness to misery, by compelling him to recognize that his wife is also his mother.

Later critics found justification for their own predilections in the authority of Greek drama and Aristotle. For example, the Roman poet Horace (65–8 BC), in his *Ars poetica* (*Art of Poetry*), elaborated the Greek tradition of extensively narrating offstage events into a dictum on decorum forbidding events such as Medea's butchering of her boys from being performed on stage. And where Aristotle had discussed tragedy as a separate genre, superior to epic poetry, Horace discussed it as a genre with a separate style, again with considerations of decorum foremost. A theme for comedy may not be set forth in verses of tragedy; each style must keep to the place alloted it.

On the basis of this kind of stylistic distinction, the *Aeneid,* the epic poem of Virgil, Horace's contemporary, is called a tragedy by the fictional Virgil in Dante's *Divine Comedy,* on the grounds that the *Aeneid* treats only of lofty things. Dante (1265–1321) calls his own poem a comedy partly because he includes "low" subjects in it. He makes this distinction in his *De vulgari eloquentia* (1304–06; "On the Vernacular Tongue"), in which he also declares the subjects fit for the high, tragic style to be salvation, love, and virtue. Despite the presence of these subjects in this poem, he calls it a comedy because his

style of language is "careless and humble" and because it is in the vernacular tongue rather than Latin. Dante makes a further distinction:

> Comedy . . . differs from tragedy in its subject matter, in this way, that tragedy in its beginning is admirable and quiet, in its ending or catastrophe foul and horrible . . . From this it is evident why the present work is called a comedy.

Fate and will in comedy and tragedy

Dante's emphasis on the outcome of the struggle rather than on the nature of the struggle is repeated by Chaucer and for the same reason: their belief in the providential nature of human destiny. Like Dante, he was under the influence of *De consolatione philosophiae* (*Consolation of Philosophy*), the work of the 6th-century Roman philosopher Boethius (*c.* 480–524) that he translated into English. Chaucer considered Fortune to be beyond the influence of the human will. In his *Canterbury Tales*, he introduces "The Monk's Tale" by defining tragedy as "a certeyn storie . . ./of him that stood in greet prosperitee,/ And is y-fallen out of heigh degree/ Into miserie, and endeth wrecchedly." Again, he calls his *Troilus and Criseyde* a tragedy because, in the words of Troilus, "all that comth, comth by necessitee . . ./ That forsight of divine purveyaunce/ Hath seyn alwey me to forgon Criseyde."

Elizabethan approaches. The critical tradition of separating the tragic and comic styles is continued by the Elizabethan English poet Sir Philip Sidney, whose *Defence of Poesie* (also published as *An Apologie for Poetrie*) has the distinction of containing the most extended statement on tragedy in the English Renaissance and the misfortune of having been written in the early 1580s (published 1595), before the first plays of Shakespeare, or even of Marlowe. Nevertheless, Sidney wrote eloquently of "high and excellent tragedy, that . . . with stirring the affects of admiration and commiseration teacheth the uncertainty of this world and upon how weak foundations gilden roofs are builded."

Since the word admiration here means awe, Sidney's "admiration and commiseration" are similar to Aristotle's "pity and fear." He differs from Aristotle, however, in preferring epic to tragic poetry. The Renaissance was almost as concerned as Plato with the need to justify poetry on ethical grounds, and Sidney ranks epic higher than tragedy because it provides morally superior models of behaviour.

Sidney goes further than mere agreement with Aristotle, however, in championing the unities of time and place. Aristotle had asserted the need for a unity of time: "Tragedy endeavors, as far as possible, to confine itself to a single revolution of the sun, or but slightly to exceed this limit." Sidney, following the lead of a 16th-century Italian Neoclassicist, Ludovico Castelvetro, added the unity of place: "the stage should always represent but one place, and the uttermost time presupposed in it should be, both by Aristotle's precept and common reason, but one day . . ." Sidney also seconds Horace's disapproval of the mingling of styles, which Sidney says produces a "mongrel tragicomedy."

Shakespeare's opinion of the relative merits of the genres is unknown, but his opinion of the problem itself may be surmised. In *Hamlet* he puts these words in the mouth of the foolish old pedant Polonius: "The best actors in the world, either for tragedy, comedy, history, pastoral, pastoral-comical, historical-pastoral, tragical-historical, tragical-comical-historical-pastoral; scene individable, or poem unlimited . . ." (Act II, scene 2). As to the classical unities, Shakespeare adheres to them only twice and neither time in a tragedy, in *The Comedy of Errors* and *The Tempest*. And through the mouths of his characters, Shakespeare, like Aristotle, puts himself on both sides of the central question of tragic destiny—that of freedom and necessity. Aristotle says that a tragic destiny is precipitated by the hero's tragic fault, his "error or frailty" (hamartia), but Aristotle also calls this turn of events a change of "fortune." Shakespeare's Cassius in *Julius Caesar* says, "The fault, dear Brutus, is not in our stars, / But in ourselves . . . ," and in King Lear, Edmund ridicules a belief in fortune as the "foppery of the world." But Hamlet, in a comment on the nature of hamartia, is a fatalist when he broods on the "mole of nature," the "one defect" that some men are born with, "wherein they are not guilty," and that brings them to disaster (Act I, scene 4). Similarly, Sophocles' Oedipus, though he says, "It was Apollo who brought my woes to pass," immediately adds, "it was my hand that struck my eyes." These ambiguities are a powerful source of the tragic emotion of Athenian and Elizabethan drama, unequalled by traditions that are more sure of themselves, such as French Neoclassicism, or less sure of themselves, such as 20th-century drama.

Neoclassical theory. In the Neoclassical period Aristotle's reasonableness was replaced by rationality, and his moral ambiguity by the mechanics of "poetic justice." In the 17th century, under the guise of a strict adherence to Classical formulas, additional influences were brought to bear on the theory of tragedy. In France, the theological doctrine of Jansenism, which called for an extreme orthodoxy, exercised a strong influence. In England, the restoration of the monarchy in 1660, with the reopening of the theatres, introduced a period of witty and lusty literature. In both nations, the influence of natural law—the idea that laws binding upon humanity are inferable from nature—increased, along with the influence of the exact sciences. Critics in both nations declared that Aristotle's "rules" were made to reduce nature into a method.

In his 1679 preface to Shakespeare's *Troilus and Cressida*, Dryden says, "we lament not, but detest a wicked man, we are glad when we behold his crimes are punished, and that Poetical justice is done upon him." Similar sentiments, calling for the punishment of crimes and the reward of virtue, were expressed in France. Catharsis had become vindication. Thomas Rymer, one of the most influential English critics of the time, in *The Tragedies of The Last Age* (1678), wrote that

Vindication rather than catharsis

> besides the purging of the passions, something must stick by observing . . . that necessary relation and chain, whereby the causes and the effects, the vertues and rewards, the vices and their punishments are proportion'd and link'd together, how deep and dark soever are laid the Springs, and however intricate and involv'd are their operations.

The effect was to rob tragedy of a great deal of its darkness and depth. The temper of the age demanded that mystery be brought to the surface and to the light, a process that had effects not merely different from but in part antipathetic to tragedy. Nicolas Boileau, the chief spokesman of the French Neoclassical movement, in his discussion of pity and fear in *Art Poétique* (1674), qualified these terms with the adjectives "beguiling" and "pleasant" (*pitié charmante, douce terreur*), which radically changed their meaning. The purged spectator became a grateful patient.

In his preface to *Phèdre* (1677), Racine subscribed to the *quid pro quo* view of retribution.

> I have written no play in which virtue has been more celebrated than in this one. The smallest faults are here severely punished; the mere idea of a crime is looked upon with as much horror as the crime itself.

Of Phèdre herself, his greatest heroine, he says,

> I have taken the trouble to make her a little less hateful than she is in the ancient versions of this tragedy, in which she herself resolves to accuse Hippolytus. I judged that that calumny had about it something too base and black to be put into the mouth of a Princess . . . This depravity seemed to me more appropriate to the character of a nurse, whose inclinations might be supposed to be more servile. . . .

For Aristotle, pity and fear made a counterpoint typical of Classicism, each tempering the other to create a balance. For Racine, pity and fear each must be tempered in itself. In the marginalia to his fragmentary translation of Aristotle's *Poetics*, Racine wrote that in arousing the passions of pity and fear, tragedy

> removes from them whatever they have of the excessive and the vicious and brings them back to a moderated condition and conformable to reason.

Corneille contradicted Aristotle outright. Discussing *Le Cid* he said, in *A Discourse on Tragedy* (1660),

> Our pity ought to give us fear of falling into similar misfortune, and purge us of that excess of love which is the cause of their disaster . . . but I do not know that it gives

> us that, or purges us, and I am afraid that the reasoning of Aristotle on this point is but a pretty idea . . . it is not requisite that these two passions always serve together . . . it suffices . . . that one of the two bring about the purgation. . . .

The accommodation of tragedy to Neoclassical ideas of order demanded a simplification of tragedy's complexities and ambiguities. The simplifying process was now inspired, however, by the fundamental tenet of all primitive scientific thought namely, that orderliness and naturalness are in a directly proportionate relationship. Racine declared the basis of the naturalistic effect in drama to be a strict adherence to the unities, which now seem the opposite of naturalistic. In his preface to *Bérénice* (1670), he asked what probability there could be when a multitude of things that would scarcely happen in several weeks are made to happen in a day. The illusion of probability, which is the Aristotelian criterion for the verisimilitude of a stage occurrence, is made to sound as if it were the result of a strict dramaturgical determinism, on the grounds that necessity is the truest path to freedom.

Racine and Corneille both contradicted Dante and Chaucer on the indispensability of a catastrophic final scene. "Blood and deaths," said Racine, are not necessary, for "it is enough that the action be grand, that the actors be heroic, that the passions be aroused" to produce "that stately sorrow that makes the whole pleasure of tragedy" (preface to *Bérénice*).

Milton was artistically much more conservative. He prefaced his *Samson Agonistes* (1671) with a warning against the

> error of intermixing Comic stuff with Tragic sadness and gravity; or introducing trivial and vulgar persons: which by all judicious hath been counted absurd; and brought in without discretion, corruptly to gratify the people.

He bypassed Shakespeare for the ancients and ranked Aeschylus, Sophocles, and Euripides as tragic poets unequalled yet by any others. Part of the rule, for Milton, was that which affirmed the unities. In his concurrence with the Classical idea of the purgative effect of pity and fear, Milton combined reactionary aesthetics with the scientific spirit of the recently formed Royal Society.

> Nor is Nature wanting in her own effects to make good his assertion [Aristotle on catharsis]: for so, in Physic things of melancholic hue and quality are used against melancholy, sour against sour, salt to remove salt humours.

Dryden spoke against a delimiting conception of either the genres or the unities. Speaking in the guise of Neander in *Of Dramatick Poesie, an Essay* (1668), he said that it was

> to the honour of our nation, that we have invented, increased, and perfected a more pleasant way of writing for the stage, than was ever known to the ancients or moderns of any nation, which is tragi-comedy.

The French dramatists, he felt, through their observance of the unities of time and place, wrote plays characterized by a dearth of plot and narrowness of imagination. Racine's approach to the question of probability was turned completely around by Dryden, who asked:

> How Many beautiful accidents might naturally happen in two or three days, which cannot arrive with any probability in the compass of twenty-four hours?

Johnson's definitive critique

The definitive critique of Neoclassical restrictions was not formulated, however, until the following century, when it was made by Samuel Johnson and was, significantly, part of his 1765 preface to Shakespeare, the first major step in the long process of establishing Shakespeare as the pre-eminent tragic poet of post-Classical drama. On genre he wrote:

> Shakespeare's plays are not in the rigorous and critical sense either tragedies or comedies, but compositions of a distinct kind; . . . expressing the course of the world, in which the loss of one is the gain of another; in which, at the same time, the reveller is hasting to his wine, and the mourner burying his friend. . . . That this is a practice contrary to the rules of criticism will be readily allowed; but there is always an appeal open from criticism to nature.

And on the unities:

> The necessity of observing the unities of time and place arises from the supposed necessity of making the drama credible. [But] the objection arising from the impossibility of passing the first hour at Alexandria, and the next at Rome, supposes, that when the play opens, the spectator really imagines himself at Alexandria . . . Surely he that imagines this may imagine more.

Johnson's appeal to nature was the essence of subsequent Romantic criticism.

Romantic theories of tragedy. Lessing was the first important Romantic critic. He stated one of Romanticism's chief innovations in his *Hamburg Dramaturgy* (1767–69):

> The names of princes and heroes can lend pomp and majesty to a play, but they contribute nothing to our emotion. The misfortune of those whose circumstances most resemble our own, must naturally penetrate most deeply into our hearts, and if we pity kings, we pity them as human beings, not as kings.

Within a generation, revolutions in Europe and America offered social expression of this literary precept, and a dramatic tradition dominant for 22 centuries was upturned. From the time of Aristotle, who thought that the tragic hero should be highly renowned and prosperous, the tragic hero had been an aristocrat, if not a man of royal blood. With the exception of their minor or peripheral characters, the tragic dramas of Athens, England, and France told nothing of the destinies of the mass of mankind. All this was now changed.

But it is not certain that what was good for the revolution was good for tragedy. Coleridge in his critical writings of 1808–18 said that:

> there are two forms of disease most preclusive of tragic worth. The first [is] a sense and love of the ludicrous, and a diseased sensibility of the assimilating power . . . that in the boldest bursts of passion will lie in wait, or at once kindle into jest. . . . The second cause is matter of exultation to the philanthropist and philosopher, and of regret to the poet, . . . namely, the security, comparative equability, and ever-increasing sameness of human life.

In accord with this distaste for an excess of the mundane, Coleridge attacked the new German tragedies in which "the dramatist becomes a novelist *in his directions to the actors*, and degrades tragedy to pantomime." To describe, or rather indicate, what tragedy should ideally be, Coleridge said "it is not *a copy* of nature; but it is an imitation."

Coleridge's operative words and phrases in his discussions of tragedy were "innate," "from within," "implicit," "the being within," "the inmost heart," "our inward nature," "internal emotions," and "retired recesses." The new philosophical dispensation in Coleridge, like the new social dispensation in Lessing, reversed the old priorities; and where there were once princes there were now burghers, and where there were once the ordinances of God and the state there were now the dictates of the heart. By means of this reversal, Coleridge effected a reconciliation of the "tragedy of fate" and the "tragedy of character" in his description of the force of fate as merely the embodiment of an interior compulsion different in scale but not in kind from the interior compulsions of character. In Classical tragedy, he said the human "will" was "exhibited as struggling with fate, a great and beautiful instance and illustration of which is the Prometheus of Aeschylus; and the deepest effect is produced, when the fate is represented as a higher and intelligent will. . . ."

Coleridge's reconciliation of fate and character

According to Coleridge, Shakespeare used the imaginative "variety" that characterizes man's inward nature in place of the mechanical regularity of the Neoclassical unities to produce plays that were "neither tragedies nor comedies, nor both in one, but a different genus, diverse in kind, not merely different in degree,—romantic dramas or dramatic romances." In his preoccupation with the mixture of genres and his distinction between the "mechanical" (Neoclassicism) and the "organic" (Shakespeare), Coleridge was influenced by *Lectures on Dramatic Art and Literature* (delivered 1808–09, published 1809–11), by August Wilhelm von Schlegel, perhaps the most influential of German Romantic critics.

Like Coleridge and most Romantic critics of tragedy, Schlegel found his champion in Shakespeare, and, also like them, he was preoccupied with the contrast between Classic and Romantic. Like Coleridge, Schlegel emphasized Shakespeare's inwardness, what Coleridge called his "implicit wisdom deeper even than our consciousness." It is in Shakespeare's most profound insights that Schlegel locates one of the principal distinctions between Classical and Shakespearean tragedy, in what he calls Shakespeare's "secret irony." The irony in *Oedipus the King* consists in the relation between the audience's knowledge of the protagonist's situation and his own ignorance of it. But Shakespeare's "readiness to remark the mind's fainter and involuntary utterances" is so great, says Schlegel, that "nobody ever painted so truthfully as he has done the facility of self-deception, the half self-conscious hypocrisy towards ourselves, with which even noble minds attempt to disguise the almost inevitable influence of selfish motives in human nature."

The irony Schlegel sees in Shakespeare's characterizations also extends to the whole of the action, as well as to the separate characters. In his discussion of it he suggests the reason for the difficulty of Shakespeare's plays and for the quarrelsome, irreconcilable "interpretations" among Shakespeare's commentators:

> Most poets who portray human events in a narrative or dramatic form take themselves apart, and exact from their readers a blind approbation or condemnation of whatever side they choose to support or oppose. . . . When, however, by a dexterous manoeuvre, the poet allows us an occasional glance at the less brilliant reverse of the medal, then he makes, as it were, a sort of secret understanding with the select circle of the more intelligent of his readers or spectators; he shows them that he had previously seen and admitted the validity of their tacit objections; that he himself is not tied down to the represented subject but soars freely above it. . . .

In Greek tragedy, the commentary by the chorus was an explicit and objective fact of the drama itself. In the presentation of Shakespeare's plays, such a commentary is carried on in the separate minds of the spectators, where it is diffused, silent, and not entirely sure of itself. When the spectators speak their minds after the curtain falls, it is not surprising that they often disagree.

In *Oedipus the King*, which Aristotle cited as the model of Classical tragedy, the irony of the protagonist's situation is evident to the spectator. In *Hamlet*, however, according to the American philosopher George Santayana, writing in 1908, it is the secret ironies, half-lights, and self-contradictions that make it the central creation of Romantic tragedy. As has been noted, Coleridge objected to the dramatist's giving directions to the actors, but part of the price of not having them is to deny to the audience as well an explicit indication of the playwright's meaning.

George Wilhelm Friedrich Hegel (1770–1831), the immensely influential German philospher, in his *Aesthetik* (1820–29), proposed that the sufferings of the tragic hero are merely a means of reconciling opposing moral claims. The operation is a success because of, not in spite of, the fact that the patient dies. According to Hegel's account of Greek tragedy, the conflict is not between good and evil but between goods that are each making too exclusive a claim. The heroes of ancient tragedy, by adhering to the *one* ethical system by which they molded their own personality, must come into conflict with the ethical claims of another. It is the moral one-sidedness of the tragic actor, not any negatively tragic fault in his morality or in the forces opposed to him, that proves his undoing, for both sides of the contradiction, if taken by themselves, are justified.

The nuclear Greek tragedy for Hegel is, understandably, Sophocles' *Antigone*, with its conflict between the valid claims of conscience (Antigone's obligation to give her brother a suitable burial) and law (King Creon's edict that enemies of the state should not be allowed burial). The two claims represent what Hegel regards as essentially concordant ethical claims. Antigone and Creon are, in this view, rather like pawns in the Hegelian dialectic—his theory that thought progresses from a thesis (*i.e.*, an idea), through an antithesis (an idea opposing the original thesis), to a synthesis (a more comprehensive idea that embraces both the thesis and antithesis), which in turn becomes the thesis in a further progression. At the end of *Antigone*, something of the sense of mutually appeased, if not concordant, forces does obtain after Antigone's suicide and the destruction of Creon's family. Thus, in contrast to Aristotle's statement that the tragic actors should represent not an extreme of good or evil but something between, Hegel would have them too good to live; that is, too extreme an embodiment of a particular good to survive in the world. He also tends to dismiss other traditional categories of tragic theory. For instance, he prefers his own kind of catharsis to Aristotle's—the feeling of *reconciliation*.

Tragedy as Hegelian dialectic

Hegel's emphasis on the correction of moral imbalances in tragedy is reminiscent of the "poetic justice" of Neoclassical theory, with its similar dialectic of crime and punishment. He sounds remarkably like Racine when he claims that, in the tragic denouement, the necessity of all that has been experienced by particular individuals is seen to be in complete accord with reason and is harmonized on a true ethical basis. But where the Neoclassicists were preoccupied with the unities of time and place, Hegel's concerns, like those of other Romantics, are inward. For him, the final issue of tragedy is not the misfortune and suffering of the tragic antagonists but rather the satisfaction of spirit arising from "reconciliation." Thus, the workings of the spirit, in Hegel's view, are subject to the rationalistic universal laws.

Hegel's system is not applicable to Shakespearean or Romantic tragedy. Such Shakespearean heroes as Macbeth, Richard III, and Mark Antony cannot be regarded as embodiments of any transcendent good. They behave as they do, says Hegel, now speaking outside of his scheme of tragedy, simply because they are the kind of men they are. In a statement pointing up the essence of uninhibited romantic lust and willfulness Hegel said: "it is the inner experience of their heart and individual emotion, or the particular qualities of their personality, which insist on satisfaction."

The traditional categories of tragedy are nearly destroyed in the deepened subjectivities of Romanticism of the 19th-century German philosophers, Arthur Schopenhauer and his disciple Friedrich Nietzsche. In Schopenhauer's *Die Welt als Wille und Vorstellung* (1819; *The World as Will and Idea*, much more than the social or ethical order is upturned. In place of God, the good, reason, soul, or heart, Schopenhauer installs the will, as reality's true inner nature, the metaphysical to everything physical in the world. In Schopenhauer, there is no question of a Hegelian struggle to achieve a more comprehensive good. There is rather the strife of will with itself, manifested by fate in the form of chance and error and by the tragic personages themselves. Both fate and men represent one and the same will, which lives and appears in them all. Its individual manifestations, however, in the form of such phenomena as chances, errors, or men, fight against and destroy each other.

Schopenhauer accordingly rejects the idea of poetic justice: "the demand for so-called poetical justice rests on entire misconception of the nature of tragedy, and, indeed, of the nature of the world itself. . . . The true sense of tragedy is the deeper insight, that it is not his own individual sins that the hero atones for, but original sin, *i.e.*, the crime of existence itself. . . ." Schopenhauer distinguishes three types of tragic representation: (1) "by means of a character of extraordinary wickedness . . . who becomes the author of the misfortune"; (2) "blind fate—*i.e.*, chance and error" (such as the title characters in Shakespeare's *Romeo and Juliet* and "most of the tragedies of the ancients"); and (3) when "characters of ordinary morality . . . are so situated with regard to each other that their position compels them, knowingly and with their eyes open, to do each other the greatest injury, without any one of them being entirely in the wrong" (such as, "to a certain extent," *Hamlet*).

Schopenhauer's three types

This last kind of tragedy seems to Schopenhauer far to surpass the other two. His reason, almost too grim to record, is that it provides the widest possible play to the

destructive manifestations of the will. It brings tragedy, so to speak, closest to home:

> those powers which destroy happiness and life are such that their path to us also is open at every moment; we see the greatest sufferings brought about by entanglements that our fate might also partake of, and through actions that perhaps we also are capable of performing . . . ; then, shuddering, we feel ourselves already in the midst of hell.

Schopenhauer finds tragedy to be the summit of poetical art, because of the greatness of its effect and the difficulty of its achievement. According to Schopenhauer, the egoism of the protagonist is purified by suffering almost to the purity of nihilism. His personal motives become dispersed as his insight into them grows; "the complete knowledge of the nature of the world, which has a quieting effect on the will, produces resignation, the surrender not merely of life, but of the very will to live."

Schopenhauer's description has limited application to tragic denouements in general. In the case of his own archetypal hero, the hero's end seems merely the mirror image of his career, an oblivion of resignation or death that follows an oblivion of violence. Instead of a dialogue between higher and lower worlds of morality or feeling (which take place even in Shakespeare's darkest plays), Schopenhauer posits a succession of states as helpless in knowledge as in blindness. His "will' becomes a synonym for all that is possessed and necessity-ridden.

Nietzsche's division of tragedy in two elements

Nietzsche's *Geburt der Tragödie aus dem Geiste der Musik* (1872) was deeply influenced by Schopenhauer. The two elements of tragedy, says Nietzsche, are the Apollonian (related to the Greek god Apollo, here used as a symbol of measured restraint) and the Dionysian (from Dionysus, the Greek god of ecstasy). His conception of the Apollonian is the equivalent of what Schopenhauer called the individual phenomenon—the particular chance, error, or man, the individuality of which is merely a mask for the essential truth of reality which it conceals. The Dionysian element is a sense of universal reality, which, according to Schopenhauer, is experienced after the loss of individual egoism. The "Dionysian ecstasy," as defined by Nietzsche, is experienced "not as individuals but as the *one* living being, with whose creative joy we are united."

Nietzsche dismisses out of hand one of the most venerable features of the criticism of tragedy, the attempt to reconcile the claims of ethics and art. He says that the events of a tragedy are "supposed" to discharge pity and fear and are "supposed" to elevate and inspire by the triumph of noble principles at the sacrifice of the hero. But art, he says, must demand purity within its own sphere. To explain tragic myth, the first requirement is to seek the pleasure that is peculiar to it in the purely aesthetic sphere, without bringing in pity, fear, or the morally sublime.

The essence of this specifically aesthetic tragic effect is that it both reveals and conceals, causing both pain and joy. The drama's exhibition of the phenomena of suffering individuals (Apollonian elements) forces upon the audience "the struggle, the pain, the destruction of phenomena," which in turn communicates "the exuberant fertility of the universal." The spectators then "become, as it were, one with the infinite primordial joy in existence, and . . . we anticipate, in Dionysian ecstasy, the indestructibility and eternity of this joy." Thus, he says, there is a desire "to see tragedy and at the same time to get beyond all seeing . . . to hear and at the same time long to get beyond all hearing."

The inspired force of Nietzsche's vision is mingled with a sense of nihilism:

> "only after the spirit of science has been pursued to its limits, . . . may we hope for a rebirth of tragedy . . . I understand by the spirit of science the faith that first came to light in the person of Socrates—the faith in the explicability of nature and in knowledge as a panacea."

Nietzsche would replace the spirit of science with a conception of existence and the world as an aesthetic phenomenon and justified only as such. Tragedy would enjoy a prominent propagandistic place. It is "precisely the tragic myth that has to convince us that even the ugly and disharmonic are part of an artistic game that the will in the eternal amplitude of its pleasure plays with itself." And, consummately: "we have art in order that we may not perish through truth."

Tragedy in music. Musical dissonance was Nietzsche's model for the double effect of tragedy. The first edition of his book was titled *The Birth of Tragedy out of the Spirit of Music*, another influence from Schopenhauer, for whom music differed from all the other arts in that it is not a copy of a phenomenon but the direct copy of the will itself. He even called the world "embodied music, . . . embodied will." Nietzsche's theorizing on the relation of the tragic theme to art forms other than the drama was in fact confirmed in such operas as Mussorgsky's version of Pushkin's tragedy *Boris Godunov*, Verdi's of *Macbeth* and *Othello*, and Gounod's *Faust*. In contrast to these resettings of received forms, Wagner, Verdi, and Bizet achieved a new kind of tragic power for Romanticism in the theme of the operatic love-death in, respectively, *Tristan and Isolde*, *Aida*, and *Carmen*. Thus, the previous progression of the genre from tragedy to tragicomedy to romantic tragedy continued to a literary-musical embodiment of what Nietzsche called "tragic dithyrambs."

An earlier prophecy than Nietzsche's regarding tragedy and opera was made by the German poet Friedrich von Schiller in a letter of 1797 to Goethe:

> I have always trusted that out of opera, as out of the choruses of the ancient festival of Bacchus, tragedy would liberate itself and develop in a nobler form. In opera, servile imitation of nature is dispensed with . . . here is . . . the avenue by which the ideal can steal its way back into the theatre.

Critical theory in the 20th century. In the 20th century, discussion of tragedy was sporadic until the aftermath of World War II. Then it enjoyed new vigour, perhaps to compensate for, or help explain, the dearth of genuine tragic literature, either in the novel or in the theatre. In the 1950s and 1960s countless full-length studies, articles, and monographs variously sought the essence, the vision, the view of life, or the spirit of tragedy out of a concern for the vital culture loss were the death of tragedy to become a reality. They also attempted to mediate the meaning of tragedy to a public that was denied its reality, save in revivals or an occasional approximation. Since the Romantic critics first ventured beyond the Aristotelean categories to consider tragedy, or the tragic, as a sense of life, there was an increasing tendency to regard tragedy not merely as drama but as a philosophical form. It is noteworthy that the Spanish philosopher Miguel de Unamuno's influential book, *The Tragic Sense of Life* (1921), barely mentions the formal drama.

From the time of Aristotle, tragedy has achieved importance primarily as a medium of self-discovery—the discovery of man's place in the universe and in society. That is the main concern of Aristotle in his statements about reversal, recognition, and catharsis, though it remained for the Romantic critics to point it out. The loss of this concern in the facile plays of the 19th and 20th centuries resulted in the reduction of tragic mystery to confused sentimentalism. Critics of the 20th century, being less certain even than Schopenhauer or Nietzsche of what man's place in the scheme of things may be, experimented with a variety of critical approaches, just as contemporary dramatists experimented with various "theatres." Although these critics lacked the philosophical certainties of earlier theorists, they had a richer variety of cultures and genres to instruct them. The hope of both critics and dramatists was that this multiplicity would produce not mere impressionism or haphazard eclecticism but new form and new meaning. (L.C.)

BIBLIOGRAPHY. A lengthier development of many of the points made in this article may be found in R.B. SEWALL, *The Vision of Tragedy* (1959). Among the works examining the origins of tragedy in ancient Greece are H.D.F. KITTO, *Greek Tragedy*, 3rd ed. (1961); and J. JONES, *On Aristotle and Greek Tragedy* (1962). Works concentrating on modern tragedy include: GEORGE STEINER, *The Death of Tragedy* (1961); WALTER KERR, *Tragedy and Comedy* (1968); and RAYMOND WILLIAMS, *Modern Tragedy* (1966). Special aspects of tragedy are treated in J.M.R. MARGESON, *The Origins of English Tragedy* (1967); EUGENE VINAVER, *Racine and Poetic*

Tragedy (1955); A.C. BRADLEY, *Shakespearean Tragedy* (1904); and GEORGE LUKACS, *The Historical Novel*, ch. 2 (1962), a Marxist view. A useful anthology of writings on tragedy is LIONEL ABEL (ed.), *Moderns on Tragedy* (1967). Other recent works on the subject include: RICHMOND HATHORN, *Tragedy, Myth, and Mystery* (1962); MURRAY KRIEGER, *The Tragic Vision: Variations on a Theme in Literary Interpretation* (1960); and DOROTHY KROOK, *Elements of Tragedy* (1969).

Trajan

Trajan, the first Roman emperor to have been born in the provinces, revived expansive imperialism, built magnificently, and, in reaction against the despotism of Domitian, one of his predecessors, took care to maintain correct relations with the Senate.

Trajan, wreathed portrait bust of gilt bronze, early 2nd century AD. In the Museum of Archeology, Ankara.

Origins and early career. Marcus Ulpius Traianus was born, probably on September 15, AD 53, at Italica (modern Santiponce, near Seville) in the Roman province of Baetica, southern Spain. Although his ancestors, whether or not original settlers, were undoubtedly Roman, or at least Italian, they may well have intermarried with natives. While his family was probably well-to-do and prominent in Baetica, his father was the first to have a career in the imperial service. He became a provincial governor and in 67–68 commander of a legion in the war the future emperor Vespasian was conducting against the Jews. In 70, Vespasian, by then emperor, rewarded him with a consulship and a few years later enrolled him among the patricians, Rome's most aristocratic group within the senatorial class. Finally, he became governor, successively, of Syria and Asia.

Early military career

Although there is little documentation of Trajan's early life, presumably the future emperor grew up either in Rome or in various military headquarters with his father. He served ten years as a legionary staff tribune. In this capacity he was in Syria while his father was governor, probably in 75. He then held the traditional magistracies through the praetorship, which qualified him for command of a legion in Spain in 89. Ordered to take his troops to the Rhine to aid in quelling a revolt against the emperor Domitian by the governor of Upper Germany, Trajan probably arrived after the revolt had already been suppressed by the governor of Lower Germany. Trajan clearly enjoyed the favour of Domitian, who in 91 allowed him to hold one of the two consulships, which even under the empire remained most prestigious offices.

When Domitian had been assassinated by a palace conspiracy on September 18, 96, the conspirators had put forward as emperor, and the Senate had welcomed, the elderly and innocuous Nerva. His selection represented a reaction against Domitian's autocracy and a return to the cooperation between emperor and Senate that had characterized the reign of Vespasian. Nevertheless, the imperial guard (the praetorian cohorts) forced the new emperor to execute the assassins who had secured the throne for him. There was also discontent among the frontier commanders. Therefore, in October 97, Nerva adopted as his successor Trajan, whom he had made governor of upper Germany and who seemed acceptable both to the army commanders and to the Senate. On January 1, 98, Trajan entered upon his second consulship as Nerva's colleague. Soon thereafter, on January 27 or 28, Nerva died, and Trajan was accepted as emperor by both the armies and the Senate. Before his accession, Trajan had married Pompeia Plotina, to whom he remained devoted. As the marriage was childless, he took into his household his cousin Hadrian, who became a favourite of Plotina.

Domestic policies as emperor. Trajan deified Nerva and included his name in his imperial title, which took the form Imperator Caesar Divi Nervae Filius Nerva Traianus Augustus (Emperor Caesar, Deified Nerva's Son, Nerva Trajan Augustus). In 114, he placed before Augustus the adjective Optimus (Best). This was undoubtedly intended, by recalling the epithets Optimus Maximus, applied to Jupiter, to present Trajan as the god's representative on earth.

Trajan listed after his names the republican powers and offices borne by his predecessors. To this traditional sequence he added, but only in the provinces, proconsul, a title that indicated a military command. Although the emperor Augustus, whose power had rested on control of the armies, had avoided any suggestion of the military basis of his control, after a century of imperial rule, such a title probably caused no offense, particularly when avoided in Italy and Rome, which had traditionally been exempt from the presence of legions or of military commands. Thus Trajan's formula followed the pattern set by his predecessors, and his slight changes and additions need not be regarded as evidence for an autocratic view of his position.

Relations with Senate and people

Despite his outward "constitutionality," Trajan was in fact a much more positive ruler than Nerva had been during his short reign. Instead of returning to Rome at once to accept from the Senate the imperial powers, he remained for nearly a year on the Rhine and Danube, either to make preparations for a coming campaign into Dacia (modern Transylvania and Romania) or to ensure that discipline was restored and defenses strengthened. He sent orders to Rome for the execution of the praetorians who had forced Nerva to execute the conspirators who had brought him to the throne. He gave the soldiers only half the cash gifts customary on the accession of a new emperor, but in general, he dealt fairly, if strictly, with the armies.

When he returned to Rome in 99, he behaved with respect and affability toward the Senate. He was generous to the populace of Rome, to whom he distributed considerable cash gifts, and increased the number of poor citizens who received free grain from the state. For Italy and the provinces, he remitted the gold that cities had customarily sent to emperors on their accession. He also lessened taxes and was probably responsible for an innovation for which Nerva is given credit—the institution of public funds (*alimenta*) for the support of poor children in the Italian cities. Such endowments had previously been established in Italy by private individuals, notably by Trajan's close friend, the orator and statesman Pliny the Younger, for his native Comum (modern Como) in northern Italy.

For the administration of the provinces, Trajan tried to secure competent and honest officials. He sent out at least two special governors to provinces whose cities had suffered financial difficulties. One was Pliny the Younger, whom he dispatched to Bithynia-Pontus, a province on the northern coast of Asia Minor. The exchange of letters between Pliny and Trajan during the two years of Pliny's governorship are preserved as the tenth book of his correspondence. They constitute a most important source for Roman provincial administration. In one exchange, Pliny asked Trajan how he should handle the rapidly spreading sect of Christians, who, refusing to conform to normal religious practices, suffered from great unpopularity but were, as far as Pliny could see, harmless. In his reply, a

model of judiciousness, Trajan advised Pliny not to ferret out Christians nor to accept unsupported charges and to punish only those whose behaviour was ostentatiously recalcitrant. Clearly in Trajan's time the Roman government did not yet have (and, indeed, was not to have for another century) any policy of persecution of the Christians; official action was based on the need to maintain good order, not on religious hostility. The corrrespondence also illustrates the wasteful expenditure of cities on lavish buildings and competition for municipal honours, an indication that the finances of the empire were already beginning to show inflationary trends.

Public works

Trajan undertook or encouraged extensive public works in the provinces, Italy, and Rome: roads, bridges, aqueducts, the reclamation of wastelands, the construction of harbours and buildings. Impressive examples survive in Spain, in North Africa, in the Balkans, and in Italy. Rome, in particular, was enriched by Trajan's projects. A new aqueduct brought water from the north. A splendid public bathing complex was erected on the Esquiline Hill, and a magnificent new forum was designed by the architect Apollodorus of Damascus. It comprised a porticoed square in the centre of which stood a colossal equestrian statue of the Emperor. On either side, the Capitoline and Quirinal hills were cut back for the construction of two hemicycles in brick, which, each rising to several stories, provided streets of shops and warehouses. Behind the square was a public hall, or basilica, and behind this a court flanked by libraries for Greek and Latin books and backed by a temple. In this court rose the still-standing Column of Trajan, an innovative work of art that commemorated his Dacian Wars. Its cubical base, decorated with reliefs of heaps of captured arms, later received Trajan's ashes. The column itself is encircled by a continuous spiral relief, portraying scenes from the two Dacian campaigns. These provide a commentary on the campaigns and also a repertory of Roman and Dacian arms, armour, military buildings, and scenes of fighting. The statue of Trajan on top of the column was removed during the Middle Ages and replaced in 1588 by the present one of St. Peter.

Military campaigns. Trajan's civil accomplishments were impressive but, except for the *alimenta*, not innovative. He is renowned chiefly for abandoning the policy, established by Augustus and generally adhered to by his successors, of not extending the Roman frontiers. Despite his title Germanicus, his first year on the Rhine–Danube

Invasion of Dacia

frontier was not marked by any major conquest. In 101, however, he resumed the invasion of Dacia that Domitian had been forced to abandon by Decebalus, the country's redoubtable king. In two campaigns (101–102 and 105–106), Trajan captured the Dacian capital of Sarmizegethusa (modern Varhély), which lay to the north of the Iron Gate in western Romania; Decebalus evaded capture by suicide. Trajan created a new province of Dacia north of the Danube within the curve of the Carpathian Mountains. This provided land for Roman settlers, opened for exploitation rich mines of gold and salt, and established a defensive zone to absorb movements of nomads from the steppes of southern Russia.

Trajan's second major war was against the Parthians, Rome's traditional enemy in the east. The chronology of his campaigns is uncertain. In preparation for them, in 105/106, one of his generals annexed the Nabataean kingdom, the part of Arabia extending east and south of Judaea. Next, about 110, the Parthians deposed the pro-Roman King of Armenia, whereupon, in 113/114, Trajan campaigned to reinstate him. In the following year (115) he annexed upper Mesopotamia and, in the same or next year, moved down the Tigris to capture the Parthian capital of Ctesiphon. He reached the Persian Gulf, where he is said to have wept because he was too old to repeat Alexander's achievements in India. Late in 115, Trajan barely escaped death in an earthquake that devastated Antioch. In 116, revolts broke out both in the newly conquered territories and in Jewish communities in several of the eastern provinces. Trajan, discouraged and in ill health,

Death and succession

left Antioch for Rome. He died in his 64th year on August 8 or 9, 117, at Selinus (modern Selindi) on the southern coast of Asia Minor. His ashes were returned to Rome for a state funeral and burial in the base of his column. Just before his death was made public, it was announced that he had adopted Hadrian, who in 100 had married Trajan's favourite niece. Although Hadrian differed completely in temperament from Trajan and initially had not been advanced with any unusual speed, Trajan, a few years before his death, had made him governor of Syria, where he was responsible for the logistical support of the Parthian campaign. But Trajan did not then adopt him or give any indication of a choice of successor. Hence contemporary gossip stamped the announcement of Hadrian's last-minute adoption as a fiction put out by the empress Plotina, though it was probably a genuine deathbed decision.

Assessment. The lack of adequate historical sources for Trajan's reign makes it difficult to give an estimate of his personality and policies. Although he has been regarded by some as having brought to the rule a provincial point of view, his upbringing had been in upper class Roman circles and in the imperial administration. His portraits in busts and on coins show a very individual face, hair brushed forward, making him look "low browed," whose large, strong features suggest a man of decision and action, not one of culture and thought like his successor, Hadrian. By the opening of the 2nd century, the empire had become monarchical—whatever outward respect was paid by "good" emperors to the tradition of Augustus that the *princeps*, the "first man" in the state, was an agent of the Senate and Roman people. Trajan's coins, inscriptions, and monuments emphasize his mission to bring happiness, security, equity, justice, and well-being to the empire. Pliny the Younger's *Panegyric* of AD 100 portrays him as the ideal ruler, the best and wisest of men who, most like the gods in character and intelligence, governs with the cooperation of other good men and in the service of the state. Possibly Pliny was holding up to Trajan a "mirror of the prince" to persuade him to conform to this characterization. In any case, Trajan, though confident of his personal abilities and ambitious for military glory, appears sincerely to have tried to maintain and improve the commonwealth.

Later Romans, dazzled by Trajan's achievements and buildings, regarded his reign as the apogee of the early empire. Under Hadrian, the historian Florus felt that the empire, senescent during the 1st century, had been rejuvenated by Trajan. In the 4th century another historian, Eutrupius, stated that the highest compliment that the Senate could pay to an emperor was to hail him as *felicior Augusto, melior Traiano*, "more fortunate than Augustus, better than Trajan." A medieval legend mentioned by Dante told how Trajan's justice and pity toward a poor widow moved Pope Gregory the Great (*c.* 600) to pray successfully for Trajan's admission to paradise. The modern Romanians claim, rightly or wrongly, descent from the Romans whom Trajan settled in Dacia.

Modern historians differ in their judgments of Trajan both as a ruler and as a conqueror. Some think that he genuinely wished to govern in cooperation with the Senate; others, that behind a facade of constitutionality he was actually autocratic. Some hold that his Dacian campaigns redeemed the costly fiasco of Domitian's defeat, brought the empire new revenues, and strengthened the Danubian frontier. Others regard his success as having been prepared by Domitian and his Parthian war as having overstrained the resources of the empire because of his megalomanic desire for military glory. Certainly, despite the Dacian gold, the financial and general economic condition of the empire began during his reign to show signs of breakdown. Moreover, his operations on the northern and eastern frontiers brought no enduring peace. To the north, barbarian pressure increased throughout the following century. Although Hadrian abandoned the eastern annexations, later emperors resumed without marked success the effort to conquer Parthia. Thus his reign may be taken either as the brilliant high noon of internal peace and external success or as a splendid sunset presaging the stormy midnight of the 3rd century.

Tranquillizer

The tranquillizers, or tranquillizing drugs, are used to allay mental states characterized by anxiety, tension, and hyperactivity. The introduction of these agents in the mid-1950s effectively revolutionized the handling of mental patients. Drugs acting on the nervous system had long been known. These included depressants (such as anesthetics and sedative-hypnotic drugs) and stimulants, or convulsants. The tranquillizers proved to be uniquely useful because of their ability to moderate anxiety while producing a minimum of other effects on the nervous system. The use of the term tranquillizer has been somewhat controversial, and the action of these compounds has been variously referred to as psychotherapeutic ("mind-curing"), phrenotropic ("mind-affecting"), neuroleptic ("nerve-seizing"), ataractic ("tending to tranquillize"), psycholytic ("mind-easing"), and psychosolytic ("psychosis-easing"). Generally, the tranquillizers are placed in two main categories depending upon the chief clinical uses to which they are put. Antipsychotic tranquillizers, used to treat psychoses, are reserpine (and other alkaloids from *Rauwolfia serpentina*) and chlorpromazine (and related phenothiazines); antineurotics, used to treat various classes of neurosis, include meprobamate and chlordiazepoxide (and the related diazepam).

Sites and nature of action. Very little is known about the sites and modes of action of tranquillizers, but it is generally agreed that the antipsychotic tranquillizers act solely on the brain itself, whereas antianxiety agents act on the spinal cord as well. Studies of the site of action of the latter drugs have been carried out by severing the spinal cords of experimental animals at various points to determine where activity occurs. The antipsychotic drugs have been found to affect the levels of the so-called transmitter substances, chemical agents that assist in the transmission of nerve impulses across the gaps between nerve cells. Prominent among the transmitter substances are a number of complex organic nitrogen-containing compounds, particularly serotonin and the catecholamines, epinephrine and norepinephrine.

Effect on transmitter substances

Biological disposition. *Chlorpromazine.* Absorption, metabolism, and excretion of chlorpromazine may be taken as typical of the phenothiazine tranquillizers. Chlorpromazine is well absorbed in man after either oral administration or injection. It would appear that all tissues take up the drug very rapidly after it has reached the bloodstream; because of this, blood concentrations are usually quite low. Scarcely any of the drug is detectable in the tissues 24 hours after administration.

The availability of radioactively labelled chlorpromazine has permitted extensive studies of its metabolism, or chemical conversion, in the tissues of the body, since the label remains with the compound as it is transformed. The chief metabolic transformation products, or metabolites, are those in which (1) the sulfur atom in the molecule has been oxidized to a sulfoxide, (2) methyl groups have been removed from the terminal nitrogen atom, or (3) a hydroxyl group has been introduced into one of the rings of the molecular structure, often with other groups, called conjugates, attached. The principal metabolite, quantitatively, is chlorpromazine sulfoxide, a compound much less biologically active than the parent drug. The compound from which nitrogen-methyl groups have been removed is only slightly less active than chlorpromazine, but the other metabolites are either much less active or completely inactive.

Chlorpromazine is presumed to cross the blood-brain barrier easily, and the highest concentration of labelled drug administered to rats was found in the cortex of the large hemispheres. After oral administration to rats only about 60 percent of the drug was absorbed, the rest being excreted unmetabolized in the feces within eight or nine days. After subcutaneous injection, metabolic products were found in the urine, and four days later, 97.4 percent of the administered dose had been excreted.

Reserpine. In contrast to chlorpromazine, reserpine is inefficiently absorbed after an oral dose, somewhat less than one percent of the dose being taken up per day. The principal metabolic products are the two main components of the drug molecule, methyl reserpate and trimethoxybenzoic acid. Despite the profound and prolonged tranquillizing action of reserpine and its depletion of serotonin and other transmitter substances in the brain, the level of reserpine detectable in the brain is both low and transient.

Meprobamate. Meprobamate is not attacked by the normal enzymes of digestion, so that—as shown by animal studies—about 10 percent of the orally administered drug is excreted unchanged in urine, along with certain metabolites (glucuronides). Similar results are seen in man. The drug is readily absorbed from the gastrointestinal tract of animals including man, and distribution in the body takes place rapidly after administration. About 60 percent of the ingested dose is excreted by experimental dogs as a metabolite bearing a hydroxyl group. In humans, there is a stimulation of meprobamate metabolism by the drug itself, suggesting that enzyme induction plays an important role in the development of tolerance.

Chlordiazepoxide. Blood levels of chlordiazepoxide are low, even after high oral doses. The unchanged drug is excreted in the urine to the extent of 1 percent to 2 percent of the administered dose each day; a further 3 to 6 percent is excreted in combined form. Excretion continues at a low rate for several days after administration is stopped. By measuring the fluorescence of chlordiazepoxide in human blood plasma at regular intervals after administration of oral doses of 15–30 milligrams, investigators found a half-life of about 24 hours for the drug; tracer studies give a similar result. The half-life of urinary excretion is 20 hours, and about 20 percent of the dose can be recovered in the feces. The major metabolite in the urine is the demethylaminated product, traces of which are also present in the plasma.

Tranquillizers in the management of psychoses. The two classes of tranquillizers used in the treatment of psychoses are different chemically and have different histories; yet they were introduced into modern Western medical practice at about the same time. Crude *Rauwolfia* root had been used in India for centuries as a sedative and hypotensive agent; the isolation of the active principle, reserpine, was accomplished in 1952. Its use (initially as the ground root) in Western medicine began in 1953. Chlorpromazine, a synthetic compound, was first used as a temperature lowering drug and then as an antivomiting agent. During an investigation of its sedative side effect, its utility in the treatment of psychoses was discovered, and it has been in use for this purpose since 1954. The introduction of reserpine and, shortly afterward, chlorpromazine into psychotherapeutic practice greatly altered the climate in mental institutions, generally changing them from custodial establishments into true therapeutic hospitals. Due largely to these new drugs, mentally disturbed patients were treated earlier and more effectively. In 1956 a long-term trend in rising mental hospital admissions was reversed; from 1956 to 1969 the resident mental patient population in the United States declined 19 percent while the total population of the country increased 20 percent. Similar results were obtained in Europe as well.

Introduction of tranquillizers

Reserpine. Although reserpine has been synthesized, the drug used for medical purposes is obtained from plant sources. Various crude, pure, or partially purified preparations are employed. High doses of reserpine can pro-

duce depression in patients; for this and other reasons, reserpine is not used extensively today in the treatment of psychoses. It is used, however, in the treatment of hypertension, in which much lower doses can be given. Side effects of the drug include gastric irritation, slowing of the heart, increased salivation, nasal congestion, and edema.

Chlorpromazine. Chlorpromazine is prepared synthetically (by the reaction of *m*-chlorodiphenylamine with sulfur, followed by alkylation with 3-dimethylaminopropylchloride). The product is crystallized in the form of one of its salts; and the drug is administered in this form.

The utility of chlorpromazine in the treatment of psychoses is well established, although the mechanism of its action is still obscure. A variety of chemical and neurological changes have been cited to explain the antipsychotic effect, but no definite connection has been established.

Chlorpromazine, the reference compound

Chlorpromazine is generally considered the standard, or "reference," compound in the treatment of psychotic patients. It is used to control agitation, to modify delusions and hallucinations, and to restore or increase the patient's response to psychotherapy. In some cases, psychiatric patients treated with chlorpromazine in institutions must be maintained on lower doses of the drug after discharge to prevent relapse. In other cases, however, once the acute phase of the psychosis has been treated, it is possible gradually to reduce the use of the drug and eventually to eliminate it altogether.

Among the conditions treated with chlorpromazine are: chronic delirium, nausea and vomiting, mania, melancholia, conceptual disorders, hypermotor activity, diminished emotional response, lack of verbal communication, catatonia, and paranoia. Many so-called psychosomatic conditions that are complicated by stress, such as arthritis, severe tension headache, gastrointestinal disorders, dermatological conditions, and asthmatic states, have responded to chlorpromazine. The drug has also been found useful in treating chronic alcoholics and mental defectives and in facilitating withdrawal from narcotics or other drugs. Chlorpromazine and other phenothiazines are used to reduce the need for preanesthetic and postanesthetic medication in general surgery and to reduce the amounts of narcotics and other analgesics needed in childbirth, thereby lowering the risk of respiratory depression for the mother and infant.

Chlorpromazine and other phenothiazines produce hepatic obstruction in a small percentage of patients, but this disappears after discontinuance of the drug. A very few cases of agranulocytosis (destruction of certain blood cells) have been noted. With large doses of phenothiazines a few persons may exhibit neuromuscular reactions resembling parkinsonism. Other side effects observed are skin pigmentation, lactation, photosensitivity, weight gain, and absence of menstrual discharge.

Tranquillizers used in the management of anxiety. *Meprobamate.* Meprobamate is used primarily in the treatment of anxiety and tension states, with such associated symptoms as irritability, restlessness, insomnia, and muscle tension. It may be used to facilitate psychotherapy. Although meprobamate is used predominantly in the treatment of certain neurotic conditions, it has also been used successfully in the treatment of psychotics in combination with phenothiazines. It has, however, little value in the treatment of delusions or hallucinations. Other conditions in which meprobamate has been successfully employed are behavioral disorders in children, headaches associated with emotional disturbances, preoperative and postoperative anxiety, and premenstrual tension. It is also used during childbirth and as an adjunct in the treatment of dermatological conditions.

Meprobamate in anxiety treatment

Meprobamate has been employed in the treatment of allergic states and gastrointestinal disturbances of emotional origin. It relieves insomnia, but it is not a true hypnotic. In orthopedic disorders and rheumatic conditions, meprobamate is often used to relieve muscular spasms. It is also useful in reducing spasticity and improving motor performance in patients suffering from cerebral palsy or spinal cord injuries. Meprobamate is helpful in certain patients suffering from minor epileptic attacks, although it is ineffective in cases of severe epileptic seizures.

Physical dependence on meprobamate may be produced after high doses for prolonged periods. Otherwise, the drug has only minor side effects, such as skin rashes, drowsiness, and allergic reactions.

For commercial use meprobamate is prepared synthetically. (The appropriate propanediol is made by condensation of formaldehyde with 2-methylvaleraldehyde or by reduction of the corresponding malonic ester with lithium aluminum hydride. It is then converted to meprobamate by ester exchange with urethane.)

Benzodiazepines. Two benzodiazepines, chlordiazepoxide and diazepam, are used clinically in the treatment of anxiety. Chlordiazepoxide and diazepam are both employed in a variety of clinical conditions, including convulsive states and neuromuscular and cardiovascular disorders. They have been used to moderate alcohol-withdrawal symptoms to help rehabilitate the chronic alcholic. They have also been employed to aid in preoperative and postoperative sedation and to relieve anxiety in dental patients. The drugs do not affect delusions or hallucinations, but they render the patient more accessible to psychotherapy. They are used adjunctively in antidepressant and anticonvulsant therapy. The most common side effects are drowsiness and ataxia (lack of muscular coordination), but skin rashes, nausea, dizziness, constipation, fainting, and headaches have been observed. Physical dependence also can occur and is a cause for caution in prolonged use.

Used to treat alcoholism

The benzodiazepine tranquillizers were discovered as the result of an unexpected chemical rearrangment observed when a synthetic procedure that had been expected to yield a certain complex organic nitrogen compound—a quinazoline derivative—gave instead another product, which proved to be a benzodiazepine.

Transfer of Training

Will one's knowledge of English help him learn German? Are skillful table-tennis (Ping-Pong) players generally good court-tennis players? Can a child learn to multiply if he does not know how to add? These questions represent the problems of transfer of training: the influence the learning of one skill has on the learning or performance of another.

KINDS OF TRANSFER

Basically three kinds of transfer can occur: positive, negative, and zero. The following examples from hypothetical experiments, purposely uncomplicated by distracting detail, illustrate each. Suppose a group of students learn a task, B, in ten practice sessions. Another group of equivalent students, who previously had learned another task, A, is found to reach the same level of performance on task B in only five practice sessions. Since the average number of practice sessions required to learn B was reduced from ten to five, transfer of training from task A to task B is said to be positive ($10 - 5 = +5$).

Positive, negative, and zero transfer

Many successful training aids, such as those that simulate the cockpit of an airplane and that are applied to teach people how to use instruments for flying blind without leaving the ground, produce positive transfer; when students who have preliminary training in such trainers are compared to those who do not, those with preliminary training almost invariably require less practice in achieving the desired level of skill.

Sometimes the effect of transfer of training is to hamper effectiveness in subsequent activity. If after learning task A a group of people need 15 practice sessions to learn task

B whereas only 10 sessions are required for those without any previous training in task A, then task A is said to lead to negative transfer of training on task B (10 − 15 = −5). Having learned to drive on the right side of the road often is observed to produce negative transfer for the tourist from Japan or continental Europe or North America when he is travelling in Great Britain, where cars are to be driven on the left-hand side of the road.

The degree to which transfer of training occurs between two different tasks is often minimal and may be so small that it is called zero transfer. If learning task B with or without previous training in task A requires ten practice sessions, then the amount of transfer from one task to the other is said to be zero (10 − 10 = 0). Learning to knit Argyle socks is apt to produce zero transfer of training in learning to sing an operatic aria in French.

Although in contemporary psychology transfer of training is a distinct topic of investigation with its own experimental designs and procedures for measurement, its implications pervade practically all of psychology, from conditioning to personality development. The Russian physiologist Ivan P. Pavlov (1849–1936) discovered that when a dog is conditioned to salivate in response to a sound wave of 1,000 cycles per second, it will also salivate if it is next exposed to a tone of 900 cycles per second, although typically the volume of saliva will be slightly reduced. In this case, transfer of training occurs between two similar auditory stimuli; in general, phenomena of this sort are called stimulus generalization. At the very root of modern theories of personality development is the assumption that what a person learns during his childhood will show a pervasive degree of transfer to his adult behaviour. In some cases stimulus generalization mediates this transfer. Some cases of excessive fears may have their origins in unpleasant experiences during early life.

EDUCATION AND TRANSFER

The experimental study of transfer of training has historical roots in problems of educational practice. Educators in Western countries at the end of the 19th century widely endorsed the doctrine of formal discipline, contending that psychological abilities, called "mental faculties" by such philosophers as Saint Thomas Aquinas (1225–74), could be strengthened, like muscles, through exercise. By learning geometry, one was expected to improve his ability to reason; studying Latin was held to "strengthen" the so-called faculty of memory, and so on. Although what contemporary educators have demoted from the doctrine to the theory of formal discipline once seemed reasonable to many, experimental tests have refuted it. When the reasoning abilities of groups of mathematics students in secondary schools were compared with those of other equally talented students who had not had the same mathematical training, no differences in general logical effectiveness were observed between the groups.

An alternative theory of identical elements was proposed in which it was postulated that transfer between activities would take place only if they shared common elements or features. Thus it was predicted that one's training in addition would transfer to his ability to learn how to multiply. It was reasoned that both tasks share identical features, multiplication basically requiring a series of successive additions, and that both tasks demand the individual's concentration.

But the identical-elements formulation soon came under attack when experimental results suggested that one's understanding of general principles, rather than the presence of identical task elements, has substantial effects on transfer of training. In one notable experiment, two groups of boys practiced throwing darts at a target placed under about a foot of water. Only one group, however, was instructed about the principle that water bends (refracts) light. According to this principle, the apparent position of the target should vary with the depth of the water. When the target depth was reduced to four inches, the group that had been taught the general principle of refraction adjusted rapidly to the change and exhibited substantial positive transfer; the other boys showed comparative difficulty in learning to hit the target at the shallower level.

Theories of transfer

These formulations (formal discipline, identical elements, and general principles), when considered carefully, might be recognized as points of view rather than as rigorously specified theories that could lead to unequivocal predictions of the results of new experiments in transfer of training. For example, failure to demonstrate positive transfer between mathematical training and general reasoning ability could be attributed to ineffective teaching of mathematics; in such case, the results need not be interpreted as refuting the theory of formal discipline. If the then-traditional manner of teaching mathematics could be changed to emphasize logical thinking (rather than routinized application of formulas), it was argued that perhaps mathematical training could improve reasoning ability in general. Some theorists also suggested that the positive transfer observed to result when boys learned the principle of refraction was consistent with the hypothesis of identical elements; these theorists observed that a general principle may be considered an element common to many tasks. According to this line of reasoning, the group of boys who exhibited positive transfer with the shift to a new target depth shared the principle of refraction as an element in common with the previous task, along with those of aiming and throwing. By contrast, the youngsters who performed without the benefit of knowing about refraction were held to have gained positive transfer from throwing but to have suffered negative transfer as a result of aiming incorrectly.

EXPERIMENTAL ANALYSIS OF TRANSFER OF TRAINING

The indeterminate character of the broad theoretical formulations offered to account for transfer of training and the often unsuccessful ways in which they were applied to the practical problems of classroom teaching led some psychologists to retreat to the laboratory in the hope of identifying more clear-cut, fundamental processes in transfer of training. As a result, a number of different transfer-of-training phenomena were discovered, several of which may be reviewed as follows.

Stimulus and response similarity. The method of paired-associate learning, in which a person is asked to learn to associate one syllable or word with another (*e.g., complete–hot, safe–green, wild–soft*), encouraged the investigation of the influence of stimulus and response similarity on transfer of learning. Typically these pairs of verbal items are presented to the laboratory subject so that the first, or stimulus, member (*e.g., complete*) is exposed alone, followed after a short interval by the second, or response, member (*e.g., hot*). The subject's task is to respond to the stimulus term before the response term appears, as when an English-speaking student in learning French is supposed to respond to *le livre* with *the book*.

When two successive lists of paired associates are learned in which the stimulus elements are the same but the response terms are changed (*e.g., complete–hot* in the first list and *complete–new* in the second), negative transfer typically results. Apparently, in learning the second list the subject tends to respond to the stimulus term (*e.g., complete*) with the previously learned correct response term (*e.g., hot*), the result being interference with new learning to produce negative transfer. If he were learning the second list without having learned the first, the subject would not be so handicapped.

Another question concerns the sort of transfer that results when response terms are different and stimulus elements are similar but not identical; for example, *entire* is similar to *complete*. After one has learned *complete–hot*, the experimental evidence is that his ability to learn *entire–new* becomes definitely more difficult. Both *entire* and *complete* seem to have a tendency to evoke the response *hot* and to be incompatible with subsequently learning the association of *entire* with *new*. The principle that appears to operate in such situations is that the greater the similarity in stimulus elements, the greater the degree of negative transfer.

The influence of response (rather than stimulus) similarity on transfer of training is more complex; in paired-asso-

ciate learning, the subject needs to learn the response term of each pair (response learning) and then to remember that it is linked with its appropriate stimulus partner (associative learning). When response terms are relatively difficult to learn (as in the case of unfamiliar or foreign words), the subject tends to profit considerably from learning the first list. But when response terms already have been learned (or are easy to learn), little if any positive transfer is likely to occur. The degree of transfer between lists that contain similar response terms depends both on how similar they are and on their level of difficulty; increasing the similarity between response terms is most likely to increase positive transfer when the response terms are relatively difficult to learn.

Although attempts have been made to formulate an all-embracing theory that would account for the effects of similarity among paired associates on transfer of training, a major obstacle that has prevented fully satisfying results is that the degree of positive or negative transfer is typically a product of many interacting influences beyond those of stimulus and response similarity. For example, the amount of training that the subject receives also has significant effects on transfer. When initial training is given on a simulated task (*e.g.*, learning to operate a set of dummy controls in preparation for a second task of acquiring a complicated skill, such as flying an airplane), negative transfer effects frequently appear during the initital stages of learning the second task and then give way with further training to generally positive transfer effects.

Obstacles to a unified theory of similarity in transfer

Another stumbling block in developing theoretical explanations has to do with the meaning of the central concept of similarity. In such experiments as those in which the salivary reflex is conditioned to different auditory stimuli, similarity is measured in terms of physical stimulus properties (*e.g.*, pitch or loudness); in other studies, as in paired-associate learning, similarity typically is expressed in terms of verbal meaning. In neither case has a universally adopted method yet been devised to measure similarity in a reliable and precise way; perhaps none can be, simply since there are so many different aspects of physical and linguistic or semantic similarity. Despite these difficulties, efforts to analyze transfer experimentally in terms of the properties of stimulus and response events have been productive in identifying conditions that can be varied to alter the direction and the degree of transfer of training.

Retroactive and proactive inhibition. Closely related to stimulus and response similarity are phenomena called retroactive inhibition and proactive inhibition; these demonstrate how forgetting seems to result from interfering activities.

In a study of retroactive inhibition, both the experimental and control groups of people learn task A (for example, a list of adjectives) and are tested for their ability to recall A after a specified time interval. The groups differ in what they are asked to do during the interval; the experimental group learns a similar task B (say, another list of words), while the control group is assigned some unrelated activity (for example, naming a series of coloured chips) designed to prevent them from rehearsing task A. The results of numerous studies of retroactive inhibition show that the experimental subjects typically are poorest in recalling information from task A. The interpolated activity, particularly a comparable one such as memorizing a second list of adjectives, apparently interferes with one's ability to recall words from the first list. Habit competition, or what is sometimes called interference, between the items of the original and the interpolated word lists at the time of recall is considered to be one of the major sources of the negative transfer exhibited in retroactive inhibition.

Interference theory

Experimental designs for demonstrating proactive inhibition differ from those used for showing retroactive inhibition in that the experimental group learns task B before, instead of after, task A. Whereas B was a task that was interpolated between the learning and the recall of task A in the retroactive inhibition study, B is a task that precedes the learning of task A in the proactive inhibition study. To evaluate the effects on the experimental subjects of their having learned B prior to A, the control people are instructed to relax during the time the experimental group is learning B. Typically an experimental subject's ability to recall from task A is inferior to that of a control person, the degree of inferiority depending in part on how similar the two tasks are; the greater the similarity, the poorer the recall tends to be. Although proactive inhibition, so called to indicate that it acts forward from the first-learned task to the second, produces appreciably less forgetting than does retroactive inhibition, they both support the theory that interference can produce forgetting (see MEMORY: RETENTION AND FORGETTING: *Theories of forgetting*).

Stimulus predifferentiation. Educational films can be considered as everyday examples of stimulus predifferentiation, in which the individual gets preliminary information to be used in subsequent learning. The student who sees a film describing the various parts of a microscope is likely to be better prepared to learn the requisite skills when confronted with the instrument itself. In laboratory studies of stimulus predifferentiation, the subject is given experience with a particular stimulus situation ahead of time; later he is asked to learn new responses in the same situation. In one illustrative study, subjects first practiced labelling four different lights and then later were asked to learn to press selectively one of four switches, each connected to one light. The rate at which they learned the appropriate pressing reactions was related to how well they had learned to label the lights.

The results of a large number of experiments covering a variety of stimulus predifferentiation techniques suggest that when a learner has an opportunity to become generally acquainted with an environment, he retains some information about its different components that prepares him for learning to make new responses to them. Various explanations have been offered to account for this facilitation; some investigators suggest that the process of labelling enhances the distinctiveness of environmental stimuli for the labeller; others hold that perceptual acquaintance can more sharply differentiate an environment into its component parts for the perceiver or that it may encourage appropriate responses of observing or attending. Nevertheless, no single process has been identified as fundamental in stimulus predifferentiation. Perhaps a number of these processes operate in different combinations from one stimulus-predifferentiation transfer experiment to another, each process representing a different method by which a learner can become familiar with the details of his environment.

Transposition. Another phenomenon that has received considerable attention in theories of transfer of training is called transposition. An initial report of transposition came from a study in which chickens were trained by rewards to respond to the darker of two gray squares. After this discrimination task was learned, the chickens were shown the originally rewarded gray square along with one that was still darker. They seemed to prefer the darkest gray to the square that had been previously rewarded. This finding was interpreted to support the hypothesis that the birds had initially learned to respond to a relationship (what a human being would call the concept "darker") and that this response to a relationship had been transposed or transferred to the new discrimination. This relational interpretation later was challenged by theorists who offered a formulation to show, on the basis of principles of stimulus generalization, how a response to a relational stimulus could be explained by assuming that organisms do indeed respond to the absolute properties of the stimuli. Both explanations were found to be too simple for the variety of findings obtained with transposition studies. As a result, the interest of many investigators shifted away from demonstrating the relative merits of absolute versus relational interpretations to identifying conditions that seem to influence transposition behaviour. Within this context, newer, more sophisticated formulations have been proposed that consider both the absolute and relational characteristics of the stimuli in transposition studies.

Transfer among animals

Learning to learn. When people are asked to learn successive lists of words, their performance tends to improve from one task to another so that much less time is commonly required to learn, say, the tenth list than was needed for mastering the first list. This improvement suggests that information beyond the specific content of lists of words is also learned. It would seem as if the subjects are learning how to learn; that is, they seem to be acquiring learning sets, or expectancies, that transfer from list to list to produce continually improving performance.

Some of the most intensive work on learning sets has been carried out with monkeys that were learning how to solve several hundred discrimination problems in succession. In each problem, the monkey learned which one of two objects (for example, a bottle cap and a cookie cutter) consistently contained a piece of food. Although the solution of each successive problem required the animals to discriminate between two previously unfamiliar objects, performance tended to improve on successive tasks; the monkeys made increasing numbers of correct choices on the second trial of each problem as the process continued. Manifestly there was no cue to indicate the correct choice on the first trial of any specific problem. If the animal responded correctly on the first trial, then on the second trial it would only have to choose the same object to be correct thereafter; if the monkey made an error on the first trial, then the other object would inexorably be the one that should be chosen next. During their efforts to solve the first few problems the monkeys were correct approximately half the time on the second attempt to solve each problem. This success increased to an average of 80 percent correct after each animal had solved 100 problems, to 88 percent after 200 correct solutions, and eventually to 95 percent after 300. Thus, after a long series of separate tasks, all of the same type, the monkey's first response to the next problem usually provided sufficient information for the animal to make the correct choice.

Since each of the successive discrimination problems was different, what actually was being transferred from problem to problem? In these discrimination problems, the monkeys seemed to have several items of information to learn in addition to which one of the two objects contained the rewarding bit of food. The animals apparently had to learn to pay attention to that part of their environment where the objects were placed. To make the correct choice, it would seem that a monkey would have to learn to abandon any preference it might exhibit for objects on either the left or the right; indeed, the animals usually did show such preferences. (The correct object was shifted from side to side in a random sequence to control for these preferences.) Ostensibly, the monkeys also had to learn that one object consistently contained food while the other was always empty. Although these learning sets by themselves would not serve to identify the correct object in each new discrimination problem, it seems likely that they could help the animal locate the reward very rapidly by eliminating initially unprofitable responses.

Reversal learning. In reversal learning, the individual first learns to make a discrimination, such as choosing a black object in a black–white discrimination problem, and then is supposed to learn to reverse his choice—*i.e.*, to choose the white object. Such reversals tend to be difficult for most learners since there are negative transfer effects; *e.g.*, the individual tends to persist in responding to the black object that was originally correct. Eventually, however, one's tendency to make the originally learned selection typically becomes weaker, and he makes the competing response (*e.g.*, to white) more frequently until a point is reached where it is almost consistently evoked. Reversal learning can be accomplished very rapidly when a laboratory animal, such as a monkey, is presented with a series of reversal-learning problems in which the same sequence of shifts is repeated (as when black is initially correct, then white, then black, then white, and so on). After extended reversal training, some animals are able to make the next reversal in the sequence in one trial. They behave as if they have mastered the abstract concept of alternation or of regular sequence.

Evolution and transfer

The speed with which representatives of a given species of animal, including human beings, can be taught to make a reversal of this kind seems to be related to the place biologists assign them in a hierarchy of evolutionary development. On first being exposed to a reversal-learning problem, normally competent adult humans who can use language are likely to achieve a solution with great rapidity. Monkeys can learn to perform equally well after a relatively longer series of reversal-learning tasks; but isopods such as pill bugs or sow bugs, small relatives of crabs and shrimp, have such primitive brains that they seem to be unable to improve their performance at all during a series of reversal-learning tasks.

DEVELOPMENTAL PROCESSES AND TRANSFER

The manner in which a problem is learned seems to have an effect on what is transferred. This conclusion is supported by experiments in which comparisons are made of the relative ease with which children of different ages execute reversal and so-called extradimensional shifts (see CONCEPT FORMATION). In performing both kinds of shift, experimental subjects learn two successive discriminations between two pairs of objects that vary simultaneously in two aspects or dimensions—*e.g.*, white triangle versus black square, and black triangle versus white square. In training subjects initially, discrimination of only one dimension (for example, black–white) is made relevant, with the child's selection of one of the cues (for example, white) being rewarded, while the other (black) is incorrect. After they have learned this, the children are shifted to the second discrimination. In the case of a reversal shift, the same stimulus dimension (black–white) remains relevant, but the child is now to learn to reverse his initial choice; black choices are now rewarded, and white selections become incorrect. For an extradimensional shift, the initially irrelevant dimension (square–triangle) is given relevance by rewarding selection of one of its alternatives and by failing to reward choices for the other.

The relative ease with which human beings learn to make extradimensional and reversal shifts is related to how old they are. Reversal shifts are relatively difficult for young children to learn and are relatively easy for adults to master. As people gain maturity, the relative ease with which they execute a reversal shift tends to increase in comparison with their ability to achieve an extradimensional shift.

Age and transfer

Explanations for these developmental changes seem to be found in the manner in which the individual solves a discrimination problem. Very young children and laboratory animals tend to learn simple habits when faced with a discrimination problem for the first time; for example, they are most likely to learn simply to approach black objects and to avoid white. Reversal shift is often extremely difficult for them, and negative transfer effects are substantial. Subjects who primarily learn simple habits are faced with the task of eliminating one habit (*e.g.*, to choose black) that has been rewarded and then of developing another habit (*e.g.*, to choose white) that previously has not been rewarded.

Human adults, on the other hand, generally find a reversal shift relatively easy; they do not behave as if they simply associate their choices to the relevant stimuli (*e.g.*, white and black) but instead appear symbolically (or conceptually) to react to both of them in terms of their common characteristic (brightness). A similar kind of symbolic or logical response is appropriate in solving reversal-shift problems; since the relevant dimension remains the same, this kind of shift tends to be easier to make than is one involving extradimensional shift, which requires the individual to switch to a new symbolic response (*e.g.*, from brightness to size). In short, when they respond concretely, learners favour their potentials for achieving extradimensional transfer; those who tend to respond symbolically enhance the probability for reversal transfer.

Whatever the validity to be found in theoretical explanations of this sort, review of how transfer phenomena may be influenced suggests that no single principle or simple theory thus far put forward accounts for all of the ob-

served data. Instead, the evidence is that several interacting processes underlie transfer of training and that their relative influence depends both on the nature of the tasks between which transfer takes place as well as on the characteristics of the learning organism. If one seeks to control the degree of transfer, as one does in educational settings, it seems useful to analyze transfer behaviour in terms of a number of component processes—*e.g.*, in the light of notions about stimulus and response similarity, stimulus predifferentiation and response learning, and the symbolic abilities of the learner.

THE PHYSIOLOGY OF TRANSFER OF TRAINING

Although available evidence for a physiological basis of transfer of training is limited, some impressive data already are recorded. Some central (brain and spinal-cord) mechanisms seem to control transfer of training. A long-established transfer phenomenon is cross education, in which there is positive transfer of a skill learned with one part of the body to another, untrained part. For example, a person who learns to throw a dart with his preferred hand exhibits positive transfer to his non-preferred hand.

Cross education

Since different muscles are involved in the equivalent action of opposite limbs, positive transfer resulting from cross education cannot be attributed simply to common muscular movements; instead it would seem that cross education depends on central processes that control the actions of both limbs.

Among highly evolved animals, transfer of training between limbs from opposite sides of the body evidently is mediated through a massive system of neural fibres, known as the corpus callosum, that connects the two hemispheres of the brain. One of the many ways in which the validity of this principle may be demonstrated is first to train blindfolded cats to discriminate with one paw between two different pedals (by feeling raised horizontal lines on one pedal and by detecting raised vertical lines on the other). Since each eye sends some of its nerve impulses to both hemispheres of the cat's brain while each paw only directs impulses to the hemisphere of the brain on the same side of the animal's body, this procedure feeds the sensory information to just one hemisphere. After learning to make the discrimination with one paw (*e.g.*, reward being given only for the pedal with the horizontal pattern), a cat that is confronted with making the same discrimination with the other front paw, which has its connections with the ostensibly "untrained" brain hemisphere, will nevertheless exhibit positive transfer. Indeed, even when the corpus callosum is surgically severed immediately after learning (to "disconnect" the two hemispheres), positive transfer will take place from one front paw to the other; manifestly, transfer of training takes place between connected hemispheres while the animal is learning. If the cat's corpus callosum is severed before it initially learns to discriminate the two pedals, however, no transfer occurs between the animal's limbs; the untrained paw fails to exhibit any benefit from what has been learned with the other paw. In other words, by severing the cat's corpus callosum, the surgeon splits the brain into two independently functioning units. The same kinds of behaviour are observable among other split-brain animals, including chimpanzees and people.

The physiological foundations of transfer of training are not limited merely to the anatomical considerations of the central nervous system. To better understand how physiological processes mediate transfer of training means also to be able to specify more fully the anatomic, electrical, and chemical basis of learning in general, a goal that remains incompletely achieved. Many physiologists and psychologists hold that the search for the neurophysiological foundations of learning can be pursued most profitably by measuring physical and chemical changes that influence the transmission of nerve impulses. It has long been established that chemical changes are part of the process of neural transmission; and it is widely agreed that, in some way, biochemical activities also are responsible for all forms of learning, including transfer of training.

One popular theory in the 1960s was that learning and remembering depend on changes in the molecular structure of such chemicals as ribonucleic acid (RNA) and peptides that are incorporated in the cells of the body, including nerve cells. Some researchers have theorized that memory traces are physically coded within the molecules of cells.

Reports of experiments have been published offering evidence that skills have been transferred from one individual to another by injecting materials taken from the brains (or even other parts of the body) of trained animals into the bodies of untrained organisms (*e.g.*, flatworms, rats, hamsters). These reports have encouraged many to hope that someday one might be able to learn a foreign language, for example, by simply taking a pill instead of through the usual time-consuming practice. Subsequent efforts to repeat such experiments sometimes have given positive results but more often have yielded no evidence of chemical transfer of training from one individual to the next. In view of such inconsistent findings, this question had become a matter of considerable controversy by the 1970s. Many investigators seemed inclined to dismiss the notion that organisms can learn by swallowing chemicals or through injection as another of those oversimplified interpretations that continue to be offered in efforts to account for complex psychophysiological phenomena.

BIBLIOGRAPHY. Introductory psychology texts that discuss transfer of training as an experimental phenomenon and its implications for a wide variety of behaviour are H.H. KENDLER, *Basic Psychology*, 2nd ed. (1968); and H.H. and T.S. KENDLER, *Basic Psychology: Brief Edition* (1971). H.C. ELLIS, *The Transfer of Learning* (1965), presents a general analysis of transfer and includes reprints of important journal articles on the topic. Undergraduate texts that review theories and experimental evidence concerning transfer of training are J. DEESE and S.H. HULSE, *The Psychology of Learning*, 3rd ed. (1967); and J.F. HALL, *The Psychology of Learning* (1966). H.W. REESE, *The Perception of Stimulus Relations: Discrimination Learning and Transposition* (1968); and D.A. RILEY, *Discrimination Learning* (1968), are accounts of how transfer of training influences discrimination learning.

Transition Elements and Their Compounds

The so-called transition elements constitute a group of 56 (the majority of the 105 known elements); while the term transition has no particular chemical significance, it is a convenient name by which to distinguish the similarity of the atomic structures and resulting properties of the elements so designated. They occupy the middle portions of the long periods of the periodic table of elements (see Figure 1) between the groups on the left-hand side

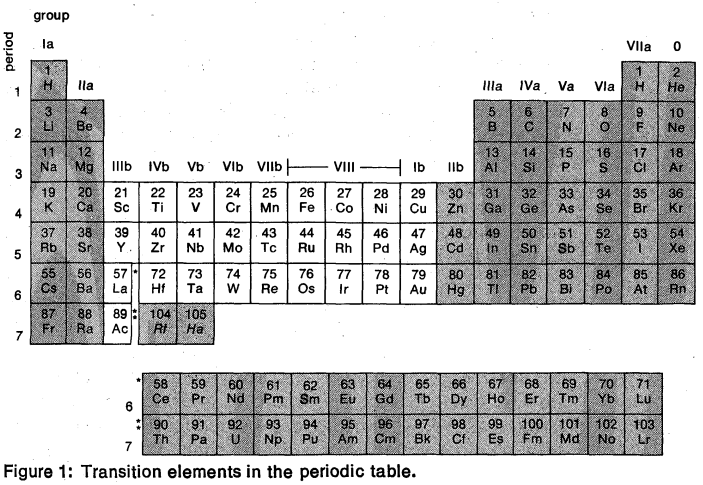

Figure 1: Transition elements in the periodic table.

and the groups on the right. Specifically, they form Groups IIIb, IVb, Vb, VIb, VIIb, and Ib. Of these 56 transition elements only 24 are treated in this article (see Table 1 for list of names), the others being treated elsewhere as explained below.

The article is divided into the following sections:

I. The transition elements as a group
General properties
Electronic structure and position in the periodic table
Terrestrial abundances and discovery of the transition elements
Compounds of transition elements
Binary compounds, bases, and salts
Coordination compounds
Organometallic compounds
Transition-metal catalysts
Biological functions of transition metals
Theories of transition-metal complexes
Crystal-field and ligand-field theories
Molecular-orbital theory
II. The chemistry of the individual transition elements
The elements of the first transition series
Titanium
Vanadium
Chromium
Manganese
Iron
Cobalt
Nickel
Copper
Elements of the second and third transition series
Zirconium and hafnium
Niobium and tantalum
Molybdenum and tungsten
Technetium and rhenium
Ruthenium and osmium
Rhodium and iridium
Palladium and platinum
Silver and gold

I. The transition elements as a group

The most striking similarities shared by the 24 elements treated here are that they are all metals and that most of them are hard, strong, and lustrous, have high melting and boiling points, and are good conductors of heat and electricity. The range in these properties is considerable, therefore the statements are comparative with the general properties of all the other elements.

Table 1: Abundance of the Transition Elements in the Earth's Solid Crust
(in grams per ton)

Titanium	5.7×10^2	Ruthenium	0.001
Vanadium	135	Rhodium	0.001
Chromium	102	Palladium	0.01
Manganese	950	Silver	0.07
Iron	5.63×10^3	Hafnium	3.0
Cobalt	25	Tantalum	2.0
Nickel	75	Tungsten	1.5
Copper	55	Rhenium	0.001
Zirconium	165	Osmium	0.001
Niobium	20	Iridium	0.001
Molybdenum	1.5	Platinum	0.005
Technetium	~0	Gold	0.004

GENERAL PROPERTIES

Many of the elements are technologically important: titanium, iron, nickel, and copper, for example, are used structurally and in electrical technology. Second, the transition elements form many useful alloys, with one another and with other metallic elements. Third, most of these elements dissolve in mineral acids although a few, such as platinum, silver, and gold, are called "noble"—that is, are unaffected by simple (nonoxidizing) acids.

Without exception, the elements of the main transition series (*i.e.*, excluding the lanthanides and actinides as specified below) exhibit variable valence and form stable compounds in two or more formal oxidation states (valence and oxidation states are explained in the following section). For most transition elements, the compounds formed in at least one oxidation state are coloured and are typically, though not uniformly, paramagnetic (capable of being weakly magnetized). In many of the simple solid compounds, such as some of the oxides, sulfides, and fluorides and in several of the pure metals themselves, complex magnetic behaviour, such as ferromagnetism (capability of being strongly magnetized) or antiferromagnetism, is observed at normal temperatures.

The transition elements may be subdivided into two main types according to the electronic structures of their atoms, which are simply indicated here but fully explained in the section immediately following.

The three main transition series are called the first, second, and third transition series. The first series consists of the nine elements from scandium (symbol Sc, atomic number 21) to copper (symbol Cu, atomic number 29). The second series includes the elements yttrium (symbol Y, atomic number 39) to silver (symbol Ag, atomic number 47). The third series extends from lanthanum (symbol La, atomic number 57) to gold (symbol Au, atomic number 79). Scandium, yttrium, and lanthanum might be excluded from the category of transition elements, because formation of their compounds is somewhat different, but, for convenience and tradition, they are here regarded as transition elements.

There are also two inner transition series. One of these comprises the elements from cerium (symbol Ce, atomic number 58) to lutetium (symbol Lu, atomic number 71); these elements are called the lanthanides because the chemistry of each closely resembles that of lanthanum. Lanthanum itself is often regarded as one of the lanthanides. The other inner transition series can be considered to begin with either actinium (symbol Ac, atomic number 89) or protactinium (symbol Pa, atomic number 91) and to end with lawrencium (symbol Lr, atomic number 103). The elements of this group are called the actinides. These inner transition series are covered by the articles RARE-EARTH ELEMENTS AND THEIR COMPOUNDS and ACTINIDE ELEMENTS AND THEIR COMPOUNDS. This article treats only the three main transition series, which are included in the set of 27 elements often called the *d*-block transition elements. Because scandium, yttrium, and lanthanum actually do not form compounds analogous to those of the other transition elements and because their chemistry is quite homologous to that of the lanthanides, they too are excluded from this article, which, then, specifically treats only the 24 elements in the three series titanium–copper, zirconium–silver, and hafnium–gold. The *d*-block transition elements and some of their characteristic properties are listed in Table 2.

d-block elements

Electronic structure and position in the periodic table. The relative locations of the transition elements in the periodic table and their chemical and physical properties can best be understood by considering their electronic structures and the way in which those structures vary as atomic numbers increase. The details of atomic structure necessary for comprehension of the properties are fully covered in the articles ATOMIC STRUCTURE; MOLECULAR STRUCTURES; CHEMICAL REACTIONS; and CHEMICAL BONDING. Only a brief summary of these subjects can be given here, with emphasis upon those aspects of atomic structure relevant to the transition elements.

Atomic structure. All of the elements exist as atoms, characteristic for each element, that combine, or form bonds, in various ways to form millions of compounds. An atom has a nucleus composed of protons (subatomic particles with a single positive electrical charge) and neutrons of about the same mass, but no charge. The number of protons or positive charges on the nucleus is the atomic number of that element. The number of neutrons varies, and atoms with the same atomic number but different numbers of neutrons are called isotopes of that element. The sum of neutrons and protons is the atomic mass number. Thus, an atom of iron has 26 protons and may have 28, 30, 31, or 32 neutrons, making the atomic number of iron 26 and the atomic masses of its isotopes 54, 56, 57, and 58. The iron isotope with mass 56 is represented as iron-56 or as ^{56}Fe.

Electrons and chemical bonding. The nucleus of an atom is surrounded by as many electrons, negatively charged particles with negligible mass, as there are protons, making the atom as a whole electrically neutral. If the elements are examined in order of increasing atomic number, it is found that the increasing number of electrons are arranged in an orderly and periodic fashion; that is, certain features of the arrangements recur. Some electronic structures of atoms are more stable than others

Table 2: Some Properties of the Transition Elements

	symbol	atomic number	atomic mass	density g cm^{-3}, 20° C	melting point °C	boiling point °C	type of crystal packing*	electrical resistivity microohm-cm	heat of atomization, at 298°, kJmole^{-1}	1st ionization potential electron volts

*hcp—hexagonal close-packed; ccp—cubic close-packed; bcc—body-centred cubic. †Does not occur in nature. The only isotope that has been obtained on a macroscopic scale has a mass number of 99. ‡Estimated value; nearly all are estimated or extrapolated values.

and atoms tend to give up or add electrons to achieve electronic configurations of greater stability, thereby becoming ions—*i.e.*, positively or negatively charged particles. An ion is represented by the symbol of the element with the electrical charge in superscript: Fe^{3+}. All metals tend to lose electrons to form positive ions, or cations, whereas nonmetals tend to gain electrons to form negatively charged ions, or anions. Oppositely charged ions attract one another and form compounds with electrovalent or ionic bonds between the ions; the solid structure of an ionic compound has no theoretical size limit because every ion holds around itself oppositely charged ions with equal bonding force. Atoms may also share electrons in covalent bonds to form polyatomic species that may be either neutral molecules (*e.g.*, water) or electrically charged ions (*e.g.*, ammonium, NH_4^+, or sulfate, SO_4^{2-}). In a third major type of bonding, called the metallic bond, electrons are freed from the parent bonding nuclei so that they can move about among the atoms unclaimed by any particular atom. Atoms of the transition elements interact with one another and with atoms of other elements in all three of these ways.

Ions

Chemical formulas. The composition of every chemical species is represented by a formula in which the symbol for an element stands for an atom of that element and the number of atoms of that element present is specified by a subscript. If a species consists of discrete, neutral molecules, the formula indicates their atomic composition; *e.g.*, benzene exists as molecules composed of six atoms of carbon and six of hydrogen and its formula is C_6H_6. Diammonium hydrogen phosphate is a crystalline solid composed of many ammonium ions (NH_4^+) and hydrogen phosphate ions (HPO_4^{2-}); each ion is a discrete entity, but no ammonium ion is associated with a particular hydrogen phosphate ion, and there are no individual species having the composition represented by the formula $(NH_4)_2HPO_4$, which specifies only the composition of the individual ions and the ratio (two to one) in which they are present.

Valence and oxidation number. All changes in electron structures of atoms, whether in the single state or bonded into groups, are chemical reactions, and the electrons accepted, donated, or shared in these processes are called valence electrons. The electronic state of an atom, alone or in combination with others, is specified by the oxidation number, the number of electrons removed from the neutral atom in changing it to the ionic level at which it is present in the species in question.

Atomic orbitals. The electrons associated with an atomic nucleus are localized, or concentrated, in various specific regions of space called atomic orbitals, each of which is characterized by a set of symbols (quantum numbers) that specify the volume, the shape, and orientation in space relative to other orbitals. An orbital may accommodate no more than two electrons. The energy involved in the interaction of an electron with the nucleus is determined by the orbital that it occupies, and the electrons in an atom distribute themselves among the orbitals in such a way that the total energy is minimum. Thus, by electronic structure, or configuration, of an atom is meant the way in which the electrons surrounding the nucleus occupy the various atomic orbitals available to them. The simplest configuration is the set of one-electron orbitals of the hydrogen atom, summarized in Figure 2. The orbitals can be classified, first, by principal quantum number, and the orbitals have increasing energy as the principal quantum number increases from 1 to 2, 3, 4, etc. (The sets of orbitals defined by the principal quantum numbers 1, 2, 3, 4, etc., are often referred to as shells designated *K*, *L*, *M*, *N*, etc.) For principal quantum number 1 there is but a single type of orbital, called an *s* orbital. As the principal quantum number increases, there are an increasing number of different types of orbitals, or subshells, corresponding to each: *s*, *p*, *d*, *f*, *g*, etc. (see Figure 2). Moreover, the additional orbital types each come in larger sets. Thus, there is but one *s* orbital for each principal quantum number, but there are three orbitals in the set designated *p*, five in each set designated *d*, and so on, as indicated at the top of Figure 2. For the hydrogen atom, the energy is fully determined by which orbital the single electron occupies. It is especially notable that the energy of the hydrogen atom is determined solely by the principal quantum number of the orbital occupied by the electron (except for some small effects that are not of concern here); that is, in hydrogen, the electron configurations of the third shell, for example, are equi-energic (of the same energy, whichever one the electron occupies), which is not the case with any of the other atoms, all of which contain two or more electrons.

The Aufbau principle. To understand the electron configurations of other atoms, it is customary to employ the *Aufbau* (German: "building up") principle, the basis of which is that, to achieve a multi-electron configuration, the required number of electrons must be added to the orbitals one at a time, filling the most stable orbitals

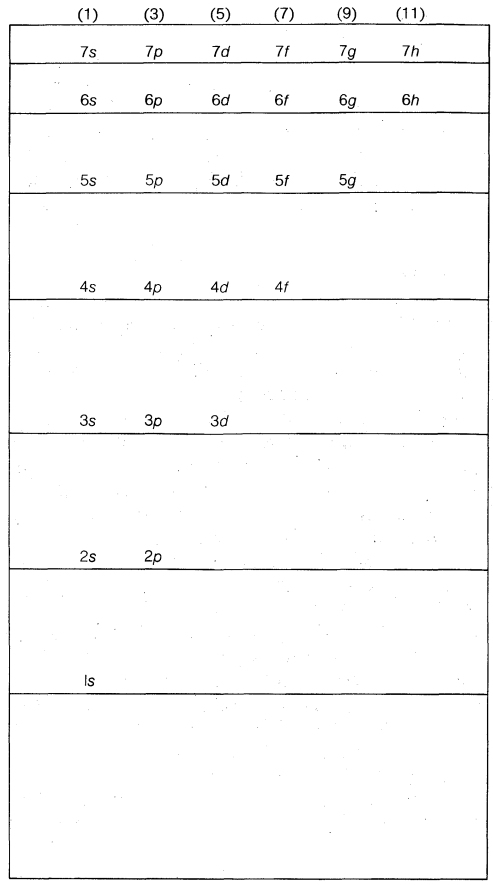

Figure 2: The hydrogen atom orbitals in order of their energies (see text).

first, until the total number has been added. There is one restriction upon this conceptualization, namely, the Pauli exclusion principle, which states that only two electrons may occupy each orbital. Thus there can be no more than two electrons in any *s* orbital, six electrons in any set of *p* orbitals, ten electrons in any set of *d* orbitals, etc. In carrying out this process, however, one cannot simply use the ordering of electron orbitals that is appropriate to the hydrogen atom as shown in Figure 2; as electrons are added they interact with each other as well as with the nucleus, and as a result the presence of electrons in some orbital causes the energy of an electron entering another orbital to be different from what it would be if this electron were present alone. The overall result of these inter-electronic interactions (sometimes referred to as shielding) is that the relative order of the various atomic orbitals is different in many-electron atoms from that in the hydrogen atom; in fact, it changes continuously as the number of electrons increases.

Shielding

As multi-electronic atoms are built up, the various subshells *s, p, d, f, g,* etc. of a principal quantum number cease to be equi-energic; they all drop, although not by equal amounts, to lower energies. Overall lowering of energy occurs because the shielding from the nuclear charge that an electron in a particular orbital is given by all of the other electrons in the atom is not sufficient to prevent a steady increase in the effect that the charge in the nucleus has on that electron as the atomic number increases. In other words, each electron is imperfectly shielded from the nuclear charge by the other electrons. In addition the different types of orbitals in each principal shell, because of their different spatial distributions, are shielded to different degrees by the core of electrons beneath them; accordingly, although all of them decrease in energy, they decrease by different amounts, and thus their relative order in energy continuously changes. In order to specify the electron configuration of a particular atom, it is necessary to use the order of orbitals appropriate to the specific value of the atomic number of that atom. The behaviour of the various *d* and *f* orbitals is to be especially noted in regard to where the transition elements occur in the periodic table.

The argon atom (atomic number 18) has an electron configuration $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6$ (*i.e.*, it has two electrons in the *s* orbital of the first shell; two in the *s* and six in the *p* orbitals of the second shell; two in the *s* and six in the *p* orbitals of the third shell: this expression often is abbreviated [Ar] especially in specifying the configurations of elements between argon and krypton, because it represents a common part of the configurations of all these elements). The 3*d* orbitals are more shielded from the nuclear charge than is the 4*s* orbital, and, consequently, the latter orbital has lower energy. The next electrons to be added enter the 4*s* orbital in preference to the 3*d* or 4*p* orbitals. The two elements following argon in the periodic table are potassium, with a single 4*s* electron, and calcium, with two 4*s* electrons. Because of the presence of the 4*s* electrons, the 3*d* orbitals are less shielded than the 4*p* orbitals; therefore, the first regular transition series begins at this point with the element scandium, which has the electron configuration [Ar] $4s^23d^1$. Through the next nine elements, in increasing order of atomic number, electrons are added to the 3*d* orbitals until, at the element zinc, they are entirely filled and the electron configuration is [Ar] $3d^{10}4s^2$. The 4*p* orbitals are then the ones of lowest energy, and they become filled through the next six elements, the sixth of which is the next noble gas, krypton, with the electron configuration $1s^22s^22p^63s^23p^64s^23d^{10}4p^6$, or [Kr].

First transition series

Throughout the next period the pattern of variation of the orbital energies is similar to that immediately preceding. When the configuration of the noble gas, krypton, has been achieved, the 5*s* orbital is more stable than the 4*d* orbitals. The next two electrons therefore enter the 5*s* orbital, but then the 4*d* orbitals fall to lower energy than the 5*p* orbitals, and the second regular transition series commences with the element yttrium. Electrons continue to be added to the 4*d* orbitals until those orbitals are entirely filled at the position of the element cadmium, which has an electron configuration [Kr] $4d^{10}5s^2$. The next six electrons enter the 5*p* orbitals until another noble gas configuration is attained at the element xenon. Analogously to the two preceding periods, the next two electrons are added to the next available orbital, namely, the 6*s* orbital, producing the next two elements, cesium and barium. At this point, however, the ordering of orbitals becomes more complex than it previously had been, because there are now unfilled 4*f* orbitals as well as the 5*d* orbitals, and the two sets have approximately the same energy. In the next element, lanthanum (atomic number 57), an electron is added to the 5*d* orbitals, but the immediately following element, cerium (atomic number 58), has two electrons in the 4*f* orbitals and none in the 5*d* orbitals. Through the next 12 elements the additional electrons enter the 4*f* orbitals, although the 5*d* orbitals are of only slightly higher energy. This set of elements from lanthanum, where the 4*f* orbitals were still vacant or about to be filled, through lutetium, in which the 4*f* orbitals are completely filled by 14 electrons, makes up the lanthanides, mentioned above.

Second transition series

At this point the next available orbitals are the 5*d* orbitals, and the elements hafnium through gold, the third regular transition series, correspond to the successive filling of these 5*d* orbitals. Following this series there are again *p* orbitals (6*p*) to be filled, and when this is accomplished the noble gas radon is reached.

Third transition series

Molecular orbitals. If two atoms are close together, some of their orbitals may overlap and participate in the formation of molecular orbitals. Electrons that occupy a molecular orbital interact with the nuclei of both atoms: if this interaction results in a total energy less than that of the separated atoms, as is the case if the orbital lies mainly in the region between the two nuclei, the orbital is said to be a bonding orbital and its occupancy by electrons constitutes a covalent bond that links the atoms together in compound formation and in which the electrons are said to be shared. If the occupation of an orbital by electrons raises the energy of the system, as is the case

if the orbital lies mainly outside the region between the two nuclei, that orbital is said to be antibonding; the presence of electrons in such orbitals tends to offset the attractive force derived from the bonding electrons.

A bonding or an antibonding molecular orbital may be disposed along the line passing through the two nuclei (Figure 3A), in which case it is designated by the Greek letter σ (sigma); or it may occupy regions approximately parallel to that line (Figure 3B and 3C) and be designated π (pi).

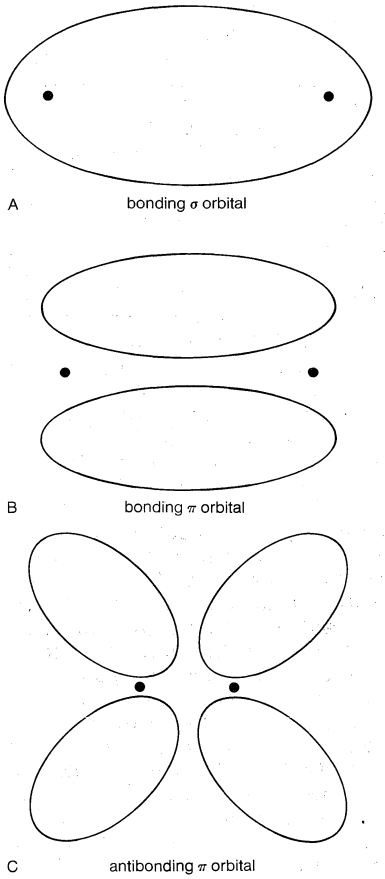

Figure 3: Electron distributions in molecular orbitals (see text).

Terrestrial abundances and discovery of the transition elements. The most abundant transition element in the Earth's solid crust is iron, which is fourth among all elements and second (to aluminum) among metals in crustal abundance. The elements titanium, manganese, zirconium, vanadium, and chromium also have abundances in excess of 100 grams (3.5 ounces) per ton. Some of the most important and useful transition elements have very low crustal abundances—*e.g.*, tungsten, platinum, gold, and silver. Table 1 lists the abundances of the transition elements.

Four of the regular transition elements were known to the ancients: iron (*ferrum*), copper (*cuprum*), silver (*argentum*), and gold (*aurum*). Their chemical symbols (Fe, Cu, Ag, Au), in fact, are derived from their alchemical (Latin) names rather than their contemporary names. The other regular transition elements were discovered (or recognized as elements) after the early 18th century. The transition element most recently discovered in nature is rhenium (atomic number 75), which in 1925 was detected in platinum ores and in the niobium mineral columbite.

Technetium (atomic number 43) is the only *d*-block element that has not been isolated from the Earth's crust. All isotopes (*i.e.*, all atoms with 43 protons and any number of neutrons) of technetium are radioactive (*i.e.*, they decay spontaneously by emitting certain particles and radiation; the time it takes one-half of a sample to decay is called the half-life); the half-life of even the stablest isotope, technetium-97, is too short to permit the survival of primordial technetium in the Earth's crust, and claims that it has been isolated or detected there must be considered erroneous. Technetium can be isolated in considerable quantities, however, from the fission products of nuclear reactors, and it is at least as readily available for chemical study as the naturally occurring similar element rhenium, of which there are no concentrated ores.

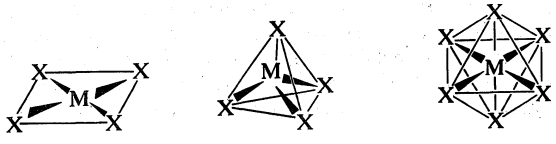
COMPOUNDS OF TRANSITION ELEMENTS

Many of the compounds formed by the transition elements are similar to those formed by nontransition elements, while others are peculiar to the *d*-block metals. The formation of the latter depends vitally upon the participation of *d* orbitals in the bonding.

Binary compounds, bases, and salts. The most important binary compounds are the oxides, the sulfides, and the halides. The oxides and halides of the metals in their lower oxidation states (+2, +3) are usually regarded as essentially ionic compounds (*i.e.*, compounds in which one or more electrons are completely transferred from one atom to another). Thus, for example chromium(III) oxide (Cr_2O_3) can be described as an electrostatically stable array of chromium ions (Cr^{3+}) and oxide ions (O^{2-}), although this description is undeniably somewhat oversimplified. Because of the approximately ionic nature of such compounds, their electronic structures can be treated by the crystal-field and ligand-field theories, as will be described.

Many binary "compounds" of the transition elements, such as carbides, nitrides, borides, phosphides, silicides, selenides, arsenides, and some sulfides, however, are not satisfactorily described by an ionic or quasi-ionic model. Such materials often have complicated structures, in which the nonmetal atoms occupy interstitial positions in metal lattices (*i.e.*, the regular geometrical arrangements of the metal atoms) or form elaborate two- and three-dimensional networks within an array of metal atoms. It is not uncommon for such substances to be markedly nonstoichiometric (*i.e.*, the component elements do not combine in characteristic proportions). For example, the cobalt (Co) telluride (Te) system forms a structural phase that is stable over the entire range of compositions from one in which the proportions of cobalt and tellurium are equal, CoTe, to one in which the proportions are 1:2, cobalt to tellurium, $CoTe_2$. Composition can vary continuously from the former to the latter by progressive loss of cobalt atoms from alternate planes in the structure until finally, at $CoTe_2$, every other plane of cobalt atoms present in CoTe is absent. Among borides on the other hand, it is a multiplicity of phases, rather than non-stoichiometry, that makes the structural situation complex. (A phase is a homogeneous, physically distinct portion of matter in a heterogeneous system.) With low boron-to-metal ratios, as those in substances with apparent formulas such as M_4B, M_5B, M_2B, M_5B_2, and M_7B_3 (in which M represents an atom of an unspecified metal and B an atom of boron), the structures contain isolated boron atoms. As the boron-to-metal ratio increases, bonding between boron atoms themselves become important. For example, there are pairs of boron atoms in trivanadium diboride, V_3B_2; and in tetranickel triboride, Ni_4B_3, two thirds of the boron atoms are linked into endless, zigzagging chains. In the many metal–boron compounds designated M_3B_4 there are double chains or bands, while in MB_2 compounds the structure consists of alternating layers of close-packed metal atoms and sheets of boron atoms.

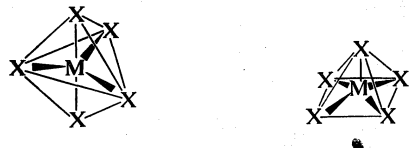
Non-stoichiometric substances



All of the transition metals form bases (*i.e.*, chemical compounds that yield the hydroxide ion, OH^-, in solution) or hydroxides, although in some cases it is doubtful if the compound is other than an amorphous hydrous (*i.e.*, containing water) oxide. Whether such substances are true hydroxides or simply hydrous oxides, however, they are precipitated from aqueous solutions of the cations (*i.e.*, positive ions) in the usual oxidation states (+2 or +3) and redissolve in acid to regenerate the cations.

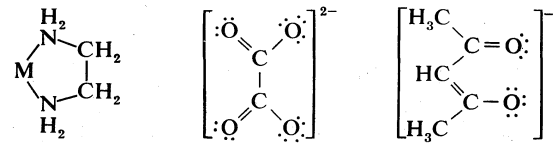
Nearly all of the transition metals, in one or more oxi-

dation states, form salts of the common oxo anions (negative ions containing oxygen atoms), such as nitrate, sulfate, and perchlorate. These salts are usually obtained as crystalline hydrates (compounds, formed by combination of water with another substance, in which water retains its molecular state as H_2O) by evaporation of aqueous solutions.



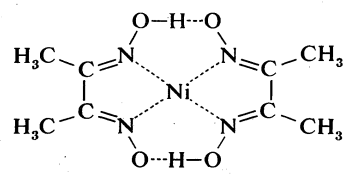
Coordination compounds. One of the most characteristic features of the chemistry of the transition elements in their normal oxidation states (generally +1 to +4) is the formation of coordination compounds or complexes. These are species in which a metal ion is surrounded by and bonded to groups of anions or molecules called ligands. The essential feature of a ligand is that it contains a donor atom, such as nitrogen or oxygen, that has an unshared pair of electrons that can be used to form a bond to a metal ion. In the classic picture of a ligand-to-metal bond the donor atom of the ligand is so oriented as to localize the donated electron pair between the donor atom and the metal ion, and a donor, or dative, bond is thus formed. The localization of electrons between a specific pair of atomic nuclei is the same phenomenon that constitutes covalent bond formation involving a sigma molecular orbital, but the fact that both electrons are supplied by the donor atom results in the transfer of negative charge to the metal atom and development of positive charge upon the donor atom so that the dative bond has considerable electrovalent (ionic) character.

Depending on the number and charges of the ligands, which need not all be the same, a coordination complex may be charged either positively or negatively or it may be neutral. Some examples are the following three complexes formed by the element cobalt: hexamminecobalt(II), $[Co(NH_3)_6]^{2+}$; trichlorotriamminecobalt(III), $[Co(NH_3)_3Cl_3]$; tetrachlorocobaltate(II), $[CoCl_4]^{2-}$. Even in the absence of deliberately added ligand species, a cation in water or other solvent is in fact part of a complex in which solvent molecules are the ligands. In water these solvent complexes are the aquo ions, of which the one with chromium (Cr), hexaquochromium(III), is representative: $[Cr(H_2O)_6]^{3+}$. The set of donor atoms around the central cation is called the coordination sphere or coordination polyhedron of the cation. The number of atoms in a coordination sphere is called the coordination number. It varies from two to nine among the regular transition metal ions, but coordination numbers 4–6 are by far the most common. For most coordination numbers, several geometric arrangements are possible as shown in the structural formulas. For coordination number 4, the two most symmetrical arrangements are square (**1**) and tetrahedral (**2**); for coordination number 6 the only important arrangement is the octahedral one (**3**):



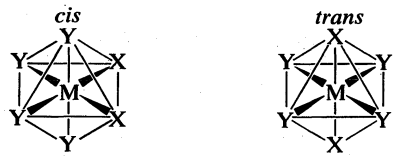
1 **2** **3**

The coordination number 5 is also common; it shows two important geometrical arrangements: the trigonal bipyramid (**4**) and the square pyramid (**5**), which are quite similar in energy.



4 **5**

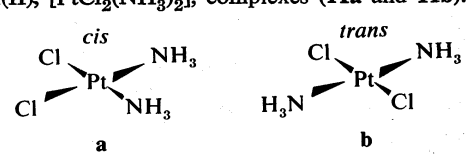
Each ligand atom need not belong to a separate ion or molecule. A ligand that has only one donor atom is called a monodentate or unidentate ligand. The halide ions (ions of the halogens: fluorine, chlorine, bromine, iodine, and astatine), the cyanide ion (CN^-), water (H_2O), ammonia (NH_3), and hydroxide ion (OH^-) are important monodentate ligands. There are also many types of polydentate or chelating ligands (a chelate is a coordination compound in which the central atom is joined to two or more atoms in the same ligand group). For example, ethylenediamine ($H_2NCH_2CH_2NH_2$) can form two nitrogen-to-metal (N–M) bonds, closing a five-membered chelate ring (**6**); thus ethylenediamine is a bidentate ligand. Some other bidentate ligands are the oxalate ion (see diagram **7**), the acetylacetonato ion (see diagram **8**), and the dimethylglyoximato ion, which is shown incorporated into the well-known bis(dimethylglyoximato)nickel complex (diagram **9**). Chelation



6 **7** **8**

9

Isomerism. In complexes containing two or more types of donor atoms the occurrence of isomers (molecules having the same number and kinds of atoms but differing in structure) becomes an important phenomenon. For octahedral complexes, the study of isomers has been carried out in great detail. Any octahedral complex in which there are two donors of one kind (X) and four of another (Y) can exist in two isomeric forms, *cis* and *trans* (see **a** and **b**, diagram **10**), called geometrical isomers.

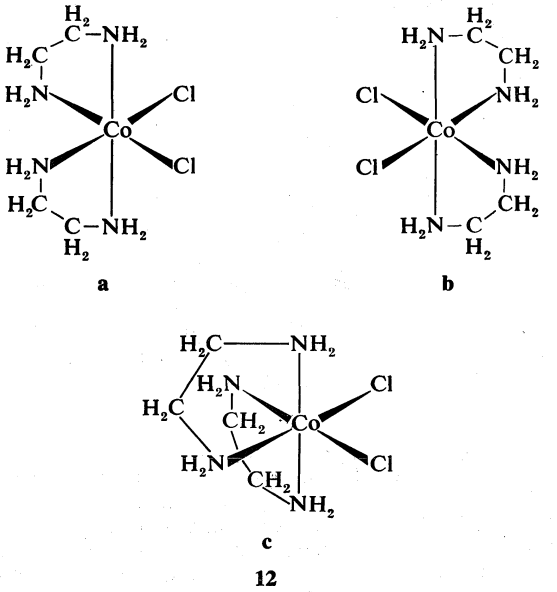


a **b**

10

The fact that there are only two geometrical isomers of MX_2Y_4 complexes is consistent with the octahedral shape of the coordination polyhedron but inconsistent with several other coordination polyhedra (*e.g.*, a plane hexagon or a trigonal prism), and observations of this kind contributed some of the earliest evidence for octahedral coordination geometry in complexes of chromium(III), cobalt(III), and platinum(IV). As the number of different donors increases, the number of isomers generally increases also. For an octahedral complex of the type expressed as $MX_2Y_2Z_2$, there are five geometrical isomers.

For square complexes, *cis* and *trans* isomers are also possible as in the case of the dichlorodiammineplatinum(II), $[PtCl_2(NH_3)_2]$, complexes (**11a** and **11b**).



a **b**

11

The occurrence of optical isomers—that is, complexes that are geometrically the same except that one is the mirror image of the other and the two mirror images are not superimposable—is of particular interest. A sample containing only one of the two isomers, or at least more Optical isomerism

of one than of the other, has the power to rotate the plane of polarized light; hence the term optical isomers. The two optical isomers have equal rotatory powers but cause rotation to occur in opposite directions.

Optical isomers are most commonly found in complexes containing chelating ligands. Thus, a complex in which there are two ethylenediamine ligands and two unidentate ligands, with the latter in a *cis* relationship, exists in two non-superimposable mirror-image forms, as shown in diagram **12** for the case of dichlorobis(ethylenediamine)-cobalt(III), $[Co(H_2NCH_2CH_2NH_2)_2Cl_2]^+$.

12

In diagram **12**, **a** and **b** are mirror images; **b** and **c** are identical, and the comparison of **a** with **c** shows very clearly that the mirror-image structures are not superimposable.

The formation of complexes in aqueous solution upon addition of ligands to a solution of the aquo ion is an important phenomenon. Such complexes form in a stepwise fashion, so that the coordinated water molecules are successively replaced by the ligand. For example, when ammonia is slowly added to a solution of nickel(II) ions, a series of ammonia complexes forms. Comparison of the stability of the ammonia complexes with that of the complexes with ethylenediamine reveals an important phenomenon called the chelate effect. When the two ammonia (NH_3) ligands are tied together to form one bidentate ligand, ethylenediamine, the displacement of two water molecules is about 540 times more favourable than when the ammonia molecules are separate unidentate ligands. The formation of chelate rings increases the degree of complex formation, other factors being equal. This is the major reason that polydentate ligands such as ethylenediaminetetraacetate (EDTA) are so important and useful in transition-metal chemistry as powerful complexing agents that reduce the concentrations of metal ions in aqueous mediums.

The chelate effect

Oxo anions. Many of the transition metals in their highest oxidation states form anions of the type MO_4^{n-}, in which M is the metal atom and n takes the values 2 for the Group VI elements and 1 for the Group VII elements. Some important examples are the ions of chromium: chromate(VI), CrO_4^{2-}; of molybdenum: molybdenum(VI), MoO_4^{2-}; and of tungsten: tungstate(VI), WO_4^{2-}; and of manganese: manganate(VII), MnO_4^-; of technetium: technetate(VII), TcO_4^-; and of rhenium: rhenate(VII), ReO_4^-. Osmium and ruthenium form the neutral compounds osmium(VIII) oxide, OsO_4, and ruthenium(VIII) oxide, RuO_4, which, even though they are uncharged, are closely related with respect to structure and bonding to the oxo anions. The stability of higher oxidation states increases, and the oxidizing power of oxo anions thus decreases, as each group in the periodic table is descended; thus the chromate(VI) ion and the manganate(VII) ion of the first transition series are powerful oxidizing agents, whereas the tungstate(VI) ion and the rhenate(VII) ion of the third transition series have no significant oxidizing power.

The chromate(VI) and manganate(VII) ions are widely used in analytical chemistry for the volumetric determination of reducing agents. In acidic solution, the chromate(VI) ion dimerizes (*i.e.*, forms a larger ion by the union of two simple ones):

$$2CrO_4^{2-} + 2H^+ \longrightarrow Cr_2O_7^{2-} + H_2O.$$

chromate (VI) ion — hydrogen ion — dichromate (VI) ion — water

The Group V and Group VI elements, especially vanadium, molybdenum, and tungsten, form complex polynuclear oxo anions, called isopolyanions. In highly basic solutions the simple mononuclear species (*e.g.*, WO_4^{2-}) are stable, but as the solution is made more acidic the polynuclear species appear. These isopolyanions are formed by the joining of metal–oxygen octahedra (MO_6) through shared vertices and edges. The ultimate products of the aggregation process, in very strongly acidic solution, are the hydrous oxides such as tungsten(VI) oxide, $WO_3 \cdot 2H_2O$, molybdenum(VI) oxide, $MoO_3 \cdot 2H_2O$, and vanadium(V) oxide, V_2O_5. When the condensation reactions leading to polynuclear species are carried out in the presence of other elements, such as phosphate ions, silicate ions, or metal ions (*e.g.*, nickel(II), manganese(II), or cerium(IV)), the heteropolyacids, or their anions, are formed. In these, the metal–oxygen octahedra are fitted together around a central site that may be either a tetrahedron or an octahedron, occupied by the phosphorus, silicon, or metal atom, which is designated the hetero atom. A typical heteropolyanion is the 12-molybdophosphate ion, $[PMo_{12}O_{40}]^{3-}$, in which 12 molybdate octahedra are interconnected to surround a phosphorus atom that lies at the centre, joined to four tetrahedrally arranged oxygen atoms.

Iso-polyanions

Metal carbonyls and nitrosyls. The metals of the main transition series form complexes in which the carbon monoxide molecule, CO, functions as a ligand. For the most part these complexes, which are called metal carbonyls, contain metal atoms in very low (+1, 0, −1) formal oxidation states. According to current theoretical views, the special ability of the *d*-block transition metals to bind carbon monoxide (and, in a similar manner, nitric oxide, NO) is attributable to the presence of electrons in *d* orbitals that have the shape and energy necessary to engage in formation of pi molecular bonds with the CO group. Only the *d*-block atoms in low oxidation states meet this requirement.

Metal carbonyls

Carbon monoxide differs from most other ligands in that the simple donation of one of its unshared electron pairs to an electron pair acceptor does not result in strong bonding. Carbon monoxide is able to form carbonyls with transition metals because the bonding of those metals to the carbon monoxide molecule is of a dual or synergic nature. This is shown in Figure 4. The electrons

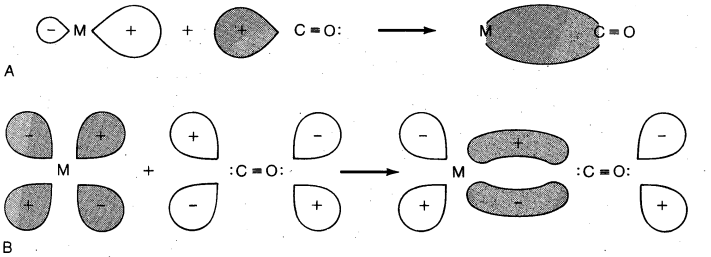


Figure 4: *The two components of a bond between a metal atom and a carbon monoxide molecule.*
(A) shows the sigma bond and (B) the pi bond.

in a sigma orbital on the carbon atom form a donor bond to the metal atom. This is not a very effective bond by itself, but it leads to a polarization, whereby the carbon monoxide group becomes positive and the metal atom, negative. The metal atom can then donate electron den-

sity from filled *d* orbitals to the empty pi antibonding orbitals of carbon monoxide. This process produces a polarity opposite to the first one. The two processes thus tend to be mutually reinforcing, or synergic, and as a result stable bonds are formed.

Some representative metal carbonyls are hexacarbonylchromium, $Cr(CO)_6$; decacarbonyldimanganese, $Mn_2(CO)_{10}$; nonacarbonyldiiron, $Fe_2(CO)_9$; and dodecacarbonyltetrairidium, $Ir_4(CO)_{12}$. In addition to binary metal carbonyls (*i.e.*, those containing only metal atoms and carbon monoxide groups), there are thousands of substances containing some CO ligands along with others.

The first metal carbonyl, tetracarbonylnickel, $Ni(CO)_4$, discovered in 1890, is the only one that can be formed readily by direct reaction of the metal with carbon monoxide, and it found almost immediate industrial application in the purification of nickel. The process is still in limited use today, affording metal of 99.90–99.99 percent purity. Impure metal reacts at 50° C (about 120° F) to form tetracarbonylnickel, which is decomposed at 200° C (about 400° F) to regenerate the metal. During the next 20 years carbonyls of iron, cobalt, and molybdenum were synthesized. Many metal carbonyl molecules of very complicated structures have been synthesized, including those formulated $M_3(CO)_{12}$ (M = iron, Fe, ruthenium, Ru, and osmium, Os), which contain triangles of metal atoms; $M_4(CO)_{12}$ (M = cobalt, Co, rhodium, Rh, and iridium, Ir), which contain tetrahedral groups of metal atoms; and $Rh_6(CO)_{16}$, which has an octahedron of metal atoms.

The simplest metal carbonyls are those in which a single metal atom is surrounded by an array of four, five, or six carbon monoxide groups. The latter are always bound to the metal through the carbon atom in the synergic manner explained above. In many, but not all, of the polynuclear (*i.e.*, containing two or more metal atoms per molecule) metal carbonyls there is another type of carbonyl group—*i.e.*, a bridging CO, in which the carbon atom forms normal covalent single bonds to two metal atoms. There are even a few cases in which a carbon monoxide group lies symmetrically over a triangle of metal atoms and is bonded to all three, thus forming a triple bridge.

Most metal carbonyls react fairly easily with phosphines, amines, and olefins, forming products in which one or more of the CO groups is replaced by these ligands. Nickel carbonyl, for example, reacts with phosphines, R_3P, in which R is an organic radical (a combining group derived by removal of a hydrogen atom from an organic compound) and P is phosphorus, to produce, for example, tricarbonyl(triphenylphosphine)nickel, $Ni(CO)_3[(C_6H_5)_3P]$, and dicarbonylbis(triphenylphosphine)nickel, $Ni(CO)_2[(C_6H_5)_3P]_2$.

The formulas of the simpler metal carbonyls can all be understood by postulating that the total number of valence electrons around each metal atom, counting those in both sigma and pi orbitals, should be equal to 18. Each carbon monoxide group is considered to contribute two electrons. Thus, if a metal atom has initially *n* electrons of its own it will form bonds to $(18 - n)/2$ carbon monoxide groups. This is illustrated by pentacarbonyliron, $Fe(CO)_5$: the iron atom, with an electron configuration $[Ar]3d^64s^2$, possesses a total of eight valence electrons; thus ten more are needed and these are supplied by five CO groups, each of which adds two electrons. When the metal has an odd number of electrons it must also interact with some univalent group, such as a halogen atom or another metal atom, thereby acquiring a share in one more electron. Manganese, for example, has seven electrons. By forming a bond to one halogen—*e.g.*, chlorine (Cl)—and to five CO groups, or to one other manganese atom and to five CO groups, the molecules chloropentacarbonylmanganese, $ClMn(CO)_5$, or bis(pentacarbonylmanganese), $(OC)_5Mn—Mn(CO)_5$ are formed.

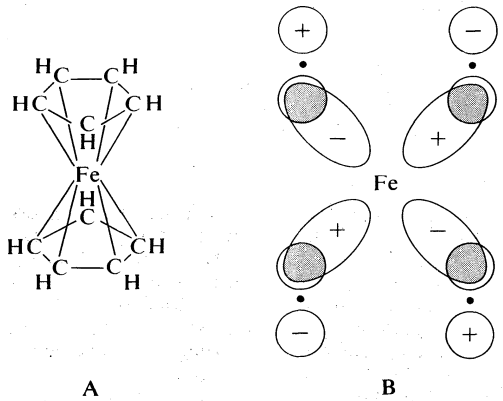
The nitric oxide molecule, NO, is very similar to the carbon monoxide molecule except for the presence of an additional electron, which can be donated to, or at least shared with, the metal atom in addition to the two electrons on the nitrogen atom that are analogous to the two electrons on the carbon atom of carbon monoxide. The nitric oxide molecule also possesses the necessary pi antibonding orbitals with which to accept electrons from metal *d* orbitals. It can, therefore, exhibit ligand behaviour similar to that of carbon monoxide. Because nitric oxide can contribute three electrons whereas carbon monoxide donates only two, two NO groups can replace three CO groups; or an NO group can replace one CO group plus a metal-to-metal bond or one CO group plus a metal-to-ligand single bond. In this way, the composition of dicarbonyldinitrosyliron, $Fe(CO)_2(NO)_2$, can be related to that of pentacarbonyliron, $Fe(CO)_5$, and the compositions of both tetracarbonylnitrosylmanganese, $Mn(CO)_4(NO)$, and carbonyltrinitrosylmanganese, $Mn(CO)(NO)_3$, can be understood in relation to those of bis(pentacarbonylmanganese) and chloropentacarbonylmanganese.

Metal nitrosyls

There are other ligands, particularly certain PR_3 groups, in which R may be any of several monovalent atoms or groups that resemble carbon monoxide in combining sigma donation with pi acceptance in their interaction with metal atoms. Phosphorus trifluoride, PF_3, is very similar to carbon monoxide in its bonding capabilities, and it forms an extensive series of complexes comparable in composition to the metal carbonyls—*e.g.*, tetrakis(phosphorus trifluoride)nickel, $Ni(PF_3)_4$.

The toxicity of carbon monoxide is due to its ability to form a complex with the iron atom of hemoglobin, thus blocking its function as an oxygen carrier. Phosphorus trifluoride is also highly toxic for the same reason.

Organometallic compounds. Scarcely any organometallic compounds of the transition elements were known (if the term organometallic is understood to imply the presence of direct metal-to-carbon bonds) prior to 1951. In that year the discovery of dicyclopentadienyliron, $(C_5H_5)_2Fe$, commonly known as ferrocene, was announced; the following year the correct molecular structure of the compound was determined. As shown in Figure 5A, it is a kind of "molecular sandwich," the two cyclopentadienyl rings lying parallel and the metal atom occupying the midpoint between them.



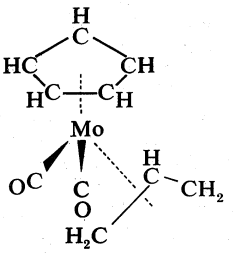


Figure 5: (A) The "sandwich" structure of the ferrocene molecule $(C_5H_5)_2Fe$; (B) sketch showing how the pi-type ring orbitals and an iron *d* orbital overlap to give a component of the metal-to-ring bonding. The view is of a section through the molecule, perpendicular to the ring planes.

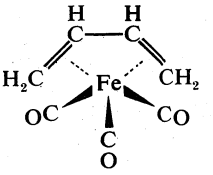
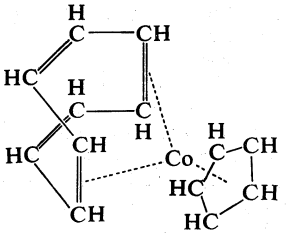
The bonding of the cyclopentadienyl rings to the iron atom in ferrocene is due primarily to the overlap of pi orbitals of the organic group with *d* orbitals of the metal. The principal component of this bonding consists of the interaction of the incompletely filled pi type orbitals with the d_{xz} and d_{yz} orbitals, as shown in Figure 5B. Soon after the nature of the ferrocene molecule was clarified it was shown that the cyclopentadienyl group (the C_5H_5 ring) could form similar bonds to almost all of the other transition metals. More importantly, it was recognized that the basic type of interaction, which can be broadly described as donation of pi electrons from an organic molecule, radical, or anion to *d* orbitals of a transition metal, could occur with a great number of unsaturated

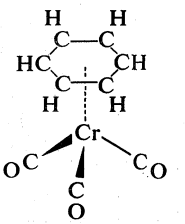


organic species. Thus ligands derived from ring systems other than cyclopentadiene—*e.g.*, cyclopropene, cyclobutadiene, benzene, and cycloheptatriene—containing 3-, 4-, 6-, and 7-membered rings, respectively—have been shown to form very similar bonds to transition metal atoms. Moreover, non-aromatic olefin and polyolefin systems of many kinds can also form bonds to transition metals by using their pi electrons, much as conventional ligands use their electron pairs, to form donor bonds.

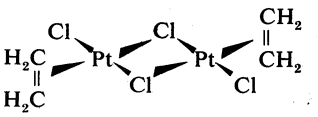
Olefinic and polyolefinic ligands



Many of the organometallic compounds in which olefins are attached to transition metal atoms through their pi electrons contain carbonyl groups. In such molecules, the metal atoms generally attain an 18-electron configuration, as they do in the metal carbonyls themselves. In counting electrons, each carbon–carbon double bond is treated as a donor of two electrons. Some representative molecules are shown in diagrams **13**–**17**. In diagram **13**



13



14

15

16

17

there is one cyclopentadienyl group (a five-electron donor), one allyl group (a three-electron donor), and two carbonyl groups (which donate two electrons each). These 12 electrons, together with the six possessed by the molybdenum atom, give the required total of 18. In **14** the organic ligand is a butadiene group, while in **15** there are both a cyclopentadienyl group and a cyclooctatetraene group that uses only two of its double bonds to attach itself to the cobalt atom. In **16** there is a benzene ring serving as a six-electron donor in place of three CO groups of a hexacarbonylchromium molecule, $Cr(CO)_6$.

The first organometallic compound of a transition metal (diagram **17**) was characterized as long ago as 1830. The nature of this and related compounds became clear, however, only in the 1950s. Simple metal–carbon sigma bonds also are formed by transition metals, but are stable only under special circumstances.

Transition-metal catalysts. One important use of transition metals and their compounds is as catalysts for a variety of industrial processes, mostly in the petroleum and polymer (plastics, fibres) industries, in which organic molecules are isomerized, built up from simple molecules, oxidized, hydrogenated, or caused to polymerize. Only a few of the most important such processes and their catalysts can be mentioned here. Catalysts are of two physical types: homogeneous (*i.e.*, dissolved in the reaction mixture) and heterogeneous (*i.e.*, constituting a solid phase separate from and insoluble in the reaction mixture). Both types are represented on the industrial scene, but the latter are much more common.

Types of transition-metal catalysts

The introduction of catalysts that allow polymerization to be carried out at relatively low temperatures and pressures revolutionized the production of polyethylene and polypropylene. Previously polyethylene had to be made by a process requiring pressures of about 1,000 atmospheres, and polypropylene of useful properties was not commercially important. The catalysts devised and applied during the early 1950s are prepared from titanium tetrachloride and an aluminum alkyl such as triethylaluminum: the precipitated, titanium-containing solid, plus the excess aluminum alkyl in solution, constitutes the catalyst. A very different sort of catalyst, consisting of chromium(VI) oxide dispersed on silica-alumina, performs similarly in polymerizing ethylene but cannot produce a useful form of polypropylene.

Chromium in the form of chromium(III) oxide on alumina is the major industrial catalyst for transforming saturated hydrocarbons (*i.e.*, those in which all available valence bonds of the atoms are attached to other atoms) to useful olefins (unsaturated organic compounds), chiefly *n*-butane to butylene and butadiene.

Iron-containing catalysts are used in various processes of which the most notable is that for producing ammonia from nitrogen and hydrogen. This process, developed early in the 20th century, represents the first major industrial application of transition metal catalysis. The catalyst is magnetic triiron tetroxide (Fe_3O_4), "promoted" by the addition of small quantities of potassium oxide, aluminum oxide, calcium oxide, and silica.

Ammonia synthesis

Molybdenum in molybdenum(VI) oxide–aluminum oxide mixtures or in cobalt oxide–molybdenum oxide–aluminum oxide mixtures finds many applications, such as desulfurizing gases and liquids; removing lead, nickel, and vanadium from petroleum refinery feed stocks; and in modifying, or "reforming," crude petroleum fractions to increase their octane rating.

Olefins that are free of such impurities as carbon monoxide, sulfur, halogen, and compounds of arsenic or lead (catalyst poisons), can be hydrogenated (*i.e.*, combined with hydrogen) at atmospheric pressure and room temperature, using various types of active nickel preparations as catalysts.

Copper is a component of a variety of catalysts, of which the copper chromites, used for selective hydrogenation of carbonyl groups (compounds containing the divalent organic radical $>CO$), are perhaps the most important. Fats and oils can also be hydrogenated to alcohols using copper catalysts. Palladium chloride together with copper(I) salts forms a homogeneous catalyst for oxidizing ethylene to acetaldehyde (Wacker process), but commercial use of this process has been abandoned. Metallic platinum has a broad spectrum of catalytic activities. One of the most important in terms of tonnage production is in catalytic reforming of petroleum fractions to improve antiknock quality of gasoline. Silver oxide, on an inactive, refractory support, catalyzes oxidation of ethylene to ethylene oxide.

The oxo process (also called hydroformylation), in which certain olefins react with carbon monoxide and hydrogen to give aldehydes (a class of organic compounds that contain the group $-CHO$), requires a homogeneous catalyst containing a transition metal. The first practicable one was hydrogen tetracarbonylcobaltate(-I), $HCo(CO)_4$, which is formed in the reaction mixture by action of hydrogen on octacarbonyldicobalt, $Co_2(CO)_8$. More recently rhodium complexes have been found to have greater activity at lower temperatures and pressures and to be more easily recovered. The net reaction in the oxo process is represented by

$$\underset{\text{a terminal olefin}}{RCH{=}CH_2} + \underset{\text{carbon monoxide}}{CO} + \underset{\text{hydrogen}}{H_2} \longrightarrow \underset{\text{an aldehyde}}{RCH_2CH_2CHO}.$$

Biological functions of transition metals. Several transition elements are important to the chemistry of living systems, the most familiar examples being iron, cobalt, copper, and molybdenum. Iron is by far the most wide-

spread and important transition metal that has a function in living systems; proteins containing iron participate in two main processes, oxygen transport and electron transfer (*i.e.*, oxidation–reduction) reactions. There are also a number of substances that act to store and transport iron itself.

Heme proteins. The chief heme proteins are the hemoglobins, myoglobins, cytochromes, and certain enzymes (enzymes are catalysts for the chemical reactions of biological processes), such as catalase and peroxidase. In all of these the iron is present as a particular type of porphyrin complex called heme (see Figure 6). Hemoglobin

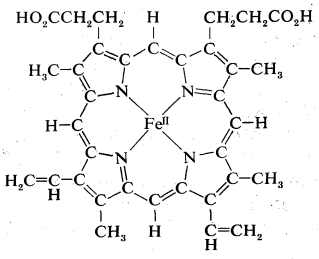


Figure 6: The structure of the heme group in hemoglobin.

Function of hemoglobin

has two functions: it binds oxygen molecules to its iron atoms and transports them from the lungs to the muscles, where they are transferred to myoglobin molecules that store them until required for biological oxidations; and it binds carbon dioxide and carries it back to the lungs. It is believed that iron is not involved in the latter function.

The effectiveness of hemoglobin as an oxygen carrier depends on cooperative interactions between the subunits, whereby the binding of molecular oxygen to one heme group increases the binding ability of the next, and so on. The coordination stereochemistry of the iron is a significant factor in the mechanism of this enhancement. Deoxyhemoglobin—*i.e.*, hemoglobin not bound to oxygen—contains iron(II) in a state in which the bonding radius of the iron is so great that it cannot fit into the plane of the four nitrogen atoms of the porphyrin ring but instead lies about 0.75 Å (angstrom; an angstrom is a unit of length equal to 10^{-10} metre) out of that plane. When an oxygen molecule is bound, the bond radius of the iron atom decreases, and it slips back into the plane of the nitrogen atoms. Thus, attachment of a molecule of oxygen to the iron atom moves it about 0.75 Å; when it moves the motion is then transmitted to certain remote parts of the subunit to which this iron atom belongs. As a result of the changes that are thus induced in one subunit, structural changes are caused in other subunits, which increase the affinity for oxygen at the other heme units.

Cytochrome *c* is the most abundant of the cytochromes, a class of important organic compounds with the ability to combine with metals, particularly iron and magnesium. It is a type of heme protein that serves as an electron carrier. The cytochrome *c* molecules in a great range of organisms are very similar, indicating an early evolutionary development with little subsequent change.

Iron–sulfur electron-transfer proteins. The relatively small proteins (molecular weights of 6,000–12,000) known as iron–sulfur electron-transfer proteins contain iron bound by sulfur atoms present in structural units derived from the amino acid cysteine. Such proteins appear to occur in all green plants, including algae, in all photosynthetic bacteria, and in some anaerobic (*i.e.*, living or acting only in the absence of oxygen) bacteria and are evidently essential in the electron-transfer processes involved in photosynthesis, but explicit chemical specification of their activities is still lacking. The ferridoxins vary in chemical type; some contain as few as two iron atoms, others as many as eight. A substance called rubredoxin, which appears to work in conjunction with ferridoxins at least in some micro-organisms, contains only one iron atom in a molecule that has a molecular weight of approximately 6,000. Proteins called hemerythrins, involved in respiratory functions of several groups of invertebrate animals, contain iron that is not bound to heme structures. Little is yet known about the chemical basis of their activity.

In man and other higher mammals, iron is stored and transported by ferritin and haemosiderin, which are present in liver, spleen, and bone marrow. Ferritin is a water-soluble substance consisting of a roughly spherical protein sheath approximately 75 Å in inside diameter and 120 Å outside diameter, within which is a structural unit of colloidal, hydrous iron(III) phosphate: as much as 23 percent of the dry weight is iron. Haemosiderin contains even larger proportions of "iron hydroxide." Transferrin is a protein that binds trivalent iron very strongly and transports it between ferritin and red blood cells.

Other transition metals in biological systems. Though cobalt is understood to be an essential trace element in animal nutrition, the only detailed chemical knowledge of its biochemical action has to do with vitamin B_{12} and related co-enzymes. These molecules contain one atom of cobalt bound in a macrocyclic ring (*i.e.*, one consisting of many atoms) called corrin, which is similar to a porphyrin ring. Copper is found in both plants and animals, and numerous copper-containing proteins have been isolated. The blood of many lower animals, such as mollusks, cephalopods, gastropods, and decapods, contains respiratory proteins called hemocyanins, which contain copper atoms (but no heme) and appear to bind one oxygen molecule per two copper atoms. Human serum contains a glycoprotein called ceruloplasmin, the molecule of which contains eight copper atoms; its biological function is still uncertain. Other proteins, called cerebrocuprein, erythrocuprein, and hepatocuprein, that are found in the mammalian brain, erythrocytes, and liver, respectively, contain about 60 percent of the total copper in those tissues; their functions are still unknown. There are a number of copper-containing enzymes; examples are (1) ascorbic acid oxidase (an oxidase is an oxidizing enzyme), which contains eight atoms of copper per molecule; it is widely distributed in plants and microorganisms; (2) cytochrome oxidase, which contains heme and copper in a 1:1 ratio; (3) tyrosinases, which catalyze the formation of melanin (brownish-black pigments occurring in hair, skin, and retina of higher animals) and were the first enzymes in which copper was shown to be essential to function.

Vitamin B_{12}

Vanadium occurs widely in petroleum, notably that from Venezuela, and can be isolated as porphyrin complexes, the origin of which is not known. Vanadium is present in high concentrations in blood cells (vanadocytes) of certain ascidians (sea squirts), apparently in a curious, complex, and poorly understood protein-containing substance called hemovanadin, thought to serve in oxygen transport. Molybdenum is believed to be a necessary trace element in animal diets, but its function and the minimum levels have not been established. Nitrogen-fixing bacteria utilize enzymes that contain both molybdenum and iron. One such enzyme, or at least a part of it that has been isolated in the crystalline state, contains two atoms of molybdenum and 40 atoms of iron. This protein in association with another, which contains only iron, can catalyze the reduction of nitrogen gas to nitrogen compounds.

Nitrogen fixation

THEORIES OF TRANSITION-METAL COMPLEXES

As has been noted, partially filled *d* orbitals account for the characteristic chemical properties of the regular transition elements, both as a class and as individuals. The interpretation and understanding of the chemical and physical properties of these elements thus depends heavily upon the description of these d^n (n is one or more but fewer than ten) electron configurations. The five orbitals of each *d* shell, regardless of principal quantum number, have the shapes and designations shown in Figure 7. The radial extent or size changes with principal quantum number, but the shapes are characteristic for all sets.

For an atom or ion in free space and not subject to any electromagnetic field, the five orbitals of a set have equal energies; but in chemical compounds, the surrounding

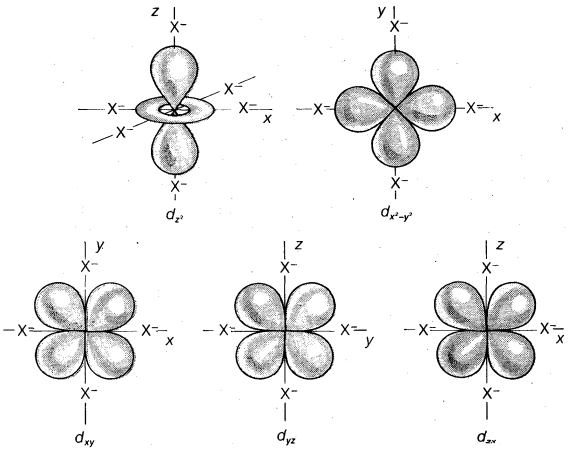

Figure 7: The shapes of the *d* orbitals and their conventional designations. The symbols X^- represent some or all of a set of six octahedrally located anions.

d-orbital subsets

atoms cause the set to separate into subsets, differing in energy. This separation has a profound influence upon the spectroscopic properties (including colour) and magnetic properties of the substance, and the analysis of such effects has stimulated a great deal of theoretical and experimental effort. The most common situations to be considered are those in which a transition-metal ion occurs in an octahedron or a tetrahedron of surrounding anions or other ligands. Such cases illustrate the handling of the problem of the electronic structure of transition-metal ions in compounds.

Three different theoretical approaches have been used: (1) the valence-bond treatment, pioneered in the United States by Linus Pauling; (2) the crystal-field or ligand-field theory, first proposed by Hans Bethe and developed extensively by the U.S. physicist J.H. Van Vleck; and (3) the molecular orbital theory, the application of which to transition-metal complexes was first discussed by Van Vleck. The second and third methods are used almost exclusively, and only those two will be outlined here.

Crystal-field and ligand-field theories. The crystal-field theory (CFT) employs an extreme electrostatic model, in which the ligands are treated as point charges (*i.e.*, as if the entire negative charge were concentrated at a single point in space) if they are anions or as point dipoles (*i.e.*, pairs of particles having equal and opposite charges that are separated by a finite distance) if they are neutral molecules. These extreme approximations are useful because they preserve certain essential features of the actual physical condition and yet reduce the mathematical problem to one that can be solved. Since the CFT treatment makes no allowance for covalence in the metal–ligand bonds, it necessarily does not account for all aspects of the electronic structures of complexes, even the most ionic ones. It can be amended, however, by empirical adjustment of certain parameters, to allow for some of the effects of covalence, without sacrificing mathematical convenience. This version of the theory, which can correlate much of the data on complexes of metals in their normal oxidation states, is called ligand-field theory (LFT).

Orbital splitting patterns. Crystal-field theory treats the question of how the energies of a set of *d* electrons or orbitals are split when a set of ligands is placed around a central metal ion; it does so by treating the ligands as a set of negative charges. The simplest case to consider is that of an ion with a single *d* electron, surrounded by six negative charges at the vertices of an octahedron. This arrangement is defined, relative to a set of Cartesian axes, *x*, *y*, *z*, shown in Figure 8. By comparing the shapes of the *d* orbitals (see Figure 7) with this arrangement, it can be seen that the d_{xy}, d_{xz}, and d_{yz} orbitals have equivalent relationships to the set of charges. Thus, the electron will be repelled to the same extent by the negative charges regardless of which of the three orbitals it occupies. The three orbitals thus have equal energy and are called triply

Octahedral complexes

degenerate. It is not particularly obvious from a pictorial argument, but mathematical analysis shows that each of the other two orbitals, d_{z^2} and $d_{x^2-y^2}$, causes the electron to experience the same amount of electrostatic repulsion from the surrounding charges; they are described as doubly degenerate. Thus, the first important conclusion of the crystal-field theory is that the spatial relationships of the *d* orbitals to the surrounding charges cause the set of five *d* orbitals to be split into two subsets; the orbitals within each subset are equivalent to each other and are thus degenerate, but they are no longer degenerate with those in the other subset. Those in the subset consisting of the d_{xy}, d_{yz}, and d_{zx} orbitals are known as the t_{2g} orbitals; the d_{z^2} and $d_{x^2-y^2}$, pair are called the e_g orbitals. When the surrounding charges are located at the vertices of an octahedron, the two e_g orbitals are of higher energy than the three t_{2g} orbitals. When an ion is surrounded by a tetrahedrally arranged set of four negative charges, the *d* orbitals also split into a set of three and a set of two, but the energy order is the reverse of that in the octahedral case. Beginning with these splitting patterns it is possible to elaborate a detailed account of the magnetic and spectroscopic properties of transition-metal ions in their compounds.

Tetrahedral complexes

Magnetic and spectroscopic properties. Discussion of magnetic properties must begin with the basic question of how many unpaired electrons will be present. This is decided by the competition between two factors: (1) the electrons tend to occupy separate orbitals since this minimizes repulsions between them; and (2) the electrons also tend to occupy orbitals of lower energy in preference to higher ones. For ions with one, two, and three *d* electrons in octahedral fields, the first factor dictates, without opposition from the second, that the electrons occupy separate t_{2g} orbitals; such ions therefore always have 1, 2, and 3 unpaired electrons. Similarly, for configurations of eight and nine *d* electrons, the only possibilities are six electrons in t_{2g} orbitals and two in e_g orbitals, and six electrons in t_{2g} orbitals and three in e_g orbitals ($t_{2g}^6e_g^2$ and $t_{2g}^6e_g^3$), and such ions must always have 2 and 1 unpaired electrons, respectively. For cases of d^4, d^5, d^6, and d^7 configurations, the number of unpaired electrons depends on which of the two factors dominates. If the splitting (the energy difference between e_g and t_{2g} orbitals) is relatively small, control by the first factor produces the high-spin configurations, $t_{2g}^3e_g$, $t_{2g}^3e_g^2$, $t_{2g}^4e_g^2$, and $t_{2g}^5e_g^2$, which have 4, 5, 4, and 3 unpaired electrons, respectively. When the difference is relatively large, control by the second factor produces the low-spin configurations t_{2g}^4, t_{2g}^5, t_{2g}^6, and $t_{2g}^6e_g$, with 2, 1, 0, and 1 unpaired electrons, respectively. In tetrahedral complexes the splitting is always sufficiently small so that the first factor dominates and high-spin states are always obtained. Once the number of unpaired electrons is known, numerical values of the magnetic moments are calculated by taking account of the interaction of the orbital-angular momentum with the spin-angular momentum.

Factors influencing magnetic properties

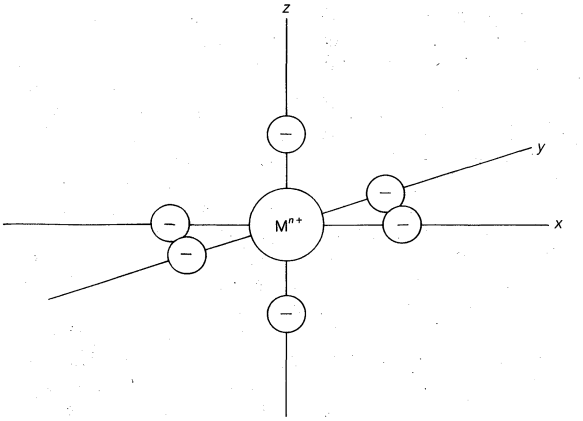

Figure 8: An octahedrally arranged set of negative charges in relation to a set of Cartesian coordinates with a positively charged metal ion (M^{n+} at the centre).

The spectra emitted by the electronic structures of transition-metal ions, which are responsible for their colours, can be understood in terms of the CFT splitting patterns. For a d^1 ion in an octahedral field, a single electronic transition, $t_{2g} \rightarrow e_g$, is expected; that is, the absorption of light raises the energy of an electron and causes it to pass from the low-energy t_{2g} orbital to the high-energy e_g orbital. The titanium(III), Ti^{3+}, ion, for example, has just a single absorption band in the visible region of the spectrum, at a wavelength of about 5,000 nanometres, corresponding to an energy of 20,000 cm^{-1}, which is assigned to this transition. This says that the orbital energy difference for Ti^{3+} in $[Ti(H_2O)_6]^{3+}$ is 20,000 per centimetre. For configurations with more than one d electron, electronic interactions require that an elaborate treatment, which cannot be explained here, be used.

The difference in the colours of hexaquonickel(II) ion, $[Ni(H_2O)_6]^{2+}$ (green), and tris(ethylenediamine)nickel(II) ion, $[Ni(H_2NCH_2CH_2NH_2)_3]^{2+}$ (purple), reflects the fact that the six nitrogen atoms cause a greater splitting than the six oxygen atoms.

In general, the relative magnitudes of d orbital splittings for a given ion with different ligand sets fall in a consistent order. This ordering of ligands according to their ability to split the d orbitals was discovered empirically in the 1930s and is called the spectrochemical series. A short list of ligands in order of their splitting power is fluoride (weakest), water, thiocyanate, pyridine or ammonia, ethylenediamine, nitrite, cyanide (strongest).

Jahn-Teller effect. According to the Jahn-Teller theorem, any molecule or complex ion in an electronically degenerate state will be unstable relative to a configuration of lower symmetry in which the degeneracy is absent. The chief applications of this theorem in transition-metal chemistry are in connection with octahedrally coordinated metal ions with high-spin d^4, low-spin d^7, and d^9 configurations; in each of these cases the t_{2g} orbitals are all equally occupied (either all half filled or all filled) and there is a single electron or a single vacancy in the e_g orbitals. Either an e_g or an e_g^3 configuration gives rise to a doubly degenerate (E) ground state, and thus a distortion of the octahedron is expected. In other words, high-spin d^4, low-spin d^7, and d^9 ions should be found in distorted, not regular, octahedral environments. It has been found by experiment that, with few possible exceptions, this is the case. The exceptions do not necessarily constitute violations of the Jahn-Teller theorem, because the slightness of the distortions may be within experimental error.

Distorted complexes

By far the most common form of distortion in the three cases given above is an elongation of the octahedron along one of its fourfold axes. Thus, two opposite ligands are farther from the metal ion than the other, coplanar (*i.e.*, lying in one plane) set of four. Such effects have been observed in compounds and complexes of high-spin chromium(II) and manganese(III) ions, $(t_{2g}^3 e_g)$; low-spin cobalt(II) and nickel(III) ions, $(t_{2g}^6 e_g)$; and copper(II) and silver(I) ions $(t_{2g}^6 e_g^3)$. The greatest body of data available is for copper(II) compounds, and some representative sets of copper–ligand distances are copper(II) chloride, four chloride ions at 2.30 Å and two at 2.95 Å; copper(II) bromide, four bromide ions at 2.40 Å and two at 3.18 Å.

Molecular-orbital theory. The molecular-orbital (MO) treatment of the electronic structures of transition-metal complexes is, in principle, a more flexible approach than the CFT or LFT treatments. Because a great many complexes and compounds in the ordinary oxidation states (II, III) of the transition metals are substantially ionic, the CFT and LFT treatments are useful though not exact. In the MO method, the ligand-atom orbitals and all of the valence-shell orbitals of the metal atom are presumed to interact to form molecular orbitals.

The interaction of a metal ion from the first transition series and an octahedral set of ligands that interact only through orbitals directed toward the metal ion results in the separation of the d orbitals of the metal ion into two sets of molecular orbitals; a t_{2g} set and a higher energy e_g set. This is the same pattern as that obtained in the CFT treatment, but the difference is that now the t_{2g} and e_g orbitals are regarded not as pure d orbitals but as molecular orbitals, having both metal d orbital and ligand orbital components. Thus, the modifications of CFT that lead to LFT—that is, inclusion of covalence effects—are in harmony with the basic ideas of the MO treatment.

II. The chemistry of the individual transition elements

Although the transition elements have many general chemical similarities, each one has a detailed chemistry of its own. The closest relationships are usually to be found among the three elements in each vertical group in the periodic table, although within each group the element of the first series usually differs more from the other two than they differ from each other. Most of the first series elements are more familiar and technically important than the heavier members of their vertical group. Thus, it is convenient to discuss first each of the metals of the first transition series and then to discuss the remaining ones in pairs.

THE ELEMENTS OF THE FIRST TRANSITION SERIES

Before considering in detail the chemistry of the individual elements, a few of the chemical trends to be found in the first transition series may be summarized.

General chemical trends of the first transition series

1. From titanium to manganese the highest valence exhibited, which usually is found only in oxo compounds, fluorides, or chlorides, corresponds to the total number of $3d$ and $4s$ electrons in the atom. The stability of this highest oxidation state decreases from titanium(IV) to manganese(VII). Following manganese—that is, for iron, cobalt, and nickel—oxidation states corresponding to the loss of all $3d$ and $4s$ electrons do not occur; higher oxidation states in general become progressively more difficult to attain because the increasing nuclear charge causes the $3d$ electrons to be more tightly bound. Very high oxidation states occur only for chromium(V, VI), manganese(V, VI, VII), and iron(V, VI) and apart from the fluorides, such as chromium(V) fluoride, CrF_5, and chromium(VI) fluoride, CrF_6, and oxofluorides such as manganese(VII) trioxide fluoride, MnO_3F, the main chemistry in these oxidation states is that of oxo anions such as manganate(VII), MnO_4^-; chromate(VI), CrO_4^{2-}; and ferrate(VI), FeO_4^{2-}. All of these compounds are powerful oxidizing agents.
2. The oxides of each element become more acidic with increasing oxidation number, and the halides become more covalent and susceptible to hydrolysis.
3. In the oxo anions characteristic of the higher valence states the metal atom is tetrahedrally surrounded by oxygen atoms, whereas in the oxides formed in the lower valence states the atoms are usually octahedrally coordinated.
4. In the oxidation states II and III, complexes in aqueous solution or in crystals are usually four-, five- or six-coordinated.
5. Oxidation states lower than II are not found in the ordinary chemistries of the transition elements, except for copper. The lower oxidation states are, however, attainable for all the elements using ligands of the carbon monoxide type.

It should be emphasized that the occurrence of a given oxidation state, as well as the stereochemistry of the compounds formed in that state, depend very critically on the experimental conditions and that species having no independent existence under ordinary conditions of temperature and pressure in air may well be the dominant species under other conditions. Thus a transition-metal ion may be obtained in a particular configuration that is difficult to produce by other means through incorporation of the ion into a crystalline host lattice, as well as by using ligands of rigid geometry. Therefore, the principal types of compounds and stereochemistries mentioned in the following descriptions are not the only ones possible for the elements, though they are the most common.

Oxidation states

The oxidation state II is important for all of the elements in the first transition series, which form well-defined binary compounds such as oxides and halides that are essentially ionic in nature in that oxidation state. With the exception of titanium, they also form well-defined aquo ions formulated $[M(H_2O)_6]^{2+}$.

All of the elements form some compounds in oxidation state III. That is the highest oxidation state known for copper and is not a stable one in its aqueous chemistry;

oxidation state III is important, however, in the normal chemical compounds of the elements. The fluorides and oxides of those elements in oxidation state III are generally ionic in nature, although the chlorides and bromides have more covalent character. The oxidation state IV is important only for the earlier elements, namely, titanium and vanadium: for chromium, manganese, iron, cobalt, and nickel, the state IV is found mainly in fluorides, fluoro complex anions, and some other unusual situations.

For the ions of the first transition series, the spectroscopic and magnetic properties can be accounted for quite well using crystal- or ligand-field theory; magnetic properties are due primarily to the unpaired spins with only secondary effects from orbital angular momentum superimposed. For the heavier transition elements, the interpretation of magnetic properties is much more difficult.

Titanium. The preparation of pure titanium is difficult because of its reactivity. Titanium cannot be obtained by the common method of reducing the oxide with carbon because a very stable carbide is readily produced, and, moreover, the metal is quite reactive toward oxygen and nitrogen at elevated temperatures. Therefore, special processes have been devised. One of the ores, such as ilmenite ($FeTiO_3$) or rutile (TiO_2), is treated at red heat with carbon and chlorine to yield titanium tetrachloride, $TiCl_4$, which is fractionally distilled to eliminate impurities such as ferric chloride, $FeCl_3$. The $TiCl_4$ is then reduced with molten magnesium at about 800° C (1,500° F) in an atmosphere of argon, and metallic titanium is produced as a spongy mass from which the excess of magnesium and magnesium chloride can be removed by volatilization at about 1,000° C (1,800° F). The sponge may then be fused in an atmosphere of argon or helium in an electric arc and be cast into ingots. On the laboratory scale, extremely pure titanium can be made by vaporizing the tetraiodide, TiI_4, in very pure form and decomposing it on a hot wire in vacuum.

Titanium production

The atoms are arranged in a hexagonal, close-packed lattice in titanium, which resembles other transition metals such as iron and nickel in being hard, refractory, and a good conductor of heat and electricity. It is quite light in comparison to other metals of similar mechanical and thermal properties, however, as well as unusually resistant to certain types of corrosion, and therefore it has come into demand for special applications in engineering.

Although titanium is rather unreactive at ordinary temperatures, it combines directly with many nonmetals, such as hydrogen, the halogens, oxygen, nitrogen, carbon, boron, silicon, and sulfur at elevated temperatures. The resulting nitride (TiN), carbide (TiC), and borides (TiB and TiB_2) are interstitial compounds that are very stable, hard, and refractory. Titanium is not attacked by mineral acids at room temperature or by hot aqueous alkali; it dissolves in hot hydrochloric acid, giving trivalent titanium species, and hot nitric acid converts it into a hydrous oxide that is rather insoluble in acid or base. The best solvents for the metal are hydrofluoric acid or other acids to which fluoride ions have been added; such mediums dissolve titanium and hold it in solution because of the formation of fluoro complexes.

Divalent titanium. The chemistry of divalent titanium is rather restricted. The well-defined compounds are titanium(II) chloride ($TiCl_2$), bromide ($TiBr_2$), iodide (TiI_2), and oxide (TiO). The halides are best obtained by reduction of the tetrahalides with titanium metal or by the decomposition of the trihalides at high temperature. The oxide, which can be made by heating TiO_2, titanium(IV) oxide, with titanium, has the same type of crystal structure as sodium chloride, but it is usually non-stoichiometric (*i.e.*, the component substances are not characteristically proportional).

Trivalent titanium. Many compounds are formed by trivalent titanium, both in the solid state and in solution. The more important solid compounds are the trichloride, which occurs in several crystalline forms, and the oxide, Ti_2O_3. One form of the trichloride, formed from the tetrachloride, is particularly important as a catalyst in the stereospecific polymerization of propylene to make the useful polymer polypropylene.

Aqueous solutions of trivalent titanium containing the hexaquotitanium(III) ion, $[Ti(H_2O)_6]^{3+}$, can be readily obtained by reducing aqueous quadrivalent titanium either electrolytically or with zinc. The violet solutions are oxidized by atmospheric oxygen and must therefore be kept in an inert atmosphere; they often are used as fairly rapid, mild reducing agents in volumetric analysis. Titanium in the trivalent state also forms a number of octahedral complexes, such as hexafluorotitanate(III) (TiF_6^{3-}), hexachlorotitanate(III), ($TiCl_6^{3-}$), and a number of others containing neutral ligands.

Tetravalent titanium. Oxidation state IV is the most important one for titanium. The dioxide, TiO_2, occurs in three crystal modifications, rutile, anatase, and brookite, all found in nature, and in all the crystal forms the dioxide is colourless when pure and is often employed as a white pigment. A hydrated form of the dioxide is obtained by adding a base to solutions of quadrivalent titanium.

The four halides, TiF_4, $TiCl_4$, $TiBr_4$, and TiI_4, are known. The most important, the tetrachloride, is a colourless liquid—melting point −23° C (−9° F), boiling point 136° C (277° F)—with a pungent odour that fumes strongly in moist air and is vigorously, though not violently, hydrolyzed by water to give the dioxide and hydrochloric acid.

Titanium tetrachloride

A characteristic reaction of aqueous solutions of tetravalent titanium is the development of an intense orange colour when hydrogen peroxide is added, and this reaction can be used for the colorimetric determination of either titanium or hydrogen peroxide.

Tetravalent titanium forms a number of complexes, including such species as hexafluorotitanate(IV), TiF_6^{2-}, and hexachlorotitanate(IV), $TiCl_6^{2-}$, and many molecular complexes that form upon the addition of two neutral ligands to $TiCl_4$. Examples of the latter are tetrachlorobis(diethyl ether)titanium(IV), $TiCl_4[O(C_2H_5)_2]$, and tetrachlorobis(triethylphosphine oxide)titanium(IV), $TiCl_4[OP(C_2H_5)_3]_2$.

Other compounds of tetravalent titanium include anhydrous titanium(IV) nitrate, $Ti(NO_3)_4$ (a volatile compound made by the action of dinitrogen pentoxide, N_2O_5, on the hydrated form of the compound), which is an extremely reactive oxidizing agent toward organic substances, and the sulfate, the structural nature of which is not known.

Vanadium. The preparation of very pure vanadium is difficult because the metal is quite reactive toward oxygen, nitrogen, and carbon at elevated temperatures. Because the major commercial use of vanadium is in steel and cast iron, to which it lends ductility and shock resistance, vanadium is produced commercially mainly in the form of an iron alloy called ferrovanadium. When the very pure metal is required, it may be obtained by processes described in the foregoing discussion of titanium. Very pure vanadium metal resembles titanium in being quite corrosion resistant, hard, and steel gray in colour. In the massive state it is not attacked by air, water, alkalies, or nonoxidizing acids other than hydrofluoric acid. It dissolves in nitric acid, concentrated sulfuric acid, or aqua regia and at high temperatures will combine with nearly all nonmetals. For vanadium the important oxidation states are II, III, IV, and V.

Preparation and uses of vanadium

Divalent vanadium. The chemistry of the divalent state is rather limited. The black vanadium(II) oxide, VO, has a rocksalt type of structure but shows a marked tendency to be non-stoichiometric: it can be obtained with from 45 to 55 atom-percent oxygen. It has a metallic lustre and rather good electrical conductivity of a metallic nature and dissolves in mineral acids to give solutions containing the vanadium(II) ion, V^{2+}. Electrolytic or zinc reduction of acidic solutions of vanadium in its higher oxidation states produces violet, air-sensitive solutions that also contain the V^{2+} ion, which is present as an octahedral hexaquo species, $[V(H_2O)_6]^{2+}$. Such solutions are very strong reducing agents and attack even water, with evolution of hydrogen. The hexaquo ion is

present in various salts as, for example, the type of double sulfate known as Tutton salts, $M_2[V(H_2O)_6](SO_4)_2$, in which M is an alkali-metal ion.

Trivalent vanadium. The chemistry of the trivalent state is more extensive. All four halides are known as well as the black, refractory vanadium(III) oxide, V_2O_3, which can be made by reduction of vanadium(V) oxide, V_2O_5, with hydrogen or carbon monoxide. The trioxide has a pronounced tendency to be non-stoichiometric, and it is entirely basic in nature, dissolving in acids to give solutions of the vanadium(III) ion, V^{3+}, or its complexes. A hydrous form of the oxide can be precipitated upon addition of hydroxides to such solutions. The hexaquovanadium(III) ion, $[V(H_2O)_6]^{3+}$, is blue in colour and subject to oxidation by air. There are a variety of complexes of the V^{3+} ion, especially with anions, such as tris(oxalato)vanadate(III), $[V(C_2O_4)_3]^{3-}$; hexacyanovanadate(III), $[V(CN)_6]^{3-}$; and hexakis(isothiocyanato)vanadate(III), $[V(NCS)_6]^{3-}$.

Tetravalent vanadium. The oxidation state IV of vanadium is the most stable under ordinary conditions. The most important compounds of tetravalent vanadium are those containing the vanadyl(IV) (VO^{2+}) unit, which can persist through a variety of chemical reactions. It readily unites with either four or five ligands to form either five- or six-coordinated complexes. The aqueous pentaaquovanadyl(IV) ion, $[VO(H_2O)_5]^{2+}$, is blue and occurs in a number of salts. The vanadium–oxygen bond is essentially a double bond with a length in the range of 1.5–1.6 Å. Vanadium(IV) fluoride (VF_4), chloride (VCl_4), and bromide (VBr_4) are stable solid compounds, but there is only indirect evidence for the existence of the iodide, VI_4, in the vapour phase. The dark blue vanadium(IV) oxide, VO_2, can be prepared by mild reduction of vanadium(V) oxide, V_2O_5.

Vanadium(V) oxide

Pentavalent vanadium. In oxidation state V, vanadium has an extensive chemistry. Vanadium(V) oxide, V_2O_5, is obtained by burning the finely divided metal in an excess of oxygen but is generally contaminated with small amounts of the lower oxides. It is amphoteric in character; *i.e.*, it dissolves in either acids or bases. Solutions so obtained are moderately strong oxidizing agents as indicated, for example, by the fact that chlorine is evolved when the oxide V_2O_5 is dissolved in hydrochloric acid. In sodium hydroxide solution, V_2O_5 dissolves to give colourless solutions containing vanadate ions. On addition of acid to about pH 6.5 the solutions become bright orange and remain so until, at around pH 2, a brown precipitate of V_2O_5 is formed; the precipitate redissolves when more acid is added and the dioxovanadium ion, VO_2^+, is formed. Vanadate solutions are quite complex in nature and still not completely understood; available data indicate the presence of mono-, di-, and trinuclear species, formulated $[VO_3OH]^{2-}$, $[V_2O_6(OH)]^{3-}$, and $[V_3O_9]^{3-}$, in basic solutions, and polyvanadate ions, such as $V_{10}O_{28}^{6-}$, in acid solution.

The only halide of pentavalent vanadium is white vanadium(V) fluoride, VF_5, which is very volatile—melting point 19.5° C (67.1° F), boiling point 48° C (118° F). The action of halogens on the oxide V_2O_5 results in the formation of the oxohalides, vanadyl(V) fluoride (VOF_3), chloride ($VOCl_3$), and bromide ($VOBr_3$), which all have structures that are polymeric in the solid because of bridging halogen atoms.

Chromium. The name of the element chromium (from Greek *chrōmos*, "colour") connotes the pronounced and varied colorations of chromium compounds. The red colour of ruby and the green colour of emerald, to mention only gems, are due to small amounts of chromium. The free metal is never found in nature; most ores consist of the mineral chromite, the ideal formula of which is $FeCr_2O_4$. Natural deposits are usually contaminated with magnesium, aluminum, and silica and their chromium content varies from 42 to 56 percent. One of the chief uses of chromium is in ferrous alloys, for which the pure metal is not required. Accordingly, chromite is often reduced with carbon in a furnace, producing the alloy ferrochromium, which contains iron and chromium in an atom ratio of approximately 1 to 2. To obtain pure chromium, chromite is first treated with molten alkali and oxygen, converting all of the chromium to the alkali chromate, and the latter is dissolved in water and eventually precipitated as sodium dichromate, $Na_2Cr_2O_7$. The dichromate is then reduced with carbon to chromium(III) oxide, Cr_2O_3, and that oxide in turn reduced with aluminum to give the chromium metal.

The metal is white, hard, lustrous, and brittle and is extremely resistant to ordinary corrosive reagents; this resistance accounts for its extensive use as an electroplated protective coating. Chromium metal dissolves rather readily in nonoxidizing mineral acids—for example, hydrochloric or sulfuric acids; it does not dissolve in cold aqua regia or in nitric acid because of a curious phenomenon known as passivation, in which the metal presumably becomes covered with a thin unreactive coating. At elevated temperatures chromium unites directly with the halogens or with sulfur, silicon, boron, nitrogen, carbon, or oxygen.

While chromium forms compounds in all formal oxidation states from −2 to +6, the oxidation states +2, +3, and +6 are of principal importance.

Binary compounds. The important binary compounds of chromium are the halides and the oxides. Divalent chromium forms all four halides, with chromium(II) chloride, $CrCl_2$, being the most common and important of these. It dissolves in water to give a blue solution containing the chromium(II) ion, Cr^{2+}. Trivalent chromium also forms all four halides, but again only the chloride is important. The anhydrous substance, chromium(III) chloride, $CrCl_3$, which can be prepared by the action of thionyl chloride, $SOCl_2$, on the hydrated chloride, sublimes in a stream of chlorine gas at about 600° C (about 1,100° F); but if heated to such a temperature in the absence of chlorine it decomposes to chromium(II) chloride ($CrCl_2$) and chlorine. The flaky appearance of $CrCl_3$ is a consequence of its crystal structure, which is of an unusual type. It consists of close-packed layers of chloride ions with metal ions present only between every other layer; because the layers between which there are no metal ions are only weakly held together, the crystal has pronounced cleavage parallel to the layers. The only stable halides formed in higher oxidation states are the tetrafluoride, pentafluoride, and hexafluorides (CrF_4, CrF_5, and CrF_6, respectively).

Oxides of chromium

Three oxides of chromium are important, Cr_2O_3, CrO_2, and CrO_3. The green oxide, Cr_2O_3, which has the same structure as corundum (aluminum oxide), is formed on burning the metal in oxygen, on thermal decomposition of CrO_3 or of ammonium dichromate, or by roasting the hydrous oxide, $Cr_2O_3 \cdot nH_2O$. The latter, commonly called chromic hydroxide despite its variable water content and the lack of direct evidence that it contains hydroxide ions, is precipitated on addition of alkali hydroxide to solutions of chromic salts. If Cr_2O_3 is ignited strongly it becomes inert toward both acid and base, but otherwise it and its hydrous form are amphoteric (capable of acting either as an acid or as a base), dissolving readily in acid to give the hexaaquochromium(III) ion, $[Cr(H_2O)_6]^{3+}$, and in concentrated alkali to form anions the exact natures of which are not known. The oxide Cr_2O_3 can be fused with the oxides of several bivalent metals to give compounds of general formula $M^{2+}Cr_2O_4$ (M^{2+} representing a dipositive ion), which are mixed metal oxides having the spinel structure (spinel is a natural oxide of magnesium and aluminum, $MgAl_2O_4$); many of these mixed oxides are of interest because of their magnetic properties.

Chromium(IV) oxide, CrO_2, which is normally synthesized by hydrothermal reduction of CrO_3, is ferromagnetic and has metallic conductance.

Chromium(VI) oxide, CrO_3, is obtained as an orange-red precipitate upon adding sulfuric acid to solutions of sodium or potassium dichromate. The red solid is thermally unstable above its melting point, 197° C (387° F); after various intermediate stages, it loses oxygen and transforms to Cr_2O_3; and it is readily soluble in water, producing highly poisonous solutions that constitute the usual medium for the electrodeposition of chromium.

Solutions of CrO_3 react vigorously and sometimes explosively with organic matter; however, such solutions are often used for controlled oxidations in organic synthesis, for which purpose solutions in acetic acid are very convenient.

As noted in the foregoing, chromium oxides supported on other oxides, such as alumina, have important applications as industrial catalysts.

Aqueous chemistry. The aqueous chemistry of chromium centres around the Cr^{2+} ion, the Cr^{3+} ion, the complexes of these ions, and the chromates, CrO_4^{2-} and $Cr_2O_7^{2-}$. Aqueous solutions of the chromium(II) ion, Cr^{2+}, which is sky-blue in colour, are best prepared by dissolving chromium metal in dilute mineral acids in the absence of oxygen, but they may also be prepared by reducing solutions of trivalent chromium with zinc amalgam or electrolytically. Various hydrated salts can be crystallized from these solutions—*e.g.*, $CrSO_4 \cdot 5H_2O$, $CrCl_2 \cdot 4H_2O$, and $Cr(ClO_4)_2 \cdot 6H_2O$.

The chromium(II) ion is readily oxidized by air, and therefore solutions must be protected. Even so they decompose, at rates varying with the acidity and the anions present, reducing water with the liberation of hydrogen.

In nearly all chromium(II) compounds the coordination is octahedral. Because of the electronic structure of the chromium(II) ion, however, the octahedron is generally quite distorted because of the Jahn-Teller effect (see above). In nearly all compounds of chromium(II), that ion is in the high-spin electronic configuration, and occupation of one of the antibonding e_g orbitals by a single electron leads to a lengthening of two of the bonds in the octahedron.

Trivalent chromium

The chemistry of trivalent chromium is very extensive. There are literally thousands of complexes that are, with almost no exceptions, of octahedral stereochemistry. The principal characteristic of these complexes in aqueous solution is their relative kinetic inertness. The hexaaquochromium(III) ion, $[Cr(H_2O)_6]^{3+}$, which has a regular octahedral structure, occurs in aqueous solution and in numerous salts, such as the violet hydrate, $[Cr(H_2O)_6]Cl_3$, and in an extensive series of chromium alums represented by the formula $MCr(SO_4)_2 \cdot 12H_2O$, in which M represents an alkali cation such as potassium, K^+. The aquo ion is readily hydrolyzed (*i.e.*, transformed by reaction with water) to the hydroxopentaaquochromium ion, $[Cr(H_2O)_5OH]^{2+}$, and as acidity is further decreased that substance condenses to give a dimeric hydroxo-bridged species and, ultimately, polymeric materials of high molecular weight that precipitate as dark green gels.

The chromium(III) ion has a particular affinity for ammonia and other ligands in which amine-type nitrogen atoms are coordinated. An enormous number of such complexes, called ammines, have been prepared and their chemistry investigated in considerable detail. In addition, many other complexes, including anionic ones such as hexafluorochromate(III), CrF_6^{3-}, and hexacyanochromate(III), $Cr(CN)_6^{3-}$, are formed. The slow reactivity of chromium(III) complexes in ligand replacement reactions accounts in part for the enormous variety of known complexes, because many that are not thermodynamically stable can nevertheless be isolated.

The electronic, spectral, and magnetic properties of the octahedrally coordinated chromium(III) ion are relatively uncomplicated but are of considerable importance. All compounds containing octahedrally coordinated chromium(III) ion are paramagnetic (weakly magnetizable) because of the presence of three unpaired electrons in the t_{2g} orbitals. The visible absorption bands that account for the colour of the chromium(III) ion in its various compounds are attributable to electronic transitions from the ground (*i.e.*, lowest energy) state. The presence of chromium(III) ions replacing some aluminum ions in α-Al_2O_3 accounts for the red colour of the mineral ruby. In addition, however, there is another important aspect to the electronic behaviour of the chromium(III) ion in this environment. Besides the transitions that cause the red colour, there are two transitions that give rise to extremely sharp, though weak, lines. In the high-energy states that result from these sharp transitions, there is but a single unpaired electron. These states play a key role in the operation of the laser that uses ruby crystals.

Chromate and dichromate ions

The chromate(VI), CrO_4^{2-}, and dichromate(VI), $Cr_2O_7^{2-}$, ions have been mentioned previously as examples of oxo ions of the transition elements. They are the most important species formed by chromium in its six-valent state. The pH-dependent equilibrium between the chromate and dichromate ions is quite labile (*i.e.*, readily undergoes change), and upon the addition of cations (*e.g.*, barium ion, Ba^{2+}; lead ion, Pb^{2+}; and silver ion, Ag^+) that form insoluble chromates, the chromate, not the dichromate, ion is precipitated. Solutions of chromates and dichromates are powerful oxidizing agents and are often so used in preparative chemistry and in analytical chemistry. Unlike the analogous oxo species of molybdenum and tungsten, the chromates have little tendency to form more complex polynuclear oxo species, although trichromates, $Cr_3O_{10}^{2-}$, and tetrachromates, $Cr_4O_{13}^{2-}$, are known.

Manganese. As with titanium, vanadium, and chromium, the highest oxidation state (+7) of manganese corresponds to the total number of 3*d* and 4*s* electrons. That state occurs only in the oxo species manganate(VII) (MnO_4^-), manganese(VII) oxide (Mn_2O_7), and manganese(VII) trioxide fluoride (MnO_3F), which show some similarity to corresponding compounds of the halogens—for example, in the instability of the oxide. Manganese in oxidation state +7 is powerfully oxidizing, usually being reduced to divalent manganese. The intermediate oxidation states are known, but, except for some compounds in the +3 and +4 states, they are not particularly important.

Manganese, first recognized as an element by the Swedish chemist Carl Wilhelm Scheele in 1774, is second only to iron among the transition elements in its abundance in the Earth's crust and is roughly similar to iron in its physical and chemical properties but is harder and more brittle. Although it is widely distributed, manganese occurs in a number of substantial deposits, mainly the oxides, of which the mineral pyrolusite (manganese(IV) oxide, MnO_2) is the most important. Manganese is quite electropositive, dissolving very readily in dilute non-oxidizing acids. Although relatively unreactive toward nonmetals at room temperature, it reacts with many at elevated temperatures. Thus manganese burns in chlorine to give manganese(II) chloride, $MnCl_2$; reacts with fluorine to give manganese(II) and (III) fluorides, MnF_2 and MnF_3; and burns in nitrogen at about 1,200° C (2,200° F) to give manganese(II) nitride, Mn_3N_2, and in oxygen to give trimanganese tetroxide Mn_3O_4. Manganese also combines directly with boron, carbon, sulfur, silicon, or phosphorus, but not with hydrogen. The most important oxidation states for manganese are +2, +3, +7.

Divalent manganese. The most important and generally the most stable oxidation state of manganese is +2, exhibited in neutral or acid aqueous solution in the very pale pink hexaquomanganese(II) ion $[Mn(H_2O)_6]^{2+}$, which is quite resistant to oxidation. In basic mediums, however, manganese(II) hydroxide, $Mn(OH)_2$, is formed, which is rather easily oxidized even by air. The important binary compounds include the oxide (MnO), the four halides (MnF_2, $MnCl_2$, $MnBr_2$, and MnI_2), the sulfide (MnS), the selenide (MnSe), and the telluride (MnTe). In addition to the anhydrous halides, hydrated species are readily formed. Although divalent manganese forms many complexes, it is not as strongly bound to ligands as are other divalent cations in the first transition series. The coordination geometry for complexes of Mn^{2+} is usually octahedral, although certain tetrahedral complexes are known. The manganese(II) ion in tetrahedral environments has a green fluorescence and is often used in making commercially important phosphors. For example, Mn^{2+} ions can be substituted for some of the zinc ions (Zn^{2+}) in zinc orthosilicate, Zn_2SiO_4.

Trivalent manganese. Oxidation state +3 occurs in the oxide Mn_3O_4, which as a mineral is called haussman-

nite (which also contains Mn^{2+}), in manganese(III) oxide hydroxide, MnO(OH), and in the mineral braunite (manganese(III) oxide, Mn_2O_3); it also occurs in a number of mixed metal oxide systems. The halides of trivalent manganese are limited to the fluoride, a red-purple solid instantaneously hydrolyzed by water, and the black trichloride, which is not stable above −40° C (−40° F). The manganese(III) ion, Mn^{3+}, can be obtained in aqueous solution by oxidation of Mn^{2+} solutions (by electrolysis or by treatment with the persulfate ion) or by reduction of the manganate(VII) (permanganate) ion, MnO_4^-, under appropriate conditions; but it cannot be obtained in high concentrations because it is capable of oxidizing water. Manganese(III) ion also has a strong tendency to disproportionate, giving Mn^{2+} and manganese(IV) oxide, but it can be stabilized by the formation of certain complexes.

Tetravalent manganese and higher oxidation states. There is a rather restricted chemistry for tetravalent manganese, but one such compound, manganese(IV) oxide (manganese dioxide, MnO_2), is the black mineral pyrolusite, an important ore. A tetrafluoride and the sulfate, $Mn(SO_4)_2$, as well as a few complexes are also known, but there is no aqueous chemistry of tetravalent manganese. In higher oxidation states, one of the best known manganese compounds is potassium manganate(VII) (permanganate), $KMnO_4$. The manganate(VII) ion and its salts have an intense purple colour, and crystalline materials appear almost black. Potassium manganate(VII) is manufactured on a large scale by electrolytic oxidation of basic solutions of lower valent manganese compounds. Solutions of manganate(VII) are unstable and decompose slowly when acidic, but decomposition of neutral or slightly alkaline solutions is immeasurably slow. The decomposition is catalyzed by light so that standard manganate(VII) solutions must be stored in dark bottles. The manganate(VII) ion is a powerful oxidizing agent in both acid and basic solutions and is often used as an oxidant, both for preparative purposes and in analytical chemistry.

Potassium manganate (VII)

Iron. Hundreds of mineral species contain iron as a constituent, and igneous rocks average 5 percent iron content. The major iron ores are the minerals hematite [iron(III) oxide, Fe_2O_3], magnetite [triiron tetroxide, Fe_3O_4], limonite [iron(III) oxide hydroxide, FeO(OH)], and siderite [iron(II) carbonate, $FeCO_3$].

For the element iron the trends already noted in the relative stabilities of oxidation states among elements of the first transition series are continued, except that there is no compound or chemically important circumstance in which the oxidation state of iron is equal to the total number of its valence shell electrons, eight; the highest known oxidation state is +6, which is rare and unimportant. Even the trivalent state, which is important at the position of chromium in the periodic table, loses ground to the divalent state at the position of iron. This trend continues in the remaining elements with the sole exception of trivalent cobalt, which is stable in a host of complexes.

The Mössbauer effect. Iron compounds are amenable to study by taking advantage of a phenomenon known as the Mössbauer effect (the phenomenon of a gamma ray being absorbed and reradiated by a nucleus without recoil). Although the Mössbauer effect has been observed for about one-third of the elements, it is particularly for iron (and to a lesser extent tin) that the effect has been a major research tool for the chemist. In the case of iron the effect depends on the fact that the nucleus of iron-57 can be excited to a high energy state by the absorption of gamma radiation of very sharply defined frequency that is influenced by the oxidation state, electron configuration, and chemical environment of the iron atom and can thus be used as a probe of its chemical behaviour.

Pure iron is a white, lustrous metal that is not particularly hard and is quite reactive. As commonly available, however, iron almost always contains small amounts of carbon, which modify its properties greatly. In a very finely divided state metallic iron is pyrophoric (*i.e.*, it ignites spontaneously). It combines vigorously with chlorine on mild heating and also with a variety of other nonmetals, including all of the halogens, sulfur, phosphorus, boron, carbon, and silicon (the carbide and silicide phases play major roles in the technical metallurgy of iron). Metallic iron dissolves readily in dilute mineral acids. With nonoxidizing acids and in the absence of air divalent iron is obtained; with air present or when warm dilute nitric acid is used, some of the iron goes into solution as the iron(III) ion, Fe^{3+}. Very strongly oxidizing mediums, for example, concentrated nitric acid or acids containing dichromate, passivate iron (*i.e.*, cause it to lose its normal chemical activity), however, much as they do chromium (see above). Air-free water and dilute air-free hydroxides have little effect on the metal, but it is attacked by hot concentrated sodium hydroxide.

Under normal atmospheric conditions iron rusts to form hydrated oxides, a process that occurs in two steps: first, iron dissolves in the acid solution produced by the moisture and the carbon dioxide of the air, to form ferrous iron—*i.e.*, iron(II)—and liberate hydrogen; second, oxygen from the air oxidizes the ferrous iron to form hydrated iron(III) oxide.

Rusting of iron

The stable structure of iron up to 766° C (1,411° F) is that of a crystal form called body-centred cubic, and it is ferromagnetic (*i.e.*, capable of being permanently magnetized). Above this temperature the structure is retained but the magnetic properties change to simple paramagnetic (*i.e.*, capable of being only weakly magnetized and only as long as the magnetizing field is present). At 906° C (1,663° F) the structure changes to a crystal form called cubic close-packed; but there is another structural change at 1,401° C (2,554° F), and iron reverts to the body-centred cubic structure.

Iron oxides. Despite differences in oxidation state, it is convenient to discuss the oxides of iron together because there are fundamental structural relationships between them. Three iron oxides are known, all of which have some tendency to occur in a non-stoichiometric condition, but the ideal compositions of the phases are FeO, Fe_2O_3, and Fe_3O_4. Iron(II) oxide, FeO, can be obtained, by thermal decomposition of iron(II) oxalate in a vacuum, as a pyrophoric black powder that becomes less reactive if heated to higher temperatures. The crystalline substance can be obtained only by establishing equilibrium conditions at high temperature and then rapidly quenching the system, because at lower temperatures iron(II) oxide is less stable than iron and triiron tetroxide, and slow cooling allows disproportionation (*i.e.*, separation into the more oxidized and the more reduced substances). FeO has the rock-salt structure. It is almost always encountered in an iron-deficient condition, typically having a composition of $Fe_{0.95}O$ (*i.e.*, in the proportion of 95 atoms of iron to 100 atoms of oxygen). Essentially stoichiometric FeO (*i.e.*, having the atomic ratio of one to one) has been prepared from $Fe_{0.95}O$ and iron metal at 777° C (1,431° F) and 50 kilo-atmospheres pressure.

Hydrous iron(III) oxide, which can be precipitated from solutions of iron(III) (ferric) ion by ammonia and other bases, exists in several forms that depend on the method of preparation. Upon heating any of these forms above 200° C (about 400° F), the water is driven off and the final product is the red-brown compound designated α-Fe_2O_3, which is identical to the mineral hematite. It has the same structure as corundum (Al_2O_3), in which the oxide ions form a hexagonally close-packed array (in each layer of the array, every ion is tangent to six others) with the metal ions occupying octahedral interstices. By careful oxidation of triiron tetroxide, Fe_3O_4, or by heating a mineral called lepidocrocite (one of the modifications of FeO(OH)) another type of iron(III) oxide, designated γ-Fe_2O_3, is obtained. The structure of the latter phase can be regarded as a cubic close-packed array (every ion is tangent to four others) of oxide ions with iron(III) ions distributed randomly over both the octahedral and the tetrahedral interstices.

Finally, there is triiron tetroxide, Fe_3O_4, a mixed iron(II)–iron(III) oxide that occurs in nature in the form of black, octahedral crystals of the mineral magnetite; it can

be made by ignition of Fe_2O_3 above 1,400° C (2,550° F) and has a structure related to that of the mineral spinel ($MgAl_2O_4$), in which the iron(II) ions all occupy octahedral interstices while the iron(III) ions are half in tetrahedral and half in octahedral interstices of a cubic close-packed array of oxide ions. Magnetite has electrical conductivity 10^6 times that of Fe_2O_3, probably because of rapid oscillation between oxidation states of iron atoms occupying different sites in the structure.

Divalent iron. The four halides of divalent iron are all known in both anhydrous and hydrated forms. Iron(II) iodide and iron(II) bromide can be prepared by direct reaction of the elements; iron must be present in excess in the case of the bromide, $FeBr_2$. For the fluoride, FeF_2, and the chloride, $FeCl_2$, it is necessary to use hydrogen fluoride, HF, or hydrogen chloride, HCl, rather than fluorine or chlorine in order to avoid formation of the trihalides. Iron metal dissolves in the aqueous hydrohalic acids, and from these solutions the hydrated halides $FeF_2 \cdot 8H_2O$ (colourless), $FeCl_2 \cdot 6H_2O$ (pale green), and $FeBr_2 \cdot 4H_2O$ (pale green) may be crystallized.

Divalent iron forms salts with virtually every stable anion, and the salts are generally green, hydrated, crystalline substances, isolated by evaporation of aqueous solutions. Iron(II) (ferrous) iron exists in aqueous solution as the hexaquoferrate(II) ion $[Fe(H_2O)_6]^{2+}$, which also occurs in many of the crystalline salts, such as the sulfate and the perchlorate. An important double salt that contains this ion is Mohr's salt, $(NH_4)_2SO_4 \cdot FeSO_4 \cdot 6H_2O$, which is fairly stable toward both air oxidation and loss of water and is commonly used in volumetric analysis to prepare standard solutions of ferrous iron. Most other ferrous compounds are more or less susceptible to superficial oxidation by air or loss of water of crystallization, or both, behaviour that is well illustrated by $FeSO_4 \cdot 7H_2O$, which slowly effloresces and becomes yellow brown. The carbonate, hydroxide, and sulfide of divalent iron may be precipitated from aqueous solutions of ferrous salts. Both the carbonate and the hydroxide are white, but they quickly darken in the presence of air as a result of oxidation. The sulfide undergoes slow oxidation. Iron(II) hydroxide, $Fe(OH)_2$, is somewhat amphoteric, readily redissolving in acids and also in concentrated sodium hydroxide. If 50 percent sodium hydroxide is boiled with finely divided iron and then cooled, blue-green crystals of tetrasodium hexahydroxoferrate(II), $Na_4[Fe(OH)_6]$, are obtained.

Aqueous solutions of the iron(II) ion are pale blue green in colour and susceptible to oxidation by molecular oxygen. Iron(II) forms a number of complexes, most of them octahedral; one particularly important example is the hexacyanoferrate(II) (ferrocyanide) ion, $Fe(CN)_6^{4-}$, which is extremely stable. Nearly all iron(II) complexes are high-spin with four unpaired electrons, but $Fe(CN)_6^{4-}$ is low-spin with a t_{2g}^6 configuration.

Trivalent iron. Iron(III) occurs in salts with most anions except those with which it is incompatible because of their character as reducing agents. Thus, no triiodide exists; the only trihalide commonly encountered is the chloride, and that is usually the hexahydrate, which forms as a yellow mass on evaporation of aqueous solutions of iron(III) (ferric) chloride. Salts with oxo anions, such as the perchlorate, nitrate, and sulfate, are generally pale pink to nearly white hydrates obtained by evaporation of aqueous solutions.

Iron(III) complexes

Among the most conspicuous and important features of the chemistry of trivalent iron in aqueous solution are its tendency to hydrolyze and to form complexes. Ferric iron has a high-spin d^5 configuration ($t_{2g}^3 e_g^2$) like that of divalent manganese; however, unlike manganese, its solutions generally exhibit a pronounced yellow to orange colour unless they are very strongly acidic. The cause of this colour is partial hydrolysis to hydroxo complexes such as those formulated $[Fe(H_2O)_5(OH)]^{2+}$, $[Fe(H_2O)_4(OH)_2]^{+}$, and $[Fe(H_2O)_4(OH)_2Fe(H_2O)_4]^{4+}$. Even at the rather acidic pH of 2 the extent of hydrolysis is considerable, and in order to have solutions that contain at least 99 percent of the iron in the form of the pale purple hexaquoferrate(III) ion, $[Fe(H_2O)_6]^{3+}$, the pH must be reduced to zero or less. As the pH is raised above 3, more highly condensed species begin to form, attainment of equilibrium becomes sluggish, and colloidal gels are formed. Ultimately, hydrous iron(III) oxide is precipitated as a red-brown gelatinous mass. There is no evidence of the existence of any definite iron(III) hydroxide, $Fe(OH)_3$.

Trivalent iron forms a large number of complexes, most of them octahedral, and the octahedron may be considered its characteristic coordination polyhedron. The affinity of trivalent iron for amine ligands is very low, and no simple complexes with such ligands exist in aqueous solution. Chelating amines, such as ethylenediaminetetracetic acid, form definite complexes, however, and iron may be sequestered (*i.e.*, rendered relatively unreactive) by the addition of such chelating agents to solutions containing small amounts of iron. In general, trivalent iron has its greatest affinity for ligands that coordinate through oxygen atoms—*e.g.*, phosphate ions, polyphosphate ions, and polyols such as glycerols and sugars —and forms fairly strongly complexes with the fluoride ion but not with the chloride ion. In extremely concentrated hydrochloric acid solutions the tetrahedral ion, tetrachloroferrate(III), $FeCl_4^-$, is formed and may be isolated as solid salts by using large cations. The complexes with thiocyanate have an intense red colour, a fact employed in sensitive qualitative and quantitative analytical tests for the iron(III) ion.

The cyanide ion forms the complex hexacyanoferrate(III), $[Fe(CN)_6]^{3-}$, which is exceedingly poisonous, in contrast to hexacyanoferrate(II) $[Fe(CN_6]^{4-}$. The reason for the difference lies in the kinetic lability of the iron(III) complex, $[Fe(CN)_6]^{3-}$, which dissociates rapidly, thereby supplying cyanide ions; whereas the iron(II) complex, $[Fe(CN)_6]^{4-}$, is kinetically inert.

Prussian blue

It has long been known that treating a solution of trivalent iron with $[Fe(CN)_6]^{4-}$ yields a blue precipitate called Prussian blue and that treating a solution of divalent iron with $[Fe(CN)_6]^{3-}$ yields a blue precipitate called Turnbull's blue. These substances are actually identical, and their true formula is $MFe_2(CN)_6$, in which M is sodium (Na^+), potassium (K^+), rubidium (Rb^+), but not lithium (Li^+), which is too small, or cesium (Cs^+), which is too big. The structure is made up of a cubic array of iron ions with cyanide ions along cube edges. Every other cube contains an M ion at its centre.

Cobalt. The trends toward decreased stability for very high oxidation states and increased stability of the +2 state relative to the +3 state, which have been evident through the series titanium, vanadium, chromium, manganese, iron, persist with cobalt. In fact there is a complete absence of oxidation states higher than +4 under chemically significant conditions, and even the latter may be represented by only a few incompletely characterized compounds. The +3 state is relatively unstable in simple compounds, but forms a host of low-spin complexes, most of them involving ammonia or amines as ligands. The oxidation state +1 is perhaps better known for cobalt than for any other element in the first transition series except copper.

The abundance of cobalt in the Earth's crust is relatively low, and the element is widely distributed; even the best cobalt ores contain only low concentrations of the element and require complex processing to concentrate and extract it. In general, little cobalt ore is mined for the cobalt content: the metal is recovered as a by-product from the ores of other metals, particularly copper and nickel.

Cobalt is a hard, bluish-white metal and, along with iron and nickel, is one of the three metals that are ferromagnetic at room temperature. It dissolves slowly in dilute mineral acids, does not combine directly with either hydrogen or nitrogen, but will combine, on heating, with carbon, phosphorus, or sulfur. Cobalt is also attacked by oxygen and by water vapour at elevated temperatures, with the result that cobalt(II) oxide, CoO, is produced.

Cobalt salts and oxides. In aqueous solutions that contain no complexing agents, the cobalt(III) (cobaltic) ion, Co^{3+}, is very unstable in comparison to the cobalt-

(II) (cobaltous) ion, Co^{2+}. Electrolytic or ozone oxidation of cold, acidic perchlorate solutions of Co^{2+}, however, yields the aqueous Co^{3+} ion, which appears to have a half-life of about a month at 0° C (32° F). At room temperature the cobalt(III) ion is rapidly reduced by water.

Oxides of cobalt

Cobalt forms only two well-defined oxides. Cobalt(II) oxide, an olive-green substance, is easily prepared by reaction of the metal with oxygen at high temperatures, by thermal decomposition of the carbonate or nitrate, and in other ways. It has the rock-salt structure and is antiferromagnetic at ordinary temperatures. When cobalt(II) oxide is heated at 400°–500° C (750°–900° F) in an atmosphere of oxygen, tricobalt tetroxide, Co_3O_4, is produced, a spinel-type compound containing Co^{2+} ions in tetrahedral interstices and diamagnetic Co^{3+} ions in octahedral interstices. There is no evidence for the existence of pure cobalt(III) oxide, Co_2O_3. Some oxide materials of uncertain composition, obtained by oxidation of cobalt(II) hydroxide, $Co(OH)_2$, with air or ozone, are known.

There are hydrated cobalt(II) salts with all common anions; they are easily obtained, for example, by reaction of cobalt(II) hydroxide, $Co(OH)_2$, with the appropriate acid. Virtually all such salts are red or pink and contain octahedrally coordinated cobalt(II) ions (Co^{2+}), in many cases the hexaquocobalt(II) ion, $[Co(H_2O)_6]^{2+}$. The hydroxide, $Co(OH)_2$, may be precipitated by strong bases as either a blue or pink solid, depending on conditions, but only the pink form is permanently stable. It is amphoteric, dissolving in acids to give cobalt(II) salts and in very concentrated alkali to give a deep blue solution containing the tetrahydroxocobaltate ion $[Co(OH)_4]^{2-}$. Cobalt(II) sulfide, CoS, can be precipitated from aqueous solutions as a black solid.

Few simple cobalt(III) salts are known. Anhydrous cobalt(III) fluoride, CoF_3, can be prepared by fluorination of the metal or of cobalt(II) chloride, $CoCl_2$, and the hydrate $CoF_3 \cdot 3.5H_2O$ is also known as a green powder that separates from electrolyzed solutions of Co^{2+} in 40 percent aqueous hydrofluoric acid. The blue cobalt(III) sulfate octadecahydrate, $Co_2(SO_4)_3 \cdot 18H_2O$, can be isolated by oxidation of solutions of cobalt(II) salts in sulfuric acid, and the hexaaquocobalt(III) ion, $[Co(H_2O)_6]^{3+}$, is also found in the alums such as dipotassium cobalt(II) sulfate dodecahydrate, $K_2Co(SO_4)_2 \cdot 12H_2O$.

Cobalt complexes. Divalent cobalt forms numerous complexes of several structural types. Octahedral and tetrahedral ones are most common, but there are a fair number of square ones as well as some that are five-coordinate. Divalent cobalt has a greater tendency to form tetrahedral complexes than any other transition metal, at least in part because, for an ion with seven *d* electrons, ligand-field stabilization energies are less unfavourable to the tetrahedral configuration relative to the octahedral than is the case for the ion of any other transition metal. The cobalt(II) ion is in fact the only commonly occurring ion with a configuration of seven *d* electrons. The hexaaquocobalt(II) ion $[Co(H_2O)_6]^{2+}$, is one of the most important octahedral complexes of divalent cobalt. Cobalt differs from all of the other first-row transition elements in that its aqueous solutions contain a small amount of the tetrahedral tetraaquo ion along with the octahedral hexaaquo ion.

Tetrahedral complexes of cobalt are formed by all of the halide ions—*e.g.*, with chloride, the tetrachlorocobaltate(II) complex, $CoCl_4^{2-}$—as well as by the thiocyanate, (SCN^-), and azide, (N_3^-), ions, alone or in combination with two neutral ligands such as phosphines or amines, *e.g.*, dichlorobis(triphenylphosphine)cobaltate(II), $Co[(C_6H_5)_3P]_2Cl_2$.

All tetrahedral complexes of divalent cobalt have three unpaired electrons, as do most of the octahedral ones. In a few cases, however, low-spin complexes are produced, but these are not expected to have regular octahedral structures because of distortion arising from the Jahn-Teller effect. In fact, those so far structurally characterized appear either to be five-coordinate rather than six-coordinate or to be dinuclear as in deca(methyl isocyanide)dicobalt(II) perchlorate, $[Co_2(CNCH_3)_{10}](ClO_4)_4$.

Cobalt(III) complexes

The complexes of trivalent cobalt are numerous. Because of the great variety of complexes that can be prepared and that undergo ligand exchange reactions at a rate slow enough to be conveniently measurable, they have been extensively studied and have provided much fundamental knowledge about isomerism, modes of reaction, and general properties of octahedral compounds as a class.

Trivalent cobalt shows a particular affinity for ligands that donate through the nitrogen atom, and the majority of its complexes contain ammonia, amines, nitro groups, etc., either alone or in combination with halide ions, water molecules, and other ligands. These complexes are generally synthesized by oxidation of divalent cobalt in the presence of the desired ligands.

Except for a few cases, complexes of trivalent cobalt are octahedral, and with the exception of trifluorotriaquocobalt(III), $[Co(H_2O)_3F_3]$, and hexafluorocobaltate(III), $[CoF_6]^{3-}$, which are paramagnetic with four unpaired electrons, all octahedral complexes of trivalent cobalt are diamagnetic.

Nickel. Typical compounds of nickel in nature, in which it occurs primarily as minerals in combination with arsenic, antimony, and sulfur, are nickel(II) sulfide, NiS; nickel(III) arsenide, NiAs; nickel(III) antimonide, NiSb; nickel(III) diarsenide, $NiAs_2$; nickel(III) thioarsenide, NiAsS; and nickel(III) thioantimonide, NiSbS. Some commercially important deposits contain the mineral garnierite, a magnesium–nickel silicate of variable composition. Also certain varieties of the iron mineral pyrrhotite contain 3 to 5 percent nickel. Elemental nickel is found alloyed with iron in many meteors, and the central regions of the Earth are believed to contain considerable quantities. The free metal is never found in the Earth's crust. The metallurgy of nickel is complicated in its details, many of which vary widely, according to the particular ore being processed. In general the ore is transformed to nickel(III) sulfide, Ni_2S_3, which is roasted in air to give nickel(II) oxide, NiO, which is then reduced with carbon to obtain the metal. Some high-purity nickel is made by the carbonyl process mentioned earlier.

Properties and reactions of nickel

Nickel is a silver-white metal with high electrical and thermal conductivity and it can be fabricated readily by the use of standard hot and cold working methods. The metal is fairly resistant to attack by air or water at ordinary temperatures when compact and is therefore often electroplated as a protective coating. Nickel reacts only slowly with fluorine, eventually developing a protective coating of the fluoride, and therefore is used as the pure metal or in the form of alloys such as Monel metal (which contains some 60 to 70 percent nickel, 30 to 40 percent copper, and small amounts of other metals such as iron) in equipment for handling fluorine gas and corrosive fluorides. Nickel is ferromagnetic at ordinary temperatures, although not as strongly so as iron, and is less electropositive than iron but dissolves readily in dilute mineral acids.

The only important oxidation state in the ordinary chemistry of nickel is the +2 state; but the stereochemistry of divalent nickel compounds and complexes is quite complicated and elaborate.

Binary nickel compounds. Nickel(II) oxide, NiO, is a green solid with the rock-salt structure; it is formed upon heating the hydroxide, carbonate, oxalate, or nitrate and is insoluble in water but dissolves readily in acids. Addition of alkali metal hydroxides to aqueous solutions of divalent nickel salts precipitates nickel(II) hydroxide, $Ni(OH)_2$, as a voluminous green gel that becomes crystalline on prolonged storage. The hydroxide is readily soluble in acids and also dissolves in aqueous ammonia, because of the formation of complexes, but it is not amphoteric. Sulfide ions precipitate nickel(II) sulfide, NiS, from aqueous solutions of divalent nickel. The sulfide is initially soluble in acid, but on exposure to air it becomes insoluble due to oxidation to nickel(III) hydroxide sulfide, Ni(OH)S.

All four nickel halides are known in the anhydrous and hydrated states. Except for the fluoride, which is best

Nickel halides

made indirectly, the halides can be prepared by direct reaction of nickel with the halogens. All of the halides are soluble in water (although the fluoride is only moderately so) and can be crystallized from aqueous solutions.

Nickel(II) cyanide, $Ni(CN)_2$, is precipitated in the green hydrated form on addition of cyanide ions to aqueous solutions of divalent nickel, and it can be converted to the anhydrous yellow-brown compound on heating at 180° to 200° C (360° to 400° F). The green precipitate readily dissolves in an excess of cyanide to form the yellow tetracyanonickelate(II) ion, $[Ni(CN)_4]^{2-}$, and many hydrated salts of this ion—such as $Na_2[Ni(CN)_4]\cdot 3H_2O$—may be crystallized from such solutions.

Other binary nickel compounds, not all of which are stoichiometric, may be obtained by direct reaction of nickel with various nonmetals, such as phosphorus, arsenic, antimony, sulfur, selenium, tellurium, carbon, and boron. The existence of a hydride is doubtful although the finely divided metal absorbs considerable amounts of hydrogen.

Aqueous chemistry of nickel. In addition to its halides, nickel forms a large number of salts with oxo acids; most commonly the salts occur as hydrates—for example, the nitrate $Ni(NO_3)_2\cdot 6H_2O$ and the sulfate $NiSO_4\cdot 7H_2O$. Aqueous solutions of nickel salts that do not contain strong complexing agents contain the green hexaaquonickel(II) ion, $[Ni(H_2O)_6]^{2+}$, which also occurs in most of the hydrated salts of oxy acids such as the foregoing two examples.

Nickel complexes. Divalent nickel forms a large number of complexes, encompassing coordination numbers 4, 5, and 6 and all of the main structural types—*i.e.*, octahedral, trigonal bipyramidal, square pyramidal, tetrahedral, and square. It is also characteristic of the complexes of divalent nickel that complicated equilibria, which generally depend upon the temperature and sometimes upon the concentration, often exist between the structural types.

The maximum coordination number of nickel is 6, and a large number of six-coordinate octahedral complexes are known. Ammonia and many organic amines displace water molecules from the coordination shell to give amine complexes. Such complexes characteristically have blue or purple colours in contrast to the bright green colour of the hexaaquo ion, because the stronger crystal fields provided by these ligands shift the absorption bands to higher energies, as already described under *Crystal-field and ligand-field theories*. Octahedral nickel(II) complexes have rather simple magnetic behaviour resulting from the presence of two unpaired electrons.

Nickel forms a considerable number of complexes in which its coordination number is 5. The structure may be trigonal bipyramidal, square pyramidal, or some intermediate arrangement. Depending on the strength of the ligand field, these complexes may be either high-spin (that is, with two unpaired electrons) or low-spin (that is, diamagnetic, with no unpaired electrons). The low-spin complexes tend to occur regardless of the arrangement of the molecules if the ligand set consists mainly of heavier atoms such as phosphorus, arsenic, sulfur, selenium, bromine, or iodine.

With coordination number 4, both tetrahedral and square arrangements occur depending on the type of ligand involved. Tetrahedral complexes can often be recognized by their spectroscopic and magnetic properties. They tend to be strongly coloured, either blue or green, and invariably have two unpaired electrons. The majority of four-coordinate nickel complexes, however, have square geometry. All square complexes are diamagnetic, and they are frequently red, yellow, or brown. An important square complex is the tetracyanonickelate(II) ion already mentioned; another is the bis(dimethyglyoximato) complex, which is bright red and highly insoluble in water and has long been used as both a qualitative and quantitative analytical test for nickel. The nickel complex with phthalocyanine has an intense, deep blue colour and has been used as a pigment.

The complicated changes among different atomic arrangements of nickel complexes are generally caused by the tendency of many nominally four-coordinate and five-coordinate complexes to add additional ligands or to associate with sharing of ligand atoms so as to increase the coordination number of each nickel atom to 5 or 6. In some cases also there are equilibria between square and tetrahedral four-coordinate complexes. Since the two types have different magnetic and spectroscopic properties, such equilibria, which may vary with temperature and environment, can cause dramatic colour changes.

Higher oxidation states of nickel. There are a few known compounds in which nickel has oxidation states +3 and +4. Although there is no evidence for anhydrous oxides of nickel in those oxidation states, there are a number of hydrous oxides and mixed metal oxides, some of considerable complexity, that contain nickel in oxidation states +3 and +4. The best defined is perhaps the compound designated beta-nickel(III) oxide hydroxide, β-NiO(OH), a black powder obtained by oxidation of divalent nickel nitrate solutions with bromine in aqueous potassium hydroxide. Electrochemical oxidation of nickel(II) hydroxide in alkaline solution gives a black oxide that does not appear to have a unique stoichiometry and that also retains some alkali metal.

The Edison battery

It may be noted that the Edison, or nickel–iron alkaline, battery (voltage approximately 1.3 V), which uses potassium hydroxide as an electrolyte, is based on the reaction

$$\underset{\text{iron}}{Fe} + \underset{\text{nickel(III) oxide hydroxide}}{2NiO(OH)} + \underset{\text{water}}{2H_2O} \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} \underset{\text{iron(II) hydroxide}}{Fe(OH)_2} + \underset{\text{nickel(II) hydroxide}}{2Ni(OH)_2}.$$

The detailed mechanism and the true nature of the oxidized nickel species are not fully understood.

Lower oxidation states of nickel. The most important compound of nickel in a lower oxidation state is tetracarbonylnickel, $Ni(CO)_4$. There are a number of other compounds of zero-valent nickel, such as bis(1,5-cyclooctadiene)nickel(0) and various derivatives of tetracarbonylnickel in which some of the carbon monoxide groups are replaced by phosphines or phosphites. These have been intensively studied as actual or potential catalysts for molecular transformations of olefins.

Copper. Copper is distributed widely in nature in the form of the free metal, sulfides, arsenides, chlorides, and carbonates. It is extracted by oxidative roasting and smelting, followed by electrodeposition from sulfate solutions, and it is technologically important, particularly in alloys, as an electroplated coating and as an exceptionally good conductor of heat and electricity. The pure metal is soft, tough, ductile, and characteristically reddish in colour and is second only to silver in thermal and electrical conductivity. Metallic copper is only superficially oxidized in air, sometimes acquiring a green coating that is a mixture of hydroxo-carbonate, hydroxosulfate, and small amounts of other compounds.

Properties and reactions of copper

Copper is a moderately noble metal, being unaffected by nonoxidizing or noncomplexing dilute acids in the absence of air; it will, however, dissolve readily in nitric acid and in sulfuric acid in the presence of oxygen and is also soluble in aqueous ammonia or potassium cyanide in presence of oxygen, because of the formation of very stable cyano complexes upon dissolution. The metal will react at red heat with oxygen to give copper(II) oxide, CuO, and, at higher temperatures, copper(I) oxide, Cu_2O. It reacts on heating with sulfur to give copper(I) sulfide, Cu_2S.

Copper forms compounds in the oxidation states +1 and +2 in its normal chemistry, although under special circumstances some compounds of trivalent copper can be prepared. It has been shown that trivalent copper survives no more than a few seconds in aqueous solution.

Monovalent copper. Copper(I) (cuprous) compounds are all diamagnetic and, except in cases of colour resulting from the anion or from ultraviolet bands, they are colourless. The important binary compounds of cop-

per(I) are the oxide, Cu_2O; the sulfide, Cu_2S; and the halides—cuprous chloride, CuCl; cuprous bromide, CuBr; and cuprous iodide, CuI. The chloride and bromide can be made by boiling an acidic solution of the copper(II) salt with excess of copper. Copper(I) iodide, CuI, forms upon addition of iodide ion to a solution of copper(II) ion. Copper(I) fluoride, CuF, is unknown. The three halides are highly insoluble in water, and it is to this fact that they owe their stability (see below). Two other fairly common compounds of univalent copper are the cyanide, CuCN, and the sulfate, Cu_2SO_4.

Only low concentrations of free cuprous ion can exist in aqueous solution because the equilibrium $Cu^{2+} + Cu \rightleftharpoons 2Cu^{+}$ lies far to the left. The equilibrium can be displaced in either direction by the addition of ligands or anions, which complex or precipitate insoluble salts of either univalent or divalent copper. The cuprous halides are stable because of their insolubility.

Stabilities of copper(I) and copper(II)

The relative stabilities of copper(I) and copper(II) also vary with solvent, as is well illustrated by the vastly increased stability of the copper(I) ion in acetonitrile, CH_3CN. In this medium, the copper(I) halides have high solubilities, and the copper(I) ion is so much more stable than the copper(II) ion that the latter is, in fact, a fairly powerful oxidizing agent. The copper(I) ion forms many complexes; those with simple ligands, such as halide ions and amines, are almost invariably tetrahedral. Copper(I) forms a number of polynuclear complexes of which the earliest to be recognized were those of composition $Cu_4I_4L_4$, in which L is a trialkylphosphine or trialkylarsine ligand. In such complexes, the four copper atoms lie at the vertices of a tetrahedron, one iodine atom lies over each face of the tetrahedron, and one of the ligands is coordinated to each copper atom.

Copper(I), but not copper(II), forms a number of organometallic compounds. The simple alkyls, such as methyl- or ethylcopper, are generally unstable, whereas some of the aryls—*e.g.*, phenylcopper, C_6H_5Cu—are stable to well above room temperature. Organometallic compounds of the type $Li(CuR_2)$, in which R represents an alkyl group, are useful synthetic reagents that react with alkyl, vinyl, or aryl halides to form carbon-to-carbon, or C–C, bonds. The copper(I) ion also interacts with alkenes and alkynes to form pi complexes.

Divalent copper. The divalent state is the more important one, giving rise to a well-defined aqueous chemistry of the copper(II) ion, Cu^{2+}, and a large number of salts of various anions, many of which are water soluble. In addition there are a great number of complexes of copper(II).

The stereochemistry of copper(II) is very characteristic. The d^9 configuration makes the ion Cu^{2+} subject to Jahn-Teller distortion if placed in an environment of cubic (that is, regular octahedral or tetrahedral) symmetry. For this reason there are virtually no regular octahedral or tetrahedral complexes of the copper(II) ion; most commonly the structure found is one in which a set of six ligands forms an elongated octahedron, with two opposite copper-to-ligand bonds being very much longer than the other four. This effect is found also in simple salts and binary compounds, because its origin is inherent in the d^9 configuration of the dipositive copper ion. The four-coordinate complexes either are square or have distorted tetrahedral structures.

The important binary compounds of divalent copper are the black oxide, CuO, which is obtained by thermal decomposition of the nitrate or other oxo salts; above about 800° C (1,500° F) it loses oxygen to form copper(I) oxide, Cu_2O. From solutions of the copper(II) ion the hydroxide is precipitated as bulky blue solid, which is amphoteric and redissolves in acids to give the Cu^{2+} ion and also in alkali hydroxide to give deep-blue solutions containing hydroxo anions. The three halides—copper(II) fluoride, CuF_2; copper(II) chloride, $CuCl_2$; and copper(II) bromide, $CuBr_2$—are known, but as noted above the iodide is unstable and cannot be isolated.

The most familiar cupric compound is the blue, hydrated sulfate, $CuSO_4 \cdot 5H_2O$, which may be completely dehydrated to the virtually white anhydrous sulfate upon heating. The hydrated nitrate is also known but cannot be entirely dehydrated without decomposition. The anhydrous nitrate can, however, be prepared by dissolving the metal in a solution of dinitrogen tetroxide, N_2O_4, in ethyl acetate, from which the salt formulated $Cu(NO_3)_2 \cdot N_2O_4$ crystallizes; when it is heated to 90° C (190° F) the salt loses N_2O_4 to give $Cu(NO_3)_2$.

Most copper(II) salts dissolve readily in water and give the aquo ion, hexaaquocopper(II) $[Cu(H_2O)_6]^{2+}$, but it is notable that the octahedron of water molecules about the copper is almost certainly distorted so that two of them are farther from the metal atom than the other four. Addition of ligands to such aqueous solutions leads to the formation of complexes such as tetraamminecopper(II), $[Cu(NH_3)_4]^{2+}$.

Copper(II) forms a considerable number of compounds that are magnetically anomalous. For an ordinary mononuclear complex of the copper(II) ion, magnetic behaviour characteristic of the presence of one unpaired electron per ion is to be expected. In many cases, however, of which the acetate, $Cu(CH_3CO_2)_2 \cdot H_2O$, is typical, the magnetic moment found at room temperature is lower than expected and decreases rapidly as the temperature is lowered. The cause of this behaviour is an interaction between pairs of copper ions that are held in proximity by bridging acetate groups, with the result that the unpaired electrons on the two copper atoms do not behave independently. Instead they interact in such a way that the most stable state, which can be reached at very low temperatures, is that in which the two spins are oppositely directed, thereby leading to diamagnetism.

ELEMENTS OF THE SECOND AND THIRD TRANSITION SERIES

While the elements in the second and third transition series for a given group have chemical properties similar to those of the element in the first series, they nevertheless show definite differences from the lighter element of the group. The following examples illustrate this point: (1) Although cobalt (of the first series) forms a considerable number of tetrahedral and octahedral complexes in its divalent state, and that valence state is characteristic in ordinary aqueous chemistry, divalent states of rhodium (second series) and iridium (third series) are rare and relatively unimportant. (2) The manganese(II) ion (Mn^{2+}) is very stable and of principal importance in the chemistry of manganese, but for technetium and rhenium the oxidation state +2 is little more than a laboratory curiosity. (3) Trivalent chromium forms a great number of complexes, which make up one of the best known aspects of the chemistry of the element; whereas trivalent molybdenum and tungsten are not particularly stable states under any conditions and form only a few complexes. (4) The oxy anions of the first-row elements in their higher oxidation states—for example, chromate(VI) and manganate(VII)—are powerful oxidizing agents the chemistry of which is essentially restricted to that function; whereas their stoichiometric analogues, such as molybdate(VI), tungstate(VI), technetate(VII), and rhenate(VII), are quite stable and have an extensive and diverse chemistry. There are, however, some cases in which quite valid and useful analogies can be found between the chemistry of the lighter element and the two heavier elements of the group. For instance, the chemistry of trivalent rhodium complexes is, in general, quite similar to that of trivalent cobalt complexes. On the whole, however, there are differences more consistently than there are similarities between the first element and the heavier elements of each group.

Differences in properties of elements in the second and third series from those of the first

For the heavier transition elements, higher oxidation states are generally more stable than is the case for the elements in the first transition series; this is true not only, as has been mentioned, for the properties of the oxo anions but for the higher halides as well. Thus the heavier elements form compounds such as ruthenium(VIII) oxide, RuO_4; tungsten(VI) chloride, WCl_6; platinum(VI) fluoride, PtF_6, etc., which have no analogues among the first-row elements, whereas the chemistry of aquo ions of lower valence states, especially +2 and +3, which is such a dominant part of the chemistry of the lighter

elements, is relatively unimportant for most of the heavier ones.

Lanthanide contraction

One of the reasons for the generally close similarity in chemistry between the second and third transition series elements of a given group is the so-called lanthanide contraction. As already described in this article, the series of elements known as the lanthanides comes between the second and third regular transition series and is formed by the filling of the *4f* orbitals. The *5d* and *6s* orbitals, which are the valence shell orbitals for the third transition series elements, are imperfectly shielded by the *4f* electrons from the increased nuclear charge. There is, consequently, a steady contraction in the size of these orbitals through the lanthanide series of elements, with the net result that the atomic and ionic radii of hafnium, which immediately follows the lanthanide series, are almost identical to the corresponding radii of the zirconium atom, which lies just above it in Group IV. Because the zirconium and hafnium atoms have almost identical sizes as well as analogous electron configurations in all of their oxidation states, their chemistry and the properties of their compounds are exceedingly similar; indeed, it is very difficult to separate the two elements because of the great similarity in properties of their compounds. In moving along the third transition series, there is a steady but slow divergence in the properties of the second and third elements in each group so that, at the end, considerable differences exist between those of palladium and platinum and of silver and gold. The differences are not as great, however, as might have been expected had the lanthanide contraction not intervened to preclude greater disparity in the orbital sizes. Although niobium and tantalum are not quite as similar as zirconium and hafnium, the differences between them are slight, and, similarly, molybdenum and tungsten, technetium and rhenium, ruthenium and osmium, and rhodium and iridium show marked similarities in their chemistries.

Zirconium and hafnium. Zirconium occurs widely in the Earth's crust, but not in concentrated deposits. The mineral zircon, $ZrSiO_4$ (zirconium orthosilicate), which is generally found in alluvial deposits in stream beds, ocean beaches, or old lake beds, is the only commercial source of zirconium. Baddeleyite, which is essentially pure zirconium(IV) oxide, ZrO_2, is the only other important zirconium mineral. These zirconium minerals generally have a hafnium content that varies from a few tenths of 1 percent to several percent. For some purposes separation of the two elements is not important: zirconium containing about 1 percent of hafnium is as acceptable as pure zirconium. In the case of the largest single use of zirconium, however, namely, as a structural and cladding material in atomic reactors, it is essential that the zirconium be essentially free of hafnium, because the usefulness of zirconium in reactors is based on its extremely low absorption cross section for neutrons. Hafnium, on the other hand, has an exceptionally high cross section, and accordingly even slight hafnium contamination nullifies the intrinsic advantage of the zirconium. Pure hafnium in fact is also used in some atomic reactors as a control element material because of its high neutron-capture cross section.

Uses of zirconium and hafnium

Separation of hafnium and zirconium is generally accomplished by a liquid–liquid countercurrent-extraction procedure. In the procedure, crude zirconium(IV) chloride is dissolved in an aqueous solution of ammonium thiocyanate and methyl isobutyl ketone is passed countercurrent to the aqueous mixture, with the result that the hafnium(IV) chloride is preferentially extracted.

Either of the metals, or a mixture of the two, is produced by the same process as that described in the section *Titanium* (see above). Both the metals have extremely high melting points: zirconium 1,850° C (3,362° F) and hafnium 2,230° C (4,046° F). Hafnium and zirconium are fairly resistant to acids and are best dissolved in hydrofluoric acid, in which procedure the formation of anionic fluoro complexes is important in stabilizing the solution. At normal temperatures neither metal is particularly reactive, but both become quite reactive with a variety of nonmetals at elevated temperatures.

Chemical properties. The atomic radii of zirconium and hafnium are 1.45 and 1.44 Å, respectively, while the radii of the ions are Zr^{4+}, 0.74 Å, and Hf^{4+}, 0.75 Å. The virtual identity of atomic and ionic sizes, resulting from the lanthanide contraction, has the effect of making the chemical behaviour of these two elements more similar than for any other pair of elements known. Although the chemistry of hafnium has been studied less than that of zirconium, the two are so similar that only very small quantitative differences—for example, in solubilities and volatilities of compounds—would be expected in cases that have not actually been investigated.

The most important respect in which these two elements differ from titanium is that lower oxidation states are of minor importance; there are relatively few compounds of hafnium or zirconium in other than their tetravalent states. The increased size of the atoms makes the oxides more basic and the aqueous chemistry somewhat more extensive, and permits the attainment of coordination numbers 7 and, quite frequently, 8 in a number of zirconium and hafnium compounds.

Oxides and halides. The four tetrahalides of each element are known, the most important being the tetrachlorides, because of their use in the separation and purification of the elements. The tetrachlorides may be prepared by chlorination of the heated metals, metal carbides, or mixtures of the metal oxides and charcoal. The tetrachlorides fume in moist air and are hydrolyzed vigorously by water. Hydrolysis proceeds only part way at room temperature, yielding the stable oxochlorides, $MOCl_2 \cdot 8H_2O$ (in which M is the metal atom). The bromides and iodides of zirconium and hafnium are similar to the chlorides but the fluorides are much less volatile and have different crystal structures.

Zirconium and hafnium halides

The addition of a hydroxide to solutions of tetravalent zirconium and hafnium causes the precipitation of the white gelatinous hydrated dioxides, which are converted on strong heating to hard, white, insoluble anhydrous dioxides, ZrO_2 and HfO_2. Zirconium dioxide is exceptionally resistant to attack by both acids and alkalies and has good mechanical properties; thus it is used in crucibles and furnace cores. At least four structurally different forms of ZrO_2 have been observed, one of which is the mineral baddeleyite already mentioned.

A number of compounds called zirconates may be made by combining oxides, hydroxides, nitrates, etc., of other metals with similar zirconium compounds and firing the mixtures at 1,000° to 2,500° C (1,800° to 4,500° F). As is the case with their titanium analogues, the products are mixed metal oxides. No discrete zirconate ions are known.

By far the most important complexes of zirconium and hafnium are those with fluoride ions. Although salts of the hexachloro ions (MCl_6^{2-}) are known, they are unstable in solution, whereas fluoro complexes are stable in solution and are sources of a great range of solid crystalline substances. Those of zirconium have been extensively investigated, and octahedral hexafluorozirconate(IV) (ZrF_6^{2-}) ions, as well as heptafluorozirconate(IV) (ZrF_7^{3-}) ions, with either pentagonal bipyramidal or capped trigonal prismatic structures, have been observed. Octafluorozirconate (ZrF_8^{4-}) units of several types have also been found; dicopper(II) octafluorozirconate(IV) dodecahydrate, in $Cu_2ZrF_8 \cdot 12H_2O$, there are discrete square antiprisms; in other cases there are square antiprisms sharing edges.

Zirconium dioxide, ZrO_2, is more basic than titanium dioxide, TiO_2, and is virtually insoluble in excess base. There is an extensive aqueous chemistry of zirconium because of its lower tendency to hydrolysis; nevertheless, hydrolysis does occur, and it is doubtful that the zirconium(IV) (Zr^{4+}) aquo ion exists, even in the most strongly acid solutions. The hydrolyzed ion is often referred to as the zirconyl ion and written as ZrO^{2+}, but there is little if any evidence for the actual existence of such an oxo ion, either in solution or in crystalline salts; no such group has ever been observed by X-ray diffraction methods. Substances for which the formula might suggest the presence of a zirconyl ion are invariably found to

have more complex structures. The best known of all zirconyl salts, for example, is formulated $ZrOCl_2 \cdot 8H_2O$; it actually contains a very complex tetranuclear cation, $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$, in which the zirconium atoms lie in a distorted square linked by pairs of hydroxo (OH^-) bridges.

Zirconium and hafnium solutions with sulfate anions show considerable difference from those containing chloride, nitrate, or perchlorate ions. Even at low acidity there appear to be very stable neutral and anionic complexes, some of which may be polymeric. Crystalline materials with compositions $Zr(SO_4)_2 \cdot nH_2O$, in which n equals 4, 5, and 7, have been characterized; they have complex structures in which the zirconium atoms are coordinated by eight oxygen atoms from water and sulfate groups.

The chemistry of these elements in lower oxidation states is limited to the nonaqueous chemistry of lower halides and a few complexes thereof. The best known compounds in such states are the trichlorides (MCl_3), tribromides (MBr_3), and triiodides (MI_3), which can generally be prepared by reduction of the tetrahalides with hydrogen or excess metal. The hafnium triiodide phase has a marked tendency to be non-stoichiometric. There are halides in even lower oxidation states, but these have not been well characterized, and a substantially pure zirconium(II) chloride ($ZrCl_2$) phase appears to exist, but its structure is unknown. The valence 1 compounds ZrCl and HfCl are reported to be isotypic (*i.e.*, analogous in chemical formula and crystal structure) and to have very metallic properties, but little else is known about them.

Niobium and tantalum. Although not quite as similar to each other as are hafnium and zirconium, niobium and tantalum differ but little in their chemistry, and, thus, separation problems are significant. Due to their great chemical similarity and consequent close association in nature, in fact, the establishment of the individual identities of the two elements was very difficult. Niobium was probably first discovered in 1801, in an ore sample from Connecticut, by an English chemist, Charles Hatchett, who named the element columbium in honour of the country of its origin, Columbia being a synonym for the United States. In 1844 a German chemist, Heinrich Rose, discovered what he considered to be a new element occurring along with tantalum and named it niobium after Niobe, the mythological goddess who was the daughter of Tantalus. After considerable controversy it was decided that columbium and niobium were the same element, and eventually international agreement was reached to adopt the name niobium. The name columbium is often seen, however, even today, especially in the metallurgical literature.

Columbium

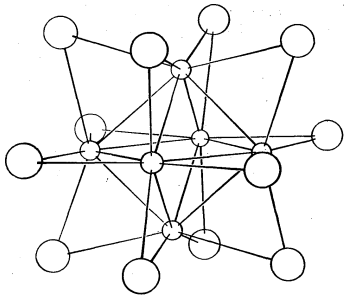
Niobium is roughly ten times more abundant in the Earth's crust than tantalum. The main commercial sources of both elements are the columbite–tantalite series of minerals, in which columbite ($FeNb_2O_6$) and tantalite ($FeTa_2O_6$) occur in highly variable ratios. Niobium is also obtainable from pyrochlore, a calcium sodium niobate. The production procedures for the metals are complex, the major problem being separation of the two elements, which is solved mainly by use of a liquid–liquid extraction process. The metals themselves are obtained by either electrolysis of fused salts or reduction of fluoro complexes with a very reactive metal such as sodium. Both metals are bright, have high melting points (niobium, 2,468° C [4,474° F], tantalum, 2,996° C [5,425° F]), and are quite resistant to acids. They can best be dissolved in a mixture of nitric and hydrofluoric acids.

Compounds of niobium (V) and tantalum (V). For niobium and tantalum the most important oxidation state is +5. Niobium(V) oxide, Nb_2O_5, and tantalum(V) oxide, Ta_2O_5, are dense white powders that are relatively inert chemically and are scarcely, if at all, attacked by acids except concentrated hydrofluoric acid. The hydrous oxides, which vary in water content, are gelatinous white precipitates obtained upon neutralizing acid solutions of pentavalent niobium and tantalum halides; the anhydrous oxides can be obtained by heating the hydrous oxides or by roasting certain other compounds in the presence of excess oxygen. When the oxides are fused with excess alkali hydroxide or carbonate, and the melts dissolved in water, isopolyniobates and isopolytantalates (analogous to the isopolyanions mentioned earlier) are obtained. The solutions are stable only when strongly alkaline and appear to consist mainly of the $M_6O_{19}^{8-}$ ions and protonated (*i.e.*, that have had one or more hydrogen ions, H^+, added) derivatives thereof. A large number of "niobates" and "tantalates" are known: they are almost entirely mixed metal oxides with the niobium and tantalum atoms occupying octahedral interstices in close-packed arrays of oxygen atoms. There are, however, a few compounds, such as scandium niobate, $ScNbO_4$, that contain discrete tetrahedral oxo anions, MO_4^{3-}.

Niobium(V), tantalum(V) halides

Both niobium and tantalum form all four pentahalides, of which the fluorides and chlorides are the most important. The pentafluorides are readily made by direct fluorination of the metals, the pentoxides, or the pentachlorides and are volatile white solids that have, in the crystal and evidently also in the melt, polymeric structures in which fluoride ions are shared between metal atoms so as to give each metal atom a coordination number of 6. When dissolved in aqueous hydrofluoric acid the metals and the pentoxides form fluoro complexes, the composition of which varies markedly with conditions of temperature and concentration. A great variety of fluoro and oxofluoro complexes—*e.g.*, the anions NbF_6^-, TaF_6^-, TaF_7^{2-}, and TaF_8^{3-}—may be precipitated by the addition of various cations. In solutions of lower acidity, niobium readily forms the oxopentafluoroniobate ion, $NbOF_5^{2-}$. All the pentahalides can be sublimed (*i.e.*, converted directly from solid to gaseous state) without decomposition in an atmosphere of the appropriate halogen; in the vapour they are monomeric (*i.e.*, simple in structure and low in molecular weight) and presumably have trigonal bipyramidal structures.

There are also a number of oxohalides, such as those having the formulas $NbOCl_3$, $TaOCl_3$, $NbOBr_3$, $TaOBr_3$, $NbOI_3$ and NbO_2I. These oxohalides, which often arise in the preparation of the pentahalides when the systems are not scrupulously free of oxygen, are less volatile than the pure halides and are thus left behind upon fractional sublimation.



Compounds of lower oxidation states. The only certain lower oxides are those of niobium, NbO and NbO_2. Substances of tantalum–oxygen composition TaO_x, in which x represents the range 2 to 2.5, are in fact tantalum(V) oxide, Ta_2O_5, phases with interstitial tantalum atoms, not discrete phases or compounds. Niobium(IV) oxide, NbO_2, has the rutile-type (*i.e.*, that of natural titanium dioxide, TiO_2) structure with pairs of fairly close niobium atoms that are presumably bonded to each other. Niobium(II) oxide, NbO, has a metallic lustre and excellent electrical conductivity of the metallic type. There are also complex series of sulfides of lower oxidation states of both niobium and tantalum.

All of the eight possible tetrahalides are known with the exception of tantalum(IV) fluoride, TaF_4. Niobium(IV) fluoride, NbF_4, is a black, nonvolatile, paramagnetic substance that differs from the other six. The tetrachlorides and tetrabromides are all brown-black or black diamagnetic solids, with structures such that pairs of metal atoms form weak metal–metal bonds, thus eliminating all unpaired electrons. The tetrahalides form a number of complexes with ligands containing nitrogen, oxygen, and sulfur donor atoms.

In addition to the halides of tetravalent niobium and tantalum, there is a considerable number of halide compounds in which the formal oxidation numbers of the metals range from +2 to about +3.1. Direct metal-to-metal bonds, metal atom clusters, and non-stoichiometry are characteristic features among these compounds.

Lower halides of niobium and tantalum

Many of the lower halides of niobium and tantalum are built up of $[M_6X_{12}]^{2+,\ 3+}$ units, in which M is the metal atom. The M_6X_{12} unit is a metal atom cluster consisting of an octahedron of metal atoms with a bridging halogen atom along each edge as shown in diagram **18.**

18

Such units are characteristic of, though not entirely restricted to, the chemistry of the lower oxidation states of niobium and tantalum.

Molybdenum and tungsten. Molybdenum (Mo) and tungsten (W) are very similar chemically, although there are some differences that are not easy to explain. They have similar abundances and occur in nature in the same sorts of compounds; neither occurs as a free metal. For molybdenum the chief ore is molybdenite—molybdenum(IV) sulfide, MoS_2—but molybdates such as lead molybdate, $PbMoO_4$ (wulfenite), and $MgMoO_4$ are also found. Although tungsten occurs as tungstenite—tungsten(IV) sulfide, WS_2—the important ores in this case are the tungstates such as scheelite (calcium tungstate, $CaWO_4$), stolzite (lead tungstate, $PbWO_4$), and wolframite—a solid solution or a mixture or both of the isomorphous substances iron(II) tungstate, $FeWO_4$, and maganese(II) tungstate, $MnWO_4$.

The small quantities of molybdenite in molybdenum ores are concentrated by foam flotation processes and roasted to give molybdenum(VI) oxide, MoO_3, which, after purification, can be reduced with hydrogen to the metal. For tungsten the ores are concentrated by magnetic and mechanical processes and the concentrate then fused with alkali. The crude melts are leached with water to give solutions of sodium tungstate, from which hydrous tungsten(VI) oxide is precipitated upon acidification, and the oxide is then dried and reduced to metal with hydrogen. The metals are quite refractory, the melting points being 2,610° C (4,730° F) for molybdenum and 3,410° C (6,170° F) for tungsten. Both metals are rather resistant to attack by acids, except for mixtures of concentrated nitric and hydrofluoric acids, and both can be attacked rapidly by alkaline oxidizing melts, such as fused mixtures of potassium nitrate and sodium hydroxide or sodium peroxide; aqueous alkalies, however, are without effect. The metals are inert to oxygen at normal temperature, but combine with it readily at red heat, to give the trioxides, and are attacked by fluorine at room temperature, to give the hexafluorides. Both elements form hard, refractory, and chemically inert interstitial compounds with boron, carbon, nitrogen, and silicon upon direct reaction with those elements at high temperatures. Tungsten carbide is extensively used for high-speed cutting tools; tungsten metal itself has wide application as a lamp filament, and molybdenum is used in a number of small-scale applications in which high resistance to erosion at high temperatures is required—*e.g.*, in jet engines, combustion liners, and afterburner parts.

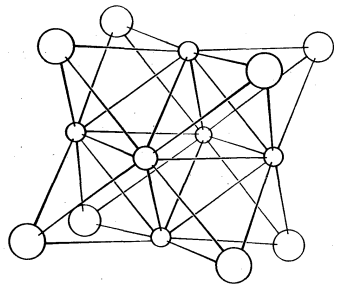
Oxides of molybdenum and tungsten. Most of the chemistry of these elements is that of the higher oxidation states, although a few lower valent compounds are of interest because of the presence of metal atom clusters or metal–metal bonds of a high order (*i.e.*, involving several pairs of electrons).

A considerable number of molybdenum and tungsten oxide phases are known. The simpler and more important oxides are the trioxides, MoO_3, WO_3, the dioxides, MoO_2, WO_2, and an intermediate oxide of molybdenum, Mo_2O_5.

The ultimate products of heating the metals or other compounds, such as the sulfides, in oxygen are the trioxides, which are not attacked by acids but which dissolve in bases to form solutions of molybdate and tungstate ions. The dioxides are obtained by reducing the trioxides with hydrogen and ammonia at moderate temperatures; they are dark solids with metallic lustre and structures similar to that of rutile but are highly distorted as a result of the formation of relatively strong, direct metal–metal bonds.

The simple molybdate ion, MoO_4^{2-}, and tungstate ion, WO_4^{2-}, which are formed by dissolving the trioxides in strong alkali, condense and polymerize (*i.e.*, form giant molecules by the union of simpler molecules with one another) into the complex polymolybdate and polytungstate species that have been mentioned above.

The reduction of oxide compounds of hexavalent molybdenum and tungsten results in several classes of interesting compounds, which contain the element in average oxidation states between +5 and +6. One such class of substances is the tungsten bronzes. The reduction of sodium tungstate in hydrogen at red heat produces a chemically inert substance with a bronze-like appearance, and similar materials are obtained by vapour-phase reaction of alkali metals with tungsten(VI) oxide, WO_3. The tungsten bronzes are non-stoichiometric substances of general formula M_nWO_3, in which M is the alkali metal and n is between 0 and 1. The colours vary greatly with composition, from golden yellow to blue-violet. The tungsten bronzes have metallic lustre and excellent electrical conductivity in which the charge carriers are electrons; those with very low concentrations of alkali metal are only semiconductors. When acidified solutions of molybdates and tungstates are reduced by mild reducing agents, such as tin(II) (stannous) ion or sulfur dioxide, bright-blue materials called blue oxides are obtained (a detailed explanation for the blue colour has not been given). Similarly, when heteropolytungstates and molybdates are subjected to mild reduction, blue materials called heteropolyblues are obtained. In these cases the phenomena occur in solution, and it can be shown that the oxidation–reduction reactions involved are reversible.



Tungsten bronzes

Sulfides and halides. Molybdenum(IV) sulfide, MoS_2, and tungsten(IV) sulfide, WS_2, which occur in nature, have been noted. In addition tungsten forms tungsten(VI) sulfide, WS_3, and molybdenum forms a number of other sulfides. Molybdenum(IV) sulfide, MoS_2, has an unusual structure, built of close-packed layers of sulfur atoms stacked so as to create trigonal prismatic interstices that are occupied by molybdenum atoms. The stacking permits easy slippage of alternate layers, and thus MoS_2 has the property of lubricity similar to that of graphite and is employed as a lubricant in specialized applications.

Both elements form a variety of halides and oxohalides in various oxidation states. By direct reaction of the metals with halogens the hexahalides MoF_6, WF_6, WCl_6, and WBr_6 can be obtained. There is not as yet any confirmed report of molybdenum(VI) chloride, $MoCl_6$, but direct reactions of the elements produce molybdenum(V) chloride, $MoCl_5$, and molybdenum(V) bromide, $MoBr_5$. The hexahalides are colourless, volatile substances; the pentafluorides and pentachlorides are well-characterized compounds that have an interesting structural difference. The pentafluorides polymerize in the solid state to cyclic tetramers (*i.e.*, molecules formed, in this case in a ring, by the union of four identical molecules), whereby each pair of metal atoms is bridged linearly by one fluorine atom. The pentachlorides, on the other hand, form dimeric (*i.e.*, formed by the union of two identical simpler molecules) units in which there are two angular chloride bridges between each pair of metal atoms. The known tetrahalides and trihalides include nearly all of the possibilities, with the conspicuous exception of tungsten(III) fluoride, WF_3.

Dihalides of molybdenum and tungsten

Of particular scientific interest are the dihalides, which actually have a complex structure that contains metal atom clusters similar to but different in detail from those formed by niobium and tantalum. The key structural unit has six metal and eight halogen atoms, written M_6X_8, and is illustrated in diagram **19**. As in the case with the analogous niobium and tantalum compounds, there is an octahedral cluster of metal atoms, but in this case there are only eight bridging halogen atoms and they

19

lie over faces of the octahedron. In the dihalides these units are linked together by the additional halide ions that serve as bridges. Tungsten compounds of this type are considerably less stable than those of molybdenum and tend to be readily oxidized.

Both elements form oxohalides in several oxidation states. In oxidation state +6, the stoichiometric types are MOX_4 and MO_2X_2, in which M is the metal atom, O the oxygen atom, and X the halogen atom. The oxohalides are readily obtained as by-products in the halogenation of the metals, unless the metal is first scrupulously reduced and the reaction system purged of oxygen. For oxidation state 5, the stoichiometric type is MOX_3, in which X may be Cl or Br.

Complexes. Molybdenum and tungsten form a variety of complexes. Molybdenum, but not tungsten, forms complexes of the type MX_6^{3-}, which are strong reducing agents. Both molybdenum and tungsten form the dinuclear complexes $M_2X_9^{3-}$, the structure of which can be considered as two octahedra sharing a face. In such systems there is some direct interaction between the metal atoms, which is quite strong in the case of tungsten. The elements also form hexahalo complexes in their higher oxidation states, particularly the hexafluoro complexes, MF_6^-.

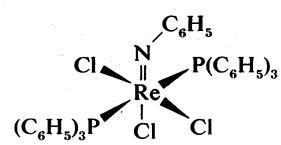
For molybdenum, though not to any appreciable extent for tungsten, there are many important complexes containing metal–oxygen double bonds or metal–oxygen–metal bridge bonds. Molybdenum(VI) oxide dissolves in aqueous hydrochloric acid to give the dioxotetrachloromolybdate(VI) anion, $[MoO_2Cl_4]^{2-}$. Complexes of the dioxo type are particularly prevalent for molybdenum, additional examples being $[MoO_2F_4]^{2-}$ $[MoO_2(ligand)_2]$, in which the ligand may be an anion derived from any of various organic compounds.

Both molybdenum and tungsten in oxidation states +4 and +5 form a series of octacyano complexes, $M(CN)_8^{3-,\,4-}$. The geometrical arrangement of the cyano groups around the metal atoms is variable, the geometry changing, depending on the surroundings, from dodecahedral to square antiprismatic. The cyano complexes are the most important, but not the only, octacoordinate complexes of these elements.

Molybdenum and tungsten multiple bonds

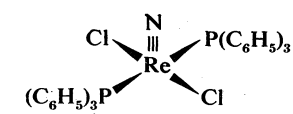
Finally, it is notable that molybdenum forms several complexes in the divalent state that are binuclear and contain very short molybdenum–molybdenum bonds, which are quadruple bonds, having four electron pairs shared between the metal atoms. Among the most important compounds containing such quadruple bonds are dimolybdenum tetraacetate, which can be obtained by boiling molybdenum carbonyl in acetic acid, and the salts of the octachlorodimolybdate ion, $Mo_2Cl_8^{4-}$, which is obtained from the acetate by treatment with hydrochloric acid. Thus far no tungsten analogue of these species has been definitely characterized. Both molybdenum and tungsten form the unusual molecules $[(CH_3)_3SiCH_2]_3M{\equiv}M[CH_2Si(CH_3)_3]_3$, in which there are metal-to-metal triple bonds (indicated as M≡M).

Technetium and rhenium. As has been noted, technetium does not occur in nature; nor does rhenium occur free in nature or as a compound in any distinct mineral; instead it is widely distributed in small amounts in other minerals. Rhenium is generally isolated from flue dusts and gases obtained on the roasting of molybdenites that contain rhenium. Such gases can be leached or scrubbed with water to dissolve the oxide, Re_2O_7, which can be converted to ammonium rhenate(VII) (perrhenate), NH_4ReO_4, and then reduced to the metal with hydrogen. The melting point of rhenium, 3,170° C, is exceeded only by those of tungsten and carbon.



Technetium and rhenium are very similar chemically and differ greatly from manganese. Their most characteristic and important compounds are formed in the oxidation states +4 and +7, although compounds are known in all formal oxidation states from −1 to +7. Rhenium has only minor uses; for example, as an alloy with tungsten in flash bulb filaments; technetium, by the early 1970s, had essentially none.

Compounds of technetium and rhenium. Rhenium forms a variety of oxides, formulated $Re_2O_3{\cdot}xH_2O$, ReO_2, ReO_3, Re_2O_5, and Re_2O_7, while the only authenticated oxides of technetium are TcO_2 and Tc_2O_7. Of these, the heptoxides, which are obtained by burning the metals, are of greatest importance. They are quite volatile, and, if acid solutions containing the pertechnetate ion, TcO_4^-, are evaporated, technetium(VII) oxide is driven off, a fact that may be utilized to isolate and separate technetium. Rhenium(VII) oxide is not lost from acid solutions on evaporation at 100° C (212° F) but can be distilled from hot concentrated sulfuric acid. The heptoxides of rhenium and technetium readily dissolve in water to give acidic solutions. Both TcO_2 and ReO_2 have distorted rutile structures.



Oxides of rhenium and technetium

For rhenium particularly, the formation of oxo compounds is of major importance, especially in the higher oxidation states, +5 and +7. The pertechnetates, containing the ion TcO_4^-, and perrhenates, containing ReO_4^-, are among the most important compounds formed by these elements. The pure acids, which have not been isolated, are very strong acids in aqueous solutions. The oxo anions are quite stable in both acid and alkaline solution and are relatively weak oxidizing agents. There are oxohalides of both rhenium and technetium in the oxidation state +7—*e.g.*, ReO_3F, ReO_3Cl, and TcO_3Cl—that are readily hydrolyzed. Technetium trioxide chloride, TcO_3Cl, however, can be prepared under aqueous conditions by adding hydrochloric acid to potassium technetate(VII), $KTcO_4$, in sulfuric acid and extracting the product into chloroform. In oxidation state +6 oxohalides of the type MOX_4 are known; and in oxidation state +5, those of the type MOX_3.

Rhenium complexes. Of the many complexes containing oxorhenium species perhaps the most important are those of the type $ReOCl_3(PR_3)_2$, in which PR_3 represents a phosphine ligand. These compounds form a starting point for the preparation of a large number of complexes of rhenium in oxidation states between +3 and +6. In addition to forming double bonds to oxygen, rhenium also forms double and triple bonds to nitrogen. Typical compounds of these types are represented in diagrams **20** and **21.**

20

21

Both technetium and rhenium form the metal hydride ions formulated as MH_9^{2-}, which are the only pure hydrido complexes of transition metals, although many related species that contain other ligands along with the hydride ions are known. Rhenium also forms a series of complexes in which the nitrogen molecule is present as a ligand. These are among the best characterized complexes of this singularly unreactive molecule.

Hydride complexes

Finally, it should be mentioned that rhenium in oxidation state +3 has a pronounced tendency to form binuclear compounds containing rhenium–rhenium quadruple bonds as well as trinuclear clusters in which there are rhenium–rhenium double bonds. The compounds containing rhenium(III) and chlorine, bromine, or iodine all have Re_3X_9 as their true molecular formulas and contain

triangular arrays of doubly bonded metal atoms. On treatment of the halides with various ligands, complexes are formed in which these triangular clusters are preserved. The quadruple bonds mentioned occur in the ions $Re_2X_8^{2-}$, in which X represents Cl, Br, or SCN, and also in the carboxyl-bridge species $Re_2(O_2CR)_4X_2$, in which R is an alkyl or aryl group and X is a halogen. The first quadruple bond to be discovered was found in the octachlorodirhenate(III) ion, $Re_2Cl_8^{2-}$.

Ruthenium and osmium. Both ruthenium and osmium have low crustal abundances of about 0.001 part per million. They occur in nature along with the other platinum metals, and processes for isolating them are an integral part of the metallurgical art that applies to all of them and is discussed elsewhere.

Ruthenium and osmium are hard, bright metals having high melting points and resistance to chemical attack. They are the most noble of the platinum metals, and cold and hot acids, even including aqua regia, are without effect on them. They can be dissolved by fused alkalies, especially if an oxidizing agent such as sodium chlorate is present. Osmium will react at 200° C (about 400° F) with air or oxygen to form the volatile tetroxide, OsO_4. Although ruthenium tetroxide, RuO_4, has similar stability and volatility to osmium tetroxide, OsO_4, it differs in that it cannot be formed from the elements.

The chemistries of ruthenium and osmium are generally similar and differ markedly from that of iron. The higher oxidation states +6 and +8 are much more readily obtained than for iron, and there is an extensive chemistry of the tetroxides, oxohalides, and oxoanions. For both elements there is little, if any, evidence that simple aquo ions exist, and virtually all their aqueous solutions, whatever the anions present, may be considered to contain complexes. In addition to carbonyl and organometallic compounds in the low oxidation states −2, 0, and +1, both elements form compounds in every oxidation state from +2 to +8. The most important oxidation states, however, are +2, +3, +4, +6, and +8.

Oxides. Ruthenium(VIII) oxide and osmium(VIII) oxide (RuO_4 and OsO_4) both form crystalline solids. They are extremely poisonous with penetrating ozone-like odors. Osmium(VIII) oxide is a particular hazard, especially to the eyes, because of its ready reduction by organic matter to a black oxide in a lower oxidation state. Ruthenium(VIII) oxide is obtained when acid solutions containing ruthenium are heated with powerful oxidizing agents such as iodate(VII), manganate(VII), or cerium(IV) ion and can be distilled from the solutions or swept out by a gas stream. Osmium(VIII) oxide, as noted previously, can be obtained by burning the metal and also by oxidation of osmium solutions. Both tetroxides have a tetrahedral structure, are extremely soluble in carbon tetrachloride, and can be extracted from aqueous solutions with this solvent. Osmium(VIII) oxide finds limited use in organic chemistry.

Both metals form dioxides that have the rutile structure as well as some hydrous oxides, such as black $Ru_2O_3 \cdot nH_2O$, ruthenium(III) oxide, obtained from ruthenium(III) chloride solutions upon addition of bases. Aqueous solutions of the tetroxide can be reduced by hydrogen to give hydrous forms of the dioxide.

Halides. Ruthenium and osmium both form hexafluorides that are relatively volatile substances containing octahedral molecules. Both will dissociate into lower fluorides upon heating. The pentafluorides are dark-green solids that have cyclic tetrameric structures in which there are linear bridging fluoride ions giving each metal a coordination number of six. The pentafluorides are very reactive and readily hydrolyzed. Tetrafluorides and difluorides are also known; they are made by various reductive procedures. For example, osmium(VI) fluoride can be reduced with hexacarbonyltungsten to osmium(IV) fluoride, while ruthenium(V) fluoride can be reduced by iodine under mild conditions to give the ruthenium(IV) fluoride or at 250° C (480° F) to give ruthenium(III) fluoride.

The chemistry of the chlorides, bromides, and iodides of ruthenium and osmium is rather complex. The action of chlorine with added carbon monoxide on ruthenium metal at 370° C (700° F) gives beta-ruthenium(III) chloride, which on heating above 450° C (840° F) in chlorine is converted to another form, designated alpha, which is insoluble in water and ethanol. Ruthenium(III) bromide, $RuBr_3$, has not been obtained pure but only as green, hygroscopic crystals by evaporation of solutions prepared by dissolving hydrous ruthenium(III) oxide in hydrobromic acid. Chlorination of osmium gives a mixture of osmium(III) chloride, $OsCl_3$, and osmium(IV) chloride, $OsCl_4$, with the former predominating below 500° C (900° F) in a restricted supply of chlorine, and pure $OsCl_4$ being obtained in an excess of chlorine above 650° C (1,200° F). Nothing is known of the structures of either of these materials, and their chemistry has not been much investigated. Osmium also forms osmium(III) bromide, $OsBr_3$, osmium(IV) bromide, $OsBr_4$, and osmium(III) iodide, OsI_3, all of which apparently decompose on heating to substances having the composition of lower halides, but nothing is known about their true nature.

Divalent ruthenium and osmium. The chemistry of ruthenium and osmium in oxidation state +2 is exclusively that of complexes and is very complicated. These complexes are usually prepared by the reduction of solutions of the elements in higher oxidation states in the presence of the desired ligands. All complexes of divalent ruthenium and osmium are octahedral, diamagnetic, and usually kinetically inert. These characteristics are consistent with a t_{2g}^6 configuration. The reduction of almost any ruthenium compound in ammoniacal solution with zinc dust yields a solution from which orange crystals of hexammineruthenium(II) chloride, $[Ru(NH_3)_6]Cl_2$, separate. This substance is a powerful reducing agent. On the other hand, ruthenium forms the complex cation tris(dipyridyl)ruthenium(III), $[Ru(dipy)_3]^{2+}$ (in which dipy represents the bidentate organic ligand dipyridyl), which is extremely stable and forms a vast number of salts to all of which it lends an intense red colour. Osmium forms a similar dipyridyl complex. Other important complexes are the very stable hexacyano anions.

The first complex of molecular nitrogen discovered was pentamminenitrogenruthenium(II), $[Ru(NH_3)_5N_2]^{2+}$.

Trivalent and tetravalent states. Complexes of ruthenium and osmium in oxidation state +3 are virtually all octahedral with low-spin (t_{2g}^5) configurations. They are among the best characterized complexes of these elements and include the hexachloro, $[MCl_6]^{3-}$; hexammine, $[M(NH_3)_6]^{3+}$; tris(oxalato), $[M(C_2O_4)_3]^{3-}$; and tris(2,4-pentanediono), $[M(CH_3COCHCOCH_3)_3]$ species. The most notable complexes of ruthenium(IV) and osmium(IV) are the oxo bridged dinuclear anions having the structure $[Cl_5M{-}O{-}MCl_5]^{4-}$, prepared by reduction of the tetroxides by hydrochloric acid. These are diamagnetic because of coupling of electron spins through the M–O–M bridge system.

Nitric oxide complexes of ruthenium. Formation of nitric oxide complexes is a prominent feature of ruthenium chemistry. Ruthenium solutions or compounds that have ever been treated with nitric acid or any other source of the NO group must be suspected of containing RuNO groups, which can be detected by their absorption of infrared radiation of characteristic energy.

Rhodium and iridium. Rhodium and iridium occur in nature in association with the other platinum metals, and their separation and refinement form part of the overall metallurgical processing of the group, which is discussed elsewhere. These metals are somewhat more reactive than ruthenium and osmium. Rhodium will dissolve in hot concentrated sulfuric acid and both dissolve in concentrated hydrochloric acid containing sodium perchlorate at 125°—150° C (260°—300° F). Both will dissolve in aqua regia.

For both elements, the most important chemistry is that of the oxidation states +1 and +3, although iridium forms some complexes in oxidation state +4 and rhodium forms the dirhodium tetraacetate, $Rh_2(O_2CCH_3)_4$ and various derivatives containing two additional ligands —*e.g.*, water, pyridine, or triphenylphosphine—in oxi-

dation state +2. Complexes in oxidation state +1 chiefly contain carbon monoxide, olefins, and phosphines as ligands. Hexachloroiridate(IV), $IrCl_6^{2-}$, and hexabromoiridate(IV), $IrBr_6^{2-}$, are the only notable chemical species containing tetravalent iridium.

Binary compounds. Rhodium and iridium form several fluorides; rhodium(VI) fluoride, RhF_6, and iridium(VI) fluoride, IrF_6, are highly reactive molecular substances formed by direct reaction of the elements. The pentafluorides are cyclic tetramers having the formulas $[RhF_5]_4$ and $[IrF_5]_4$. Rhodium(IV) fluoride, rhodium(III) fluoride, and iridium(III) fluoride are also known.

Halides of rhodium and iridium

The only important halides, other than the fluorides, are the trihalides; rhodium(III) chloride, $RhCl_3$, and iridium(III) chloride, $IrCl_3$, can both be made by direct chlorination of the metals, while lower halides are obtainable only by removal of water from their hydrates, which octahedral and have t_{2g}^6 configurations.

Hydrous oxides having the formulas $Rh_2O_3 \cdot nH_2O$, $RhO_2 \cdot nH_2O$, $Ir_2O_3 \cdot nH_2O$, and $IrO_2 \cdot nH_2O$ can be precipitated from aqueous solutions; anhydrous compounds having the formulas M_2O_3 and MO_2 are also known. The latter have the rutile structure.

The monovalent state. Both four-coordinate (square) and five-coordinate complexes of rhodium(I) and iridium(I) are formed, and the criteria for stability of four- versus five-coordinate species are not well established. Bis[chlorodicarbonylrhodium(I)], $[RhCl(CO)_2]_2$, easily prepared by passing carbon monoxide saturated with ethanol over rhodium(III) chloride trihydrate, $RhCl_3 \cdot 3H_2O$, at 100° C, is an important reactant in the preparation of other univalent rhodium compounds. Thus it is cleaved by various donors L (*e.g.*, phosphines or chloride ion) to give mononuclear complexes of the type $RhCl(CO)_2L$. Action of triphenylphosphine on solutions of rhodium(III) chloride in ethanol produces the compound $RhCl(CO)[P(C_6H_5)_3]_2$, which can then be converted by action of sodium borohydride to the hydrido complex, $RhH(CO)[P(C_6H_5)_3]_3$, which is an extremely useful catalyst for homogeneous hydrogenation of olefins and for several other reactions.

Vaska's compound

The iridium complex having the formula *trans*-$IrCl(CO)[P(C_6H_5)_3]_2$, often called Vaska's compound, and related ones in which chloride is replaced by bromide or iodide, and triphenylphosphine is replaced by other phosphines, has a remarkable ability to bind small molecules such as oxygen, nitrogen, and sulfur dioxide and to add others such as iodomethane and chlorine. These reactions have been extensively studied because they are convenient models for a wide range of such reactions.

The trivalent state. A large number of complexes, cationic, neutral, and anionic, is known for both rhodium and iridium in oxidation state +3. The cationic and neutral complexes of trivalent rhodium are generally kinetically inert, while the anionic ones are usually labile; for iridium all three types are usually quite inert. In all cases, the complexes are diamagnetic because they are octahedral and have t_{2g}^6 configurations.

Rhodium forms the cation hexaaquorhodium(III), $[Rh(H_2O)_6]^{3+}$, when hydrous rhodium(III) oxide is dissolved in cold acids, and the deliquescent perchlorate having the formula $[Rh(H_2O)_6](ClO_4)_3$ can be isolated.

Both elements give amine complexes having the compositions $[M(NR_3)_6]^{3+}$, $[M(NR_3)_5X]^{2+}$, and $[M(NR_3)_4X_2]^{+}$, in which M represents rhodium or iridium, (NR_3), an amine or ammonia, and X, a halide; chloropentammine-rhodium(II) chloride, $[Rh(NH_3)_5Cl]Cl_2$, is a typical example. These are similar to the corresponding cobalt complexes. The most important anionic complexes are hexachlororhodate(III), $RhCl_6^{3-}$, and hexachloroiridate(III), $IrCl_6^{3-}$, which have no cobalt analogues.

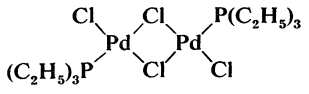
Rhodium(III) chloride is an important compound that is a starting material for the preparation of many others, in various oxidation states. In aqueous emulsions it can catalyze a number of useful organic reactions.

Palladium and platinum. Platinum and palladium are more abundant than any of the other platinum metals. Platinum is by far the best known and technologically the most important. Both palladium and platinum are more reactive than the other platinum metals. Palladium is readily attacked by concentrated nitric acid and in its sponge form will dissolve even in hydrochloric acid in presence of chlorine or oxygen. Platinum is not attacked by any single mineral acid, but it dissolves readily in aqua regia and slowly in hydrochloric acid in presence of air. Both metals are rapidly attacked by fused alkali oxides and peroxides and also by fluorine and chlorine at about 500° C (900° F). They also combine with a number of nonmetallic elements on heating, such as phosphorus, arsenic, antimony, silicon, lead, sulfur, and selenium.

Both metals, but especially palladium, are capable of absorbing large volumes of hydrogen. At 80° C (180° F) and one atmosphere, palladium will absorb up to 900 times its own volume. The absorption causes both the electrical conductivity and magnetic susceptibility to decrease. These and other observations have led some investigators to conclude that there is a definite palladium hydride phase, although its structure and ideal composition are not firmly established.

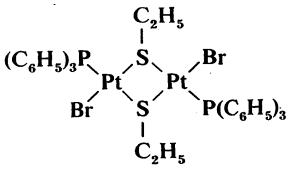
Binary compounds. The oxides of platinum and palladium are of little importance. Hydrous palladium(II) oxide is a yellow gelatinous precipitate that turns brown and then black on drying and cannot be completely dehydrated without decomposition. When a solution of hexachloroplatinate(IV), $PtCl_6^{2-}$, is boiled with sodium carbonate, hydrous platinum(IV), oxide, $PtO_2 \cdot nH_2O$, is formed. It can be dehydrated to PtO_2, anhydrous platinum(IV) oxide, which decomposes above about 200° C.

Platinum forms a hexafluoride as well as the tetrameric pentafluoride, $[PtF_5]_4$, and the monomeric tetrafluoride PtF_4, whereas palladium is the only one of the platinum metals that forms no hexafluoride. Palladium forms the tetrafluoride, PdF_4, and the difluoride, PdF_2. Platinum(IV) chloride, $PtCl_4$, bromide, $PtBr_4$, and iodide, PtI_4, are all known but have no palladium analogues. Platinum(IV) chloride is important as a starting material in preparing complexes of tetravalent platinum. The dihalides of both metals (chlorides, bromides, and iodides) are all known, and the chlorides are important compounds. Both dichlorides exist in two forms. The beta forms are isostructural and consist of M_6Cl_{12} units, like those in lower halides of niobium and tantalum except that the metal–metal distances are so great as to preclude significant metal-to-metal bonding. The compound Pt_6Cl_{12} dissolves in benzene. The alpha form of palladium(II) chloride consists of very long chains of $PdCl_2$ units in which pairs of bridging chlorine atoms give square coordination about each metal atom. The structure of the alpha form of platinum(II) chloride is uncertain but appears to be different from that of the alpha form of palladium dichloride.



Reactions with the noble gases

Platinum(VI) fluoride, PtF_6, reacts with oxygen to give a compound having the formula $[O_2^+][PtF_6^-]$. This reaction was first observed in 1962 by N. Bartlett, who reasoned that because xenon has an ionization potential almost identical to that of molecular oxygen, a similar reaction might occur between platinum(VI) fluoride and xenon. He confirmed this by obtaining a red solid, of variable composition $Xe[PtF_6]_x$, in which x ranges between 1 and 2. This discovery led others to examine the reaction of xenon with fluorine and thus the chemistry of the noble gases was discovered.



The divalent state. The characteristic stereochemistry of platinum(II) and palladium(II) is square though a few five- and six-coordinate species are known. Palladium forms an ion, tetraquopalladium(II) $[Pd(H_2O)_4]^{2+}$, which is obtained when hydrous palladium(II) oxide dissolves in dilute nitric, perchloric, or sulfuric acids; platinum does not form the analogous ion. Palladium also dissolves in glacial acetic acid containing some nitric acid and, after boiling, brown crystals of the acetate, which has the formula $Pd_3(O_2CCH_3)_6$, can be obtained. The molecule of this compound contains a triangle of palladium atoms with two acetate groups bridging each edge. An anhydrous nitrate can also be obtained by action of nitrogen pentoxide, N_2O_5, on the hydrated nitrate.

The most common compounds of divalent platinum and palladium are salts of the red tetrachloropalladate(II),

$PdCl_4^{2-}$, and the tetrachloroplatinate(II), $PtCl_4^{2-}$, ions. From these, by substitution reactions, a great variety of other square complexes can be made. Some representative compounds have the formulas $K[Pd(NH_3)Cl_3]$, $Pt(NH_3)_2Cl_2$ (*cis* and *trans* isomers), $[Pt(NH_3)_4]$ $[PtCl_4]$, $[Pd(NH_3)_4]$ $[Pd(SCN)_4]$, $Pt[P(C_6H_5)_3]_2Cl_2$. Bridged binuclear species such as those shown in diagrams **22** and **23** are also well-known.

22

23

The compound $[Pt(NH_3)_4]$ $[PtCl_4]$, tetraammine platinum(II) tetrachloroplatinate(II), is known as Magnus' green salt. It has a structure in which the square cations and anions are stacked alternately in infinite columns and the colour is due to interactions between the metal atoms. A number of similar compounds are also known.

The tetravalent state. Oxidation state +4 is not a very stable one for palladium; only a few complexes are known and they are not common or important. Platinum, however, has an extensive chemistry in this oxidation state, and in all such compounds the platinum has octahedral coordination. The most extensive series of complexes of quadrivalent platinum are those in the series having the formulas $[Pt(NR_3)_6]X_4$, $[Pt(NR_3)_5X]X_3$, ... $M[Pt(NR_3)X_5]$, $M_2[PtX_6]$, in which (NR_3) represents an amine or ammonia, X is a halide, thiocyanate (SCN^-), or nitrite (NO_2^-) ion, and M is an alkali metal cation.

There are no compounds containing trivalent palladium or platinum, even though some substances have stoichiometry that might suggest this oxidation state. Thus, for example, the compound having the formula $Pt(NH_3)_2Br_3$ actually consists of molecules of compounds formulated $Pt(NH_3)_2$ Br_4 and $Pt(NH_3)_2Br_2$ stacked in linear chains.

Other compounds of platinum. Platinum, and to a smaller extent palladium, forms a number of interesting compounds containing negatively charged organic groups or the hydride ion, H^-, as ligands; it also forms some phosphine complexes in which it is formally zero-valent. Many of the organic and hydride complexes are white substances formulated $Pt(PR'_3)_2XR$, in which X stands for Cl, Br, I, and R and R', for H or an alkyl or aryl group. Among the most stable of organometallic compounds are those formulated $[(CH_3)_3PtX]_4$, in which there are four $(CH_3)_3Pt^+$ groups at alternate vertices of a cube with the remaining vertices occupied by triply bridging chloride, bromide, iodide, or hydroxide ions (represented by X in the preceding formula). These compounds can be degraded with preservation of the $(CH_3)_3Pt$ moiety to give mononuclear complexes, such as cyclopentadienyltrimethylplatinum(IV), $C_5H_5Pt(CH_3)_3$.

Neither platinum nor palladium forms a simple carbonyl analogous to tetracarbonylnickel, but platinum forms $Pt(PF_3)_4$, tetrakis(phosphorus trifluoride)platinum, as well as a number of polynuclear mixed carbonylphosphine derivatives having formulas such as $Pt(CO)(PR_3)_3$, $Pt_3(CO)_3(PR_3)_4$, and $Pt_4(CO)_5(PR_3)_4$. Of particular interest are the triphenylphosphine complexes designated $Pt[P(C_6H_5)_3]_n$, $n = 2, 3, 4$, which are interconvertible in solution by varying the triphenylphosphine concentration. Bis(triphenylphosphine)platinum, $Pt[P(C_6H_5)_3]_2$ can bind a number of small molecules such as oxygen and sulfur dioxide and react with others such as chloromethane and bromine. The oxygen complex $Pt[P(C_6H_5)_3]_2O_2$ acts as an oxidant toward carbon monoxide, sulfur dioxide, triphenylphosphine, and other substances.

Silver and gold. Silver and gold are two of the noblest —that is, least chemically reactive—of the transition elements, and both are found in nature in the free state. For silver the more important deposits commercially are such compounds as the mineral argentite (silver sulfide, Ag_2S), which is usually associated with other sulfides such as those of lead and copper, as well as several other sulfides, some of which contain antimony as well. Silver is found generally in lead ores, copper ores, and cobalt arsenide ores and is also frequently associated with gold in nature. Most silver is derived as a by-product from ores that are mined and processed to obtain these other metals. Gold is most commonly found free, the only compounds of gold in nature being various tellurides.

Commercial deposits of silver

Silver is a white, lustrous metal and is among the most ductile and malleable ones known. Pure silver has the highest electrical and thermal conductivities of all metals. Gold is a soft, yellow metal that has the highest ductility and malleability of any element.

Reactivity of silver and gold

Silver is less reactive chemically than copper except toward sulfur and hydrogen sulfide, which rapidly blacken silver surfaces. The metal will dissolve in oxidizing acids and in solutions containing cyanide ions in the presence of oxygen or peroxides. Gold is much less reactive and is not attacked by oxygen or sulfur, although it will react readily with halogens or with solutions containing or generating chlorine, such as aqua regia. It also will dissolve in cyanide solutions in presence of air or hydrogen peroxide. Dissolution in cyanide solutions is attributable to the formation of the very stable dicyanoargentate(I), $Ag(CN)_2^-$, and dicyanoaurate(I), $Au(CN)_2^-$, ions.

As does copper, the elements silver and gold have a single *s* electron outside a completed *d* shell, but in spite of the similarity in electronic structures and ionization potentials there are few close resemblances between silver and gold on the one hand and copper on the other.

Both silver and gold find their chief applications in the form of the metals themselves, but silver is also of unique utility as silver chloride in photographic emulsions. Despite the relatively high cost of the material no satisfactory substitute has ever been found.

For silver the pre-eminently important oxidation state in all of its ordinary chemistry is the state +1, although the states +2 and +3 are known. With gold, on the other hand, the state +1 is generally quite unstable, and most of the chemistry of gold involves the state +3.

Silver compounds. The silver(I) (argentous) state is represented by a large number of compounds, most of which are insoluble in water. Silver nitrate, silver chlorate, silver perchlorate, and a few other salts with less common anions such as tetrafluoroborate, BF_4^-, hexafluorophosphate, PF_6^- and trifluoromethanesulfonate, $CF_3SO_3^-$, are readily soluble in water, and silver sulfate and acetate are sparingly so. Silver fluoride, AgF, is also water soluble and can be crystallized in the form of hydrates such as that formulated $AgF \cdot 4H_2O$, but it is an uncommon compound. The other halides are all insoluble in water, increasingly so in the sequence silver chloride, silver bromide, silver iodide. Silver chloride can be obtained as rather tough sheets that are transparent throughout much of the infrared region and have been used for optical purposes in infrared spectroscopy. The sensitivity to light of chloride and bromide as well as many other silver compounds accounts for their importance, particularly that of the chloride, in photography.

Other important silver compounds include the oxide, which is obtained as a dark brown precipitate upon addition of alkali hydroxides to solutions of the silver(I) ion, Ag^+. The addition of hydrogen sulfide or other soluble sulfides to solutions of the Ag^+ ion precipitates black silver sulfide, Ag_2S, which is the least soluble in water of all silver compounds. The black coating on tarnished silver articles is composed of this sulfide.

The silver(I) ion forms a great variety of complexes in both solution and the solid state. For the most part the coordination number of Ag^+ in its complexes is 2, and the complexes have the linear structure L–Ag–L. Because of this structure chelating ligands cannot readily form simple complexes and thus tend to give complicated polynuclear products. The coordination number of silver does in some cases exceed 2 and complexes of general stoichiometry AgL_3 and AgL_4 can exist. It is, of course, highly probable that in solution even the formally linear species, such as the ion $Ag(CN)_2^-$, contain water molecules bonded to the silver ion in the plane perpendicular to the axis. Silver forms its most stable complexes with ligands

containing the donor atoms nitrogen, phosphorus, arsenic, sulfur, and selenium, and with cyanide. It has a low preference for oxygen ligands. Many silver salts, except for the most insoluble ones (the sulfide and the iodide), dissolve readily in aqueous ammonia as the result of formation of the diamminesilver ion, $Ag(NH_3)_2^+$. Another very important ligand for the silver(I) ion is the thiosulfate ion, $S_2O_3^{2-}$, which is employed in photography to fix the image by removing from the photographic plate the silver chloride grains that have not been photochemically reduced to metallic silver by light.

Silver(II) and silver(III)

The oxidation state +2 is much less stable for silver than for copper, but there is a significant amount of chemistry for it. The ion Ag^{2+} can exist in strongly acid solutions, but it is a powerful oxidizing agent, and such solutions are gradually reduced by water. Many oxidations which are carried out by the peroxodisulfate ion, $S_2O_8^{2-}$, are catalyzed by added silver(I) ion. Detailed kinetic studies indicate that the effective catalytic agent is silver(II) ion, Ag^{2+}. The apparent oxide of divalent silver, AgO, actually contains a mixture of Ag^+ and Ag^{3+}. The Ag^{2+} ion, as the Cu^{2+} ion, is paramagnetic, having one unpaired electron. The most important and numerous compounds of silver(II) are various complexes normally prepared by persulfate oxidation of silver(I) solutions containing the required ligand. Nearly all silver(II) complexes have square coordination. A few compounds containing trivalent silver are known, such as the oxide, AgO, just mentioned and another black oxide with a composition approximating to Ag_2O_3, as well as a few complexes such as bis[hexaoxoiodato(VII)]argentate(III), $[Ag(IO_6)_2]^{7-}$, and tetrafluoroargentate(III), AgF_4^-.

Silver forms organometallic compounds exclusively in the oxidation state +1. The simple alkyl and aryl derivatives are very unstable and generally decompose below 0° C. The more important compounds are those derived from acetylenes, olefins, and aromatic compounds. The silver ion has the ability to interact with the pi electron systems of such substances, and the resulting complexes are often useful in the isolation and separation of substances, either purely organic or organometallic, that contain unsaturated organic moieties.

Gold compounds. The chemistry of gold in either of its oxidation states (+1 or +3) is mainly one of complex compounds. There is no evidence for gold(I) oxide but gold(III) oxide, Au_2O_3, is known as a brown powder obtained by dehydration of the brown precipitate of $Au(OH)_3$. The chloride and the bromide of trivalent gold are dimeric molecules, Au_2Cl_6 and Au_2Br_6, which form red crystals. They are made by direct reaction of gold with chlorine or bromine at about 200° C. On heating gold(III) chloride in absence of excess chlorine it is decomposed to form gold(I) chloride, AuCl. Gold(III) fluoride, AuF_3, can be made by fluorination of gold(III) chloride at 300° C (about 600° F).

The gold(I) ion, like the silver(I) ion, forms mainly linear complexes, of which the most important are dicyanoaurate(I), $Au(CN)_2^-$, dichloroaurate(I), $AuCl_2^-$, and chlorotrialkyl (or aryl)phosphinegold, R_3PAuCl, in which R represents an alkyl or aryl group. Gold also forms some curious compounds in which there are clusters of metal atoms, an example being one formulated $Au_{11}I_3[P(C_2H_5)_3]_7$, which contains a polyhedron of 10 gold atoms with the 11th gold atom in the centre and iodine and triethylphosphine ligands appended to the outer gold atoms. The full extent of this type of gold chemistry is still unknown. Gold mercaptides, $(AuSR)_n$, in which R is an alkyl group, are obtained from sulfurized terpenes; they are highly soluble in organic solvents and are used for decorating china and glass articles with gold film. They may contain clusters of gold atoms.

Complexes of trivalent gold are more numerous and important. When gold is dissolved in aqua regia or Au_2Cl_6, gold(III) chloride, is dissolved in hydrochloric acid and the solution evaporated a substance known as chloroauric acid is obtained as yellow crystals. It has the formula $H_3O^+(AuCl_4)^-\cdot 3H_2O$. Other water-soluble salts containing the tetrachloroaurate ion, such as potassium tetrachloroaurate(III), $KAuCl_4$, or sodium tetrachloroaurate(III) dihydrate, $NaAuCl_4\cdot 2H_2O$, are readily obtainable. Other complex anions are tetracyanoaurate(III), $[Au(CN)_4]^-$, and tetranitratoaurate(III), $[Au(NO_3)_4]^-$. There are also a variety of complex cations in which the ligands are a mixed set of amine molecules, chloride ions, and water molecules, as for example dichlorodipyridineaurate(III), $[AuCl_2(pyridine)_2]^+$ in which the gold is four-coordinate.

Although organogold compounds are not of major importance, it is worth mentioning that alkyls of gold, formulated RAu, were among the first organometallic compounds of transition metals to be prepared.

BIBLIOGRAPHY. FRANK A. COTTON and GEOFFREY WILKINSON, *Advanced Inorganic Chemistry*, 3rd ed. (1972), presents a comprehensive discussion of fundamental descriptive chemistry and theory; EDWIN M. LARSEN, *Transitional Elements* (1965), gives a much briefer and more elementary topical discussion. S.F.A. KETTLE, *Coordination Compounds* (1969), is an excellent introduction to its subject. FRED BASOLO and RALPH G. PEARSON, *Mechanisms of Inorganic Reactions*, 2nd ed. (1967), presents much general information on coordination compounds. IRVING WENDER and PIERO PINO (eds.), *Organic Syntheses Via Metal Carbonyls* (1968), has excellent coverage of metal carbonyls; and M.L.H. GREEN, *Organometallic Compounds*, vol. 2, *The Transition Elements*, 3rd ed. (1967), deals with the organometallic compounds systematically and in detail. J.P. CANDLIN, K.A. TAYLOR, and D.T. THOMPSON, *Reactions of Transition-Metal Complexes* (1968), covers its subject matter in great detail. CHARLES L. THOMAS, *Catalytic Processes and Proven Catalysts* (1970), reviews the actual uses of industrial catalysts by process type. CARL J. BALLHAUSEN, *Introduction to Ligand Field Theory* (1962), gives a working account of how ligand field theory is applied to the *d*-block elements. WILLIAM P. GRIFFITH, *The Chemistry of the Rarer Platinum Metals* (1967); R.J.H. CLARK, *The Chemistry of Titanium and Vanadium* (1968); RAY COLTON, *The Chemistry of Rhenium and Technetium* (1965); FRED FAIRBROTHER, *The Chemistry of Niobium and Tantalum* (1967); and J.H. CANTERFORD and RAY COLTON, *Halides of the Second and Third Row Transition Metals* (1968), are encyclopaedic accounts of their respective subjects.

Transplants, Organ and Tissue

A transplant, in the context of this article, is a section of tissue or a complete organ removed from its original natural site and transferred to a new position in the same or a separate individual. The term, like its synonym, graft, was borrowed by surgeons from horticulture. Both words imply that success will result in a healthy and flourishing graft or transplant, which will gain its nourishment from its new environment.

Historical background. Transplants of animal tissue have figured prominently in mythology since the legend of the creation of Eve from one of Adam's ribs. Historical accounts of surgical tissue grafting as part of the cure of patients date back to the early Hindu surgeons who, some 600 years before Christ, reconstructed noses from skin flaps taken from the arm. This method was introduced to Western medicine by the great Italian surgeon Gaspare Tagliacozzo in the 16th century. The flap was left attached to the arm for two to three weeks until new blood vessels had grown into it from the nose remnant. The arm was then freed from the new nose.

Purposes and sites of transplants. It was found that extremely thin pieces of skin could be cut free and would obtain enough nourishment from the serum in the graft bed to stay alive while new blood vessels were being formed. This free grafting of skin, together with the flap techniques already mentioned, have constituted the main therapeutic devices of the plastic surgeon in the correction of various types of defects. Skilled manipulations of such grafts can produce surprising improvements in the appearance of those born with malformed faces and in the disfigurements resulting from severe burns. Cornea, which structurally is a modified form of transparent skin, can also be free grafted, and corneal grafts have restored sight to countless blind eyes.

Structural implants of dead tissue, such as bone, cartilage, arteries, or heart valves, are not true grafts or transplants, but are more akin to the stick to which the rose

is attached for support—they are perhaps essential to its welfare, but their function does not depend on biological processes; in fact, inert manufactured devices may often be equally suitable substitutes.

Blood transfusion can be regarded as a form of tissue graft. The blood-forming tissues—bone-marrow cells—can also be transplanted. If these cells are injected into the bloodstream, they home to the marrow cavities and can become established as a vital lifesaving graft in patients suffering from defective marrow.

Organ and limb grafts

The chief distinguishing feature of organ and limb grafts is that the tissues of the organ or limb can only survive if blood vessels are rapidly joined (anastomosed) to blood vessels of the recipient. This provides the graft with a blood supply before it dies from lack of oxygen and nourishment and from the accumulation of poisonous waste products.

As can be seen from the examples cited, living-tissue grafts may be performed for a variety of reasons. Skin grafts can save life in severe burns, can improve function by correcting deformity, or can improve appearances in a cosmetic sense, with valuable psychological benefits. Organ grafts can supply a missing function and save life in cases of fatal disease of vital organs, such as the kidney.

Types of transplant. A skin graft removed from one part of the body and transplanted to another site in the same individual is called an autograft. Autografts cannot be rejected. Similarly, grafts between identical twins or highly inbred animals—isografts—are accepted by the recipients indefinitely. Grafts from a donor to a recipient of the same species—allografts or homografts—are usually rejected unless special efforts are made to prevent this. Grafts between individuals of different species—xenografts or heterografts—are usually destroyed very quickly by the recipient.

Tissue or organ grafts may be transplanted to their normal situation in the recipient and are then known as orthotopic—for example, skin to the surface of the body. Alternatively, they may be transplanted to an abnormal situation and are then called heterotopic—for example, kidneys are usually grafted into the lower part of the abdomen instead of into the loin (the back between the ribs and the pelvis), as this is more convenient. If an extra organ is grafted, it is called auxiliary, or accessory—for example, a heterotopic liver graft may be inserted without removal of the recipient's own liver.

Grafts are usually performed for long-term effects. Occasionally, the limited acceptance of a skin allograft may be lifesaving, by preventing loss of fluid and protein from extensive burned surface in severely ill patients. The graft also provides a bacteria-proof covering, so that infection cannot occur. When the allograft is removed or rejected, the patient may be sufficiently recovered to receive permanent autografts (see BURNS).

Scope of this article. In this article the present state of organ and tissue transplantation is summarized. Specific instances are included, especially if these are of established or potential value. A short account is given of graft rejection, the central problem in tissue transplantation, and the methods by which rejection can be overcome, immunosuppression. Selection of donor, organ and tissue preservation, and the ethical and legal aspects of transplantation are considered. The article concludes with speculations on the future of transplants and the role of artificial organs.

TISSUE TRANSPLANTS

Skin. Most skin grafting practiced at present is with autografts; the special indication for skin allografts in severely burned patients has been mentioned. Skin allografts seem to be rejected more aggressively than any other tissue, and there are many experimental situations in which skin grafts between two inbred strains of animal fail, although kidney grafts between the same strains survive indefinitely. There can be no doubt that if rejection could be predictably and safely overcome, there would suddenly be a whole new field of surgery. With autografts, the donor skin is limited to what the patient has available, and sometimes in extensive burn cases this becomes a matter of robbing Peter to pay Paul. If allografts were not rejected, skin from cadavers could be used for coverage of burned areas without the need for subsequent autografting, and many lives would be saved.

Flap grafts. Flap grafts as used by Tagliacozzo are particularly valuable if fat as well as skin has been lost. The procedure of raising a flap and keeping the donor site adjacent to the recipient bed can be complicated and uncomfortable for the patient. The cosmetic results are good, and the fat under the skin contained in the flap can be used to cover exposed bone or to allow movement in a contracted joint or to fashion a new nose.

Full-thickness free-skin grafts. Full-thickness free-skin grafts are the maximum thickness that can survive without a blood supply, and they are therefore in some danger of failure to survive. They produce good cosmetic appearances and are especially useful on the face. Their main defect is that, unless they are very small, the donor site from which they come is a defect that needs to be closed in its own right and may itself need skin grafting.

Split or partial-thickness skin grafts. Split, or partial-thickness, skin grafts are by far the most commonly used grafts in plastic surgery. Superficial slices of skin the thickness of tissue paper are cut with a hand or mechanical razor. The graft, which contains living cells, is so thin that it usually gains adequate nourishment directly from the raw surface to which it is applied, and the risk of failure to take (that is, to survive in the new location) is therefore much less than with full-thickness grafts. Another major advantage is that the donor site is not badly damaged. It is tender for only two or three weeks, and it resembles a superficial graze both in appearance and in the fact that healing takes place from the deep layer of the skin left behind. Split skin grafts can be taken quickly from large areas to cover big defects. They tend to have an abnormal shiny reddish appearance that is not as satisfactory cosmetically as the other types of skin graft.

Cornea, blood vessel, and heart valves

Other tissue transplants. *Cornea.* There are certain forms of blindness in which the eye is entirely normal apart from opacity of the front window, or cornea. The opacity may be the result of disease or injury, but, if the clouded cornea is removed and replaced by a corneal transplant, normal vision can result. Since cells of the cornea remain viable for some 12 hours after death, a cornea can be grafted if it is removed within that period. Cooling will slow the process of deterioration, although the sooner the section of cornea is transplanted the better. The graft bed to which a cornea is transplanted has no blood supply. Nourishment comes directly by diffusion from the tissues. Because most rejection factors are carried in the bloodstream, the lack of blood vessels permits most corneal allografts to survive indefinitely without rejection, a circumstance that has been of great benefit to many patients.

Blood vessels. By far the most satisfactory blood-vessel transplant is an autograft, similar in principle to skin autografts. One of the commonest and most serious blood diseases in the legs is caused by blockage of the main artery in the thigh by fatty deposits in the degenerative form of arteriosclerosis (hardening of the arteries), the disease that is responsible for most heart attacks and strokes. In the leg the result is, first, pain in the calves, and then gangrene of the foot, necessitating amputation of the leg. If dealt with early, the effects of the arterial blockage can often be overcome by removing a nonessential superficial vein from the leg, reversing it so that the valves will not obstruct blood flow, and then joining this graft to the thigh artery above and below the block—thus bypassing the obstruction.

Vein or arterial allografts are far less successful. In time the walls tend to degenerate, and the vessels either dilate, with the danger of bursting, or become obstructed.

Heart valves. Valvular diseases of the heart can be dangerous, since both a blocked valve and a valve that allows blood to leak backward create a strain on the heart that can lead to heart failure. If the valve is seriously damaged it can be replaced with an allograft valve or a manufactured mechanical valve. Neither is ideal. Allograft valves have a normal central blood flow, but after a

few years they may become rigid and cease to function. Plastic valves—usually of ball valve type—allow blood to flow around the surface of the ball, and this tends to damage red blood cells and cause anemia.

Bone. When fractures fail to unite, autografts of bone can be extremely valuable in helping the bone to heal. Bone allografts can be used for similar purposes, but they are not as satisfactory, since the bone cells are either dead when grafted or are rejected. Thus, the graft is merely a structural scaffold that, although useful as such, cannot partake actively in healing.

Fascia. Fascia, sheets of strong connective tissue that surround muscle bundles, may be used as autografts to repair hernias. The principle of use is like that for skin.

Nerves. Nerves outside the brain and spinal cord can regenerate if damaged. If the delicate sheaths containing the nerves are cut, however, as must happen if a nerve is partially or completely severed, regeneration may not be possible. Even if regeneration occurs it is unlikely to be complete, since most nerves are mixed motor and sensory paths and there is no control ensuring that regenerating fibres take the correct path. Thus, there will always be some fibres that end in the wrong destination and are therefore unable to function. Defective nerve regeneration is the main reason why limb grafts usually are unsatisfactory. A mechanical artificial limb is likely to be of more value to the patient.

Transfusions

Blood and bone marrow. Mention has already been made of blood transfusion and of transplantation of bone marrow. Blood transfusion has been one of the most important factors in the development of modern surgery. There are many lifesaving surgical procedures that are possible only because the blood loss inevitable in the operation can be made up by transfusion. Blood transfusion is of value in saving life following major injury, bleeding ulcers, childbirth, and many other conditions involving dangerous loss of blood. Bone-marrow transplantation has only recently been used in man with success. The potential value will not be realized until allograft rejection can be more effectively controlled; then a variety of diseases of the blood-forming tissues might be treated by marrow transplantation.

ORGAN TRANSPLANTS

Organ transplantations are relatively new surgical procedures, and, in general, they are, for a variety of reasons, not all of which are surgical or medical, more difficult to perform successfully than are most other grafts.

It is justifiable to consider a new and dangerous form of treatment only when all conventional methods have been tried and failed and the patient is not well enough to lead an independent existence outside of the hospital in the interval before death. In such circumstances, most persons would prefer a chance to live, even if it were small, rather than the alternative of certain death.

Although new treatments are based on careful and prolonged investigations in animals, the results of certain operations in animals may not be the same in man. There can be no guarantee, therefore, that successful results of an operation in the laboratory will be equally successful in man. Careful and cautious trial in human beings is eventually undertaken of methods that seem to be promising in the laboratory. Often the first patients to be selected for a new and dangerous operation are desperately ill or even moribund and are unlikely to withstand the extensive surgery and live long enough to demonstrate whether the operation can have a long-term success. If the patient and his relatives wish the operation to be attempted, then it would seem to be morally justifiable to proceed. Many failures can be expected, but the occasional success represents a definite and valuable gain. There have been early disappointing results in many new operations, but eventually the operation has become standard practice. Operations on the stomach at the turn of the century had an extremely high mortality, but now they are routine and are often performed on patients at a relatively early stage in their disease. This has also been the pattern of development in organ transplantation. Approximately 10,000 kidney grafts had been performed in man prior to January 1, 1973. There have been more than 100 heart grafts, and liver grafts, but fewer than 30 lung grafts. Other organ grafts have not been performed in sufficient numbers to make any assessment of their possible value.

The kidney. The surgery of kidney transplantation is straightforward, and the patient can be kept fit by dialysis with an artificial kidney before and after the operation. The kidney was the first organ to be transplanted successfully in man, and experience is now considerable. Effective methods of preventing graft rejection have been available for only about a decade. It is, therefore, too early to predict how long a kidney might function. Fatal kidney disease is relatively common in young people. There are, for example, some 2,000–3,000 deaths from this cause each year in England and Wales out of a population of 50,000,000.

Effects of kidney disease

When there is deterioration of kidney function, eventually, despite all conventional treatment, the patient becomes extremely weak and anemic. Fluid collects in the tissues, producing swelling, known as dropsy or edema, because the kidneys cannot remove excess water. Fluid in the lungs may cause difficulty in breathing and puts an excessive strain on the heart, which may already be suffering from the effects of high blood pressure as a result of kidney failure.

Waste products that cannot be removed from the body can cause inflammation of the coverings of the heart and the linings of the stomach and colon. As a result, there may be pain in the chest, inflammation of the stomach leading to distressing vomiting, and diarrhea from the colitis. The nerves running to the limbs may be damaged, resulting in paralysis. Kidney failure is, therefore, exceedingly unpleasant for the patient and a source of great distress for his relatives. Treatment with the artificial kidney followed by kidney grafting can eliminate all these symptoms and has a good chance of permitting the dying person to return to a normal existence. Unfortunately, only a minority of patients receive this treatment because of a shortage of donor kidneys.

Artificial kidney treatment for about 12 hours, two to three times a week, removes all the features of kidney failure in one to two months, and the patient is able to leave the hospital. He then can be assessed as to his suitability for receiving a kidney transplant. It is customary to remove both diseased kidneys, as the presence of one that is diseased may interfere with the patient's future health after a successful kidney transplant.

Transplantation and postoperative care. The patient may receive a kidney from a live donor or a dead person. Such cadaver kidneys may not function immediately after transplantation, and further treatment with the artificial kidney may be required for two to three weeks while damage in the kidney is repaired. The patient is given drugs that depress his immune responses and prevent the graft from being rejected. Immediately after the operation, for the first week or two, every effort is made to keep the patient from contact with bacteria that might cause infection. He is usually nursed in a separate room, and doctors and nurses entering the room take care to wear masks and wash their hands before touching the patient. The air of the room is purified by filtration. Close relatives are allowed to visit the patient, but they are required to take the same precautions. When stitches have been removed the patient is encouraged to get up as much as possible and to be active, but in the first four months after operation careful surveillance is necessary to make sure that the patient is not rejecting the graft or developing an infection. He may be discharged from the hospital within a few weeks of the operation, but he will need to make frequent visits to the hospital for medical examination and biochemical estimations of the blood constituents to determine the state of function of the graft and to make sure that the drugs are not damaging the blood-forming cells in the bone marrow. Each patient requires a carefully adjusted dose of the immunosuppressive drugs that prevent transplant rejection.

Once the dosage of immunosuppressive drugs is stabilized, the patient is encouraged to go back to a normal

Maintenance of health after transplantation

existence and return to work. The only restrictions are that he must continue to take his drugs and make frequent visits to the outpatient department for surveillance. Restrictions are rather similar to those for patients with diabetes but perhaps less rigorous, since diabetics need a special diet and insulin has to be injected, while the immunosuppressive drugs can be taken by mouth. Patients can return even to heavy work, such as driving a bulldozer, but more often a relatively light job is preferable. Women can certainly bear normal children after a transplant, and men can become fathers. The course of events is not always so happy, unfortunately. If the patient rejects the kidney or develops a serious infection, it may be necessary to remove the graft and stop administration of the immunosuppressive drugs. The patient must then return to regular maintenance treatment with an artificial kidney.

Data on kidney transplant results. In Boston, a kidney transplantation registry was set up to collect the results of transplants throughout the world. This was later moved to Chicago, where the registry, under the joint auspices of the American College of Surgeons and the National Institutes of Health, follows the results of the transplants of all organs. The pooled results of the first 10,000 kidney patients are encouraging and compare favourably with the results of treatment for many common forms of cancer. Kidney grafting has not been practiced long enough to provide knowledge of the eventual outcome. It is not known, for example, whether a kidney graft in a young person will last for his full life span. Even though the outcome is not known, restoration from an unpleasant illness, which would certainly lead to death, to a normal life with a functioning transplant is worthwhile, and nearly all patients are well aware of the benefits even after as short a period as six months. A few years of full and enjoyable life resulting from kidney transplantation entirely justify the procedure. It is now possible to offer nearly an 80 percent chance of a two-year survival with a kidney graft from a close blood relative, but the figure drops to around 50 percent when the graft comes from an unrelated cadaver donor. Even if the graft fails, it is common practice to return the patient to artificial kidney treatment and then provide him with a second transplant or even a third or fourth.

The heart. A group of American investigators perfected the technique of heart transplantation in the late 1950s. They showed that a transplanted dog's heart can keep the animal with a normal circulation until the heart is rejected. The features of rejection of the heart are similar to those of the kidney. The cells that produce immune reactions, the lymphocytes, migrate into the muscle cells of the heart, damage it, and also block the coronary arteries, depriving the heart of its own circulation. In most experiments it has been more difficult to prevent rejection of the heart than of the kidney. Despite this, rejection has been prevented for long periods in animals. The liver and the heart are both more sensitive to lack of blood supply than the kidney. They need to be removed from the donor more quickly and can be preserved without damage for only a short period.

The heart is a pump with a built-in power supply; it has a delicate regulatory mechanism that permits it to perform efficiently when excessive demands are not made on it. During moments of fear, passion, or violent exercise, the heart rate increases greatly, and the contractions become more forceful, so that the pumping of the blood intrudes on the consciousness; this is experienced by the individual as palpitations. Activity in the bowels may also produce alarming physical symptoms at moments of fear and stress, and the ancient biblical scribes made reference to these sensations in their sacred texts. Prudish medieval translators substituted the word heart for bowel. Cessation of the heartbeat has also been, throughout the ages, the cardinal sign of death. Thus, it is perhaps not so surprising that there was a pathological public interest when the first attempts were made at grafting a heart in man. The objectives of heart transplantation, nevertheless, are the same as those of other organ grafts.

One of the most important advances in surgery after World War II was in direct operations on the heart. Heart valves are repaired or replaced with artificial valves, and techniques have been developed so that the heart can be stopped and its function taken over by an electrical pump. If, however, the muscle of the heart is destroyed, as occurs in certain diseases, the only operation that could cure the patient would be to replace the heart with a graft or possibly, someday, an artificial heart, since the temporary artificial substitutes presently available cannot be implanted safely within the chest. Blockage of the coronary arteries and certain other heart muscle diseases can kill the patient because the muscle of the heart cannot contract properly. A patient with one of these diseases who is close to dying is, therefore, a possible recipient for a heart transplant. Since the experimental work has been done in animals, it would seem to be perfectly justified for a cautious approach to be made with clinical heart grafting. To transplant a heart in man was a logical step forward, and the South African surgical team in Cape Town showed that the results of animal investigations could be applied to man. A number of patients have now lived more than four years after heart transplantation.

Appropriate circumstances for a heart transplant

The liver. Many of the functions of the liver are not known. It is a complicated organ producing many vital substances in the blood and is in effect a chemical factory. The two categories of fatal liver disease that may be treated by liver grafting are nonmalignant destructive diseases of the liver cells—for example, cirrhosis—and primary cancer of the liver affecting either the main liver cells or the bile ducts. The liver is extremely sensitive to lack of blood supply and must be cooled within 15 minutes of the death of the donor. The operation can be difficult, since the liver is rather large and of complex structure. Both its removal from the corpse and its grafting into the recipient are major surgical operations. In man, the operation is more difficult than in animals; particularly, the removal of the diseased liver from the recipient. This may be much enlarged and adherent to surrounding structures so that its removal may result in serious bleeding. Once transplanted, the liver must function immediately or the patient will die. There is no treatment available that is comparable to the use of the artificial kidney for kidney disease. If the liver functions well immediately after transplantation, the rest of the management is similar to that followed in kidney operations, and the same drugs are given. Many liver transplantation operations have failed, but the procedure is certainly possible and capable of restoring dying patients to normal existence. The longest survival is now more than four years after grafting. Of the 102 liver grafts performed so far, eight patients have survived a year or more and two for more than two years.

The lung. Chronic fatal disease of the lung is common, but the progress of the disease is usually slow, and the patient may be ill for a long time; when the lung eventually fails he is likely to be unfit for a general anesthetic and an operation. The function of the lung is to allow exchange of gases between the blood and the air. The gas passes through an extremely fine membrane lining the air spaces. This exposure to air makes the lungs susceptible to infection, more so than any other organs that have been grafted. Lung infection is one of the commonest causes of death after grafting of other organs, and it is consequently not surprising that infection has caused failure of many lung transplants. Even a mild rejection reaction can severely damage the gas-exchange membrane, and the patient may die before the rejection is reversed. The actual ventilation of the lungs with air produced by a rhythmic breathing is a complicated movement controlled by nerves connecting the lungs to the brain, and the muscles that produce the breathing to the brain. Cutting the nerves can interfere with the rhythmicity of breathing, and this may be an important cause of the difficulties of successfully transplanting both lungs. Nevertheless, these difficulties have been overcome. If only one lung is transplanted, however, the patient's own diseased lung may interfere with the function of the graft by robbing it of air and directing too much blood into the graft. The longest survivor with a lung transplant was a

Failure of lung transplants from infection

Belgian who lived for ten months after receiving a cadaver lung transplant. Instead of being bedridden and continually using an oxygen mask, he was able to leave the hospital and return to activity, but eventually rejection and infection caused function of the new lung to deteriorate. Further progress in lung transplantation may depend on a safer, more perfect control of rejection.

Special legal and ethical problems. *Legal aspects.* In most countries, the law on organ transplantation is poorly defined, as legislation has not yet been created to cope with this advance in surgery. The existing framework relating to physical assault and care of the dead has no provision for organ transplantation. It is customary to ask the permission of the relatives, but, because organ removal must take place immediately after death, it may be impossible to reach the relatives in time. It has been suggested that there should be a widespread campaign to encourage persons to provide in their wills that their organs be used for transplantation. An alternative is to provide by law that permission is assumed unless removal has been forbidden by the individual in his lifetime. Such laws have been passed in Denmark, France, Sweden, Italy, and Israel. Compulsory postmortem examination, a far more extensive procedure than organ removal for grafting, is required in most countries after unexpected death, and this compulsion is not a matter of public concern and debate.

There would seem to be no reason why organ removal for transplantation purposes should not also be acceptable to public opinion, provided there is a mechanism by which individuals in their lifetime can refuse this permission. This, of course, requires an efficient register of those who indicate their refusal; the register would be consulted before any organs would be removed. It is important that there be public reassurance that considerations of transplantation would not impair normal resuscitative efforts of the potential donor.

Ethical considerations. Transplantation has obviously raised important ethical considerations concerning the diagnosis of death, and, particularly, how far resuscitation should be continued. Every effort must be made to restore the heartbeat to someone who has had a sudden cardiac arrest or breathing to someone who cannot breathe. Artificial respiration and massage of the heart, the standard methods of resuscitation, are continued until it is clear that the brain is dead. Most physicians consider that beyond this point efforts at resuscitation are useless.

REJECTION

Transplantation research is focussed on the tendency of the body to destroy the lifesaving graft. It would be an immense advance if this process could be predictably controlled in a safe manner, but there are other difficulties to be overcome, particularly in providing undamaged organs of suitable size in sufficient numbers for those requiring such grafts.

As a result of evolution, there are in human beings complex defense mechanisms against bacterial and viral invaders. One attack of viral disease, such as measles, usually results in specific immunity to a further attack. The artificial utilization of immunity to provide immunization against smallpox and poliomyelitis represents one of the greatest contributions to modern medicine. Unfortunately, this life-protecting defense mechanism cannot differentiate between infective micro-organisms and potentially lifesaving organ grafts.

Selection of donor and tissue matching. The factors that provoke graft rejection are called transplantation, or histocompatibility, antigens. If donor and recipient have the same antigens, as do identical twins, there can be no rejection. All cells in the body have transplantation antigens except the red cells, which have their own type of red-blood-group antigen. Tissue typing involves the identification of an individual's transplantation antigens. The typing is done with lymphocytes, which are one of the main types of white blood cell. It is important also that the red blood cells be grouped, since red-cell-group antigens are present in other tissues and can cause graft rejection.

Tissue and blood-cell typing

Although transplantation antigens are numerous and complicated, the principles of tissue typing are the same as for red-cell grouping. Incompatibility results in agglutination or death of the lymphocytes tested. Persons who have rejected grafts or have had multiple blood transfusions or multiple pregnancies may develop antibodies to transplantation antigens in their blood. The serum that results when the cells are removed from the blood taken from such a patient can be used as a typing serum.

If the lymphocytes of both donor and recipient are killed by a given serum, then, as far as that typing serum is concerned, the individuals have antigens in common. If neither donor nor recipient lymphocytes are affected, then donor and recipient lack antigens in common. If the donor lymphocytes are killed but not those of the recipient, then an antigen is present in the donor and is missing from the recipient. Much careful work has been done on tissue typing between related and unrelated people, and the results of the typing have been tested by skin grafting.

There is now considerable knowledge concerning the inheritance of transplantation antigens, but, even so, tissue typing is not sufficiently advanced to give an accurate prediction of the outcome of a graft in an individual case, particularly when the donor and recipient are not related to one another.

Immunosuppression. The aim of transplantation research is to allow the recipient to accept the graft permanently with no unpleasant side effects. With current drugs that are used for this purpose, after some months the dosage can often be reduced and sometimes even stopped without the graft's being rejected. In such a case, the patient is no longer susceptible to infections. There would appear to be adaptation of the recipient toward the graft and the graft toward the recipient. The adaptation is probably akin to desensitization, a process used sometimes to cure patients suffering from asthma by giving them repeated injections of small doses of the pollen to which they are sensitive.

There are many agents that prolong graft survival, but the two most effective and widely used are the anticancer drug azathioprine and the corticosteroids.

Azathioprine. Azathioprine, which has been used to treat leukemia and also protects animals from the rejection of kidney grafts, can be given by mouth, but the dose must be carefully adjusted so that the blood-cell-forming tissues in the bone marrow are not damaged, which could lead to infections and bleeding. The white-blood-cell and platelet counts need to be determined frequently to make sure that azathioprine is not being given in too large a dose. It is an extremely valuable drug and has been the basis of most immunosuppressive regimens in patients with organ grafts. At first high doses are given, but eventually the doses may be reduced. Even years after transplantation, small doses of azathioprine may still be needed to maintain coexistence between graft and host. The exact action of the drug is not known.

Adrenocorticosteroids. Cortisone and its relatives, prednisone and prednisolone, are very useful in patients with organ grafts. They can also be given by mouth, but although not damaging to the blood-forming cells, they do predispose the body to infection and have other injurious effects. Persons receiving these substances may develop bloated complexions with swollen faces, may tend to gain weight and become diabetic, and their bones may become brittle. Few recipients of organ transplants, however, can do without corticosteroids, particularly when there is an acute rejection crisis.

Antilymphocyte serum. If rabbits receive repeated injections of mouse lymphocytes, they become immunized and develop antibodies against the mouse cells. The serum from the rabbits' blood after it is clotted can be injected into mice and will often prevent them from rejecting grafts, both from other mice and even, sometimes, from other species. Such antilymphocyte serums can be produced between a variety of species, but in higher mammals, particularly man, it has been difficult to obtain a powerful immunosuppressive serum without side effects of toxicity.

Most of the activity of the serum lies in its gamma

globulin, which contains most of the antibody proteins. Antilymphocyte globulin is used in man but still contains many proteins that are ineffective and may be harmful. It can be added to standard azathioprine and cortisone treatment without adding to the toxicity of these agents, but antilymphocyte serum has its own disadvantages. It can cause severe pain at the point at which it is injected, or, if injected into the circulation, it can cause unpleasant allergic responses. Sometimes, the serum can form compounds that damage the kidney, a particularly unfortunate sequel for an agent used to prevent kidney graft rejection. Antilymphocyte globulin destroys lymphocytes but may have other actions that are important but are not well understood. It has been difficult to obtain a consistently effective product, and there are not good methods of assaying the potency of one serum compared with another. Even when they are prepared by exactly the same methods and the same species, one batch may differ greatly from another. The horse has usually been used to produce antilymphocyte serum for the treatment of human patients, but some persons are sensitive to horse proteins and can become extremely ill when treated with horse serum. It is expected that many of these difficulties will be overcome and that an effective, safe product will be available in the future.

Ill effects of antilymphocyte serum

It is clear that none of the agents so far used to prevent rejection is ideal. No one would use such dangerous agents except as a last resort in a desperate situation. This, unfortunately, is the exact plight of a person in need of a vital organ transplant. For the present, azathioprine, cortisone, and antilymphocyte globulin must be utilized.

ORGAN AND TISSUE BANKS

Without a blood supply organs deteriorate rapidly. Cooling can slow down the process but cannot stop it. Organs differ in their susceptibility to damage. At body temperature, irreversible destruction of the brain occurs after more than three to five minutes; of the liver, after 15 to 20 minutes; of the heart and lung, after 30 to 40 minutes; of the kidney after 50 to 100 minutes; and of the skin and cornea, after 6–12 hours. Although the shorter the time the organ is deprived of its blood supply the better, the cornea can be removed for grafting at relative leisure, but every minute is of vital importance for a liver transplant.

Preservation of kidneys for transplantation

When a kidney is removed from a living donor, it is not necessary to use elaborate preservation techniques. The operations on the donor and recipient are performed at the same time, and the recipient is prepared to receive the graft by the time that the donor organ is removed. Kidneys are removed from cadavers as soon as possible after death, and, preferably within an hour, cool solutions are infused into the blood vessels of the kidney, which is then kept at 4° C (39° F) in a refrigerator or surrounded by ice in a vacuum flask. At the same time, the recipient is prepared for operation. Kidneys can be conserved in this simple way for eight to 12 hours with little deterioration, and during this time they can be moved for long distances. For a kidney to be preserved from 12 to 72 hours, a complicated machine is required to provide artificial circulation. Cool, oxygenated, physiological solutions, solutions with the same osmotic pressure as blood, are passed through the blood vessels of the kidney. The imperfections of the machinery mean that there is a slow deterioration of the organ that does not occur normally in the body. To keep a kidney undamaged for longer than 72 hours is difficult. Blood cells, spermatozoa, and certain other dissociated tissue cells can be frozen to subzero temperatures and kept alive indefinitely. Special preserving fluids will prevent cell destruction by ice crystals, but these fluids have damaging effects if introduced into whole organs such as the kidney.

Long-term storage and banking of organs seem unlikely in the near future. Preservation techniques for the heart, lung, and liver have not been so extensively studied as the kidney. The principles are the same, although these other organs will not tolerate such long periods without a blood supply. Much research will be necessary before it is possible to keep organs banked in the way that blood can be stored.

THE FUTURE OF TRANSPLANTS

It is likely that better immunosuppressive drugs that are less harmful and more certain in their actions will be discovered, but biological control of rejection in a manner akin to desensitization is the ideal method of retaining a graft. There are reasons to be hopeful that production of biological tolerance in mature animals may be possible if transplantation antigens can be prepared in a form that would cause desensitization. It is possible that the tolerance effect could be produced by treatment with antigen at the time of transplantation, but, if a course of pretreatment should be required, antigen from the donor could not be used in the case of cadaver transplants. It might be possible, however, to use antigen of an identical specificity from other sources. Antigen might be prepared from a large number of tissue-typed cadavers, and material of known specificity could be stored and subsequently used to desensitize recipients requiring organ transplants. There is a great deal of work going on in this field, and new knowledge is rapidly becoming available.

Artificial cornea

The functions of the cornea are to transmit light and protect the eye. Corneal grafts fulfill these functions, and it is possible to construct inert synthetic materials that are equally effective. In cases in which corneal grafts have failed, these inert preparations may be preferable to attempting a second graft. Mechanical substitutes for the heart are used routinely in operations on the heart. They are effective for only a few hours. Like a normal heart, the mechanical substitute has pumping chambers, valves, and a supply of energy, but, despite much effort, there has been no success in devising an artificial built-in rhythmic energy supply that is similar in its main characteristic to normal heart muscle. Artificial hearts are cumbersome and cannot be used as long-term heart substitutes. They do not compare at present with heart transplants, which function well, provided that they are not rejected by the recipients.

The difficulties of devising artificial substitutes for the lung are similar to those mentioned with the heart. Artificial devices are excellent for oxygenation of the blood over short periods of time, but the process requires cumbersome machinery.

Much more successful is the artificial kidney, because intermittent treatment with a machine can keep patients in good health indefinitely. The principle depends on a cellophane membrane, on one side of which is the blood and on the other, the so-called dialyzing fluid. There is a tendency for dissolved substances to pass back and forth across the membrane until their concentrations are the same on each side. The patient's blood containing waste products is dialyzed against a fluid containing normal body salts. Protein and blood cells cannot get through the cellophane membrane, but waste products can. To maintain reasonable health, the patient needs to be treated by dialysis for approximately 14 hours two to three times a week. His bloodstream is joined to a large and complicated machine that can develop faults either electrical or mechanical. The points of attachment for the body to the machine have limited lives and, eventually, dialysis may become extremely difficult for an individual patient. Most patients would prefer to have a well-functioning kidney transplant, even though the risks of rejection are greater than those of death on the artificial kidney.

Most of the vital synthetic processes of the liver are not understood and certainly cannot be artificially reproduced. There are many functions of the liver that are not even known. There is, therefore, no basis on which to construct a satisfactory artificial substitute for the liver. Significant progress cannot occur until more is known of normal liver function.

Transportation, Air

Air transportation includes the design and operation of airports, air-traffic control (ATC), and the operation of passenger and cargo aircraft. For most of its history the great bulk of traffic consisted of scheduled airliners, but in the 1960s tremendous growth took place in the two other types of air transportation: unscheduled or chartered airline and private business air transport.

Overall growth of air transportation has been spectacular throughout the world since the late 1940s, with steady increases in numbers, speed, and, probably most significantly, carrying capacity of aircraft. The trend toward increased size was continued in the 1970s with the introduction of the "jumbo" jets. One result was chronic congestion, sometimes of crisis proportions, at nearly all of the world's major airports. New airports planned for Paris, London, New York, Chicago, and elsewhere may take up to 12,000 acres (5,000 hectares) of land, further complicating problems of moving passengers and cargo within the airport. Noise is another continuing problem of airports near large cities.

A high degree of international and national organization has always been required of air transportation. Problems of international traffic rights and freedom of passage, and questions of air safety, health, and commercial competition had to be dealt with in the decade after World War I, but these did not receive comprehensive treatment until the immense expansion of air transportation after World War II.

By 1970 a massive body of international regulations, based largely upon bilateral agreements between governments on traffic rights and upon international operating practices recommended by the International Civil Aviation Organization (ICAO)—the aviation agency of the United Nations—and backed up by national air navigational regulations and international airline agreements, had been accumulated to guide the operation of worldwide air services. (The history of aviation in general may be found under FLIGHT, HISTORY OF.)

This article is divided into the following sections:

I. History of commercial aviation
  The origin of commercial airline operations
  Post-World War II developments
II. Airport design and operation
  Evolution of airports from early landing fields
  Modern airports
III. Air-traffic control
  General considerations
  Control in different types of airspace
  Navigational aids and procedures
  Operation of air-traffic control
  The future of air-traffic control
IV. Air-transport industry
  The structure of a modern airline
  General aviation
  Air cargo
  Economic significance

I. History of commercial aviation

The immense stimulus that World War I gave to aviation in general paved the way for the immediate development of commercial operations. Twin-engine bombers were converted for passenger use, and a scattering of commercial flights was recorded in the United Kingdom, the United States, the Soviet Union, and India. Almost at once the idea of sustained, scheduled operations came into being.

THE ORIGIN OF COMMERCIAL AIRLINE OPERATIONS

In 1919 sustained daily schedules were begun on three routes in Europe: Berlin to Weimar, Paris to Brussels, and London to Paris. These operations were rapidly extended or superseded as experience was gained in the regular operation of aircraft on domestic and international routes. The economic problems of air transport were met in a variety of ways in different countries. During the 1920s major efforts were made to produce transport aircraft that would be economical to operate, reliable in service, attractive to passengers, safe, and reasonably comfortable. The range of aircraft with an economic payload was strictly limited, and refuelling at intermediate points was required on trips of more than 300–400 miles (500–650 kilometres). Aircraft could be designed with seating for 12 to 15 persons or more, but it was not until the mid-1930s that the associated technology of engines, propellers, general structures, movable wing surfaces (flaps), and retractable undercarriages (landing gear) had progressed to a stage that resulted in the availability of the first economically viable transport aircraft to meet the various requirements. In the United States, United Kingdom, Germany, and France, 30- to 40-seat aircraft were introduced, and a worldwide network of air services had come into operation by the outbreak of World War II.

The first successful air transport

Pre-World War II developments. In the United States, the major concentration was on the domestic routes. It was for these routes that the most famous of the prewar transport aircraft, the Douglas DC-3, was developed. The DC-3 was flown from New York to Los Angeles, with three or four stops, in about 24 hours (18 flying hours). In Europe, the colonial empires of Great Britain and France and the ambitions of Germany and Italy encouraged the development of long-distance overwater operations. The Soviet Union developed long-distance airlines to link distant regions with Moscow.

In 1937 flying-boat service was inaugurated by British Imperial Airways Ltd. between Southampton and the Far East, with a preliminary flight to New Zealand. Flying-boat services, however, involved specialized handling facilities. Route planning at this stage of airline growth was restricted by the limitations of aircraft range and capability, and by the limited ground navigational and landing aids available. The Imperial Airways service to Cape Town, South Africa, involved three landplane sectors (London–Paris, Cairo–Khartoum, and Kisumu–Cape Town), two flying-boat sectors (Brindisi–Alexandria and Khartoum–Kisumu), and two rail journeys (Paris–Brindisi and Alexandria–Cairo).

Stiff competition developed between Royal Dutch Airlines (KLM), operating the DC-3, and Imperial Airways, operating flying boats; and by mid-1938 both lines were operating an eight-day service from western Europe to Sydney. In 1934, Imperial Airways and Qantas, the Australian airline, had formed Qantas Empire Airways, which operated that part of the U.K.–Australia route between Singapore and the Australian east coast. Other routes developed from Europe before World War II were the Air France routes from Paris, through Tangier and Dakar in Africa to Natal, Rio de Janeiro, Montevideo, and Santiago in South America, and in the East to Cairo, Beirut, Calcutta, and Hong Kong. The German airline Deutsche Lufthansa had routes to South America via Lisbon, and to Bangkok via Baghdad and Karāchi.

Airship services. Airship (dirigible) services also were inaugurated in Germany at an early stage. Between 1932 and 1937 paying passengers were carried on the "Graf Zeppelin" and the "Hindenburg" on transatlantic flights from Frankfurt am Main to Lakehurst, New Jersey, and to Pernambuco (Recife) in South America. With the destruction by fire of the "Hindenburg" at Lakehurst in 1937, transatlantic service came to an end. Britain also planned to develop airship services, and successful flights were made by the airships R-100 and R-101 to India and Canada, but the loss of the R-101 in a crash at Beauvais, France, in 1929 ended the venture.

The "Hindenburg" disaster

Air transport in World War II. Immensely important contributions to the development of long-haul air transport occurred during the years of World War II. Following pioneer Pan American World Airways and Imperial Airways flying-boat flights in 1937, inaugural air-mail services between Britain and North America took place in August 1939 with the aid of in-flight refueling. Tanker aircraft were based at Foynes, Ireland, and Botwood, Newfoundland. Both British and U.S. flying-boat services were in operation when war broke out. After a series of U.S. neutrality acts were passed in the late 1930s, the Pan American Clippers could fly only to Ireland. Early in the war, however, another service, known as the North Atlantic Return Ferry, was introduced and

eventually maintained a year-round service; it was taken over completely by British Overseas Airways Corporation (BOAC). Because of its good weather record in winter months, Prestwick, Ayrshire, was chosen at an early stage as the U.K. terminal for the transatlantic ferry.

The Far Eastern routes from Europe were cut at an early stage in the war (1940) when Italy began hostilities. In due course the famous horseshoe route was established, linking 16 countries, from Durban, South Africa, to Sydney, Australia, via Khartoum, Cairo, Karāchi, Bangkok, and Singapore. Landplane and flying-boat routes linked West Africa and the Far East.

In the Pacific, the services of the flying boat and landplane also expanded steadily throughout the war. Thus, at the end of hostilities in 1945, the world was extensively provided with military air-transport services, equipped predominantly by flying boats that were to provide the capacity for many scheduled long-haul services in the immediate postwar era.

POST-WORLD WAR II DEVELOPMENTS

International agreements. The new pattern of air-transport organization emerged in the post-World War II era as a result of international conferences at Chicago (1944) and at Bermuda (1946). The Chicago conference established a form for international organization of air transport on lines more restrictive than that sought by the United States, but it established a permanent International Civil Aviation Organization (ICAO), which still exists and has proved highly effective. The problems of air-traffic regulations between the U.S. and the U.K. were effectively resolved at the Bermuda conference when a bilateral agreement was reached that proved of lasting significance as a standard. One of the features of the Bermuda agreement was that fares and rates were to be regulated by governments after agreement by the International Air Transport Association (IATA), a private association formed by the principal international world airlines. The traffic, financial, and technical conferences of IATA have notably aided the advance of the air-transport industry through the postwar era. By 1969 membership exceeded 100, and collaboration, encouraged through operation of common types of aircraft and equipment, promoted a steadily increasing level of professional work.

International regulation of fares

The immediate postwar period. World War II had the effect of establishing the United States as the world leader in the civil-aircraft manufacturing and airline industries. While Europe was at war and concentrating on building fighting aircraft, U.S. airlines were re-equipping with the ubiquitous Douglas DC-3. During the war years, U.S. airlines took advantage of the better economics of the DC-3 to meet a new surge in demand for air transport. More than 800 DC-3s had been produced directly for commercial use when production ceased in 1944. By the end of the war, U.S. airlines were preparing to put the newly developed four-engine DC-4 and Lockheed L.049 Constellation into sustained scheduled service. The scheduled routes with the largest passenger volume in the United States at the end of the war were the New York to San Francisco and Los Angeles, and the New York to Chicago routes. Transcontinental and Western Air (currently Trans World Airlines, TWA) introduced Constellations on the New York to Los Angeles route in February 1946, a few weeks ahead of American Airlines' introduction of the DC-4. In the same month American introduced the DC-4 onto the high density New York to Chicago route, and National Airlines Inc., also used the DC-4 on the direct overwater route from New York to Miami. The postwar availability of large numbers of former military-transport aircraft (particularly the DC-3 and DC-4), together with a rapidly rising demand for air transport, furthered the expansion of airline activity. This rapid U.S. expansion was not confined to the trunk airlines (*i.e.*, the airlines operating on the main domestic routes), and in the period up to 1950 some 20 local service airlines emerged, mainly operating the DC-3, to develop feeder services connecting with the principal points on the trunk airlines route networks.

The end of World War II also left the U.S. airlines in a dominant position on the most important of the international routes, the North Atlantic. U.S. airlines started the postwar era with 90 percent of the North Atlantic traffic and achieved two significant firsts. American Overseas Airlines (later acquired by Pan American World Airways) was the first airline to operate scheduled transatlantic flights with a landplane (the DC-4); and TWA, in February 1946, introduced the long-range pressurized Constellation in the New York–London flights.

First landplane transatlantic service

The revival of postwar civil air transport in Europe was led by Great Britain. British European Airways Corporation (BEA) was formed in 1946 to take over the European services previously operated by BOAC and the domestic services of the small British independent airlines. BEA was soon established as the leading airline in Europe, and its route network was rapidly extended to the North African coast and to the eastern Mediterranean. By 1970 BEA was the eighth largest passenger-carrying airline in the world. With the exception of Aeroflot, the Russian state airline, all the others above it were American.

BEA's expansion was aided by the introduction of Britain's first successful postwar civil aircraft, the Vickers Viking, which was significantly faster than the DC-3, and entered BEA service in September 1946 initially on the Scandinavian routes. The Viking was the first of a series of British aircraft launched by BEA. British Overseas Airways Corporation, Britain's principal long-haul airline, was not able to support the British manufacturers as was BEA, so BOAC had to put Constellations into service in 1946 to remain competitive as it developed an extensive intercontinental route network.

Air France, the French national airline, was re-formed at the beginning of 1946 and quickly established a European network and transatlantic services. The French airline was second only to BEA in European air transport. An international cooperative airline emerged in the third position, Scandinavian Airlines System (SAS), formed as a consortium of the principal airlines of Sweden, Denmark, and Norway in July 1946. Sweden held three-sevenths of the airline's capital shareholding and the remainder was shared equally between Denmark and Norway. This consortium enabled the three Scandinavian countries to play a major part in the development of civil air transport.

It is not possible to summarize the development of all the world's airlines during this important postwar period, but it should be noted that there was considerable growth in airline service in the less developed areas of the world, as well as in the United States and Europe.

The transition to turbine-powered aircraft. The period between 1946 and the mid-1950s was one of maturation for many of the world's leading airlines. Douglas and Lockheed four-engined aircraft offered the airlines more range, better standards of comfort, and better economics. The immediate postwar stalwarts, the DC-4 and Constellation, were gradually replaced on the trunk routes by the Douglas DC-6 and DC-7 and the Lockheed Super Constellation series, and on the short-haul routes the DC-3 gave way to the twin-engined Convair series and the Martin 404. During this period, the U.S. manufacturers, supported by a booming domestic market, consolidated the lead they had held at the end of the war. In Britain, the postwar adaptation to peacetime production had prevented the aircraft industry from competing with the U.S. to any significant extent in developing large piston-engined civil aircraft. British thoughts turned instead to the development of turbine-engined aircraft (see also AIRCRAFT).

The Vickers Viscount. The British Vickers Viscount was the first propeller-turbine (turboprop) civil aircraft to go into production, and BEA played an important part in the definition and early development of this very successful short-haul aircraft, powered by Rolls-Royce Dart turbine engines. BEA ordered 20 Viscount Series 701 in August 1950, and the aircraft was put into service in April 1953 on the London–Cyprus route. The Viscount attracted the interest of the world's airlines, and within two years, Air France, Aer Lingus (Ireland), and Trans-Australia Airlines (TAA) all ordered Viscounts. Trans-Canada Airlines (TCA) introduced the Viscount onto

North American scheduled services on the Montreal–Toronto–Lakehead–Winnipeg and the Montreal–New York routes in April 1955. In 1954 Capital Airlines of the U.S. ordered 60 Viscounts. The turboprop Viscount brought new standards in airline comfort and speed and boosted air traffic and airline profits throughout the world. Approximately 440 Viscounts of all variants eventually were sold.

Viscounts in U.S.

The Bristol Britannia. While the Viscount was making its impact on the short-haul networks, the medium- and long-haul routes were still dependent on the U.S. piston-engined aircraft; and it was not until some four years after the introduction of the Viscount that the first large turboprop aircraft, the Bristol Britannia, was put into service. Following a number of delays during its development, the Britannia 100 finally entered service with BOAC in February 1957 on the London–Johannesburg route. The following month it was introduced on BOAC's Australian routes, taking over from the Constellation and reducing the time to Sydney from 56 to 47½ hours. The longer range Britannia 300 Series entered service on the London–New York route in December 1957, offering for the first time a reliable nonstop service in each direction.

The Britannia was sold to only nine airlines, and apart from BOAC the largest order was for five aircraft from Canadian Pacific Airlines. The U.S. Lockheed Electra was the only large turboprop aircraft produced in the U.S. for the civilian market, and both the Electra and its British counterpart, the Vickers Vanguard, were too late (1959–60) to be widely adopted by the airlines, which were at that time already converting to jet equipment.

Introduction of the jet. The commercial jet era started in May 1952, when BOAC put the British de Havilland Comet 1 onto the London–Johannesburg route. By 1953, BOAC, UAT (French), and Air France were operating the Comet 1 on routes to the Far East, India, and Africa. In 1954, however, disaster struck; there were two serious accidents, and the Comet 1 was withdrawn from service. Investigations revealed the cause of the Comet 1 disaster as the previously unknown problem of metal fatigue; that is, the gradual weakening of metal under continued stress and vibration. De Havilland retained faith in the Comet and modified the basic design to produce the larger and longer range Comet 4, which entered service with BOAC in 1958.

On October 13, 1955, Pan American ordered 20 Boeing 707 and 25 Douglas DC-8 jet airliners. These orders heralded the rush of orders from the world's long-haul airlines for the big jets. The Soviet Tupolev Tu-104, however, was the first jet to enter sustained commercial service, in September 1956. The Soviet state airline had previously operated only twin-piston-engined aircraft, and the Tu-104 had a dramatic impact in developing communications across the U.S.S.R.

Tupolev Tu-104 introduced

Transatlantic jet services began in October 1958 with BOAC operating the first scheduled London–New York service with the Comet 4, just three weeks before Pan American introduced the Boeing 707–120 on the route. Pan American consolidated its leading position on the North Atlantic route ten months later by introducing the long-range Boeing 707–320; BOAC, with the Comet, was its only jet competitor. The 707–320 was the first commercial jet specifically intended for intercontinental service, and most of the transatlantic operators used this aircraft. Another competitor, the DC-8–30, was first operated on the North Atlantic in April 1960 by the Dutch KLM (Royal Dutch Airlines).

The wider use of jet aircraft. Throughout 1960 and 1961 most of the world's leading airlines operating on the ten major trunk routes took delivery of 707 and DC-8 aircraft. The others chose either the Comet 4, the Convair CV880 or CV990, or the Boeing 720, the smaller version of the 707.

The Caravelle. It was left to the French to counteract the jet's high operating costs on short- and medium-haul operations. The twin jet Sud-Est (later Sud-Aviation, and then Aérospatiale France) Caravelle was unique in that it was the first aircraft to adopt the rear-engined design philosophy. Air France gave strong support to the development of the Caravelle, giving the manufacturer its first order for 12 aircraft in February 1956, nine months after the first test flight.

When the Caravelle entered service with Air France in May 1959, more than 50 Caravelles were on order, mainly from the European scheduled airlines. By February 1961 nine airlines were operating Caravelles on services in Europe. Air France and SAS, the second airline to order the Caravelle, rapidly established extensive short-haul jet services. United Air Lines was the only U.S. airline to order the Caravelle, first putting it into service on the New York–Chicago route in July 1961.

Only three of the more important European airlines did not buy the Caravelle. BEA chose a short-range version of the Comet called the Comet 4B, while KLM and Lufthansa continued with short-range turboprop equipment until the second generation short-haul jets became available.

Other jets. The medium-range, medium-capacity jet requirement brought about the Comet 4C, which was operated by Mexicana, East African Airways Corporation, and some of the Arab airlines, and the Boeing 720/720B series. The Boeings were widely adopted in the United States because of their flexibility of operation and similarity to the Boeing 707, from which the 720 was derived. The success of the 707 and 720 established Boeing as the leading commercial jet company, and this success was followed by the even greater success of the Boeing 727 series. The 727 design incorporated a T-tail configuration that permitted the installation of three engines, an integral aft (rear) boarding stairway, and an auxiliary power unit to provide power and air conditioning on the ground without running the main engines. These aircraft and the stretched 727–200, developed from the earlier 727–100, offered the world's airlines an extremely flexible and economic aircraft with which to meet the air-traffic boom brought about by the wider development of jet travel in the 1960s. United Air Lines alone was operating more than 150 727s during 1970.

Three-engine design

The de Havilland (Hawker Siddeley) Trident and the Vickers (BAC) VC10, attempts by British manufacturers to compete with Boeing and Douglas, were designed to meet BEA and BOAC specifications, respectively, and because they were not as large or as economic as their U.S. alternatives, neither aircraft sold well abroad.

Development of regional and feeder routes. By the early 1960s the Caravelle and the Viscount were being introduced on those principal secondary routes that had sufficient traffic to warrant their operation. There was, however, a further airline demand for a twin-turbined aircraft to replace the DC-3 on the low traffic-density routes that had been initiated throughout the world during the 1950s.

The most successful DC-3 replacement came from The Netherlands, the Fokker F.27, which first entered airline service in 1958 with Aer Lingus Teoranta (Irish International) in Europe, and West Coast Airlines in the U.S. Both the F.27 and its British equivalent, the Hawker Siddeley HS 748, were widely used to extend regular air-service networks to remote locations previously not served by air, often utilizing unprepared runway strips.

Short-haul jets. The mid-1960s saw the beginning of one of the most competitive aircraft sales campaigns in commercial aviation history as the airlines prepared to replace the Viscounts and F.27s operating on the more important regional routes with short-haul jets. The British BAC One-Eleven was the first short-haul jet to enter service, being first operated by British United Airways and Braniff International Airways in April, 1965. The Douglas DC-9–10 entered service eight months later, and by offering a developed stretched DC-9–30 for early delivery, Douglas captured the largest part of the market.

The roles to which the short-haul twin-jets were applied varied considerably. In the Hawaiian Islands, Aloha and Hawaiian Airlines operated these aircraft over an average distance of 118 miles (190 kilometres), whereas in Europe a number of tourist airlines operated them over distances of more than 800 miles (1,300 kilometres). From 1967 Eastern Air Lines in the U.S. operated DC-9s on the air shuttle—an hourly departure, no reservation,

Air shuttle service

guaranteed-seat commuter service from New York to Boston and Washington. The unique service carried 3,272,000 passengers in 1969.

A much lower level of service was offered in many parts of the world by small operators using small aircraft on feeder routes. The third-level airlines, or commuter carriers as they were called in the United States, developed rapidly in the late 1960s, although the number of commuter carriers in the U.S. fell from 240 in 1968 to 150 in 1969.

Helicopter services. In 1971 there were still only a small number of operators providing limited scheduled helicopter services. Experimental helicopter services began in Britain, the United States, and Belgium after World War II. A few of these services developed into more sustained scheduled services during the 1950s and early 1960s. SABENA, the Belgian airline, started the only international scheduled helicopter service in 1953, linking Brussels with Paris, Rotterdam, Cologne, and six other cities in France, The Netherlands, and Germany. The SABENA service ceased in 1965 because the operation was uneconomical. At the beginning of 1971 the principal scheduled helicopter services remaining in operation were New York Airways, Inc., in the U.S., which had 64 flights daily among the three New York airports, and BEA Helicopters, which connected Penzance in the southwest of England with the Scilly Isles. Both of these airlines were using Sikorsky S-61 helicopters.

Growth of nonscheduled passenger services. Nonscheduled passenger services grew largely from the efforts of the postwar private airlines in the United States and Europe to expand their limited operations to an economic level. On both sides of the Atlantic, postwar troop transport and military freight contracts allowed the supplemental, or charter, airlines to expand while the growth of nonscheduled commercial traffic gained momentum.

By the early 1950s commercial charter traffic was beginning to exploit tourism to a significant degree. Because the scheduled airlines feared a fall in their rate of traffic growth, a new tourist-fare class was introduced in 1952 to compete with the lower rates of the charter airlines. These scheduled fare reductions had an immediate effect. On the North Atlantic route 63 percent of the passengers travelled at tourist fares in the first full year, and the tourist proportion rose to 71 percent by 1957. A further scheduled fare reduction occurred in 1958 with the introduction of the economy class, which eventually replaced the tourist fare.

The new scheduled fares came at a time when, in the United States, the military contract rates were being reduced, and in Great Britain a large number of small independent airlines were being grouped into larger operating units. The result in the U.S. was that the charter airline industry experienced a setback and a number of airlines failed. In Great Britain, British United Airways Ltd., (BUA) and British Eagle International Airlines became established as the leading independent (privately owned) airlines.

By the mid-1960s the U.S. supplemental (nonscheduled) airlines were acquiring long-haul jets, and with the help of a revised system of awarding military contracts, this addition set a firm base for expansion. The supplementals began to concentrate on developing nonmilitary charter work and specialized in Affinity Group Charters, in which an aircraft's capacity was chartered to a club or organization for its own members, who shared the costs of the flight equally. Two other types of commercial charter were also developed—single entity charters, where a person or corporation chartered an aircraft for his or its own use, and Inclusive Tour Charters (ITC). In ITC's the aircraft was chartered to a tour promoter who sold the aircraft's seating capacity as one part of a travel package.

Inclusive Tour Charters

In the United States, the booming demand for affinity charters was the main commercial attraction to the supplementals. The ITC market in the U.S. had been exploited only to a small extent by the beginning of the 1970s. The principal ITC operations were to Hawaii and the Orient. In Europe, however, the inclusive tour led to the development of a vast new type of air traffic in the late 1960s.

The British independent charter operators led the development of ITC's in Europe with the promotion, through travel agents, of Mediterranean summer-holiday packages, principally to Spain and Italy. By the early 1960s Scandinavian and German charter airlines were also offering inclusive tour arrangements, and by 1965 the Europe–Mediterranean ITC business was booming. Until 1965 the charter airlines had been using such turboprop aircraft as the Viscount, but in that year BUA introduced new BAC One-Eleven jets on inclusive tour services. The European tour promoters were able to offer inexpensive holidays by obtaining large contract booking rates with both the charter airlines and the hotels at the destination points.

In 1969 more than 10,000,000 passengers were carried on inclusive tour flights in the Europe–Mediterranean area. The Danish charter carrier Sterling Airways was Europe's largest ITC airline. One of the main problems for the European charter airlines was the highly seasonal variation in ITC traffic. To overcome the difficulties of low aircraft use during the winter months, the airlines negotiated long-term contracts (often five years) with the tour promoters, who guaranteed sufficient aircraft use to warrant the purchase of new jets. Thus, the charter airlines obtained jets as modern as those operated by the national scheduled airlines.

The growth of charter operations during the 1960s gave the independent charter lines a new status and contributed significantly to the growth of world tourism. By 1970 it was estimated that in Europe nonscheduled passenger traffic would exceed the scheduled traffic by the mid-1970s.

The world airline industry in the 1970s. *Jumbo jets.* A most significant stage in the development of air transportation was reached in 1970 with the introduction of the Boeing 747 into airline service. The Boeing 747 was the first of the wide-bodied, or "jumbo," jets as they were commonly called; they could seat as many as 500 tourist-class passengers. Their first competitors, the Lockheed 10–11s and McDonnell Douglas DC-10s, could seat up to 400 passengers.

Supersonic transports. In 1970 the world's airlines also had placed optional orders for two new supersonic transports (SST's), the Anglo-French BAC Aérospatiale Concorde and the Boeing 2707. In the Soviet Union, the Tu-144, the first SST to fly, was also being developed. But while the Boeing was still in the preliminary design stage, public debate developed in the United States over the cost and over the environmental problems; that is, the noise generated in the airport environment and the sonic boom that would result from the supersonic speed of the plane. The possible pollution of the upper atmosphere was largely discounted. In March 1971, the U.S. Senate voted to end further funding of the aircraft, and financing from private sources seemed unlikely. The economic operation of the SST's would depend to a large extent on whether they would be allowed to fly at supersonic speeds over land.

The SST debate in the U.S.

Financial status. The 1970s did not begin with high profitability for the airlines. As an economy measure, early in 1971 United Air Lines and American Airlines took the step of reducing the frequency of scheduled flights on some U.S. transcontinental routes. The financial position of the world's scheduled airlines in 1970 began to show an increase in operating profit after a two-year decline. Scheduled passenger traffic, which accounted for 80 percent of revenue, had increased to 307,000,000 passengers.

While the growth of total scheduled air traffic over the decade up to 1970 had averaged about 15 percent per year, traffic forecasts in 1970 were for a rate of growth up to 1980 of 12 percent per year. This increase compared with estimates for the growth of charter traffic at rates of more than 16 percent. This significant rate of growth of charter traffic and the introduction of high-capacity jets was influencing the major scheduled airlines to concen-

trate more effort on marketing charter services and inclusive tour holidays based on reduced scheduled service fares. As part of this expansion into the tourist field, the major international airlines also began to invest in the development of hotels, often through consortiums of several international airlines and hotel organizations.

Pollution problems. One effect of growth of commercial jet transportation during the 1960s was the increased public reaction against aircraft noise and exhaust pollution. To combat the problem of noise, engine and aircraft manufacturers intensified research into reducing noise at the source by developing quieter engines. Another possible solution was development of short take-off and landing (STOL) and vertical take-off and landing (VTOL) aircraft. The high angles of approach and "climb out" of these aircraft would lessen the surface area affected by the aircraft's noise. The airlines, however, were cool toward STOL and VTOL, which could not be placed in extensive commercial operation for several years; besides this, the airlines, in the midst of heavy investment for the wide-bodied jets, were looking toward the late 1970s and early 1980s to recoup. With the technology available it was possible that limited STOL services could be started by the mid-1970s, using 30- to 50-passenger propeller-driven STOL aircraft on short-range high-density services, but the commercial impact would probably not be significant before the mid-1980s, when 80- to 100-passenger V/STOL aircraft might be available.

STOL and VTOL

II. Airport design and operation

An aerodrome is described by the International Civil Aviation Organization as a defined area on land or water (including any buildings, installations, and equipment) intended to be used either wholly or in part for the arrival, departure, and movement of aircraft. The term airport has, however, come into common use and refers particularly to those aerodromes where air-transport movements occur on a considerable scale, and especially in the United Kingdom where full-time customs facilities are available. Airfield is used in reference to small aerodromes, generally without hard runways or facilities for handling large transport aircraft or their passengers and cargo.

EVOLUTION OF AIRPORTS FROM EARLY LANDING FIELDS

The essential requirements for a landing field have expanded steadily since the earliest days of flying. Just before World War II, the landing and takeoff distance required was a maximum of 650 yards (600 metres), and the additional demands that could result from an engine failure were not clearly defined. In these terms the airfields at New York, London, Paris, and Berlin were laid down, the area involved rarely exceeding 500 acres. London's airport at Croydon had no runway. Hard runways were rare. Tempelhof (Berlin), constructed in 1929, was one of the busiest airfields in prewar Europe; it became a major social centre with restaurants and rooftop observational areas. More than 750,000 visitors were recorded during its first year of operation. Le Bourget (Paris), Croydon (London), and La Guardia (New York) likewise attracted many visitors. The aircraft and the air passenger at that time had made little impact upon the design of airfields or air terminals. Such a situation, in fact, still exists in the great majority of airfields throughout the world. In the overall world pattern, the small grass airfield with simple terminal building, rudimentary control tower, and negligible landing aids is still dominant.

A wide variety of airports and airfields has developed to accommodate the great range of modern aircraft types and the different kinds of facilities needed for passenger and cargo handling.

The increasing demand for air travel has created the need for the large transport aircraft, now almost exclusively of multijet design. The demands such aircraft make upon all kinds of ground facilities, runways and taxiways, fire fighting and safety services, passenger and cargo-handling facilities, car parking, and lighting, navigational, and approach aids, are the principal determinants in the design of the large, sophisticated airports adjacent to the main centres of world population.

Of the 13 airports handling more than 8,000,000 passenger movements in 1969, ten were located in the United States, a reflection of the fact that about 60 percent of the world's air transport occurs there. Chicago (O'Hare) heads the list. Of the non-U.S. airports, London (Heathrow) was sixth, Paris (Orly) was 12th, and Frankfurt (Rhine-Main) was 13th.

It should be noted that it is primarily at these large airports that the problems of noise, congestion in the air and on the ground, and conflicts in land use with other regional planning objectives have arisen. The difficulties of smaller airports have been largely those of economics.

MODERN AIRPORTS

The elements of a major airport. The four principal elements of a major airport are airport management and control; passenger and cargo terminals; the runway, taxiway, and apron systems; and airport services.

The airport management and control function embraces the day-to-day operation and long-term planning of the airport; the terminal; runway and taxiway system; local air-traffic control; the lighting, navigational, and aircraft approach guidance system; as well as fire fighting, fuel supply, and all ancillary services, including customs facilities.

The passenger and cargo terminals provide for handling passengers, baggage, and cargo and the related activities.

The runway, taxiway, and apron systems are required to meet the needs of the aircraft for landing and takeoff, for positioning correctly for these manoeuvres, for aircraft location to receive and discharge loads, and for the operating and servicing crews to work.

Airport services related to the aircraft comprise the apron (the part of the airport surface adjacent to the terminal), the handling of aircraft, passengers' baggage, cargo, aircraft fuel supply, aircraft catering, cabin cleaning, and engineering services. Ground-related services include passenger-terminal catering and the concessionary facilities within the terminal (such as car rental), and the car parking and garage arrangements in the airport-terminal area for the travelling public and the airport staff.

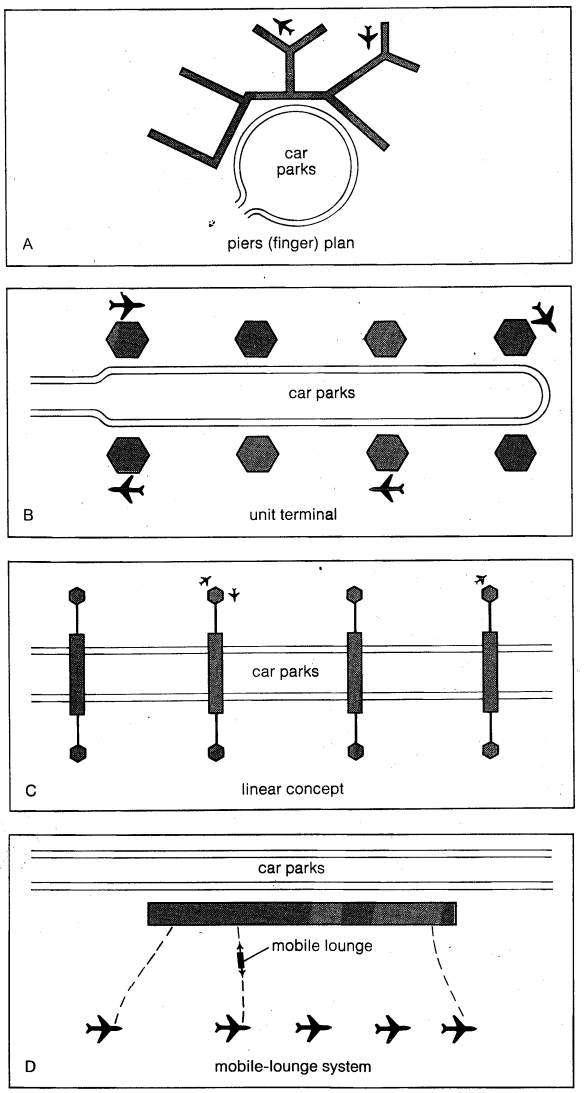
Airport planning. There is no uniform pattern of airport layout and design. In the hierarchy from the great metropolitan airport to the small-town field with a single landing strip of tarmac, an immense variety of layouts has proved successful. The site itself is a critical factor. Runway orientation is the starting point for design, site selection being generally determined by its suitability for an appropriate runway system. Particularly important elements are the availability of level, well-drained land without approach-path obstruction or possible conflict with roads and urban development and access to existing major road systems. As in all exercises in technical development, conflicts arise at every stage in decision making, the most significant being that between noise and access to the urban community.

Site selection

It is important to note that airport layout and operation are keyed to development. The industry is dynamic and there are two sources of change: traffic growth and technological change. Most airports are in a period of dramatic growth, with passenger movements doubling every four to five years. In the major city airports such conditions are almost universal, but the small-town airport is often in a less favourable position. Technological change in aviation, however, is worldwide, being based on advanced aircraft and avionics industries in the United States, United Kingdom, France, Germany, Italy, The Netherlands, and Japan. These industries are steadily promoting new types of aircraft, usually of increased size and performance, forcing modifications in airport design virtually each decade.

Runway, taxiway, and apron systems. The essentials of a runway and taxiway system for a given airport are related to the types of aircraft, the scale of traffic, and the prevailing meteorological conditions.

Modern types of jet aircraft can accept higher crosswinds than the aircraft of the immediate postwar years.



Thus, in the mid-1970s fewer runways were needed than formerly. Light aircraft may need to land and take off at an angle to the main runway because of limited handling capability in strong crosswinds, but the operation of such aircraft would not be sanctioned at major international airports. Indeed, considerable controversy exists concerning the use of large airports by executive and private aircraft.

Meteorological information is fully recorded and analyzed to determine the most desirable orientation for the principal runway(s), subject always to the suitability of the weather (visibility, cloud base, etc.) for an airport development in any region.

Experience in air operations has encouraged the International Civil Aviation Organization (ICAO) of the United Nations to establish standards of practice for the design and layout of airports and runway systems. These complex requirements have been incorporated in the Air Navigational and Air Terminal Regulations of most member governments of ICAO. Certain of these relate to the length, strength, and width of runways and taxiways, the limiting position of obstructions, and the lighting, navigational, communications, and approach aids.

Safety standards

Airworthiness standards are promulgated by the governments of aircraft-manufacturing nations to safeguard the operating standards, performance, and weight of aircraft in the various stages of flight, including takeoff and landing. Air-navigational regulations (based predominantly upon ICAO recommended practices) set down the runway specifications essential to allow the safe operation of transport aircraft.

Typical airport terminal layouts.

Detailed requirements specify the many other critical design factors in runways, taxiways, and aprons. Runway length has probably reached a limit that is unlikely to be exceeded even with the development in the next decade of larger jets and SST's. More stringent standards in design of equipment and layout for airfields are, however, gradually being incorporated by the licensing authorities.

Airport layout and terminal design. Different styles of airport layout and terminal design have developed since 1960 to meet the demands of the jet transport and the massive traffic increases.

The principal characteristic types of layout that have developed in this period are shown in the illustration. The essential need is to deploy a large number of aircraft into positions for unloading and loading so that passengers can embark and disembark with minimum expenditure of time and effort and so that the other essential apron services can be performed. The essential terminal services must be provided and a high order of access, especially for road traffic, must be arranged. Provision for expansion of all such facilities, with full retention of efficiency, must be built into the system.

The finger system (A), extensively developed through the 1960s, is entirely suitable for medium-sized terminals with twin-jet aircraft and also the four-jet Boeing 707 and McDonnell Douglas DC-8. A major problem has been the long distances the passengers must travel from the reception room to the aircraft.

Breaking the passenger flow into a number of units is effectively achieved in the unit terminal (B), which has the merits of shortening the passenger walk, allowing more space for expansion, and providing a convenient geometrical arrangement for the "nosing in" of large transports; the design has proved especially effective with the jumbo jets.

The linear concept (C) is also under active development and incorporates many of the basic features of the unit terminal. A new airport planned for Louisville, Kentucky, is based on the linear concept. The British Airport Authority has described plans for the third London airport based on the linear concept. A decision has been made by the British government (1971) that this should be built on the coast at Foulness.

The mobile-lounge system (D) has been applied at Dulles International Airport outside Washington, D.C. Mobile lounges transfer passengers between aircraft and terminal. This method offers a more intensive and flexible use of the apron space for the aircraft but at a high cost in motorized transfer and some congestion of vehicles on the apron when aircraft are being serviced at peak times.

Apron servicing. Terminals and aprons must be designed so that the aircraft is held for the shortest possible time in the turn-around phase on the apron. This is most important in handling short-haul aircraft, for which ground time is a high percentage of operating time. A typical transit turn-around time for a modern airbus type of aircraft is 25 minutes. A large number of vehicles are in circulation on the apron during the turn-around, and marshalling of aircraft and vehicles is critical to the smooth operation of a large airport. During peak periods at O'Hare International Airport (Chicago), for example, an aircraft comes on the apron or taxis out every 20 seconds.

Passenger and cargo terminals. The principal passenger and cargo areas should be related to the expected traffic flows. The limit of traffic through an airport may be determined by several factors, including aircraft landing and takeoff movements, congestion on the apron, or congestion in the air-traffic-control system. Limits may also arise in the passenger terminal or, less frequently, through congestion in the road or rail approaches to the airport buildings and parking areas.

The terminal areas may be self-contained and restricted, as originally on the central island site at Heathrow, or they may develop on the satellite principle, as at John F. Kennedy International Airport (New York City). More recent designs for large city airports have concentrated, however, on the linear concept, in which a continuous process of development and growth can be provided.

Factors in terminal size

The determining factors that fix the scale of the buildings are the standard busy rates of aircraft and passenger and cargo movements in the different categories of arrival, departure, domestic, and international movements. Standard busy rates are defined as submaximum movement rates, likely to be exceeded on about 20 occasions a year. With growth rates in passenger traffic in some cases exceeding 20 percent per annum, the need to make provision for the growth of all facilities becomes apparent.

Air-cargo movement on the apron is conducted in a variety of ways. At major airports, automated systems can be justified by the high use achieved and the reduced manpower required. Lack of flexibility is inherent in such systems. Labour problems beset the early introduction of such arrangements (*e.g.*, at Heathrow). In smaller airports, truck transport from warehouse or freight shed to and from the aircraft is all that is required. Special accommodations for freight forwarders and bonded stores are provided at major international airports.

The airlines normally provide their own cargo handling and storage facilities at the airport. Cargo is delivered to the terminal by the freight forwarder, agent, or shipper and is documented and located for loading or consolidating on a pallet or in a container for the next flight departure. Cargo aircraft tend to operate during the latter part of the day and at night; thus, it is generally true that cargo flights do not contribute greatly to congestion in the air or on the ground at major airports.

Congestion. At major airports, congestion has reached a high level both in the air and on the ground. Takeoff delays sometimes reach a point at which aircraft must return to the apron to refuel because of depletion of fuel while waiting to take off. It is largely because of the cost of such delays that an immense program of airport building is underway throughout the world.

Some cities in the United States and Europe have sought to encourage general aviation use of the smaller aerodromes rather than the main air hub. Congestion in the air space, on aprons, and on runways becomes a matter for air-traffic control; it also arises in the terminal, in the car parking spaces, and on the access routes to and from the airport. Space at congested airports, such as Kennedy International (New York City) and Heathrow (London), is at such a premium that ancillary services such as car parking, restaurants, and sales stands may need to be moved from the airport precincts. Off-airport parking has become a feature at London airport; rates, including the transport of passengers by bus to the airport terminal, are considerably lower than on the airport. Passenger and freight processing may eventually be carried out only at central city points or at peripheral sites, airport space being reserved exclusively for loading and unloading aircraft and essential ground vehicles.

Proposals to situate airports away from congested zones have found favour with some regional planners and with most conservationists. Air transport, however, must be accessible to its markets, and the offshore sites proposed for a London airport at Foulness as well as the Seadrome ten miles (16 kilometres) west of Los Angeles in Santa Monica Bay have been strongly resisted by the airlines.

Airport noise problem. A serious threat may exist to the development of aviation if action to curtail aircraft noise is not effective. In the early 1970s, action took a number of forms. Restrictions on jet-aircraft movements were introduced, especially at night (*e.g.*, at London and New York City). Restraints on urban (particularly residential) development were imposed by many planning authorities within the zones having high-noise ratings. Control of the flight path of aircraft (especially after takeoff) and in the use of runways (for landings and takeoff) was exercised to minimize noise nuisance in the airport environment and over a wider area. Airport development and new site selection were directed to minimize deterioration in the environment. Aircraft noise certification standards for new types of jet transport aircraft were introduced, and intensive research was under way to produce quieter engines.

Airport links to local ground transportation. One aspect of an airport is that of a transport hub where different transport modes connect. Passenger and cargo consignments change between ground and air. Thus, access for surface vehicles is as critical a factor in airport design as in site selection.

The road traffic generated by the large air terminals is already on a scale that demands special consideration of the layout and width of roads and access routes to the city centres.

Highway congestion

The peak traffic in the airport approach roads tends to occur in the morning and evening, coinciding with other peaks of suburban traffic, so that journey times to and from an airport from the downtown areas are difficult to forecast in the rush periods. Because major airports have gradually moved farther away from the city centres, journey times to airports have increased. Road traffic congestion has accentuated the problem, and the cost of idle time has become critical in the economic comparison of air and surface transport. A major argument for vertical takeoff and short takeoff aircraft lies in their lesser requirements for airport space, promising sites close to the central city.

III. Air-traffic control

GENERAL CONSIDERATIONS

If aircraft flew in a random fashion across the surface of the earth and within its atmosphere, the chances of collisions would be remote. The greatest number of aircraft, however, fly on the most popular routes and converge on the most frequently used destinations. With the growing popularity of air transport in the 1920s and 1930s, it became necessary to mark the most frequently used aircraft routes, first by aerial navigational lights at airfields and at strategic points on the ground beneath the intended routes. Later, with the introduction of radio aids, came rules to help aircraft traversing the same route to avoid one another, particularly at night or in conditions of low visibility.

An alerting service was provided to confirm aircraft arrivals and to initiate a search for overdue planes. Air-to-ground radio communication introduced such other services as up-to-date weather forecasts and warnings of major atmospheric disturbances.

International standards. During World War II the need for international standards was recognized by the International Civil Aviation Organization at its 1944 Convention in Chicago. ICAO set up a Rules of the Air and Air Traffic Control (RAC) Division to make recommendations for standards, practices and procedures for air-traffic control. This action produced an annex to the convention—Annex 11—the title of which was later changed to "International Standards and Recommended Practices—Air Traffic Services," to include other functions besides that of control. Annex 11 defines the various types of airspace and procedures and gives recommendations for an Air Traffic Services (ATS) organization. It is then the responsibility of each contracting state to implement, as it sees fit, these recommendations and to notify ICAO of deviations from them. Each state has sovereign rights applicable to the airspace above its own territory, and each determines which portion of that airspace will be provided with an air-traffic service and defines the various areas (geographically and by altitude) that will comprise the various types of controlled airspace. Parts of the world where large stretches of airspace exist and over which no state has sovereign rights, such as the oceans, are allocated by ICAO to such states as are willing to provide a service for them.

There are naturally quite wide variations among states as to the degree of compliance with these publicized practices. The ICAO has to make careful compromises when deciding on standards. A standard involving the introduction of the latest, most sophisticated navigational aids, for example, might be implemented by the prosperous countries of the world, but if it is beyond the budgets of other countries its adoption as an international standard can have only limited value.

Air-traffic control—definition and purposes. The term air traffic is used to describe movement of passengers, cargo, and aircraft, depending on the context. In the

term air-traffic control, however, it refers solely to the movement of the aircraft itself, and it covers movement and manoeuvring both on the ground and in the air.

The four main purposes of air-traffic control (ATC) are to prevent collisions between aircraft; to prevent collisions between aircraft and obstructions on the ground; to provide for a fast, orderly flow of traffic; and to provide advice and information useful in planning and executing flights.

Divisions of airspace

To fulfill these ends, the air above all countries of the world is divided into various areas, zones, and routes, each with its own set of rules for flying. The various areas are explained later in this article, but the two main divisions are controlled airspace and uncontrolled airspace. As the names imply, controlled airspace refers to areas where air-traffic control is exercised in a positive manner for some types of flights. In uncontrolled airspace the air-traffic-control services offer only a minimum advisory and information service.

Visual- and instrument-flight rules. There are two sets of rules under which a flight may be carried out, and the use made of air-traffic control depends on which set of rules is being applied to a particular flight. The differences between these sets of rules must be appreciated before the regulations applying to the various kinds of airspace are examined.

The first set of rules is referred to as visual-flight rules (VFR), and an aircraft being flown under these rules is referred to as being on a VFR flight, or flying under VFR. To operate under VFR, the pilot must be capable of avoiding collision with other aircraft or with obstructions on the ground by visual observation of the hazards and by taking necessary action. For these rules to apply, therefore, the pilot must have adequate vision; the rules specify that he must remain away from all clouds, separated from them by at least one nautical mile horizontally and at least 1,000 feet (300 metres) vertically. Visibility itself must be at least five nautical miles. Outside controlled airspace these rules are relaxed slightly by specifying that if the aircraft is flown at a 3,000-foot altitude or below, then so long as the pilot remains clear of clouds and in sight of the ground, he may fly under visual-flight rules. It is the pilot's responsibility to ensure that his flight is conducted under VFR and that weather conditions permit him to continue to fly under these rules.

If aircraft are unable to comply with visual-flight rules, they must be flown under instrument-flight rules (IFR). An aircraft being operated under these conditions is said to be on an IFR flight, or flying under IFR. While the words "instrument flight" are derived from the weather conditions when a pilot has to rely on his instruments to maintain his altitude and course, without reference to the ground, it is important to understand that instrument-flight rules do not apply solely to aircraft flying in poor weather conditions or low visibility. While the term visual-flight rules is to some extent self-explanatory within the conditions laid down above, the term instrument-flight rules should be regarded as a set of regulations that can apply to the flight of an aircraft quite independently of what the weather conditions may be.

CONTROL IN DIFFERENT TYPES OF AIRSPACE

The basic zone of airspace as defined for air-traffic-control purposes is the flight information region (FIR). Within this region, as geographically defined, are provided air-traffic-control services, the services provided being dependent on the types of airspace within the FIR. It is common practice to name each FIR by the name of the centre providing the ATC service, thus Paris FIR, London FIR, etc. These centres are termed air traffic control centres (ATCC's). Within the FIR the airspace is divided into the two basic areas mentioned earlier, controlled and uncontrolled airspace, and a third termed advisory airspace.

ATC service

Uncontrolled airspace. Even within uncontrolled airspace the ATCC's will provide a minimum service for aircraft within their FIR. It is not, however, compulsory for aircraft flying in uncontrolled airspace to make use of this service. Aircraft whose pilots do choose to participate in the service provided are given proximity warnings of other aircraft that the FIR controller knows to be in its vicinity. This information is strictly limited because aircraft in uncontrolled airspace are not required to communicate with Air Traffic Control. Indeed, some may not have the radio equipment necessary to do so. Hence, the FIR controller does not know the position, or even the presence, of all aircraft in his area. To participating aircraft, the FIR controller also provides an alerting and flight-information service.

Advisory airspace. As a kind of halfway step between uncontrolled and controlled airspace, some of the FIR is divided into advisory routes and areas. As in the case of uncontrolled airspace, the advisory service provided by ATC is not obligatory. Aircraft that do choose to use the advisory airspace service, however, are required to comply with the ATC instructions given. Separation is not provided by ATC between all aircraft using advisory airspace.

Controlled airspace. Within each FIR and outside uncontrolled and advisory airspace each country establishes controlled airspace. This area takes the form of control zones, which normally surround airfields and airports; control areas providing a larger area of control surrounding major hubs of aviation activity; and control areas in the shape of corridors, termed airways, that connect these major hubs with each other. Within all these types of controlled airspace, aircraft are required to conform to air-traffic-control procedures and regulations. Separation is provided by the air-traffic-control service, and all aircraft are required to remain in communication with the air-traffic controller. To maintain separation between aircraft the controller obviously must be aware of the position of each aircraft under his control, both in terms of geographical location and in terms of height. He obtains this data and exercises control by two distinctly different methods: procedural control and radar control.

Procedural control. Each airway and route within control areas is defined by radio beacons. The beacons are of different types, which will be described later, but basically they provide heading information for the pilot of a suitably equipped aircraft. This information tells him which course to take to fly to the beacon, and it is presented to the pilot in the form of a pointer on his instrument panel. It tells him also when he is over a beacon, since the pointer swings around as the aircraft passes overhead, continuing to point to the beacon, which by this time is behind the aircraft. Some beacons have an associated facility for indicating the aircraft's distance from them known as distance-measuring equipment (DME).

The pilot keeps the controller informed of his progress along the airway and of his altitude by radio-telephonic communication. The controller has a board in front of him on which he places "flight progress strips." These small rectangular pieces of paper identify the aircraft with its call sign, type, and other information, so that the controller has a ready visual reference of the traffic proceeding down the airway for which he is responsible. He is thus able to space aircraft out along the airway and provide minimum separations. Should this minimum separation become endangered (for example, if a faster aircraft is catching up to a slower one), he can regain adequate separation by ordering a change of altitude on the part of one of the aircraft; or if another altitude is not available, he can "hold" one aircraft over one of the reporting points. Holding is a procedure whereby an aircraft circles over a given location, and it is much more common in a control area, where aircraft are queueing to land on a runway, than along the airways. It is, however, an acceptable way of providing separation.

Radar control. Procedural control as described above has certain limitations, especially when traffic is heavy. First, it depends on two-way radio transmissions between the pilot and the controller; even if reception conditions are good, the actual transmission and receipt of messages takes time. Second, the controller is often unaware of the precise geographical position of the aircraft. With the advent of surveillance radar, the controller can be presented with a cathode-ray tube display of each aircraft's

"Blips"

position. The aircraft reflect the radar beam, and each aircraft shows up as a spot, or "blip," on the tube. Thus, the controller has an indication of all the aircraft within the range of his radar, and the necessity for frequent voice communication between pilot and controller is reduced. On this primary radar, however, the controller still does not know the height of individual aircraft; and, all blips being essentially identical, he cannot make positive identification. He can, by radiotelephone, ask an aircraft to make a turn—which is known as turning for identification—and so identify that particular aircraft on his tube. Such a procedure is time-consuming and undesirable, and modern techniques are being introduced to overcome this deficiency of primary radar.

Transponders and secondary radar. The aircraft itself acts as a "reflector" for the radar beam associated with primary radar. This is why the air-traffic controller cannot distinguish between the blips on his radar screen. To overcome this disadvantage of primary radar and to provide the controller with routine information to reduce voice transmission between pilot and controller, secondary surveillance radar (SSR) is being progressively introduced into the air-transport (ATC) system.

This radar system requires that the aircraft themselves carry a special transmitter and responder called a transponder. On a request from the controller, the pilot activates his transponder, which provides a second blip alongside the original blip representing his aircraft. The second blip eliminates the need for identification turns. Also being introduced are two extra facilities provided by the transponder—the transmission of the aircraft identification, in the form of letters and numbers, and its altitude. These data are displayed on the controller's radar screen alongside the aircraft blip. With this system, the radar controller has full, immediate information on the aircraft's geographical position and its identification and altitude.

NAVIGATIONAL AIDS AND PROCEDURES

Airways and routes within controlled areas are marked by radio beacons of various types.

Route aids. *The nondirectional beacon.* The nondirectional beacon (NDB) provides a radio station for use by aircraft. The equipment in the aircraft consists of an automatic direction finder (ADF, or radio compass), which gives the pilot information in the form of a pointer indicating the bearing of the NDB transmitter. The pilot can thus fly courses to or from the NDB. If dual ADF equipment is provided on an aircraft, it is possible to fix position by combining the information provided by two NDB's. The term nondirectional is derived from, and indicates the insensitivity of, the transmitted radio beam to direction; that is, it transmits indiscriminately in all directions. There are still many NDB's throughout the world, providing navigational aids to aircraft. The tendency, however, is to replace them with the VOR (see below).

The VHF omnidirectional radio range (VOR). The VHF (very-high-frequency) omnidirectional radio range (VOR) is the radio aid selected by the International Civil Aviation Organization as the recommended standard short-distance aid for aerial navigation. It operates in the very-high-frequency wave band. Like the NDB, the VOR transmits in all directions but has two separate transmitting signals—one stationary and one rotating. The second signal alters phase as it rotates, the two signals together providing distinct "radials," which are identifiable on the aircraft receiving equipment. The radials can be visualized as 360 lines radiating from the VOR station, representing the 360 degrees of a circle. (In practice, there are an infinite number of radials.) The 90-degree radial radiating outward from the VOR represents magnetic east, the 180-degree radial represents magnetic south, and so on. The pilot can select any of the 360-degree radials and fly toward or away from the VOR station. A simple "fly right, fly left" indicator on his instrument panel indicates when he is on the radial. An alternative instrumentation is a radio magnetic indicator (RMI), similar to that used in the NDB instrument, with a pointer mounted above a compass card, the pointer indicating the direction of the VOR station. With the pointer at the "top" of the instrument, a direct course to the VOR station is indicated. The advantage of the VOR over the NDB lies in the relatively static-free VHF band operation, simplicity of use, and identification of precise radials to and from the VOR.

VOR transmitting signals

Distance-measuring equipment. Distance-measuring equipment (DME) is often used in conjunction with VOR. Used in combination, the system is designated VOR/DME. An interrogator carried on DME-equipped aircraft transmits radio pulses, triggering a reply from one ground-based DME responder. The time between transmitting and reply is electronically measured, giving an indication of aircraft distance from the ground station. This distance is given the pilot in nautical miles in a form similar to the mileage meter in an automobile. Without DME, the only time the pilot knows his precise position is when he is directly over the NDB or VOR transmitting antenna. At other times he only knows his bearing from the station. The VOR/DME enables the pilot to fix his position precisely once he knows his bearing from a point on the ground and his distance from it. Such position-fixing systems are known as rho-theta systems (distance-bearing).

Tactical air-navigation (Tacan) system is basically a military navigation rho-theta aid, but it is the distance-measuring element of Tacan that provides the DME element for VOR/DME. The original ICAO intention was to recommend VOR as the standard short-range navigational aid, associated with co-located distance measuring equipment. With the widespread introduction of the military Tacan system, however, this intention was modified on economic grounds and use is made by civil aircraft of the Tacan distance-measuring element.

Fan markers. Fan markers are also used to mark specific points along the airways and in control zones. A fan marker transmits identification signals in the form of dots and dashes, but the transmission is arranged by means of the aerial design to radiate a narrow fan-shaped beam vertically upward. The "length" of fan extends across the airway, while its width is limited so that an aircraft flying through the beam receives the transmission for a relatively brief period. The pilot in the cockpit is given the data by a flashing light, and the signal is also transmitted through the pilot's headset. Fan markers are also used in conjunction with the instrument-landing system discussed later.

Area-coverage aids. The most commonly used area-coverage aids are based on a master ground transmitting station and two or more subordinate, or "slave," stations. The master and slave stations, separated from each other in some cases by hundreds of miles, are synchronized so that the transmissions from each can be identified and used as position lines in the shape of hyperbolas surrounding the stations. Such area-coverage systems are also referred to as hyperbolic systems (see also NAVIGATION). In the long-range navigational aid loran, for example, the master station transmits a series of pulses, the slave transmitters retransmitting these pulses after a measured delay. If a line is drawn representing a constant delay between the two signals, it takes the form of two hyperbolas, one focussed on the master station and one on the slave station. Identification of two position lines, one associated with each master–slave pair, provides the aircraft position.

Hyperbolic systems of navigation

A short-range hyperbolic aid more applicable to airways flying is the decca navigation system. Decca consists of a master station surrounded by three slaves, but it uses continuous waves, as opposed to the pulses used in loran. Decca can be used in conjunction with a flight log, which consists of a moving map display on which the aircraft track is continuously traced by an ink pen. The accuracy and simplicity of the decca flight log combination have resulted in its increasing use.

Long-range aids. The radio navigation aids discussed earlier have been mainly those used for flying along airways and within control areas, with the exception of loran, which introduced the basis of hyperbolic aids. Other aids are available for long-range navigation, the most important being the Doppler system and the inertial navigation system (see also NAVIGATION).

The Doppler system is a self-contained airborne system using transmissions from the aircraft and measuring the time taken for their return from the earth's surface. The system provides a measurement of ground speed and of drift caused by wind.

The inertial navigation system is also completely self-contained within the aircraft and uses gyroscopes to measure aircraft acceleration in three planes and integrates the accelerations to obtain aircraft speed. As in the Doppler system, these data must be used in conjunction with some known datum in the form of a precise starting position (see also GYROSCOPE).

Instrument-landing system. The radio aids described above allow the pilot to fly precise tracks along the airways and within control areas. Having reached the terminal area surrounding his destination, he needs some form of aid, especially in adverse weather, to allow him to descend from a safe altitude and land on the runway. Runways equipped with such aids are termed instrument runways, and the standard approach aid is the instrument-landing system (ILS).

The ILS is not strictly a landing system at all but rather a means of giving the pilot guidance so that he can make his final approach to the runway and arrive at some point that gives him sufficient visual reference to the ground to enable him to land the aircraft. The ILS system consists of two radio transmitters, called the localizer and the glide slope. The localizer antenna is situated in line with the runway but beyond the far end; that is, the end remote from the touch-down end and toward which the aircraft lands. The antenna transmits a thin horizontal beam divided into two. These two transmissions overlap by an angle of five degrees, the centre of this overlap being accurately aligned with the centre line of the runway. If the approaching aircraft is within the five-degree overlap, a pointer on the pilot's instrument hangs vertically from its hinge at the top of the instrument, telling the pilot he is approaching in line with the runway. Should the pilot fly to his left outside the overlap, the vertical pointer will swing to the right, indicating "fly right" to regain the centre line; if the aircraft deviates to the right, the pointer will indicate "fly left" by moving to the left. The amount of deviation of the pointer from the vertical indicates the distance of the aircraft from the localizer (and hence runway) centre line.

This system gives the pilot accurate guidance in azimuth, or track. Altitude and rate of change of altitude information is provided by the glide slope transmitter, located to the side of the runway and at the opposite end from the localizer; that is, near the point of touch-down. Like the localizer, the glide slope transmitter provides a pattern of two interlocking radiations, but in this case they are in a vertical plane. The upper and lower signals overlap by about one degree, and this overlap slopes up from the glide slope antenna at approximately three degrees to the horizontal, corresponding to a generally acceptable angle of approach. A horizontal pointer is incorporated in the same instrument as the vertical localizer pointer on the pilot's instrument panel. If the aircraft is above the three-degree glide slope this pointer indicates "fly down" by moving down; if the aircraft descent is below the glide slope it moves up, indicating "fly up."

The glide slope transmitter

By reference to both localizer and glide slope pointers in the one ILS meter instrument, the pilot can fly an accurate approach path to near the end of the runway. Standard ILS, however, is not accurate enough to permit him to descend all the way to runway level, and landing of the aircraft is accomplished visually.

To complete the instrument landing system, it is common practice to provide two fan markers along the ILS approach path. These fan markers, described earlier, allow the pilot to determine his precise position on the final approach path and enable him to check his actual altitude against the glide-slope indication.

OPERATION OF AIR-TRAFFIC CONTROL

Outlined above are the basic practices and instruments that form a framework on which air-traffic control can work. This section describes how it works in practice.

The flight plan. When flying within any part of a flight-information region (FIR), a pilot can file a flight plan. This flight plan, on an internationally standardized form, gives details of the pilot's intention: his expected time of takeoff; the route and altitudes at which he intends to fly; his estimated time at various points along the route; his destination airfield; and his expected landing time. The flight plan also specifies an alternate destination, to be used if he is unable to land at his chosen first destination. In addition, the flight plan includes information that would be useful in case the aircraft makes a forced landing, such as the number of people aboard and the nature of the emergency equipment carried.

Flight plans must be filed if the pilot intends to fly within controlled airspace under instrument flight rules or if he wants to use the Air Traffic Advisory Service in controlled or advisory airspace. In some countries, it is necessary to submit a flight plan if the flight is to be undertaken in controlled airspace at night, regardless of weather conditions.

Flight plans are usually filed with the Air Traffic Service Office at the departure airfield. If the aircraft is outside controlled airspace, they can be filed in flight by radio, normally with the FIR controller. A copy of the flight plan is sent to the destination airfield and to all air traffic control centres responsible for the areas through which the flight will pass.

Air Traffic Control personnel consider the flight plan in conjunction with other flight plans that have been filed that refer to the use of the same airspace at the same time. A clearance is then given that will, where possible, clear the pilot to use the route, altitudes, and timing as shown on the flight plan. If there is conflicting traffic, however, the clearance may alter the flight plan.

From all these filed flight plans, the controller at the ATCC prepares the flight progress strips mentioned earlier, which contain the aircraft identities and radio call signs. These strips of paper are inserted on a board viewed by the executive controller who, if the flight is in controlled airspace, moves the strips along the board as the aircraft passes each reporting point. The reporting points, geographically marked by radio aids, are mandatory if the flight is taking place under IFR in controlled airspace; the pilot must report to the controller when he reaches them. He then indicates his estimated time of arrival at the next reporting point. The ground controller is thus enabled to record the progress of aircraft under his control and to provide each with adequate separation from other flights.

Separation standards. Aircraft are considered to be adequately separated if the distance between them, both vertically and horizontally, allows for inaccuracies in position fixes, errors in instruments such as altimeters, and other variables. The actual distance depends on a number of factors and is not constant. Up to an altitude of about 29,000 feet (8,800 metres) vertical separation is considered adequate if there is at least 1,000 feet (300 metres) between aircraft; that is, up to this altitude aircraft can fly over the same geographical point at the same time if their altitude differs by at least 1,000 feet. Above 29,000 feet, separation is increased to 2,000 feet (600 metres). If aircraft are at the same altitude, a succeeding aircraft flying in the same direction may not pass over a reporting point within ten minutes of the first aircraft overflying it. (This time may be reduced to five minutes, if the first aircraft is flying at a speed 20 knots faster than the succeeding aircraft, or to two minutes if it is 40 knots faster). Similarly, aircraft on converging tracks at the same altitude, and aircraft climbing or descending through other aircraft's tracks, are separated by ten minutes.

Vertical separation of aircraft

The controller progresses all aircraft with filed flight plans in controlled or advisory airspace by using these separation standards. He clears aircraft from point to point, ensuring adequate time separations at each reporting point. He issues clearances to each aircraft to continue to the next reporting point when he is satisfied that adequate separation exists. For climbing or descending aircraft, he issues clearance to change altitude only when

he is sure that the new altitude, or the altitudes through which the aircraft will fly to reach it, are clear of other aircraft or that other aircraft are adequately separated in time as the cleared aircraft passes through their altitudes. If one aircraft is climbing and another descending on opposite courses, for example, vertical separation of at least 1,000 feet must exist ten minutes before the aircraft pass each other and for ten minutes afterward.

As the aircraft moves from one controller's area to the next, responsibility is handed over to the adjacent area controller by telephone, with relevant information on the aircraft, intended route, altitude, and identity. The pilot is instructed to contact the adjacent controller by radio.

On approaching his destination airfield, the pilot is given clearance to leave his airway altitude and begin descent.

Aerodrome approach procedures. If aircraft are queued up, waiting to land on the airfield, an arriving aircraft joins the holding pattern, located over the final reporting position. All aircraft in the pattern are separated by 1,000 feet in altitude and are flying a "racetrack" pattern, turning over the beacon to fly outbound for one or two minutes before reversing direction again and flying inbound toward the beacon, each circuit taking four or six minutes. Aircraft are taken from the lowest altitude of this "stack" to begin intermediate approach procedures. As one aircraft leaves, the aircraft above it is cleared down by 1,000-foot steps to the vacant altitude and so on up the stack—the aircraft descending in 1,000-foot steps as cleared, until the lowest altitude (normally 5,000 feet) is reached. Usually the intermediate approach—that is, from the final beacon until the aircraft is lined up with the runway—is conducted by radar control. The radar controller accepts responsibility from the procedural controller and gives the pilot a course to steer—known as "vectoring"—so that he approaches the extended centre line of the runway. The radar controller uses vectoring to provide the final spacing between aircraft as they turn onto final approach. This spacing is normally four to five miles (six to eight kilometres). Leaving the beacon, the aircraft is vectored until instructed to turn onto the final approach usually at eight to 15 miles (13 to 24 kilometres) from the runway end. During vectoring, the aircraft is also let down from the lowest altitude in the stack to 2,000 or 3,000 feet (600 or 900 metres), at which height it turns onto the final, straight run in toward the runway and picks up the instrument-landing system radio beams described earlier. When the preceding aircraft has turned off the runway, the approaching aircraft is given clearance to land, and control is handed over to the aerodrome controller, whose responsibility it is to direct the aircraft after landing to its position at the terminal. For this purpose, at larger airports, he is assisted by ground radar, which shows the position of all moving vehicles on the airfield surface.

Precision approach and ground-controlled approach

At some airfields an additional, very accurate radar provides a service similar to the ILS. This is called PAR (precision-approach radar) or GCA (ground-controlled approach). In this system voice transmission to the pilot enables the PAR controller to pass on instructions regarding the aircraft heading and glide path as shown to him on two radar screens (one shown in the horizontal plane, the other in the vertical plane). This system has been largely superseded by the more accurate and readily used ILS, although some units are still operated for monitoring approaches.

The procedures and techniques of procedural control and the use of radar in the terminal area have been described in some detail to provide an appreciation of the practicalities and theory of ATC. In principle, these are used throughout the world wherever there is sufficient traffic density to warrant formal control and the provision of controlled airspace. All centres, of course, are not equipped to the same standards, although the International Civil Aviation Organization lays down certain standards and recommendations to ensure uniformity of techniques and equipment and to provide assistance to those countries that need help in implementing them.

Air-traffic control is itself becoming more sophisticated and automation is being introduced. In the United States and Europe, the air-traffic controller is becoming part of an integrated system aimed at exploiting both the advances in radar and the availability of computers. Flight plans are submitted directly to the computer, which carries out a more thorough check for traffic conflicts than is possible using manual means. In addition, meteorological information can be combined in the computer with flight-plan information, and the whole can be displayed on cathode-ray tubes to the controller, who thus has more accurate and more detailed information available to help him make his decisions.

Another development is one in which adjacent ATCCs will have computer connections, and ATC will become better integrated in an international sense. Steps in this direction have already been taken in Europe, where the many national boundaries make the need greatest. This situation has led to the formation of Eurocontrol, a supranational authority contributed to by the United Kingdom, Ireland, France, West Germany, and the Benelux countries, which will finally provide a truly international ATC system, eliminating the present discontinuities experienced at national boundaries.

Meteorological services. It is of prime importance that pilots be provided with first-class weather information. The majority of airfields have their own observation stations and send reports to a central meteorological office, which provides weather forecasting and advisory services for all purposes.

Each air traffic control centre has a main meteorological office that services a number of subsidiary offices. Weather charts are prepared every three hours, and reports on existing weather conditions and forecasts are supplied as requested.

Supplementary to the international teleprint methods over which meteorological information is transmitted for general purposes are special telecommunications links for purely aviation purposes. In Europe, the Meteorological Operational Telecommunications Network Europe (MOTNE) collects and distributes airfield weather reports and forecasts for most large airfields. The ATCCs and major airfields are connected to this network, and weather reports are issued at half-hourly intervals. Aerodrome forecasts are prepared every three hours and cover a period of nine hours.

The pilot has ready access to up-to-date weather information at all stages of flight. During the critical last few miles of his approach, approach control provides him with continual information on wind strength and direction and, in marginal weather, on the visibility along the runway. Enroute he has a number of sources of information.

Automatic weather printout

Receiving and copying weather information over the radiotelephone link is time-consuming, however, and often distracting for a pilot, who is usually engaged in other activities. The trend is to install in aircraft data-recording equipment that automatically prints out the weather information. This printout, rather like an ordinary telex printout, is then available for the pilot to consult at his convenience. Such a system also eliminates the difficulties in receiving voice transmission when radio reception is bad.

Ocean station vessels located in the North Atlantic also provide services for air navigation. These are maintained under international agreements and provide weather information to aircraft in flight, on request.

THE FUTURE OF AIR-TRAFFIC CONTROL

Although the new techniques and equipment are providing better safety standards and improved traffic flow, the rapidly expanding volume of traffic is beginning to impose many strains on the system.

Some of the world's major airports are becoming congested at peak periods. Uneconomic "flow control" methods have had to be used at New York City's Kennedy International. This involves "queueing" arrivals as far back as the airport of origination, allowing an aircraft to take off only when it can be assured of a "slot" of time during which to land at Kennedy. Such methods are patently undesirable.

In addition to the high rate of traffic growth, new types of aircraft are being introduced which impose their own problems on ATC. Air turbulence behind the Boeing 747 during its introduction led to the imposition of increased separation of other aircraft following it down on the approach path, thus compounding the problems of congestion.

The supersonic transport will require larger areas of airspace in which to manoeuvre. It will impose additional constraints on the ATC system because it will not be allowed to operate supersonically over some landmasses. In addition, wide-ranging changes in altitude and in speed will become necessary, larger holding areas may prove desirable, and certainly better landing aids will be essential.

ATC has, since 1946, developed into an advanced and sophisticated service that generally has been adequate. Safety in the air is the cornerstone of ATC policy, both long-term and short-term, and no major development in equipment or in procedures can be introduced until it has been thoroughly tested and proved adequate. Consequently, ATC must plan well ahead of the growth in air traffic itself, matching each new generation of aircraft and each surge of growth as it emerges. Thus ATC and ATC planning have become one of the most dynamic sectors of the aviation industry.

IV. Air-transport industry

THE STRUCTURE OF A MODERN AIRLINE

The air-transport industry has been built up on a framework of scheduled and charter services provided by short-, medium-, and long-haul air carriers. Many large airlines operate both short- and long-haul routes in the domestic, continental, and intercontinental fields. Such operators are TWA (U.S.), Air France, Lufthansa (West Germany), and KLM (The Netherlands). On the other hand, Pan American, BOAC, Qantas, Air Canada, and Japan Air Lines have little freedom to operate on domestic or short-haul regional sectors. Air-route licensing in the U.S., Europe, and in many other countries elsewhere has firmly defined the region of individual airline activity and has determined the pattern of competition.

The pattern of airline organization. The organization of a major airline has become highly complex, more especially since the introduction of jet fleets in the early 1960s. The increased scale of operations and the intense competition have increased the need for rapid decision making. Frequent reorganization has become characteristic of the industry. Although this section of the article deals primarily with the major airlines, a wide range of airlines exists, down to the small commuter airlines or operators who provide feeder services on a small number of sectors in one region.

Factors used in rating airlines

There are many measures of airline achievement, and the list of the top airlines varies slightly depending on whether passenger miles, passengers carried, or freight ton miles is the selected criterion. On the basis of passenger kilometres flown in 1969, the top ten airlines of the world are listed in Table 1. Although the Soviet airline Aeroflot is certainly the largest in terms of passenger kilometres, passengers, and staff, it is not included in the table because the appropriate statistical information is not available. It is clear that size of staff is not directly related to the passenger kilometres travelled. The field of operations, the spread and intensity of services, and the length of the average flight sector may strongly affect the staff complement. The most powerful factors determining staff required per unit of traffic carried are the intensity of traffic per route mile and the number of airport arrivals and departures per unit of traffic generated.

Table 1: Leading Airlines of the World (1970)

	passenger kilometres (000,000)	staff numbers
United	38.2	51,679
TWA	29.9	38,555
American	26.8	35,919
Pan Am	26.4	39,279
Eastern	23.6	32,129
Delta	15.6	20,943
Air Canada	10.6	17,447
BOAC	10.5	24,086
Air France	10.2	27,593
Northwest	7.3	12,695

Many small nations have considered it politically expedient to operate their own airlines. As a mode of national publicity this is probably effective. Such objectives will not lead, however, to outstanding records for airline operating efficiency. Nations in strategic global situations (*e.g.*, Greece, Italy, and India) are well placed to obtain reciprocal traffic rights from nations with strong air operating industries, namely, the United States, Great Britain, Germany, and France. Traffic, however, has tended to support the airlines with a long and trusted record of operation.

Organization of some major airlines. Numerous studies undertaken in the 1960s sought without success to establish the optimum size for an airline. Increased potential for efficiency with growth in scale of operations has proved difficult to realize in practice.

For a consideration of airline organization four major airlines have been chosen: Pan American, United, BEA, and Lufthansa.

Figures on the number of staff members of these airlines were broken down in 1970 as shown in Table 2.

Table 2: Staff Makeup of Four Major Airlines (1970)

	U.S.		Europe	
	Pan Am	United	Lufthansa	BEA
Pilots and copilots	2,201	4,034	869	1,347
Other cockpit crew	977	2,118	365	0
Cabin attendants	4,195	6,007	1,694	1,757
Maintenance and overhaul	10,125	10,447	6,323	7,257
Traffic and sales	10,440	13,746	8,751	7,585
All other staff	11,341	15,327	3,946	6,986
Total	39,279	51,679	21,948	24,932
Ton-kilometres carried (millions)	4,018	4,561	1,284	506
Average flight sector (miles)	1,295	635	585	357

Source: *World Air Transport Statistics*, I.A.T.A., Number Fifteen, 1970.

Pan American World Airways. Pan American is the largest of the intercontinental airlines. In 1970 it operated a fleet of 175 aircraft (all jets) with a staff of 39,279 and carried a total of 4,018,267,000 ton-kilometres of passenger and cargo transportation in that period. As in the great majority of modern airlines, the operations, technical, and marketing or traffic/sales departments are run as three separate units under vice presidents.

The pattern in Pan American, as in BOAC and in Air France (also long-established companies with a tradition of delegation of responsibility to trusted and experienced middle management), is to decentralize where possible and control when essential through clearly defined instructions and manuals.

United Air Lines. United, the second largest airline in the world (28 million passengers in 1970) and still largely confined to operations in the United States, is organized on a slightly different basis, with two major departments, marketing and services, and operations, the latter including the engineering/maintenance and flight operations departments.

The major staff concentrations are in San Francisco, Chicago, New York, Los Angeles, Washington, D.C., and Denver. More than 80 cities are served.

Education and training form an important part of the organization of an airline the size of United. At a centre near O'Hare International Airport 4,000 stewardesses and management employees are trained annually. Flight-deck training is also given on a large scale, a $30,000,000 centre at Denver's Stapleton International Airport training more than 6,000 pilots annually, including flight crews of other airlines. United Air Lines's engineering and maintenance base at San Francisco is the largest of its kind in the Western world.

British European Airways. One of the two British corporations (the other being BOAC), BEA is unique in that it

is the only major airline to operate exclusively within the confines of Europe. The high staffing ratio per unit of transport generated is clearly a reflection of the short-haul characteristic of BEA. A reorganization in 1967 confirmed the most common executive management framework of three departments, traffic and sales, engineering, and operations, with the first of these reorganized to give considerable autonomy to the regional general managers. In 1971 another reorganization further decentralized the corporation by setting up divisions based in Manchester, Scotland, and the Channel Islands.

A significant achievement of BEA and one stimulated by the problems of the short-haul airline has been the introduction of integrated management planning and control technique (known as IMPACT), a concept of management control based on the use of advanced computer technology. A group of interrelated computer models has been developed to aid planning and decision making at both the corporate and divisional levels. Computerized control systems are also available for regulating seat reservations, passenger and cargo acceptance and load control, and flight information and control. In addition, an extensive set of largely independent information and accounting systems is under development to support the control of aircraft maintenance servicing. Such developments are typical of the current activity of major international airlines in setting the computer to work for increased airline productivity.

IMPACT concept

Lufthansa. Following early recognition of the significance of the North Atlantic route, Lufthansa by 1968 had outpaced Air France to become fourth (after Pan American, TWA, and BOAC) of the North Atlantic air carriers.

Since 1967 Lufthansa has extended its interests to include the hotel business in developing countries as well as in major cities in Germany and overseas. The company also owns a number of subsidiaries, of which the most important are Condor Flugdienst, a Frankfurt-based charter company active in the holiday-tour business, and Lufthansa Service GmbH, a catering company.

The three main departments are: (1) operations, including flight operations, maintenance, and engineering, based primarily at Hamburg; long-haul aircraft, however, are maintained at Frankfurt, where the flight operations department is also located; (2) administration and commercial, based at Cologne; and (3) sales and traffic, based at Frankfurt.

The integration of airline organization on an international basis in the interests of overall operating economy is illustrated by the Atlas Group project, whereby five airlines—Lufthansa, Air France, UTA, Alitalia, and SABENA—will cooperate in the maintenance and stocking of spares for the Boeing 747. Lufthansa is to cover engines and simulator training at the Frankfurt base.

A characteristic of the Lufthansa system is that international air services are operated from nine airports in West Germany. This considerable choice for departure from the country reflects the regional pattern of government in the republic.

GENERAL AVIATION

The category of air transport known as general aviation covers business aircraft and private aircraft used for business and pleasure. Aircraft belonging to industrial or financial concerns are usually classified as business aircraft and vary in size from converted airliners to small single-engined machines; they may also include rotorcraft such as helicopters and autogiros (rotorcraft in which the rotor is not powered). Private aircraft cover the whole range of smaller types, including in many countries a number of former military aircraft.

By far the largest number of business and private general aviation aircraft are found in the United States, where, by 1970, the total had for several years exceeded 100,000. It is estimated that 60–70 percent of these aircraft are used for business purposes. Other nations with sizable numbers of business and private aircraft in 1969 were Canada (7,130), France (5,400), Australia (3,550), Germany (3,000), Great Britain (2,070), South Africa (1,850), and Italy (1,050).

In France, government grants and subsidies encourage private flying as is shown in the number of business and private aircraft. Because of the large domestic demand, U.S. manufacturers dominate the general aviation market and in total can produce over 14,000 aircraft per year, considerably more than the rest of the world combined.

Business aircraft. The largest general aviation aircraft are those operated by international companies, which frequently use them for transoceanic flights. The aircraft employed may be current medium-range jet airliners, costing over $4,000,000, which have been equipped with special interiors and fuel tanks for intercontinental range. Alternatively, they may be special-purpose business jet aircraft intended for as many as 15 passengers. Such aircraft are operated to airline standards in terms of flight crew, navigational equipment, all-weather capability and performance, and licensing standards. The next category consists of the smaller special-purpose jets capable of carrying six to ten passengers in comfort at 450 miles (725 kilometres) per hour for distances of up to 1,200 miles (1,900 kilometres). In general, these aircraft are able to operate from hard runways of about 4,000 feet (1,200 metres). Next in size and performance are turboprop executive aircraft, which cruise at about 300 miles (480 kilometres) per hour over distances of at least 1,000 miles (1,600 kilometres), carrying up to 10 passengers. As might be expected from their lower speed, they are significantly cheaper than the pure jets in purchase cost and in operating costs. Aircraft in the above categories are invariably operated by full-time professional flight crews; for long hauls a relief crew may also be carried.

Use of airline standards in business aircraft

International use. Transatlantic flights by business aircraft are commonplace, and at least one type of business aircraft can fly from New York to London nonstop. A small number of international corporations use such aircraft extensively for long-distance overseas flights of 2,000–3,000 miles (3,200 to 4,800 kilometres). Special high-frequency radio communication equipment is fitted in these aircraft as well as Doppler or inertial navigation systems. Special arrangements are often required for their servicing and maintenance if their stay abroad is lengthy. Flight planning, customs, and proof of airworthiness may necessitate special arrangements when planes visit foreign countries for the first time.

Advantages of business aircraft. Despite the costs, a large corporation can achieve considerable savings in executive staff time, and even in travel costs by operating its own aircraft, if scheduled flights to necessary destinations are infrequent or nonexistent. Where plants are far apart, a company aircraft is almost essential for staff mobility and shipment of critical materials. Investment grants, depreciation, and tax allowances can often be used to reduce the funding and operating costs.

Smaller business aircraft. Smaller aircraft, usually below 6,500 pounds (2,950 kilograms) gross weight, are used extensively by smaller businesses and by larger firms to fill in for the bigger corporate aircraft on short flights. Planes of smaller firms are often flown by the owner or by company staff. With the advent of the small, supercharged piston engine, these aircraft may have pressurized cabins and be capable of ranges up to 1,200 miles at altitudes of over 20,000 feet. They will have full radio and navigation systems, autopilots, and often anti-icing.

Further down the scale are the lighter, unpressurized twin- and single-piston-engined aircraft, with seating for four or more. These represent the minimum investment and, though usually fully equipped with radio and navigation aids, may lack full all-weather capability because of limited altitude performance. Typically, this category flies below 10,000 feet (3,000 metres) at between 160 and 230 miles per hour (260 and 370 kilometres) over ranges from 500 to 600 miles (up to 1,000 kilometres).

Rotorcraft. The use of rotorcraft in general aviation showed a marked growth in the 1960s because of the availability of small, fast helicopters with small, lightweight gas turbines and improved rotor aerodynamics. Since 1960 their cruise speed has increased from 90 to 135 miles (140 to 220 kilometres) per hour, and at the same time passenger seating has increased from two to

five. As a result, they now offer excellent average speeds over short distances and can land in areas only 100 feet (30 metres) square. The capital and operating costs are high because of the requirement for complete integrity of the rotor system, which propels, lifts, and controls the flight path of the machine; this complex system requires frequent inspection and component replacement. Twin-engined helicopters are becoming available in the smaller sizes, and the additional security of a second engine may make them more acceptable as corporate aircraft in the future.

The problem of helicopter complexity

Business aviation costs. Capital cost is a major factor in purchasing a business aircraft, and it is reflected in depreciation, insurance, hangar costs, and, to some extent, crew salaries. Operating costs include these factors, together with fuel and oil, maintenance, landing, parking and navigation fees, handling charges, customs charges, and license fees. Some costs, such as fuel and oil, are directly related to the annual aircraft use (*i.e.*, the number of aircraft flying hours in a year). The greater the use, the lower the cost per flying hour, a common cost criterion for this class of aircraft. Utilizations of over 400 hours are desirable to make economic use of the capital cost of a large business aircraft.

Private aircraft. This category includes aircraft that may be used for business and for private travel and are usually flown by the owner or by nonprofessional pilots. Many different aircraft types are involved, some dating from the 1930s. Though perhaps not strictly in the air transportation category, many pre-1930 aircraft are still flying, and the building of replicas of World War I aircraft is popular.

"Home builts"

The smallest aircraft in the private category are the "home builts" or "ultralights." Many of these are superb examples of ingenuity, workmanship, and aerodynamic efficiency. Design, construction standards, and licensing are usually controlled by national bodies, such as the Experimental Aircraft Association in the United States and the Popular Flying Association in the United Kingdom, which have the approval of the national aviation regulatory body. Home builts, often powered by automobile engines, have been produced for as little as $2,000.

Since the 1960s, motorized gliders have been produced commercially, particularly in Europe (140 in West Germany alone), and these represent a halfway step between the ultralights and the more conventional light aircraft. One- and two-seat versions are available, fully certificated, and because of their inherent aerodynamic efficiency, they offer excellent fuel economy at a cruise speed of about 100 miles (160 kilometres) per hour. Some private rotorcraft exist, the majority of which are autogiros. These are usually single-seat kit-built aircraft, with cruising speeds of 60 to 70 miles (95 to 110 kilometres) per hour and limited range. Landing and takeoff runs required are only about 50 feet (15 metres).

The next large category, one- to four-seat single-engined aircraft, is by far the most popular in every country, representing, for example, 83 percent of general aviation aircraft in the United States in 1968. These aircraft are fitted with engines of from 90 to 250 horsepower and cruise between 100 and 200 miles (160 and 320 kilometres) per hour over distances up to 1,000 miles (1,600 kilometres). This class of aircraft is manufactured principally in the United States, France, and Germany. Metal construction is almost universal, though reinforced plastic has also been used. Equipment varies enormously and may be extensive in the larger aircraft; the cost of equipment may well add 50 percent to the bare aircraft cost. A number of types can be fitted with floats for water operation or with skis for snow landing and takeoff. A few true amphibians, capable of landing on land or water, are also available. Aircraft in this size category are capable of operating from 2,000-foot (600-metre) strips, many requiring less than half this distance. Their unsupercharged engines, however, reduce their effective use in areas where the ground is 5,000 to 10,000 feet (1,500 to 3,000 metres) above sea level.

Private balloons

One minor category of private air transportation is the free balloon. A number are registered in Europe, particularly in Switzerland, and are normally of the hot-air type. Small private airships also exist, classified as business aircraft.

Use in sparsely populated areas. In less populous parts of the world, where distances are large, as in Australia, Africa, South America, and Canada, light aircraft have been a vital method of transportation for as long as 40 years. Casualty evacuation, transport of doctors, and freighting of vital supplies are among the uses remote regions make of such aircraft. In Canada, extensive use is made of the country's thousands of lakes to operate float planes.

Where landing is impossible, ingenious methods of air dropping and picking up are used. In most remote-area operations, funds, and consequently facilities, are at a minimum; the use of rotorcraft has not so far made a great impact except for exploration and survey work.

Regulation. The regulation of private flying, both in terms of pilot licensing and aircraft certification, is similar to that employed for commercial aircraft. Efforts usually are made to simplify the procedures to reflect the less sophisticated requirements of the majority of lighter aircraft.

Nations with sizable general aviation fleets have at least one national body to represent this sector of aviation. Each nation is represented also at the International Council of Aircraft Owners and Pilots Association (IAOPA), the general aviation equivalent to ICAO, which represents more than 300,000 members worldwide.

Activity and growth. Worldwide figures for the activity of all general aviation are difficult to obtain, but in 1967 there were 98,000,000 general aviation movements in the United States and 383,000 in Great Britain. In 1968 there were, respectively, 282,000 and 12,000 pilots holding private licenses in each country. The economic value of general aviation shipments in the U.S. was estimated at $596,300,000 in 1968, with the probability that this figure would be nearly doubled by 1975.

AIR CARGO

Air cargo is an essential part of the air transport industry, with all-cargo airlines and all-cargo aircraft offering specialized facilities and services, supported by the freight-forwarding industry, in all parts of the world.

Increasing importance of cargo

Some observers forecast that air cargo will be the dominant element in air transport well before 1990. It is receiving increasing attention by the airline industry, if only because the integration of cargo, passenger, and combined services is economic and encourages the provision of cargo and passenger services that complement each other. Although freight and mail revenues for nearly all air carriers are a small proportion, seldom more than 10 percent, of total revenue, such revenues play an important part in the overall financial position of the airlines. The major world airlines make full use of the increased capacity and improved performance of modern jet aircraft. All-cargo jets now provide the greater part of the capacity on the North Atlantic routes. Air cargo may be defined as the load carried by air-transport companies, excluding passengers and their baggage allowance. Thus air cargo includes revenue-earning freight, mail, and excess passenger baggage.

Air-cargo growth. The air transport of cargo has developed into an industry with a growth rate higher than any other field of transportation. On the most favourable sectors, such as the North Atlantic where aircraft have a great time advantage, the carriers recorded traffic increases of well over 30 percent per annum in 1969 and 1970. On the intra-European routes development has been less rapid, but traffic doubled in the 1965–1970 period.

Even in the United States, the domestic air-cargo growth has not compared with that on the North Atlantic. International trade acts as the vital stimulus to air cargo, and 40 percent of all cargo moving in the United States has its origin or destination in an overseas territory. Domestic air freight in the United Kingdom and in Europe is of small significance. The historic trading links between the western European states and the Middle and Far Eastern

countries, as well as with Africa, have formed a basis for the developing pattern of world air-cargo business. Restrictions on imports still affect the air trade of more than 50 nations, and all-cargo flights are restricted on a number of transatlantic routes even within the framework of bilateral agreements.

During the 1965–69 period, the freight revenue carried by the world's scheduled airlines increased to approximately three times the mail revenue. Cargo traffic carried by the scheduled airlines grew by 106 percent in this five-year period. On the North Atlantic routes the growth in the total carrier cargo traffic of members of the International Air Transport Association (IATA), including charter flights, has been increasing at a greater rate, and from 1965 to 1969 grew by 152 percent. It should be noted that in this period a dominant factor in the development of traffic was the increasing number of all-cargo aircraft flights.

The private operation of cargo aircraft, on the same lines that some companies operate their own executive aircraft, is generally ruled out by cost considerations. The economics of cargo aircraft require high minimum flight loads on a regular basis of at least 3,000 hours per year per aircraft. Few organizations can provide such traffic single-handedly on a routine basis.

Necessity of high minimum loads

New transport aircraft and containers. The introduction of the wide-fuselage "super-jet" passenger aircraft of very large capacity (350–550 seat) with large under-floor capacity may modify this trend toward all-cargo services.

The Boeing 747 passenger aircraft offers more than 6,000 cubic feet (170 cubic metres) and approximately 45,000 pounds (20,400 kilograms) of under-floor cargo and mail capacity. There is also an all-cargo version (747F), whose payload may exceed 200,000 pounds (90,000 kilograms) on the North Atlantic. Containerization, whereby loads are prepacked in large consignments at the individual production plant, the premises of a freight forwarder, or the airline cargo centre, should reduce costs. Air-shipper associations and co-operatives are active in the promotion of consolidation services for container loads. Greater security against loss and pilferage are important advantages claimed for the unitized and containerized load. Lack of standardization of container sizes, the rental cost of containers, and the low-load factors are restraining the greater use of these methods of handling and transport. Moreover, a deterrent to the use of containers is the time lost in waiting for shipment until a complete container load has built up. Ship containers may offer considerable cost competition to air containers on routes where a reasonably good ship frequency is achieved, as is the case on the North Atlantic. Ship frequencies from Europe to West Africa, on the other hand, cannot yet offer competitive service.

In most cases air shipment costs more than surface shipment; its advantage lies in the reduction of ancillary costs and in the generation of new business. A wider market in extent and time can be reached by faster transport modes. Thus, the speed of air transport has been found to be significant in generating business, presuming always that delays are small at the air terminals, and that the loading, unloading, and surface-delivery times are related to the time saved in the air.

Air-cargo commodities. A pattern of commodities most suitable for air transport is apparent in most countries. High-value goods naturally predominate. Few really low-value commodities are candidates for air freight. Engineering goods, chemical and pharmaceutical products, textiles, paper products, livestock, and samples of all kinds form the bulk of air freight shipments into most markets. Automotive spare parts are at the top of the list of scheduled airline cargo commodities in the United States. Automotive spares ranked sixth in import tonnage and ninth in export tonnage through New York airports in 1969. Air freight is also used extensively by European automobile manufacturers. The international trade in such commodities is increasing more rapidly than that of other industrial goods. Thus, air cargo is in a favourable growth position. It seems reasonable to expect that the air-cargo trade will grow throughout the 1970s and that there will be a greater range of goods airlifted.

Manufacturers have increasing reluctance to carry large quantities of high-value goods in inventory. Moreover, technological obsolescence is becoming a critical factor in advanced industries such as avionics (electrical and electronic devices for use in aviation). Air delivery can be helpful in both cases.

Shipping services. The air-cargo business must not be considered as the province only of airline and shipper. A complex pattern of operations and procedures has developed that is the concern of manufacturers of aircraft and equipment, groups providing ground facilities at airports and at cargo terminals, and worldwide freight-forwarding agencies. The air-freight forwarder provides an increasingly important service to both airline and shipper. He consolidates small packages into a large consignment to take advantage of the improved economy of handling by pallet or container. He can provide complete pickup and door-to-door delivery service. He provides a single responsible agent for the forwarding and accounting process from origin to destination. As the air-freight business moves into the lower value commodity groups, the functions of the agent or forwarder become more significant. The pattern is worldwide, and approximately 20 percent of air cargo is now handled internationally by the agent.

Regional variations in air cargo. The use of aircraft for the transport of goods has regional variations. Aircraft are extensively used for access to the frozen wastes of Northern Canada and the Soviet Union, and in such cases the costs per ton-mile may be far lower than alternative surface transport.

In South America, air-freight service to mountainous areas has maintained communities that otherwise might have vanished. Thus Avianca, the Colombian airline, had over 33 percent of its total air traffic in 1969 in the form of air cargo (freight and mail). Aircraft of older types, such as the piston-engined DC-3 (Douglas), are still in operation in such areas.

Use of older aircraft

Africa provides special opportunities for air cargo, since heat causes spoilage and a lack of refrigerated cars and trucks from seaports restricts onward surface shipment for a wide range of goods. Such a situation arises also in the Middle East and the Persian Gulf, in Central America, and in parts of South America.

Air-cargo traffic on domestic services in most countries has grown at a moderate rate. On sectors of less than 350 to 400 miles (560 to 640 kilometres), especially when no natural barrier exists, the lower costs of road and rail transport are decisive and air is used mainly in emergencies. Such traffic can rarely support all-cargo flights except on special charters.

ECONOMIC SIGNIFICANCE

While the volume of air-transport business trebled during the 1960s, net profit as a percentage of revenue fell steadily from the middle of the decade. Operating revenues and expenses of the world's scheduled airlines (1965 and 1970) are given in Table 3. Where private resources support the air-transport industry, major efforts have been made to find answers to its widespread unprofitability. Wage increases and capital investments, including costs of introducing the new jet fleets, have escalated operating costs. Moreover, airline capacity has continually grown in anticipation of higher levels of traffic. Serious problems can be expected if the anticipated traffic growth does not materialize. A similar situation arose in the early 1960s at the time of the acquisition of the first turbojet fleets.

The impact of air transport upon the economy of nations is far wider than the traffic growth itself would indicate. The air-transport manufacturing industries themselves have become important national assets in a number of countries.

The purchase and operation of home-built aircraft and the export of aircraft to foreign governments and airlines can be an important factor in the balance of payments of nations with aircraft industries. It may be an argument for retaining such capability if prospects for export sales

Table 3: Operating Revenues and Expenses of the World's Scheduled Airlines
($000,000)

	1965	1970*
Operating revenues		
Scheduled services		
Passengers	7,378	16,825
Freight	904	1,694
Mail	404	619
Nonscheduled services	469	709
Incidental	217	487
Total operating revenues	9,372	18,015
Operating expenses		
Flight operations	2,177	4,610
Maintenance and overhaul	1,462	2,448
Flight-equipment depreciation	950	1,954
Station and ground	1,317	2,789
Passenger services	714	1,619
Ticketing sales and promotion	1,343	2,621
General and administrative	509	985
Total operating expenses	8,472	17,026

are also adequate. The potential advantage to the United States and to the United Kingdom and France, respectively, in international monetary balance has been used as an argument by the protagonists of supersonic aircraft.

The balance-of-payments argument for the SST

A national airline can provide a saving in foreign exchange, and this advantage has given many small states an incentive to operate their own airlines. Moreover, receipts from foreign travellers, export freight, and airport expenditures by foreign airlines provide revenues of great value in the balance of foreign exchange for many airline-operating states. In the United States, for example, the expenditure by foreign visitors reaches approximately one-half of the U.S. overall travel expenditure abroad, and on the air-transportation ledger the account is far more evenly balanced.

Further economic gains are achieved by the use of air transport as a stimulant to trade and industry. No adequate measure of this benefit has yet been evolved, but it is evident that it greatly exceeds the expenditure on passenger and cargo transport. The location of one or more great airport terminals in the vicinity of a capital city is a factor critical to national growth.

As noted earlier, air cargo has created new markets and has contributed notably to the development of international trade in certain high-cost commodities.

In travel and tourism, airlines are finding an even more expansive field. The wide-ranging opportunities offered by long-haul aircraft are already bringing tourists and related economic benefits to smaller and less-developed countries where scenery, climate, or historical associations may be outstanding. The airlines are themselves taking part in providing new ground facilities, such as hotels. In helping to redress the imbalance in the wealth of nations, air transport may thus play a far-reaching role in the 1970s.

Transportation, History of

From earliest times the conditions in which man lives have been powerfully influenced by the ease and speed with which he has been able to move himself and his materials from point to point on the earth's surface. By harnessing nature directly and indirectly, man has been able to explore and exploit the earth's resources. The chief landmarks in the history of transportation—the wheel, the sail, the steam engine, the internal-combustion engine, the electric motor, and the great technological breakthrough of flight—promise, as the 21st century approaches, to be capped by the rocket engine, which frees man from dependence on earth's atmosphere and permits him to visualize travelling to other planets. (E.A.J.D.)

PRIMITIVE TRANSPORTATION

Early man was a wanderer—of necessity rather than choice. Food was scarce and hard to come by; enemies abounded. Techniques were invented for carrying loads, on the end of a stick on one shoulder, on the single yoke, or on both ends of a pole carried across the shoulders, the double yoke. A slain deer or buffalo could be carried on a pole borne by two men; a 5,000-year-old alabaster relief from Sumer shows a large vessel carried thus between two bearers.

The travois. The earliest agricultural workers probably shifted hay on the forked branch of a tree. From this developed the Y-shaped sledge, or travois, used in more recent times by North American Indians. The travois was two poles tied together, with the inverted V resting on the back of a man or animal. Between the poles was slung a wooden or net frame. The Y-sledge was widely used in northern Europe and throughout the cattle regions of Africa.

The slide car. Whereas the travois can be put together and taken apart as necessary, the slide car is permanent. In the slide car, two shafts are harnessed to a horse or other draft animal; their ends drag along the ground and the shafts are kept apart by crossbars. The very wide geographical distribution of the slide car is proof of its antiquity, and it held its own in some mountainous districts of Europe until recent times.

Sledges and skis. By 5000 BC the sledge was in common use in northern Europe, North America, Egypt, Assyria, and the Middle East. Originally a simple rectangular platform that could be either hauled or pushed, it was soon improved by the addition of runners. Sledges can travel well over snow, marsh, clay, or grass, and to this day are used in Lapland, northern Asia, and British Columbia. The Egyptians and Assyrians used them to move the materials required for their pyramids, obelisks, and huge river statues, and they constructed some of the earliest known roads to enhance the capabilities of the sledge. The use of runners in the form of skis is also very old. A carving on a rock-face in northern Norway dating to about 2000 BC is clearly identifiable as a man on skis.

Use of sledges for hauling

Animal transport. The ass, native to northeastern Africa, was almost certainly the first draft animal and was in common use in northeast Africa, upper Egypt, the Mediterranean Basin, and the Near and Far East well before 3000 BC. By that date pack animals were in regular service on the caravan routes stretching from eastern Europe and North Africa to India and China. A graphic presentation of convoys of pack asses regularly crossing the Syrian Desert and the Taurus Mountains (Turkey) is

obtained from the surviving business letters of a group of Assyrian merchants established at the court of a Hittite prince in central Asia Minor about 2000 BC. An Egyptian relief from Bari Hasan, dated around 1900 BC, shows the arrival of the Canaanites with their pack asses laden with children and tribute. The ox, the reindeer, the elephant, the yak, the buffalo, and the llama were also used in earlier times. The camel, both the one-hump (Arabian) and the two-hump (Bactrian) varieties, was uniquely fitted by nature for long overland journeys because of its extraordinary capacity to store food and water and its ability to walk on soft sand. The camel could carry up to 600 pounds (270 kilograms) in weight. The most important draft animal for the future, the horse, was a relative latecomer. When or where horses were first domesticated is not known; they were introduced to Egypt by the Hyksos about 1675 BC.

Early water transport. Before ships and even boats, man must have had recourse to a wide variety of rafts and similar craft. The type varied according to environment; in Egypt, where the Nile was once flanked by masses of papyrus, and timber was scarce, the first floats consisted of bundles of rushes tied together. While the small models that have survived are not sufficiently detailed to indicate their mode of construction, a close parallel can be seen in modern Peru, where coastal fishermen use reed rafts, known as caballitos. Basically, the caballito consists of two or three conical bunches of reeds, cut off square at their bases and lashed side by side, with the pointed end turned up to form a prow. Caballitos have a considerable history; an extant pottery vase made in the form of such a boat is dated around 1200 BC.

Boats of inflated skins

In Mesopotamia and the eastern Mediterranean development proceeded on different lines. On the Tigris and Euphrates, where papyrus was lacking, an early skin float inflated with air provided a vehicle on which a man could lie and kick or paddle himself across a river. From the single or double float there evolved the wooden raft to which were attached a number of inflated skin floats, producing a platform capable of supporting a substantial load. One of the earliest pictorial records of these rafts comes from Nineveh. At destination, after disposal of the cargo, the timbers of the raft were sold and the skins deflated and transported by pack animal back to their place of origin for future use. Similar craft were used until recently on downstream journeys on the Tigris.

Closely allied to the skin float, which is kept buoyant by air pressure, is the skin boat, which consists of a flexible leather cover stretched around an internal frame. Such craft survive today in the kayaks of the Eskimo, the curraghs of the west coast of Ireland, the coracles of Wales, the modern canvas canoe, and other counterparts scattered widely over Asia and America.

There is strong evidence that the coracle type was first developed in Asia. Coracles were in common use for carrying cargo on the Tigris and Euphrates as early as the 9th century BC.

The dugout. As Neolithic man acquired better tools, dugouts superseded bark canoes. Dugouts are found wherever there are suitable forests, the limiting factor being the tree diameter. Dugouts constructed in North Africa often had beams of no more than 18 inches (46 centimetres). The ancient British canoe of the Bronze Age was 35 feet (11 metres) long with a depth of two feet (0.6 metre) and a beam of nearly five feet (1.5 metres).

The development of larger craft from the primitive dugout involved more complex construction. From the remains of two boats, probably of the Iron Age, found in the river Humber in England, one possible line of advance can be deduced. The hull was roughly pontoon-shaped, with five thick floor planks bevelled and grooved to fit each other and sewn together with withies (willows). A more promising line of development may be inferred from various types of canoe hulls in the Pacific. In the Maori type of canoe, the tree trunk was hollowed out, and additional freeboard was provided by lashing beams to either side, thus providing bulwarks, which did not quite reach stem or stern. Where the available timber did not have a diameter large enough to provide sufficient stability, outrigger floats were fitted. To secure the necessary freeboard for any carrying capacity required, additional planks were fitted at each side, as in the canoes of the Marshall Bennett Islands today. As time went on and the craft became more and more complex, the dugout part of the hull made a smaller and smaller contribution to buoyancy, and in the end survived only as the keel.

Of the earliest forms of water transportation, the raft, the coracle-type craft, and the dugout, there can be no doubt that the dugout is the most primitive; yet the line of descent to the cargo ships and passenger liners of today is clear and direct from the dugout.

THE WHEEL AND THE ROAD

Development of vehicle wheel. Archaeological evidence is insufficient to enable us to say whether the wheel as used in transport was an outgrowth of the potter's wheel or contemporaneous with it. On logical grounds it might be possible to argue that horizontal rotatory motion seems likely to have preceded vertical rotatory motion, but in the absence of evidence any conclusion must be tentative. All that can be said with reasonable certainty is that the revolution in transport caused by the introduction of the wheel occurred very soon after, if not at the same time as, the transformation of the ceramic industry brought about by the potter's wheel.

The earliest indication of the use of wheeled vehicles is the representation of a sledge on four solid wheels. It is a conventionalized symbol used as a pictographic character in the oldest extant written documents, the tablets of the Inanna Temple at Erech in lower Mesopotamia, inscribed not long after 3500 BC. The royal tombs at Kish, Sura, and Ur (3000 to 2000 BC) contained actual vehicles, while works of art and clay models of vehicles are found not only in Mesopotamia but in northern Syria and the Indus Valley and provide detailed information about their design and use. The archaic vehicles known from the archaeological record in Mesopotamia and the Indus River Basin before 2000 BC have parallels in China, Sindh, the Balkans, Sardinia, Spain, Scandinavia, and the British Isles.

All the oldest vehicles known to archaeology (and the types most widespread in the nonindustrialized countries of today) are distinguished by two peculiarities, solid wheels and provision for paired draft animals. Solid wheels have another distinguishing feature of their own. Most wheels before 2000 BC are constructed in the form of tripartite disks, consisting of three planks carved to fit segments of a circle and clamped together by transverse struts, with a raised area in the middle of the central plank forming a hub around the axle. The rims of these wheels were sometimes bound with heavily studded metal hoops. The axle was constructed independently and projected beyond the hub; the evidence is insufficient to determine whether the wheels revolved freely or turned with the axle.

Tripartite disk wheels

The tripartite disk is demonstrably the oldest as well as the most widespread form of wheel, but it is by no means the only conceivable form, nor is it theoretically the simplest. The wide distribution of this particular form of wheel throughout the Near East and prehistoric Europe accordingly argues strongly for its diffusion from a single Mesopotamian or other west Asian source. Spoke wheels, some 1,500 years later, appear on clay models in northern Mesopotamia, eastern Turkey, and northeast Iran. By the 15th century BC, spoke wheels were in common use on chariots in Syria, Egypt, and the eastern Mediterranean generally, and it is a safe inference that the spoke wheel rapidly supplanted its solid predecessor for all the purposes for which wheeled transport could then be used.

The roads of the ancient world. In the central and eastern Mediterranean areas, and particularly in Greece and Asia Minor, wheeled vehicles were in more common use than elsewhere, and some progress was made in primitive road construction. The deliberately made rut, characteristic of the central and eastern Mediterranean, makes its first and most prominent appearance in Malta, in association with a society in the Late Neolithic and

Early Bronze ages. These ruts were more or less uniform in their depth (three to six inches, or eight to 15 centimetres), width (eight inches, or 20 centimetres), and gauge (44–57 inches, or 112–145 centimetres). That they were deliberately constructed is shown by the fact that in some cases ruts occupy the centres of specially hollowed stone blocks placed in paved roads. Though they are of course a different type of construction, these roads foreshadowed the wooden and stone railways used in the mining industries of central Europe and Great Britain before the Industrial Revolution. Their likeness to modern railways is emphasized by the provision of sidings and passing places.

The roads of China. China developed the oldest known network of roads for everyday use; centuries before the Persian Empire, and over 2,000 years before the Incas, the Chinese had a fully developed system. Even before the Chou dynasty (*c.* 1122–221 BC) communications were controlled and roads maintained by a highways commissioner, with a separate budget of his own. During the Chou dynasty the volume of traffic necessitated the establishment of a uniform scale of size for wheeled vehicles, the prohibition of reckless driving, and traffic regulations for busy intersections. Roads were classified in five grades: pathways for men and pack animals; roads capable of taking narrow-gauge vehicles; roads that could accommodate larger vehicles; roads on which single vehicles could pass each other; and highways taking three wagons abreast.

Roads of the Persian Empire. The ruling dynasty in Persia, masters in their day (559–330 BC) of the entire Middle East, in order to maintain speedy communications with their provincial administrators, were forced to construct a road system. More accurately described as levelled and partly paved tracks, these roads were policed by guards posted at rest houses every 15 miles (24 kilometres). A continuous line of stations linked Sardis, on the Aegean shore, with Susa, the capital, 1,600 miles (2,600 kilometres) away; special messengers could cover the distance between Susa and Babylon (200 miles) in two days.

The Roman road system. It was the Romans who brought the art of road building in antiquity to its highest pitch. The Romans may have taken their road-building techniques from the Etruscans. The roads built by the Greek colonists in southern Italy may also have had some influence.

The Appian and Flaminian ways

The first of the great Roman highways was the Via Appia, begun in 312 BC by the censor Appius Claudius. Built to link Rome with the military centre of Capua, it was later extended southeast to Tarentum (Taranto). The Via Flaminia, completed in 220 BC, gave Rome direct communications with the Po Valley.

By AD 200 the Roman system stretched from Hadrian's Wall in north Britain to the edge of the Sahara, and from Morocco to the Euphrates. Its primary purpose was to provide for speedy and safe military and civil contacts between the central seat of government and the capital cities of the imperial provinces. Horses that drew the two- or four-wheeled vehicles could be changed at stations along the road at intervals of six to 16 Roman miles. Rest houses were spaced at intervals of 20 to 30 Roman miles.

Medieval roads. The disintegration of the Roman Empire had disastrous effects on the imperial road system. The decline in security reduced trade and commerce, and the fragmentation of political authority brought a neglect of maintenance. One should, however, note the introduction of the iron horseshoe and horse collar which permitted horses to pull heavy loads long distances.

The Inca civilization. No account of the history of transportation would be complete without some mention of the astonishing achievements of the Incas in north and central South America. The Inca Empire reached its zenith under Pachacuti and Topa Inca (Tupac; 1438–93), when it stretched from the present Colombia–Ecuador border to central Chile, a coastal distance of over 2,500 miles and covering an area of approximately 380,000 square miles. From the capital, Cuzco, well constructed roads ran to all parts of the empire. Staging posts were frequent, and relay runners were stationed at them to carry messages and parcels quickly. The Incas knew something about bridging, and where necessary they carried their roads over canyons, using suspension bridges.

The beginnings of modern roads. The revival of commerce in Europe and the Near East brought advances in water transport in the High Middle Ages, but land transportation developed more slowly. Four-wheeled wagons gradually came into commercial use; the four-ton carrier's wagon was a common sight in Shakespeare's England. In the mining industries of central and northern Europe, wooden and stone rails were used to facilitate the haulage of heavily laden ore trucks.

Though medieval people travelled extensively on pilgrimages, such journeys were either by water or on foot or pack animal. Two prerequisites were necessary for the expansion of travel for pleasure, a reasonably efficient and comfortable vehicle and a reasonably efficient and safe system of roads. It is a fair presumption that the invention of the former gave impetus to the development of the latter, although the needs of commerce and government of course played a large role.

Introduction of the coach. Legend has it that the coach was first introduced into England in 1564 by a Dutchman, who later became chief coachman to Queen Elizabeth I. The name, found in most European languages, derives from the reputed place of origin of the coach, the village of Kocs in Hungary, though what specific features of the coach are Hungarian will never be known. The covered wagon had been in use in the Far East, the Middle East, and Europe in the Middle Ages and probably much earlier, but the distinguishing feature of the coach that made the traveller's journey more comfortable was that its body was suspended by straps from the chassis. Another feature was that the front axle was attached to the chassis through a pivot, providing a turning train.

The introduction of iron rims on coach wheels meant severe wear and tear on the roads, and there was a period in the England of Charles I (1625–49) when stagecoaches were actually banned in order to protect the highways for other traffic. For the same reason the minimum width of these iron tires was for many years regulated in England by law, being at one time 18 inches (46 centimetres). The stagecoach grew to a considerable size, weighing in some instances as much as eight tons and being driven by teams of up to 12 horses. The introduction of springs, which supported the body of the coach on C-shaped straps of tempered steel, can be dated to approximately 1665.

Introduction of staging posts

To earn their keep, coaches had to travel considerable distances at a time, which meant the introduction of staging posts where the horses could be fed, watered, and changed. This made for a marked increase in the speed of travel, up to ten miles (16 kilometres) an hour being frequently recorded in good conditions (by contrast, when the King of Scotland's ransom had to be brought to London "with all speed" in 1375 it travelled no more than 30 miles per day).

The revival of road building. During the medieval period responsibility for making and repairing the roads rested as a rule on the parishes and landowners through whose land the road passed; those employed on road work were usually farmers and forced labourers. The widespread use of bundles of faggots, erroneously supposed to improve the drainage of the subsoil and the carrying quality of the road, was harmful. But in the 16th century Italian architects and engineers gave attention to the scientific study of road building; a Reims lawyer, Nicholas Bergier, studied the remains of a Roman road that he found in his garden and with the aid of material collected from classical texts and archaeological data compiled a book, *Histoire des grands chemins de l'empire romain*, which attracted wide attention.

The emergence of the nation states of western and central Europe made possible the gradual development of strong, centralized administrative and technical bodies to train engineers and impose uniform standards of road

building. The change began to take place at the end of the 16th century, in the France of Henry IV. In 1599 Henry created the post of chief road engineer, with local lieutenants in the provinces. Royal grants were made for new roads. By 1664 the state of the road system allowed for the establishment of a stagecoach service. Many country roads were paved with stone blocks (the *pavés du roi*).

After a decline in road building caused by the demands of the wars of Louis XIV (1643–1715), progress was resumed under Louis XV. The Corps des Ponts et Chaussées, created in 1716, was the first body of road and bridge experts and engineers in Europe to be financed by a government. The method of construction employed was, in general, to trench the road and then lay successive layers of smaller and smaller stones until a smooth surface was reached. By 1776 France had no fewer than 25,000 miles of highway completed or under construction, of which half were being reconstructed or aligned as avenues.

Another factor contributing powerfully to the pressure for more and better roads was the expansion of trade and commerce and the constant pressure of merchants and manufacturers for improved communications. The process was most marked in Britain, where the presence of large quantities of easily mined coal and iron ore gave that country a head start in the Industrial Revolution. Indeed, the rapid growth of industrial production from the middle of the 18th century onward made better communications not so much a desirable objective as a pressing and immediate necessity. Initially, priority was given to canals, known in those days as navigations; cheap labour imported from Ireland in large quantities dug these canals, and the workmen were known as "navigators," hence the modern use of "navvies" to cover any type of unskilled heavy labourers. Canals, however, could not possibly be built on a sufficient scale to meet the demands of industry; thus, the crying need for more and better roads. John Loudon McAdam was the best known of a number of self-taught engineers, of whom John Metcalf and Thomas Telford were also outstanding. They were fully aware of the necessity for a proper drainage system, and McAdam invented an inexpensive, self-sealing road surface, consisting of small stones, chips, or gravel, which could be applied directly to the soil or subsoil of a properly made roadbed. His first experiments in Bristol in 1815 were so successful that they set in motion a road-building explosion that has continued with increasing momentum for 150 years.

John Loudon McAdam's new road

SAILS AND OARS

Early Egyptian, Greek, and Arab vessels. As early as 4000 BC the boats or rafts in use on the Nile had advanced a long way from the primitive bundles of reeds from which they derived. The Egyptian vessel was by now essentially a built-up dugout consisting of a massive outer shell formed of many pieces of timber dowelled and dovetailed together. It lacked stem, stern, and keel; the sail, when fitted, was a simple rectangular affair slung amidships.

By 1500 BC Crete had become the dominant sea power in the eastern and central Mediterranean. Little is known of the Cretans or of the Phoenicians, who inherited maritime supremacy after the eclipse of Crete in about 1200 BC. The Phoenicians were primarily traders, and, in search of fresh markets, carried their wares through the Straits of Gibraltar as far as Britain in the west and down the west coast of Africa. The Cretans and Phoenicians worked from the beginning on a ship design basically different from that used by the predynastic Egyptians. Stem, stern, and keel all formed an integral part of this design, and both Crete and Phoenicia had begun to differentiate between the fighting vessel and the merchantman and between the rowing galley and the sailing ship. Phoenician vessels (*c.* 700 BC) illustrate two further striking developments: the arrangement of oars in two banks at different levels, and the fitting of a ram in the bows of a fighting galley.

Athens, the dominant sea power in the eastern and central Mediterranean in the 5th century BC, had shipyards at Piraeus and neighbouring towns that could handle hundreds of vessels at a time. Their galleys carried mast and sail but were primarily rowing vessels, whereas the merchantman of this and later periods was a sailing vessel pure and simple. Its draft and beam were much greater than those of the galley, it did not carry a ram, and had stem- and sternposts curving down to a comparatively short keel. The mainsail was square, set on a yard slung horizontally from a mast erected amidships and carried more or less at right angles to the ship's fore and aft line. At first there was only one mast and one sail, but by the beginning of the Christian Era Mediterranean merchantmen carried a second, much smaller sail on a mast projecting from the bows and could also set a triangular sail or topsails from the mainsail. The steering gear (an inheritance from Egypt) consisted of two large paddle-shaped rudders, or steering oars, one on each quarter.

Chinese shipping and shipbuilding. In the other principal cradle of ancient civilization, China, shipbuilding followed an entirely different course. In Europe and eastern and southern Asia the keel was joined at each end to beams that slanted upward to form the stem- and sternposts, respectively. The planks of the hull that connected them were held apart, and the hull was given its strength and stability, by an internal framework. But the design of Chinese junks, from the earliest times to the epoch of the great voyages as far as the coasts of East Africa between AD 1405 and 1433, lacked all the three components—keel and stem- and sternposts—regarded elsewhere as essential. The ship's bottom was flat and slightly rounded, and the hull did not close in toward the stern but ended abruptly, leaving a space that was filled by a solid transom of planking. In most classical types there was no stem either but a similar rectangular transom bow. There was no true framework or ribbing; what took its place was a system of solid transverse bulkheads, of which the stem and stern transoms may be regarded as the outward units. Dr. J. Needham has suggested that the basic features of a Chinese ship may have derived from the structure of the bamboo used by the Chinese for a thousand purposes. A split section of bamboo, with transverse dividing walls, has clear affinities with Chinese ship design.

Design of Chinese junks

The lateen sail. If the first revolution in the history of shipping was the transformation of a river or seagoing craft from a simple dugout or raft to a more functional artifact with stem, stern, keel, and molded hull, the second was undoubtedly the adoption of the lateen sail. The lateen is triangular in shape and trimmed so as to take the wind on either side. It is set on a long yard coming down nearly to the deck forward and rising to well above the masthead at the other end. It is known to have been in use in the eastern Mediterranean as early as the 2nd century AD, and while its place of origin is not precisely known, the probabilities point to Egypt or the Persian Gulf. In any case, it is clear that Arab and Muslim conquest did much to extend its use. By the 10th century the lateen sail was in common use in the Mediterranean and on all European coasts, spreading to the East by way of the Red Sea, the Persian Gulf, and the Indian Ocean.

With the invention of gunpowder and the carrying of guns on ships soon after 1350, two processes were under way—one consisting of the gradual increase in dimensions and complexity of the masts and rigging of all ships, the other the increasing differentiation between the sailing man-of-war and the merchantman. In 1400, ships still had one mast and one sail; by 1450 some had three masts and three sails; by the end of the century the largest had four masts and eight sails.

Toward the end of the 12th century there came another of the great advances in the history of sailing ships—the supersession of the single-side starboard (steering board) rudder by the sternpost rudder. When or where this type of rudder first appeared in the Western world is uncertain, but it must have been about 1200, and its place of origin was in all probability the Netherlands or thereabouts. It had been in use in China more than 1,000 years earlier. The introduction of the sternpost rudder was important not only because of the improvement in navigation that it brought about but also because it forced a

The sternpost rudder

differentiation between bow and stern and in consequence the transformation of the double-ended ships of the Baltic and northern Europe into something far more like their Mediterranean contemporaries. When, about 1300, the maritime nations of southern Europe recognized the superiority of the sternpost rudder and incorporated it into their vessels, the standard European ship was not far off.

The magnetic compass was first carried on ships in the Western world around 1000 and was in common use by the 12th century. Originally the magnetized needle floated on straw, but by the latter half of the 13th century it was mounted on a pivot. The use of charts for maritime navigation developed at the same time; the first recorded use of a chart aboard ship (*c.* 1280) relates to the Mediterranean and Black Sea area.

The combination of the sternpost rudder and lateen sail made it possible to sail closer to the wind, and thus made for greater accuracy and safety of navigation; it is from this period that the development of many new sea routes is dated. Notable pioneers were the Genoese, who in the early 1300s began to undertake regular winter sailings and by the end of the century had established a defined sea route between Italy and the ports of the North Sea and the Baltic.

The opening of the oceans. The higher standards of navigation made possible by the use of such instruments as the magnetic compass and the astrolabe, for angle measurement, extended the field of exploration. This in turn led to a sharp increase in the size of cargo vessels. Beginning about 1418 with Prince Henry the Navigator (inaccurately so named, as he apparently never voyaged personally farther afield than Tangier), a succession of captains probed farther and farther down the west coast of Africa to the Cape of Good Hope, opening the sea route to India and China. At the same time Columbus sailed from Spain to make his accidental but history-making discovery of the New World. The discovery of the extent of the Pacific Ocean by Magellan in 1519–21 completed a generation of titanic achievements in ocean exploration, though major details remained to be filled in. The most notable of the later explorers was Capt. James Cook, who in the 18th century explored the Pacific and Antarctic oceans and was the first of the truly scientific navigators.

Jetties and harbour improvements. There is no conclusive evidence as to the dates of the first artificial harbour constructions, but it is known that the Phoenicians built harbours at Tyre and Sidon as early as the 13th century BC. Many other Mediterranean harbours, both natural and artificial, were of considerable commercial and military importance in Greek and Roman times.

In medieval times the prosperity of such cities as Venice, Genoa, and Alexandria (already a famous port in antiquity) required the building of harbour works for the protection and accommodation of their seaborne trade. The Pharos (lighthouse) of Alexandria was one of the seven wonders of the ancient world. Some of the early works at Venice and Genoa remain to this day. Natural harbours are more numerous in north Europe than in the Mediterranean. For many centuries these natural facilities, combined in some cases with rudimentary artificial harbour works, sufficed. From the late Middle Ages, Britain gave special prominence to the development of its port facilities. Artificial harbour works existed at Hartlepool (on the northeast coast) from about 1250 and at Arbroath in Scotland from about 1390. Dover lacked natural facilities but, because of its favourable situation on the English Channel, was a busy military and commercial port from the reign of Henry VIII (1509–47) onward, and a stone and timber breakwater was built there in his reign. Across the English Channel, Le Havre, Dieppe, La Rochelle, and Dunkerque were among the early ports to embark on harbour construction.

Harbour-building on the English Channel

The history of ports on the American continent followed the Mediterranean and northern European pattern. In the early days, natural havens offering protective anchorages were sufficient, but as the North American economy developed, ships became larger and of deeper draft, demanding larger and deeper harbours. Both natural and artificial harbours had to be dredged to maintain and increase the depth of water at quayside. All the great natural harbours in the world today have seen their native facilities improved, and in some cases transformed, by dredging, by the construction of breakwaters to enclose an area of protected water, and by running jetties into deep water to accommodate the giant tankers and bulk carriers that dominate their trades today.

Worldwide seaborne trade and the discovery of the New World brought new traffic to ancient ports but above all created a number of entirely new ones. Gorée (the predecessor of Dakar, on the West African coast) came into being before 1450. In the 16th century such famous ports as Havana (*c.* 1514), Lima (*c.* 1535), and Manila (*c.* 1750) were founded, to be followed in the next century by New Amsterdam (New York), Cape Town, and Calcutta, among many others.

This multiplication of ports was the outstanding feature of world port development in the period up to 1800. The chief engineering works on these "new" ports were devoted to fortifications against attack, particularly from the sea. Ships could be beached or worked at anchor within a defensible natural harbour. In the late 16th century the then small port of Rotterdam built an artificial harbour that served for two centuries. More typical, and certainly more expensive and elaborate, were the works of military engineering such as the late-16th-century fortifications of Valletta (Malta) or, on a smaller scale, the Morro Castle of Havana (1590–1640).

Military engineering rapidly developed, and by the late 17th century the lagoon-harbour of Dunkerque had been enclosed within the complex fortifications of the town and was approached from the sea between timber jetties armed with timber forts.

By the 18th century the increasing number of ships and quantities of cargo justified more expensive commercial facilities, at major ports at least. The earliest commercial wet docks (for example, Liverpool) date from the early 18th century. Near the end of the century there came the most remarkable work of harbour engineering of the century: the breakwater at Brest, constructed between 1783 and 1795. Over 9,800 feet (3,000 metres) long and built of stone and prefabricated timber units floated into position, it was built partly as a fortification.

The breakwater at Brest

All this activity, widely spread though it was, only faintly foreshadowed the spectacular development of port facilities that gathered momentum throughout the 19th century and matched in its complexity the equally spectacular growth in trade and industry. (D.O'N.)

Growth of inland waterways. Throughout the centuries rivers have provided an obvious means of transport, but natural obstacles in the riverbeds and changes in water levels have hampered movement. With the invention of the lock, these could be overcome by lifting vehicles from one level to another and bypassing such hazards. Following the development of the lock in the 13th century, river navigation was improved and many artificial waterways were built.

To meet the demand for transport resulting from trade expansion, from the 16th century onward a network of canals was established linking Europe's navigable rivers. With technical improvements, and with further development of the mitre lock (see CANALS AND INLAND WATERWAYS), many canals incorporated unique engineering features including lock staircases, hydraulic lifts, and inclined planes that raised and lowered craft from one level to another. The expansion of trade created a need for the transport of raw materials and manufactured products that could not have been met by slow and hazardous road transport; as a result, canal construction was embarked upon on a grand scale. In the United Kingdom a series of canals joined the industrial Midlands to London and the ports, and links in the waterway system were forged in France to provide through navigation from the English Channel and the Atlantic to the Mediterranean. In Belgium and The Netherlands industrial expansion also led to the extension of canals that were more closely integrated with the French and German waterways. Russia pro-

vided through waterways from the Baltic to the Caspian Sea and interconnected its great rivers. In Greece, the Corinth Canal, abortively started by Nero to connect the Aegean and Ionian seas, was built. In the United States construction of canals contributed to the opening up of the West, with the Erie Canal, 363 miles (584 kilometres) long, joining the Hudson to Lake Erie and resulting in the establishment of New York as the predominant port on the Atlantic seaboard. Thus it was that apart from seagoing trade the main means for the transport of goods throughout the period of great industrial development of the late 18th and early 19th centuries was the river and canal.

Drawbacks in barge transportation

Transport by inland waterways did have some serious handicaps: goods were transported in dumb barges, drawn mostly by horse along towpaths, and the canal boats often had to be manually handled through the numerous locks and tunnels. Because of the large number of locks, transport was slow and the volume carried per unit was small. The railways, with their larger volumes, greater carrying power, and higher speeds, inevitably encroached upon the canals and brought the canal era to an end. In many countries, however, navigable rivers and canals continued to be used as a major means of transport; and with the coming of steam, tugboats supplanted the horse. Heavier loads could be carried at increased speeds. Heavy investment in ocean canals became worthwhile; the Suez Canal, joining the Mediterranean Sea to the Red Sea and thereby considerably reducing the voyage to India and the Far East, was opened in 1869, and the Panama Canal, connecting the Atlantic and Pacific, was completed in 1914. Meanwhile in North America navigation on the Mississippi was improved with the construction of link canals that joined this system with the St. Lawrence and the Great Lakes; thus an extensive and combined network of inland waterways was established. Development of this system continued, climaxed by the St. Lawrence Seaway, opened in 1959, providing a continuous deep waterway for oceangoing ships from the Atlantic to the Great Lakes. In Europe and the Soviet Union also, after World War II the inland waterway networks of canalized rivers and artificial waterways were being brought up to modern standards, and with the application of the latest technological skills larger loads were capable of being carried at increased speeds.

(E.A.J.D.)

STEAM TRANSPORTATION

The railroad. *The first locomotives.* The first reported self-propelled steam vehicle was created in Peking about 1681 by a Jesuit missionary named Ferdinand Verbiest. Nicolas-Joseph Cugnot, a French artillery officer, built a full-sized steam car in Paris in 1769. He intended it to haul army cannon or munitions, but it was demonstrated as a passenger carrier. Richard Trevithick, a Cornish engineer, demonstrated a steam car on hilly roads near Camborne, Cornwall, in 1801 and his second, bigger version in London in 1803, attaining a speed of six miles (ten kilometres) per hour. In 1804 Trevithick created a four-wheeled tramway locomotive that hauled a five-wagon load of ten tons of iron and 70 men at a speed of five miles per hour. The locomotive set several trends for the future; besides justifying Trevithick's preference for high-pressure instead of low-pressure steam used in stationary steam engines of the period, its single large cylinder was set horizontally and had a sliding crosshead, and exhaust steam was adapted for drafting the boiler to improve thermal efficiency.

In 1805 Trevithick's second locomotive was built at Gateshead, Northumberland, and in 1808 he laid down a circular track in London to demonstrate a third, "Catch-Me-Who-Can." The ten-ton machine achieved ten miles per hour with an open coachload of passengers, but like its two predecessors it was eventually derailed by the flimsy track of the period, and Trevithick, discouraged, directed his talents elsewhere.

Others pursued the concept. John Blenkinsop, superintendent of a colliery near Leeds, strengthened the track and sought to improve traction by laying a toothed rack rail outside one running rail. In 1812 a Leeds engineer named Matthew Murray designed two locomotives, each with a pair of double-acting cylinders connected by crankshafts to cogwheels that engaged the rack. These were the world's first commercially successful steam locomotives.

Meantime, the Northumberland colliery that had employed Trevithick rebuilt his track with cast-iron plates. The colliery's superintendent, William Hedley, designed two locomotives, "Puffing Billy" and "Wylam Dilly," that were successfully employed on coal haulage from 1814 until the colliery closed in 1862. Built as four-wheelers, they broke the plate rails and were soon rebuilt as eight-wheelers, to spread the axle loading, but in 1830 they were again reconstructed with four flanged wheels after the colliery line had been relaid with edge rails. A notable feature of Hedley's engines was their return flue boiler, with rear-end exhaust chimney; this was a first step to improved steam locomotives. The next was George Stephenson's adoption of a multitubed boiler in the "Rocket" of 1829.

George Stephenson and the "Rocket"

George Stephenson, born at Wylam, followed his father's profession as colliery fireman but rapidly graduated to supervision of all machinery at Killingworth Colliery, north of Newcastle. In 1814 the owners allowed him to build for their wagonway his first locomotive, "Blücher." In its original form "Blücher" represented little advance, but in subsequent locomotive construction Stephenson perfected the direct drive from cylinders to flanged wheels via a sliding crosshead and connecting rods.

In 1826 George Stephenson was appointed engineer of a new passenger and freight railway between Liverpool and Manchester. The Newcastle works were taken over by his son Robert, who revolutionized much of the design; he was largely responsible for the multitube boiler that distinguished the "Rocket" of 1829 and set the pattern of future steam locomotive construction. Such a boiler had been pioneered also by the French engineer Marc Séguin. To be assured of steam's reliability for passenger haulage over a 30-mile route, the Liverpool and Manchester Railway directors organized the Rainhill Trials of October 1829, to assess the performance of several contending designs. "Rocket" alone passed the tests set; it touched 29 miles per hour on its own and maintained an average of 13.8 miles per hour with a load of nearly 13 tons. The railway era had started.

Meanwhile experiments were taking place with engines for use on the roads.

Spread of railways. The railway era had started in earnest. In 1830 the Liverpool and Manchester Railway became the first railway to seek primarily passenger traffic. It obtained at least half its income from passengers at the outset, building up an average daily traffic of more than 1,000 passengers, double the previous business of road coaches between the two cities. The 30 miles were covered in 90 minutes at an average fare of five shillings, about half the cost in time and money of the coaches. By 1843 fast trains in Britain were travelling 30–35 miles per hour, and by 1850 the best surpassed 40. Coach operators and canal owners were forced to give up the struggle.

Social impact of railways

The same story was repeated in France and elsewhere on the European continent and in the United States. Everywhere the railway had tremendous social and economic impact, perhaps best illustrated by a statistic of population growth in Britain; in the first half of the 19th century the number of towns in England and Wales with populations of over 20,000 increased from 15 to 63, an increase for which the steam railroad was given substantial credit.

(G.F.A.)

Railroad bridges and tunnels. Virtually the only important development in bridge building since Roman times had been the development of the elliptical masonry arch in place of the unnecessarily heavy and obstructive Roman circular arch. The advent of the railroad suddenly brought a demand for a vast number of bridges, many of great length, capable of carrying heavy loadings. The Stephensons were among the important pioneers of railroad bridges in Britain; Robert Stephenson's unique box girder, the Britannia Bridge (over the Menai Strait, in Wales), through which trains ran completely enclosed,

became a national landmark. Capt. James B. Eads built the powerful triple-arch bridge over the Mississippi at St. Louis that inaugurated steel construction (1867–73). John and Washington Roebling built a number of suspension bridges that were capable of taking railroad loadings, notably over the gorge at Niagara Falls (1851–55) and over the East River between New York and Brooklyn (1869–83) (see also BRIDGES, CONSTRUCTION AND HISTORY OF).

The timber-truss bridge, pioneered principally by a number of American inventors in the early 19th century, was adapted for railroad loadings in iron, in a number of designs.

The invention of the tunnelling shield by Marc Brunel for his tunnel under the Thames, the world's first subaqueous tunnel (1828–42), made it possible to carry railroad traffic conveniently into major cities. The Mont Cenis Tunnel in the Alps, driven by Germain Sommeiller with the aid of dynamite and compressed-air drills (1857–71), similarly pioneered long-distance rock tunnelling, indispensable to the crossing of mountain ranges by railroad lines. (H.N.G.)

Steam-powered road vehicles. In somewhat surprising contrast to the success of steam power on rails is its failure on roads. Many experiments were made, of which the most extensive were those of the English inventor Sir Goldsworthy Gurney, who produced a number of steam carriages that in his words resembled "common stage carriages but without the horses." Several regular services were started, some averaging between ten and 20 miles per hour with 20 or more passengers, but many difficulties were encountered, particularly regarding delays due to refuelling every few miles. By 1840 the first generation of steam carriages had come to a halt. Not until the end of the 19th century were further experiments successful, following which a number of steam buses were put on British roads, a few running in London up to World War I. (G.F.A.)

Steam navigation. *The first steamships.* As early as 1685 a French physicist, Denis Papin, had asserted that steam propulsion could be utilized to drive a ship's paddle wheel. Credit for the first steamship to take the water also goes to France; in 1783 the "Pyroscaphe" managed to move upstream on the Saône River near Lyon for some 15 minutes. Two years later Joseph Bramah, an Englishman, took out a patent for a propeller; his patent application says, in part,

> instead of the paddlewheel may be introduced a wheel with inclined fans or wings . . . This wheel . . . may be . . . wholly under water, when it would . . . cause the ship to be forced backwards or forwards. . . .

It was many years, however, before the superiority of the propeller over the paddle wheel was recognized.

The first steamship to be put to practical use was the "Charlotte Dundas." She was built to replace the horses that hauled barges along the Forth and Clyde Canal in southern Scotland. In March 1802 she towed two 70-ton barges 19½ miles along the canal in about six hours against a strong wind. Horses continued to be preferred for canal work because of the damage caused to the canal banks by the action of the paddle-wheel blades; the "Charlotte Dundas" was laid up, and her builder, William Symington, died in poverty.

Robert Fulton of the United States saw his first steamboat, after an initial disaster, successfully tested on the Seine in August 1804. He took his talents back to the United States, and the first steamship to go into commission was the "Clermont," built by him in 1807 and operating on the Hudson River. By travelling from New York, where she was built, to Philadelphia, the "Phoenix," built in 1807, can claim the distinction of being the first seagoing steamship.

Robert Fulton's "Clermont"

The "Comet," launched on the Clyde in 1812, was the first merchant steamship in Europe. With a speed of 6.7 knots, she operated between Glasgow and the ports of Greenock and Helensburgh on the Clyde. The largest steamship of the day, 141.8 feet (43.2 metres) long and 47 feet (14 metres) wide at the paddle boxes, was the "James Watt," which plied on the coastal service between London and Leith, in southeast Scotland. The first iron steamship was the "Aaron Manby," built in England but put into service on the Seine.

The first crossing of the Atlantic by a steamship was made by the "Sirius," built for the run between London and Cork but in fact chartered for traffic to the United States in 1838. This honour is sometimes claimed for the United States ship "Savannah." But the "Savannah" was in fact a fully rigged ship, with an accessory engine and collapsible paddle wheel, and when she made the crossing from the United States to Liverpool, during the summer of 1819, she very seldom used her machinery. The "Sirius" carried sail on two masts but relied much more on her paddle wheels, and they were in almost continuous use as she battled her way westward against strong winds.

The first propeller-driven ship to cross the Atlantic was the "Great Britain," in 1843. Designed by Isambard Kingdom Brunel, she was built wholly of iron. Her length was 322 feet (98 metres), her beam 50.5 feet (15.4 metres), and her draft 32.5 feet (9.9 metres), with a displacement of 3,618 tons. Confidence in steam was not yet firm, however, and the "Great Britain" carried, in addition to her engines, a total of 15,000 square feet (1,400 square metres) of sail on six masts.

In 1845 the British Admiralty, in an attempt to settle the propeller versus paddle wheel argument, arranged a tug-of-war between two steam sloops, the propeller-driven "Rattler," 888 tons with a 200-horsepower engine, and the paddle-driven "Alecto," 800 tons and also with a 200-horsepower engine. On a completely calm day the "Rattler" triumphed over the "Alecto" and succeeded in towing her stern-first at a speed of 2.8 knots.

From timber to iron. Iron took considerable time to oust timber as the principal component of a ship's hull. It was argued that ships built of iron would sink and that in the event of damage an iron hull would be more difficult to repair. Even when these and other fallacies had been disproved by experience, the shift to iron, and later to steel, was slow. The first iron ship was a barge launched on the Severn in 1787, but the first iron ship to cross the English Channel did not take the water until 1822; what was to become the great firm of Cammell Laird in Birkenhead, England, did not begin constructing iron ships until 1829, and Clydeside not until 1839.

Iron (and later steel) had the major advantages over wood of strength and economy of production; potentially, too, iron ships could be built to a greater length, 300 feet (90 metres) being reckoned the maximum safe length for a wooden ship. But what finally ensured the triumph of iron was the parallel development of steam power. Wooden ships were indeed built with paddle wheel or propeller, but as engines grew more powerful it was found that only an iron frame and an iron hull could withstand the vibration set up.

Brunel's "Great Eastern"

Built by Isambard Kingdom Brunel, and perhaps the most costly economic failure in the history of shipping, the "Great Eastern" was divided into ten watertight compartments, and the iron plating was double from keel to waterline. She was the only vessel in the world to carry two paddle wheels as well as a propeller. Her dimensions were: length 692 feet (211 metres), beam 82.7 feet (25.2 metres), draft 35 feet (11 metres), and her fully loaded displacement was 27,400 tons. Her speed was about 15 knots. Her six masts could spread a sail area of 58,000 square feet (5,400 square metres). She had passenger accommodations for 800 (first class), 2,000 (second), and 1,200 (third), a crew of 400, and a cargo-carrying capacity of about 6,000 tons. The "Great Eastern" was expected to cope successfully with the pitching and rolling experienced on the North Atlantic in bad weather; she did not, and the ship was unpopular with her passengers from the beginning. She turned out to be under-engined; few ports were large enough to handle her. She was an enormous economic liability and was sold for scrap in 1888. She did have one great achievement to her credit: the first telegraph cable between the United States and Europe was laid by her in 1865.

Sail held its own for many years and in many fields. The continuous expansion of seaborne trade throughout the

The clipper ships

19th century called for more and more large and swift merchantmen of all kinds. These demands were met in part by the U.S. and British clipper ships, such as the "Flying Cloud" (U.S., 1851) and the "Cutty Sark" (U.K., 1869). The most famous of all clippers, the "Cutty Sark," was expressly designed to capture the China tea trade. But though oceangoing sailing ships were still being built in the early years of the 20th century, the battle for the means of propulsion of the long-distance oceangoing passenger liners, tramps, and bulk carriers had been effectively won before the turn of the century by steam, and the great fully rigged ships, with their graceful lines and their vast spread of sail, were a thing of memory.

Decline of the sailing fleets. The ascendancy that steam and motor vessels had established over sailing ships by the time of the outbreak of World War I is best illustrated by a comparison between the tonnages of the registered fleets of the principal maritime nations in 1886 and 1914. In the earlier year, vessels registered at ports in the British Empire totalled 11,166,000, of which 4,626,000 were sailing ships. In 1914 the gross figure was 21,046,000, of which only 522,000 represented sailing ships. Similar figures for the other leading maritime countries are (sailing ships in parentheses): France 1886, 1,057,000 (319,000), 1914, 2,319,000 (397,000); Germany 1886, 1,410,000 (806,000), 1914, 5,460,000 (325,000); United States 1886, 2,053,000 (1,587,000), 1914, 5,368,000 (1,038,000); Spain 1886, 521,000 (159,000), 1914, 899,000 (15,000); The Netherlands 1886, 419,000 (229,000), 1914, 1,497,000 (25,000). (Figures taken from *Lloyd's Register of Shipping.*)

(D.O'N.)

DEVELOPMENT OF MODERN TRANSPORTATION

The automobile. Although for two decades before the close of the 19th century there was much experimentation in the construction of road vehicles powered by the internal-combustion engine, not until the motorcar was mass-produced was the full impact felt by other forms of transport. Road transport, which had begun to encroach on rail and water transport before World War I, made great strides between the wars and challenged rail as the chief carrier of both passengers and goods in the two decades following World War II.

Although the automobile was pioneered in France, England, and Germany, it remained a novelty and a luxury until Henry Ford's Model T took to the road in the United States in 1908. A transport revolution followed, comparable in scale and effect to the Industrial Revolution of the previous century. The internal-combustion engine made a tremendous impact on the economic and social development of all developed countries and stimulated the advancement of underdeveloped countries by facilitating the opening up of previously inaccessible areas. Socially, by providing the individual with means of rapid personal travel, it provided a far wider choice of living space and consequently influenced urban environment. By generating a new volume of travel, the motor vehicle changed the relative importance of the different forms of transport and created a need for new and improved highways, resulting in expenditures on road networks comparable to that on the railways during the 19th century.

By the end of 1970 the United States had over 98,000,000 motor vehicles on the roads. Two or three cars per family became common. In the United States there was one car for 2.5 persons, in Sweden one for 3.7 persons, in France one for 4.3 persons and in the United Kingdom one for every 4.8 persons. Japan had one car for every 14.3 persons, with the ratio rapidly increasing. The more densely populated countries had the greatest congestion problem with relatively more cars per road mile.

The impact of motorization on freight transport was equally significant, with the railways suffering a major encroachment. This trend continued at an accelerated rate through the 1960s and into the 1970s. In the U.S. between 1958 and 1968 ton-miles of intercity freight carried by motor trucks increased over 60 percent and in 1969 accounted for 21.5 percent of the total ton-miles of all such traffic. The trend in other countries was similar: in the United Kingdom in the same ten years the total ton-miles of freight carried by road nearly doubled while rail declined about 20 percent. Of the combined total of freight measured in ton-miles carried by road and rail, the former's share increased from 55.8 percent to 75 percent and rail's fell from 44.4 percent to 25 percent between 1958 and 1969.

Increases in truck traffic

To counter this encroachment on their traffic the railways streamlined their systems, closed uneconomical lines, consolidated freight depots, and reduced track mileage. Whereas U.S. railroads were operating 106,000 miles of passenger service track in 1958, the network totalled only 51,000 miles in 1970; in Europe, excluding the Soviet Union and eastern European countries, track mileage was reduced from 122,000 miles in 1953 to 110,000 miles in 1968. The railways also sought more efficient forms of traction, and by the 1970s steam had been eliminated from most of the major systems and replaced by diesel and electric traction. In Europe, steam traction, in terms of train-miles, in 1969 was less than 13 percent of the 1955 level, while electric traction more than doubled, and diesel traction more than quadrupled. Advanced forms of traction capable of higher speeds were being developed with gas-turbine locomotives hauling high-speed trains in France and North America.

By the 1970s the motor car was the accepted form of transport for the vast majority of families, and in many countries motor vehicles were carrying the larger proportion of freight. The passenger traffic of the railways was largely limited to commuter service and intercity travel up to the distances where air travel becomes practical. The role of the railroad in freight shipment was in the bulk shipment of goods and shipment of containers for transshipment by road or ship.

(E.A.J.D.)

Modern road-building

Roads, bridges, and tunnels. Modern road builders still use traditional materials, but quality is now closely controlled by scientific testing. Since World War II, machines have largely replaced hand labour; powerful diggers, scrapers, bulldozers, and graders handle the massive excavations needed in the cuttings and embankments of high-speed roads, and paving machines lay and surface both macadam and concrete roads. Modern pavers, guided by electronic sensors and preset alignment wires, can lay a mile of highway in a day. Firm foundations, efficient drainage, adequate thickness of base or slab, and strong antiskid surfaces are essential in good road building, as are adequate signs, markings, and lighting for the safe use of the finished road.

Bridge improvements during the past century stem from improved materials, new design concepts, more refined calculations, and better construction techniques. High strengths of concrete and steel, the development of steels resistant to brittle fracture at low temperatures, and, recently, the introduction of self-protecting steels to reduce maintenance costs have all helped to advance design. Computers have enabled engineers to save structural costs by quickly obtaining precise data. Wind effects on large structures are now better understood and can be confirmed by wind-tunnel tests.

Eugène Freyssinet's pioneer work in France on prestressed concrete, dating from 1928, marked a major advance in concrete construction, used in many notable bridges throughout the world. For the longest spans, steel suspension bridges are still favoured. This method was pioneered in the United States by John A. Roebling, whose greatest achievement, Brooklyn Bridge in New York City, was completed by his son in 1883. This was the first of many long suspension bridges constructed in the United States.

British engineers advanced the design of suspension bridges by substituting a shallow-plated box girder for the stiffening trusses and by inclining the suspenders for extra stability in the Severn Bridge linking England and Wales (1966). Steel box girders, acting on their own or compositely with concrete, have advanced the design of medium-span bridges (Tinsley Viaduct, Sheffield, England, 1968; and Europa Bridge, Austria), while box girders

with cable stays can be used to attain spans of about 1,475 feet, or 450 metres (Severin, Cologne, West Germany, 1959).

The design of small bridges has been stimulated by their frequency on freeways, and, as more urban roads are built, refinements in elevated viaducts can be expected. In construction, rivetting has been almost entirely superseded by shop welding, and high-strength friction grip bolts are now used for site bolting. Foundation construction methods, especially in deepwater, continue to be improved.

Alpine tunnels for roads derive from the many 19th-century railway tunnels built throughout the world, but because tunnelling is very expensive and because motor vehicles can climb steep grades, there are as yet few major mountain-road tunnels. However, road traffic is now beginning to justify their cost on important routes as at Mont Blanc (7.8 miles, 1965) between Italy and France and Great St. Bernard (four miles, 1964) in the Swiss Alps and Straight Creek (1.6 miles, 1971) in the Colorado Rockies (see also TUNNELLING AND UNDERGROUND EXCAVATION).

Underwater tunnels for pedestrians, trains, and motor vehicles are to be found in many parts of the world. They avoid the use of high-level bridges over navigable waterways; and in populated areas, where they are usually found, they make less demand on surface space than bridges do. Since 1950 the trend has been toward the use of immersed tube tunnels, especially for estuarial crossings. Large prefabricated sections are built on shore, either of concrete or steel, then floated out and sunk into a trench in the riverbed. Urban tunnels, mostly short underpasses, are being built in many major cities to reduce traffic congestion. (H.N.G.)

Mass urban transport. A phenomenon of the 19th century was the development of vehicle systems for movement in urban areas. Following introduction of the horse bus in Paris (1819), the word "omnibus" was coined and services were started in New York (1825) and London (1829). Increasing street traffic congestion brought the underground steam railway. London's first subway was completed in 1863. The first electric deep-level line, in London in 1890, was followed by lines in Budapest, Boston, Paris, New York, and eventually most of the world's great cities. Electric street tramways appeared in Berlin in 1881 and became general in many large cities. The electric trolleybus originated in France in 1901 and reached a peak of popularity 40 years later. High investment and fixed route characteristics were disadvantages, and it was progressively disappearing with the streetcar (tramway) after World War II. Streetcars are retained in some European cities.

The bus was motorized about the turn of the century, and after 1930 it became the most widely used form of public transport in urban areas. Outside urban areas a close mesh of rural and interurban services grew up. Routes and services were generally allocated by franchise and were subject to public service requirements and, frequently, fare control. Bus sizes expanded from the 34-passenger double-decker bus of 1910 to the 53-seat single-decker and 80-passenger double-decker bus of the 1970s.

With the great rise in automobile ownership after World War II, most developed countries shared the experience of a decline in patronage of urban public transport. Resultant traffic congestion led to deterioration in services, which declined even further with fares raised to meet growing deficits. Traffic management measures taken to meet the problem included priority treatment for buses, exemption from directional traffic regulations (one-way streets, turn bans, etc.), provision of segregated bus lanes and reserved rights of way, and priority at traffic signals. Electronic devices were also used to monitor vehicles and adjust headways and frequencies. To maintain uneconomic but socially desirable services in some countries, subsidies were granted from public funds and capital grants made to enable fleets to be modernized and new systems built or improved or extended. New rapid-transit systems were being constructed, as in Toronto, San Francisco, and Washington, D.C., and others were extended and improved, as in London and Paris. In the 1970s there was a growing realization of the need to maintain mass transportation to control automobile usage in city centres. The resultant trend was the consolidation of operators, to provide better integrated and organized services of all transport modes as in New York, Paris, and London. In Britain, Passenger Transport Authorities were made responsible for integrating all public transport services in four areas, while interurban bus services were merged into a publicly owned National Bus Company. Looking to the future, new forms of transport were being sought to provide services competitive with the automobile and thereby to attract patronage. But in the 1970s urban mass transportation had made no major technological advance comparable to those made by other forms of transportation.

The growth of traffic congestion

For the most part mass transportation continued to be provided by the bus, streetcar, or rapid rail transit, as it had been since the 1920s. This accounted in part for its failure to meet the challenge of the automobile and for its subsequent decline. (Ed.)

Traffic networks. The form of each road and traffic network is dictated by geographical, historic, and traffic factors; today, the traffic factor is perhaps the most important.

Networks emerged with the development and expansion of successful early settlements at harbours, river crossings, or mountain passes, or where minerals existed. The roads linking the settlements, large and small, formed the rural road networks. These sufficed for private and commercial travel until the 20th century, when the motor vehicle and road systems generally proved unfitted in alignment, construction, and safety for the new motor vehicle. Carrying heavy loads over long distances at high speeds, motor vehicles required new national highways, and in urban areas, which were the destinations of the majority of the journeys, traffic congestion made the replanning of road systems essential.

The growth of road networks can be followed especially well in the United States. The American road network gradually spread as settlers pushed westward. In the East, harbours, rivers, and mountains established road patterns, as did similar features in the far West, and the Mississippi River–Great Lakes system. In the Midwestern plains, land development based on surveys produced a grid network that was absorbed into the primary road system.

Before World War I, most countries had realized the need for improving existing rural networks. Existing roads were widened and straightened, new bypasses built around congested towns, old bridges realigned and strengthened. Only three countries, however, embarked at that time on the building of new long-distance national routes to supplement existing networks: the United States and Italy, where tolls were charged, and Germany, where the new autobahns were toll-free.

Since World War II, most advanced countries have modernized their rural networks with new road construction patterned for modern traffic. The United States led the way with its nationwide system of interstate highways, mainly freeways without tolls, all of which are dual carriageways (divided highways) with controlled access. When completed in 1972 the total system will comprise 42,500 miles (68,400 kilometres), and all large towns, harbours, and strategic sites will be served (see also ROADS AND HIGHWAYS).

Germany, with its 3,000 miles of autobahns, is building a further 8,000 miles due for completion in 1985. Italy is rapidly extending its prewar *autostrada* system, and in Britain 1,200 miles of motorway were in use during the early 1970s. France and Belgium are also constructing new national routes, and Japan had 600 miles in use in 1971 out of a total projected 4,700 miles. The United Nations through its various economic commissions sponsored the building of such intercontinental routes as the Asian Highway, while the Pan-American Highway system was initiated by the Organization of American States.

The adaptation of urban networks to modern needs is

difficult and expensive. Long-distance traffic can be removed from town centres by the provision of new routes, generally urban motorways, although in large towns and cities this through traffic is only a small proportion of all the total traffic movements.

Traffic engineering

Traffic engineering measures, including centralized regulation of traffic flow over wide areas by electronic computer, are now applied in many large urban areas to ensure the effective use of road space, while parking restrictions are used to deter journeys to city centres. A common pattern of the urban road system is a hierarchy of roads: primary roads, ring or tangential, coping with through traffic or bringing it to the periphery; radial roads bringing it to the city centre; and distributory roads serving it. The spacious layout of many American cities aided the containing of traffic, but construction of new urban expressway systems, of which Los Angeles has the most extensive, was general in the postwar period. More recently the trend has been to limit such construction and to consider the provision of mass transportation systems, especially rapid transit, with a view to restricting the use of the automobile, particularly for commuting to work.

(H.N.G.)

Air transportation. The rapid development of air transport might not have been possible but for military requirements and direct government aid, which, in some form, was made available almost universally until the 1950s, when the United States and United Kingdom terminated their subsidies or grants, but many other countries still continued to assist their national airlines and were doing so in the 1970s. Airlines were pioneered from 1919 onward by Britain and by European countries with relatively advanced aircraft industries and subsidies justified by the need for better communications, especially with overseas territories. Services followed in areas of Latin America, Canada, Africa, and Australia, where surface communications were slow, difficult, or nonexistent.

By contrast, airline progress in the United States was slow until 1930, though the Post Office had been operating coast-to-coast mail services from 1920 to 1927. Under the Air Mail Act of 1925 these services were taken over by the airlines themselves under contract. The mergers that resulted produced, by the mid-1930s, a pattern of internal trunk airlines that was to remain effectively unchanged for more than 35 years, while overseas routes were being continuously developed. The bigger airlines were capable of ordering fleets of specialized aircraft, such as the Boeing 247 and the Douglas DC-2 and, later, the highly successful DC-3. With a monopoly of overseas services and with ample government aid, Pan American World Airways advanced in the 1930s through Latin America and across the Pacific. Earlier, the European airlines had been extending their route networks through the continents of Asia and Africa.

In 1940 a system of controlled competition was introduced in the United States through the formation of the Civil Aeronautics Board (CAB), which was given the responsibility for route licensing. Elsewhere, competition had been limited by governments, by the sharing out of international traffic rights, and by tariff and other agreements reached by the then International Air Traffic Association.

The U.S. airlines, essentially unaffected by World War II and backed by a strong aircraft industry, were in a good position to advance rapidly after 1946. Further route expansion followed the CAB's decision in 1943 to encourage new airlines to operate subsidized feeder services over local networks connecting with the trunk routes.

The DC-4 and the Lockheed Constellation, which, with the DC-3, made worldwide postwar airline recovery possible, were the result of civil requirements, but war production meant that they were available quickly and in quantity. The more positive influences of the war were in progress with equipment such as navigation aids and radar, the ready acceptance of flying, and the availability of more and better airfields.

The requirements of war also provided the turbine (jet) engine, but air transport was already a major industry when this came into airline use in the late 1950s. Its most important effect was to reduce operating costs. These were reaching a practical minimum by the mid-1960s. Further reductions were possible only with big increases in payload capacity. The early 1970s saw the entry of the 300–450-seat "wide-body" jets, led by the Boeing 747. Whether the next generation of aircraft would be supersonic remained unresolved in the early 1970s, with the Anglo-French and Soviet projects well advanced. Vertical takeoff and landing (VTOL) aircraft were also being developed and could well have a considerable impact on the future pattern of civil aviation. Already, however, there was excess capacity, which arose when jet aircraft were first introduced; and the situation was repeated when the big jets were entering service in 1970. Nonetheless, new air routes were being continually developed, including those from Europe to the Far East over the North Pole.

The coming of the jets

Excluding figures for the Soviet Union and for nonscheduled carriers, world passenger traffic increased from 18,000,000 in 1946 to 310,000,000 in 1970. Practically every part of the world became accessible by air transport. By 1958 more passengers were travelling over the North Atlantic by air than by sea, and by 1970, 97 percent were travelling by air and only 3 percent by sea.

(H.A.T.)

TRANSPORTATION TRENDS

New forms of transportation have always evoked new problems, not least because each new mode has required an increasing amount of land space for its tracks and vehicles both in movement and at rest.

The universal availability of present automobile transport has not only made a vast demand for land use but also has created ecological and environmental problems. Transportation and land-use studies and the drawing of development and transport and traffic plans have become essential to contain uncontrolled use of both land and transport and to ensure the availability of suitable transport facilities. But their implementation would be of little value without the application of the latest technologies to the transport modes needed. Technology is being exploited to produce transportation systems that make the least demand on land use and cause the minimum of congestion in urban areas but maximize the return on capital already invested in existing forms and new capital investments.

On the railways, replacement of steam by electric and diesel traction has made possible far higher overall average speeds, and many scheduled services now run at over 100 miles per hour on existing tracks and faster in Japan on such specially constructed tracks as those of the New Tōkaidō Line. New forms of traction are being developed: turbo trains are in service in Canada and France and on the Metroliner in the "northeast corridor" between Washington and Boston in the U.S. Other new forms of traction being developed include the tracked hovertrain, an air-cushion vehicle propelled by linear induction motors, which is being studied in Britain, France, and the United States. In addition, the advanced passenger train (APT) being built in Britain represents an entirely new approach by applying aeronautical principles to the conventional train to raise its speed to 150 miles per hour and eventually to 250 or more, on existing tracks.

On the road a major thrust of effort is certain to be the application of electronics to increase traffic control. Centralized computer control of signals over a wide area is already in use in many cities, and its effectiveness is being continuously improved. Another approach is to bring automation to the vehicle on the highway. Experiments are being conducted on systems for guiding vehicles and controlling their progress by electronic impulses transmitted from circuits in or outside the road and received by the vehicle. Many other new concepts of transport systems and vehicles for urban transportation are being considered, while others have reached the development stage. One concept in a variety of forms is for driverless vehicles to be routed by computer to a destination preselected by the passengers. One variety would link the

The driverless car

vehicles on guideways after the passengers had driven them there. Other systems are based on the conveyor belt that travels continuously, with passengers boarding and leaving from moving walkways. Many types of electric cars are being tried out to combat air pollution but are waiting for a breakthrough in battery development, while the mounting traffic-accident rate has led to a search for new designs to produce safer cars.

Another possibility for future travel is the gravity-vacuum train, consisting of wheeled trains in tubes rolling downhill at great speed and then being propelled by a combination of the acquired momentum and vacuum pressure for the uphill section of the journey.

At sea the supertanker of up to 1,000,000 tons' capacity, the giant container ship, and the barge-carrying ship are among foreseen developments. The air-cushion principle, mentioned earlier in connection with advanced rail designs, has been successfully applied to water craft, and many types are in civilian and military service. In the air, supersonic liners and vertical takeoff and landing aircraft may serve the airlines of the future.

Another form of transport being developed is the pipeline, through which an increasing variety of products may be carried. While some of these concepts may prove impracticable, others not yet conceived may be evolved and radical changes in transport, not yet imagined, may take place in the last decades of the 20th century.

(H.A.T./G.F.A./H.N.G./D.O'N./E.A.J.D.)

Transportation, Urban

Urban transportation includes the movement of people and materials within any town or city but particularly within large metropolitan areas. In the last third of the 20th century, such movement was primarily by automobile and truck powered by internal-combustion engines, despite the fact that mass transit had long been recognized in all developed countries as desirable and necessary.

Before taking up the problems and possible solutions within the framework of urban transportation itself, it should be observed that solutions may come from technological advances outside the system. The picturephone, facsimile transmission, and other developments in communications may reduce the need for person-to-person contacts and eliminate many trips now considered necessary. Energy presently transported by railroads or trucks in the form of coal or oil can also be moved by pipelines. Generating plants can be built at mine mouths or other nonurban areas, and electricity can be transmitted by buried, high-voltage power lines to the urban area. Advances in building construction may also have large impact on transportation by facilitating development of more efficiently organized urban agglomerations.

HISTORY

While freight movement by water determined the location of many cities, major local transportation has rarely been by boat. Wheels have been paramount from the horse-drawn buggy and omnibus to the bicycle, streetcar, subway, and automobile. The first successful omnibus service was inaugurated in Paris in 1819; within a dozen years, London, New York, and other major cities had copied the idea. Electric traction was tried out in Richmond, Virginia, in 1888, followed by a rapid spread of electric transit first in the U.S. and then in Europe.

First subway

Meanwhile, London had pioneered the subway, or underground, as early as 1862 with a line of about four miles connecting the principal railroad terminals. The line was so successful that it was rapidly expanded, taking advantage of a tunnel driven under the Thames River a generation earlier by Marc Brunel; the tunnel had been intended for vehicular use, but suitable approaches had not been constructed. From this beginning the City and South London Railway grew, at first using steam traction and later (1890) electricity. Budapest, Boston, Paris, Berlin, New York, and other cities followed in rapid succession; within a few years hundreds of miles of subway were built, mostly by trenching streets and covering over (cut-and-cover method). A parallel development was the interurban system of electric surface traction, widely used in suburban areas and between small, neighbouring cities.

Like the subway the elevated railroad was conceived and built before electric traction, the first operating with a cable drive on Ninth Avenue, New York City, in 1867, and shifting in 1871 to steam locomotives. The first elevated to be equipped with electric power was the West Side Metropolitan Elevated Railroad in Chicago in 1895, soon followed by all other such railroads. The first use of multiple-unit cars, in which most units are powered but controlled from a single location, also came in Chicago, on the South Side Elevated, in 1897.

The last major component of the modern urban transportation system to arrive on the scene, but the one with the largest impact of all, was the automobile. As early as World War I, the automobile was an important user of city streets, especially in the U.S. but also in Europe; taxicabs were numerous enough in Paris in 1914 to be commandeered for a critical troop movement in the Battle of the Marne. Motor buses began to make a significant impact in the 1920s, especially in the U.S., where by mid-century they had nearly replaced electric streetcars. Buses received favoured treatment from government in the belief that they provided advantages, some of which, such as routing flexibility, subsequently proved illusory. Britain and France followed the U.S. lead, but other European countries generally retained their streetcars. In the U.S., the expectation that bus service could be upgraded through such devices as reserved lanes on freeways or preferential access at intersections was not widely borne out. In Detroit an experiment with operation of buses on freeways showed rider resistance and preference for the old surface-street routes. In Europe, efforts were

made to separate tramlines from automobile traffic by placing them at the side of highways or on elevated tracks, by building grade separations at main intersections, and, especially in West Germany, by using special vehicles with high manoeuvrability.

The automobile's relationship to mass-transit systems proved complicated. As soon as commuter railroads developed in the late 19th century, isolated suburban clusters began to form. Streetcars and interurbans extended the reach of the railroads and filled in gaps in the system. The automobile, however, played the principal role both in extension and filling in, thus becoming indispensable to suburban living. The automobile thus created further demand for highways and expressways, both around and into the central business district. Expressway development both in the U.S. and Europe so accelerated growth in city and suburban areas that the word megalopolis was coined (or, more precisely, revived) to describe such areas as the chain of metropolitan regions along the northeast U.S. coast. The density of traffic in such areas had the effect of reducing the value of the automobile; by the 1960s, technologically innovative transportation modes were under consideration.

Planning land use

Possibly even more important in the changes in transportation thinking in the 1960s and 1970s was the growing conviction that land use must be planned. This concept was much more widely accepted in Europe than in the U.S., where the multiplicity of local and regional political units created a chaotic situation. In some small countries such as Sweden, it appeared possible to predict future land use, to design construction as transit lines were extended, to build roads to complement the transit lines, and thus to have appropriate facilities available when the suburb was developed rather than setting in motion an uncontrolled cycle of growth.

PROBLEMS OF URBAN TRANSPORTATION

The automobile's readiness and versatility has been the catalyst of spectacular suburban growth in almost all developed countries, making possible the exploitation of unused land areas farther out from the central city. The experience of Japan, Europe, and the U.S. has been the same; those who can afford new houses can afford automobiles to reach them.

Yet even apart from the inevitable pattern of overgrowth and congestion, public transit systems are indispensable for the large groups of persons who cannot drive autos, such as the poor, the very young or very old, and the disabled. In recent years a need for public transit has been shown in cities as small as 30,000.

Traditionally, transportation problems have been considered under the headings of cost and convenience, meaning primarily speed of travel. To these aspects have now been added such questions as pollution abatement and safety, the latter a question of increasing complexity.

High costs. In most countries the history of mass transit has been a history of maintenance problems versus rising fares. Lengthened trips combined with popular resistance to fare increases create maintenance problems; when these become acute, fares rise, often sharply. Flat fares discourage the short-distance rider, who may pay two or three times as much per mile as the long tripper. Zone fares are difficult and expensive to collect. Too often the result is a cycle of rising flat fares that discourages short-distance passengers and reduces revenue gains.

Another aspect of rising costs in mass transit is the substitution of subways for surface lines; a system such as the Montreal subway built in the 1960s cost 1,000 or 2,000 times as much per mile or kilometre as did the surface transportation that served the city at the turn of the 20th century.

While costs of both automobiles and highways have likewise risen steadily, apparent in Europe, the U.S., and Japan has been the willingness of the public to pay more for automobiles and to support highway construction through bond issues and toll collections while exhibiting marked resistance to paying more for improved mass transit. Signs of this public attitude have even become discernible in the Communist countries.

Social effects. The high cost of urban transportation has invariably fallen most heavily on the poorest classes, who pay a higher proportion of family income for transportation, and often cannot find adequate means of reaching employment. In modern industrial centres new jobs tend to be located away from the congested districts where the poor traditionally live.

Speed of travel. Normal walking speed for a man has remained at about 3.1 miles (4.9 kilometres) per hour since the beginning of recorded history. Horses and horse-drawn omnibuses raised the speed of travel to approximately 6 miles (10 kilometres) per hour. Buses and trolleys provide average speeds of 5 to 6 miles per hour in rush-hour traffic to 12–14 miles per hour on most city streets in other time periods. Speeds of up to 50 miles (80 kilometres) per hour are often reached by buses in outlying streets of large cities, but schedule speeds, which include stopping times, are much lower.

Studies of relative speeds of principal mid-20th-century urban-transit modes showed average automobile speeds of up to 19 miles per hour, compared with 16 miles per hour for suburban railroads, and substantially less for other mass transit. While doubtless valid statistically, such studies are misleading because of the different functions of the different types of transit. To gain a real picture of urban transit speeds in a city like Paris or New York would require a rationale that included the number of persons moved per mile, how near the centre of the city the movement took place, and also station spacing. Broadly speaking, it may be said that while speed of movement, especially during rush hours, still leaves something to be desired in most cities, it is not as critical a problem as that of costs.

Pollution. The relationship between air pollution and health began to be investigated in the 1950s, with London pioneering in research and abatement. The importance of automobile emissions in air pollution in urban centres was well established by 1970. The diesel engine, widely used in freight movement by truck and railroad both in Europe and the U.S., has been found to contribute a relatively minor amount as compared with the gasoline engine almost universally used on passenger vehicles. Because urban travel is largely start and stop and emissions are generally higher when vehicles are idling; it can probably be assumed that more than half of the motor-vehicle pollutants are concentrated in urban areas. Efforts were underway in the 1970s to eliminate lead from gasoline and otherwise reduce emissions.

Another side effect of urban transportation is noise pollution, which takes the form of rumbling elevated railroads, aircraft takeoffs and landings, and trucks and autos in heavy concentrations on freeways and downtown streets. Such European cities as Rome, Florence, Genoa, Marseilles, and Dijon, with ancient or medieval street layouts, are especially noisy.

So-called visual pollution by the urban transport system is another cause of urban blight. The abandoned automobile, for example, stripped of useful parts and not valuable enough as scrap to pay for removal, is a growing problem in the U.S. Another form of visual pollution is actually hazardous; many municipalities have done a poor job in maintenance of street hardware, permitting saturation of intersections with confusing directional signs that fight for space with commercial signs. Long delays in repairing broken street lights and even broken traffic signals are also dangerous as well as unsightly.

Many U.S. cities fail to keep streets adequately clean. Some European and Japanese cities set a better standard, despite high concentrations of vehicles and people.

Space pollution

Finally, the automobile has produced what might be termed space pollution, simply through its ubiquity. Parking lots now occupy squares and open spaces; in many cities, sidewalks have been reduced in width to accommodate extra traffic lanes for automobiles. In such European cities as Naples, and throughout the tropics, people normally overflow the sidewalks into the streets.

Several interesting experiments have been carried out to restrict or eliminate automobile traffic from certain sections or streets. Rome barred motor vehicles from one of

its principal squares, the spacious Piazza Navona. Other Italian cities, such as Pisa, closed streets to auto traffic at certain hours. New York and other cities have temporarily or permanently closed some of their main avenues for the benefit of shoppers and strollers. Side streets may be closed for the benefit of children. These measures, however, have hardly counteracted the prevailing trend toward greater and greater domination of the city by the automobile.

Safety hazards. Though transportation in all ages has involved hazards to life and limb, the appalling toll in deaths and injuries brought by the automobile in the 20th century raises entirely new questions. Even if private automobiles can be shown to provide a substantially greater convenience, it is uncertain that a rationale can be supplied for their use in competition with safer public transit. The London underground, for example, had only one serious accident, in which 12 were killed, throughout the 1950s and 1960s. The Paris Metro had no deaths between 1930 and the late 1960s. The Tokyo subway had no deaths during the 1960s. The Toronto subway had no accidents in the 15 years following its opening in 1954.

Other types of urban mass transit, such as buses, have much less dramatic records but are still far ahead of the private automobile in safety.

Planning problems. Attempts by government agencies and others to plan systems to meet urban transit needs encounter chronic problems. The type and quality of transit systems that may be technically feasible a few years hence are difficult to predict safely; in addition, the public response even to improved versions of existing systems is difficult to determine. That people want a substantially improved urban-transit system in Tokyo, New York, and London cannot be doubted; how much they are willing to pay for what degree of improvement is uncertain. When the long lead time involved in planning a new or radically altered transportation system is taken into account, it becomes evident that considerable courage is needed on the part of planning authorities. In countries where public ownership or substantial government control over land use exists, some of the more obvious problems can be mitigated.

ELEMENTS OF URBAN TRANSPORTATION

Streets, expressways, and associated facilities. Since cities first developed, the construction and maintenance of urban streets have been almost exclusively a governmental function. Many methods of classification have been used in attempts to define street networks in a systematic way to provide for maintenance and expansion. One widely used method is based on volume of through traffic; those with nearly 100 percent through traffic are classed in the highest category, with high speeds and maximum traffic control required; those with the lowest percent of through traffic are placed in the lowest category. The classification is complicated by the obvious fact that most urban streets are in an intermediate role, carrying several kinds of traffic. This necessitates an attempt to classify on the basis of the predominant role of a given street, which may vary at different times of day and may change over a period of time.

Street planning

Street planning has always been a complex process, involving local commissions, intermediate agencies, and national governmental authorities. Land-use problems in metropolitan areas are particularly troublesome. Political agencies that let design contracts for new highways in urban areas permitted wide latitude to the engineers in determining location as well as design and construction details; this is done because intruding an expressway into the tightly congested metropolitan area involves major technological problems. A good illustration is furnished by the Arch of Triumph tunnel in Paris. The rotary traffic pattern, without traffic lights, at the twelve-way intersection that circles this famous monument was established in the early years of the century and served very well until the congestion of the 1950s and 1960s. The problem was defined as finding a route that would keep through traffic out of the rotary pattern. The solution undertaken in 1968 was an underpass of almost one-quarter mile capable of passing 200,000 vehicles a day under the Arch of Triumph. The presence of five subway (Metro) tunnels, various pedestrian walkways and utility lines, and a large parking garage complicated the work, which also had to be carried out with minimum disturbance of existing traffic patterns. The crowns of three of the subway tunnels had to be removed to make room for the two-lane roadway.

Many other ingenious devices have served engineers attempting to reduce congestion and facilitate through traffic in cities. In several cities waterways have been used as sites, with a new expressway occupying the bed of a disused canal, or with an expressway built out over one side of a river. But for most expressway projects demolition and removal of residences and businesses is necessary, which creates problems much broader than the merely technological. Not only engineers, but sociologists, city planners, political scientists, and architects are commonly involved in the decision making.

Even after an urban expressway is completed, problems arise because of the difficulty of performing maintenance work on a road surface in constant use.

Parking. In recent years urban parking has gone increasingly underground, though above-ground, multilevel structures are still being built. In Europe and the U.S. it is becoming more and more common to integrate parking with new office and residential buildings by utilizing the lower several floors. Another trend is to reserve the surface above the underground structure for park space.

Traffic control. A complex traffic-control system embracing several transportation modes is inseparable from modern urban movement. Auto-traffic devices range from parking meters and signal lights to automatic scanners that measure traffic flow and adjust lane entrances. One problem is uniformity; a present goal is to establish worldwide sign standards. Western Europe has long employed an ingenious system of wordless signs, on which symbols indicate "no entrance," "one-way street," "stop," and other directives, thus overcoming the language barrier (see also TRAFFIC CONTROL).

Surface transit. Many European and American cities abandoned electric trolley systems in favour of buses, which were believed to have certain advantages. Some of the advantages have proven illusory—for example, the greater flexibility of routing possible with buses. In addition, buses are contributors to air pollution, albeit primarily disagreeable odours. In the 1960s San Francisco, Philadelphia, and Boston, in the U.S., and Hamburg, Frankfurt, and other cities in Europe were maintaining and expanding their limited surface transit lines (tramlines). In some European cities, limited tramlines are being built in parkways or moved to one side of expressways or other through road arteries.

Interurban lines

Interurban transit lines have also largely been abandoned in the U.S., despite remnants in Chicago, Philadelphia, and elsewhere. In Europe and Japan, several such lines survive, some in private ownership, most government operated. In the 1970s, however, the gasoline or diesel-powered bus has become the most ubiquitous form of mass transit for the whole world.

Subway and elevated transit. Subways are best adapted for carrying large numbers of people over short and medium distances into and through the central business district. The money savings achieved by building elevated lines has been shown to represent false economy in the long run because of the damaging effects of elevated structures on business and residential streets. Though arguments have been advanced that aesthetically pleasing and quiet monorail lines could be built in city streets, present experience is not favourable. Though most world fairs of recent years have had monorail systems, and Dallas has a short line connecting the airport parking area to one passenger terminal, no successful system has been built for a central business district.

Subways have continued to be built despite mounting costs and engineering problems because they are the most satisfactory solution to moving large numbers of people inside a city. They do no damage to streets and neigh-

Proposed Rail Transit Service Standards

service standards	subway-elevated	supersubway	suburban rapid transit	suburban railroad
Service territory (distance from Manhattan)	0–11 m	9–17 m	15–35 m	25–50 m
Average service speed	22 mph	35 mph	45 mph	45 mph
Peak-hour period passenger loading				
Passengers per track	48,000	40,000	30,000	30,000
Percent seated	30%	60%	100%	100%
Service frequency (outlying lines)				
Peak period	4 min	6 min	8 min	15 min
Off peak	8 min	12 min	15 min	30 min
Night-weekend	12 min	20 min	30 min	60 min
Fare level	$.15	$.25–$.45	$.50–$1.00	$.75–$1.40
Train characteristics				
Car type	standard rapid transit	modified rapid transit	modified rapid transit	standard suburban
Seats per car	50	80	100	125
Hourly trains per track	30	30	30	20
Hourly cars per track	300	300	300	240

bourhoods overhead; and on the contrary they usually contribute to rising land values. The Toronto subway is a good example of the common effect of increasing population density along a new line.

The stations on the newest subway lines are much improved over those built early in the century; in some, as the Moscow and Rome subways, serious efforts have been made to create aesthetically pleasing as well as comfortable and convenient station facilities. The newer aluminum and stainless steel subway cars are also much improved, with easily cleaned plastic or plastic-covered seats, and increasingly, with air conditioning. Recorded vocal announcements and visual displays assist strangers and speed passenger loading and unloading. Higher rates of acceleration in the all-powered-car trains further increase overall speeds.

Automatic systems control has been installed in some subways, including a variety of automatic fare collection devices. Television monitoring of stations by central observers is increasingly provided, along with radio communications, also widely used for bus spacing.

Commuter rail service. Suburban or commuter railroads grew out of the desire of 19th-century railroad management to increase the number of collection and distribution points in metropolitan areas for its long-range passenger service. With long-range rail service undergoing radical modification in most of the world and facing abandonment in some areas, notably in the U.S., this concept is far out of date, yet suburban rail service has become an increasingly indispensable component of metropolitan transit. The situation has led toward increasing participation in suburban rail management of governments and commuter groups, with ultimate results yet to be seen. In the U.S., public agencies formed for the purpose in various metropolitan areas have sought operational control of suburban lines (see also RAILROADS AND LOCOMOTIVES).

The supersubway. One increasingly discernible tendency of the early 1970s, worldwide, was a blurring of distinction between rapid-transit lines and suburban railroads. In some cities, such as Philadelphia and Boston, in the U.S., standard subways have been extended over suburban railroad lines. In some cases the suburban rail lines have been abandoned by the former operators, and in some the subway trains are being integrated into an ongoing operation. In 1965 the New York City Planning Commission outlined what may be the shape of metropolitan rapid transit in the world's large cities in the later years of the century. The commission proposed that rail transit be differentiated by service standards only and suggested the plan shown in the Table for the differentiation.

The supersubway would have a higher fare than present subway–elevateds in New York, but would provide seating for 60 percent of the riders instead of 30 percent, thus giving better service for those more able to pay. Better service includes higher speeds, more seats, and transverse seats giving better support during acceleration and deceleration. The service would not operate as frequently, but its quality would be upgraded.

People movers. The moving stairway, or escalator, is one of the earliest examples of a people mover. Although initially provided inside retail establishments to replace the elevator, today such stairways facilitate the movement of people in railroad or subway stations as they move upstairs or down in the station or from station to street. Although fewer have been constructed, the moving sidewalk is similar to the moving stairway in concept. Generally, a moving sidewalk is a rubber belt approximately 30 inches (76 centimetres) wide, carried on rollers, and is equipped with a moving handrail. The belt is rigid enough to carry the load between rollers but flexible enough to turn around drums at each end. Other designs use a belt that is rigid in the centre with rollers at the edge. Entering and leaving requires some agility, so that people with slow reflexes, particularly the elderly, often find it difficult to utilize these facilities. Consequently, though speeds of 10 miles (16 kilometres) per hour are possible, present units rarely operate at more than one-fifth this speed.

Moving sidewalks

Mixed modes. In its broad sense, the term mixed modes simply refers to the use of more than one technology for a single trip; thus the Japanese and western European combination of bicycle and commuter railroad is a mixed mode. A narrower form of mixed mode is two kinds of public transportation, such as railroad or subway train and city bus. A possibility under discussion on the 1970s is a cross of taxicab and bus to provide an on-call form of public transportation from suburban or metropolitan home to railroad or subway terminal. A computer would be programmed with appropriate data, and when a telephone call activated the system the computer would assign an available vehicle to pick up the passenger. The computer would further optimize the route of the vehicle for origins and destinations.

Another possibility is that small vehicles or buses could be designed to operate on both railroad tracks, or other types of guideways, and on city streets. These vehicles would pick up passengers along the street system, move to a guideway and travel off-street and out of congestion to their destination. Railroads have equipment permitting track supervisors to drive on-street to a section of track, drop steel-flanged wheels onto the track structure, and drive along the track for inspection purposes. Similarly, buses have been equipped with retractable flanged wheels and axles to permit operation on either streets or rails. Technical problems with this type of vehicle will require substantial sums of money and time to resolve, relating primarily to the truck design and quality of the ride. The vehicle must be light enough to travel easily over the roads but heavy enough to function on track or structure

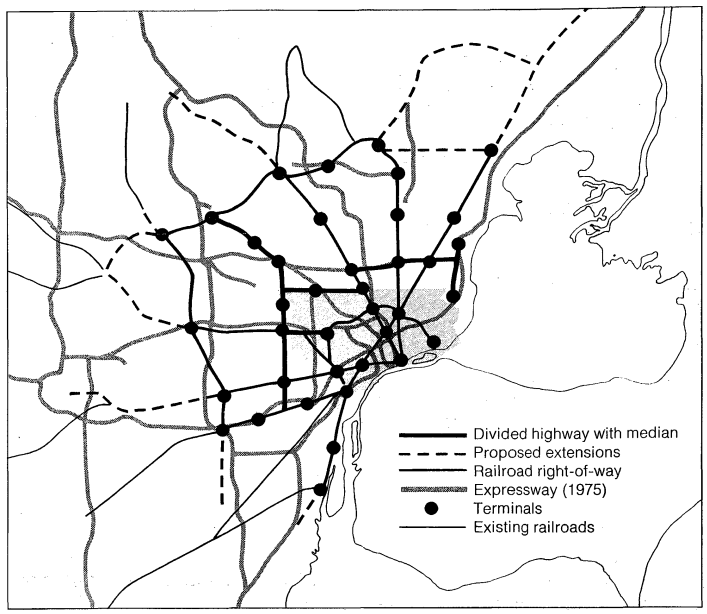

Figure 1: Artist's conception of a dual-mode guideway network superimposed on Detroit and its suburbs utilizing rail, air rights, and expressway median strips. The dots illustrate the location of local stations where ingress and egress can be made. In most cases, these are near shopping centres, airports, the central business district, as well as residential areas.

in moderate snow. Inadequate maintenance of lightly used track is a problem, and proponents of this system have rarely estimated the cost of upgrading and signalizing track for frequent use by small vehicles. Union conflicts can also be anticipated as the technique bridges transit and rail modes where different labour unions have contracts.

Just as trucks are being moved on flatcars, or containers on trucks and flatcars or both, it has been suggested that passenger containers be loaded in key sectors of a city and flown to airports by helicopter. When this proposal was evaluated in Los Angeles, investigators concluded that it was not feasible at the time. Special vehicles designed to move passengers from terminal to airplace, however, are being utilized at major airports in such cities as London and Washington, D.C.

NEW CONCEPTS AND NEW TECHNOLOGY

Increasing efforts are being put forward on many levels in all of the developed countries to untangle the urban transportation problem. These include both modes of conceptualization and technological innovations (Figure 1).

The systems concept. The systems approach, which has been used successfully in solving many complex engineering problems, has an obvious application to urban transportation. The systems engineer seeks to analyze a large problem by identifying its components and calculating the approximate effects of the trade offs that can be made among them. In viewing urban transportation, he asks such questions as these:

Is a cardinal aim the reduction of congestion in the central business district? Must congestion also be reduced on all links of the system or is there a tolerable level that can be permitted on some? Are these radial or circumferential to the central business district? How important is safety? Must the present automobile accident rate be radically reduced? How important are the transportation requirements of nondrivers? Must air and noise pollution be reduced? By how much?

Once the list of factors is determined and put in reasonable order of importance, engineers synthesize a design and analyze its performance, estimated cost, and socioeconomic attributes. The engineer can easily state the performance anticipated from the design in factors like acceleration and deceleration, overall speed, noise levels, and amount of pollutants from the engine. Cost of facilities can readily be estimated, especially for subsystems or components that have already been built. It is more difficult to evaluate the socioeconomic attributes and to weigh the costs of externalities to the system. Externalities are those factors that affect third parties who have no direct connection with the system. How important is it to soundproof the track of a transit line that goes through a densely populated neighbourhood? What is it worth to reduce air pollution if emission meets the present public health standards but still has an adverse impact on health or increases the cost of laundry for citizens living nearby? As difficult as such evaluations are, they must be attempted.

Correcting design deficiencies

After making his evaluation, the engineer attempts to correct the deficiencies where the design falls below the established goals or the ranking of the criteria. Correcting the deficiencies may increase the cost, so cost estimates must be changed. When the new design is completed it is evaluated by the same process. Reiteration continues until the design is acceptable in terms of performance, cost, and socioeconomic effects.

Unfortunately, the decision-making process in respect to urban transportation is fraught with so many complications that the systems approach at present promises only limited benefits. Government authorities overlap; pressure groups abound. A small town or village may block the development of an off-street transit line that would benefit a whole region. This is especially a problem in the U.S., but there are serious difficulties in applying the systems approach to metropolitan transit everywhere.

Technological innovations. Of the many directions of research on road transportation under active pursuit in the 1970s, perhaps that of most immediate interest for urban transportation is the automatically controlled vehicle. One imaginative concept involves completely relieving the driver of responsibility, substituting an electronic roadway control connected to a central computer system. The principal aim would be to increase safety. Cost estimates, however, run very high. Another possibility is to have the vehicle operate under its own power and driver on local streets but move onto a guideway with central power and control for longer distances. Among the many problems of such a system is the prospective overloading of ramps leading to and from guideways.

Another version, designed to eliminate the downtown parking problem, would provide an army of small vehicles that would be automatically controlled once the destination was identified. So ambitious a system probably will have applicability, even when technical problems are solved, only within a "new city," which can be designed

with the system in mind or reconstruction of a very large area.

Gravity-vacuum tube system

In mass transit, several intriguing ideas have been put forward. One, the gravity-vacuum tube system (Figure 2), is a new model of a concept dating to the 19th century; a train that would be accelerated and braked by a combination of gravity and atmospheric pressure. The

After a painting by Pierre Mion © 1969 National Geographic Society

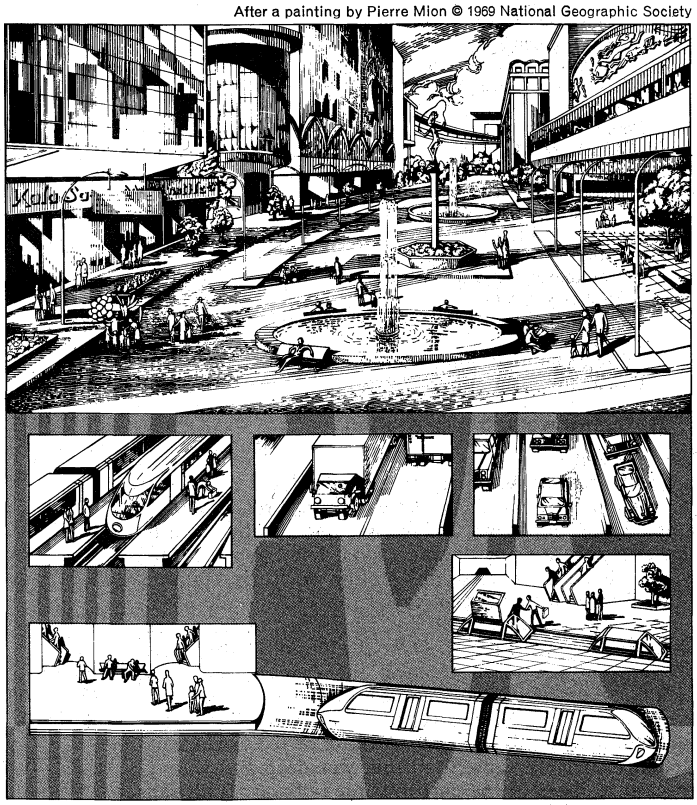

Figure 2: *Possible urban transportation system of the future.* In this system, streets are for pedestrian use. Underground, starting at left, is space for trains, truck traffic, automobile traffic, and special capsules directed by computer and capable of carrying four persons. At the lowest level is a pneumatic train, which travels between stations by means of gravity and air pressure (see text).

train would be circular in cross section and considerably longer than most trains, with the wheels located between the cars and inset so that the train could act as a seal while in the tunnel. The tube would descend from each station and rise toward the next. Gravity would reinforce the pressure from the atmosphere, exerted as air was evacuated from the portion of the tube in front of the train. The economy of power makes the idea attractive, but several problems remain, among which is the cost of the tunnel construction and the difficulty of precise braking.

Another old concept that has been tried with success in France and elsewhere is the linear-induction electric motor, in which the stator (magnetic coil) is attached to the vehicle while the "rotor" is stretched out flat to become the rail along which the train runs. High speeds have been attained; costs and reliability appear favourable. The possibility of combining linear induction with air-cushion support is promising (see also ELECTRIC MOTOR).

Less innovative in detail is the Japanese National Railroad's new lines; the New Tokaido, opened between Tokyo and Osaka in the mid-1960s, has proved that conventional railroad technology, when fully exploited, can produce a highly satisfactory high-speed system.

In the air helicopters have a growing potential for many roles, and vertical takeoff and short takeoff aircraft (VTOL and STOL) may be useful within metropolitan regions as well as between cities, though existing forms present noise problems.

Research and development programs are under way in Europe, the U.S., Japan, and other countries on these and many other possibilities. The Railway Technical Research Institute of Japan, the British Railways Board, the French National Railways, and other national railroad systems, though concerned with the problem of rail transportation generally, produce valuable information for urban transit. Such national railroad systems have usually found government research grants easier to obtain than is the case with privately owned railroads.

Despite the efforts of these and many other agencies, public and private, the most important requirement of urban transportation in the 1970s remains funds for research and development. The cost of developing a system capable of meeting the needs of today's congested, pollution-plagued metropolis is fully comparable to that of a major space program. Only a public and government commitment on such a scale can produce favourable results.

BIBLIOGRAPHY. Surveys of the current status of urban transportation, including its economics, problems, and some proposed solutions, are presented in W. OWEN, *The Metropolitan Transportation Problem*, rev. ed. (1966); J.R. MEYER *et al.*, *The Urban Transportation Problem* (1965); and G.M. SMERK (ed.), *Readings in Urban Transportation* (1968). R.L. CREIGHTON, *Urban Transportation Planning* (1970), outlines the planning process, drawing on the author's experience with the Chicago and Niagara Frontier studies. Origin-destination techniques, trip generation, and travel expeditures are discussed in W.Y. OI and P.W. SHULDINER, *An Analysis of Urban Travel Demands* (1962). E.N. THOMAS and J.L. SCHOFER, *Strategies for the Evaluation of Alternative Transportation Plans*, a report prepared for the National Cooperative Highway Research Program (1970), applies systems analysis to transportation decision making.

Additional materials useful for review of urban transportation planning are UNIVERSITY OF CALIFORNIA INSTITUTE OF TRANSPORTATION AND TRAFFIC ENGINEERING, *Fundamentals of Traffic Engineering*, 7th ed. (1969), *Urban Mass Transit Planning* (1967); and WILBUR SMITH AND ASSOCIATES, *Transportation and Parking for Tomorrow's Cities* (1966), *Parking in the City Center* (1965). Pricing of streets, rather than the limitation of street use by congestion, is explored in G.J. ROTH, *Paying for Roads: The Economics of Traffic Congestion* (1967). C.D. FOSTER, *The Transport Problem* (1963), covers the economic criteria for transport investment.

Rail and bus transit are discussed in A. SCHEFFER LANG and R.M. SOBERMAN, *Urban Rail Transit: Its Economics and Technology* (1964); ORGANIZATION FOR ECONOMIC COOPERATION AND DEVELOPMENT, *Improvements and Innovations in Urban Bus Systems* (1969); WILBUR SMITH AND ASSOCIATES, *The Potential for Bus Rapid Transit* (1970), and *Motor Trucks in the Metropolis* (1969).

Concern for system environment and amenity is expressed in the BRITISH MINISTRY OF TRANSPORT, *Traffic in Towns: A Study of the Long Term Problems of Traffic in Urban Areas* (1963); L. HALPRIN, *Freeways* (1966); H. BLUMENFELD, "Criteria for Judging the Quality of the Urban Environment," in H.J. SCHMANDT and W. BLOOMBERG, JR. (eds.), *The Quality of Urban Life* (1969); G.R. TAYLOR, "The Beginnings of Mass Transportation in Urban America," *Smithsonian Journal of History*, vol. 1, no. 2 pp. 35–50 and vol. 1, no. 3, pp. 31–54 (1966), traces the growth of urban transportation in Boston, New York, and Philadelphia between 1820 and 1860. B. RUDOFSKY, *Streets for People: A Primer for Americans* (1969); and D.N. LEWIS (ed.), *The Pedestrian in the City* (1965), consider city planning and pedestrian circulation.

Conclusions of a study on new concepts for urban transportation are presented in U.S. DEPARTMENT OF HOUSING AND URBAN DEVELOPMENT, URBAN TRANSPORTATION ADMINISTRATION, *Tomorrow's Transportation: New Systems for the Urban Future* (1968). Other studies on this subject include: R.A. WOLF, *Metrotran 2000: A Study of Future Concepts in Metropolitan Transportation for the Year 2000* (1967); and the MPC CORPORATION, *Report on Testing and Evaluation of the Transit Expressway* (1967).

Transportation, Water

The movement of goods and persons by water dates back to the earliest times. Over the centuries the discovery of new lands by seagoing adventurers and the continuing exploitation of technological advances by the shipping industry have steadily expanded the role of water transportation in the growth of international trade and the

world economy. Despite the invention of new and faster forms of movement, technological progress within the shipping industry has enabled it to remain a provider of facilities for international trade on a scale unsurpassed by any other transport mode. Carryings more than doubled in the 1960s alone, reaching a total of 2,570,000,000 tons in 1970. The world's merchant fleet continues to increase both in types and size of ships and in total tonnage: ships of 100 gross registered tons or more in 1970 totalled 227,490,000, or 338,838,000 deadweight tons. (For an explanation of the methods by which ship weight is computed, see *Tonnage measurement* below.)

Beginning of the modern shipping industry

The shipping industry as it exists today dates from the invention of the marine steam engine, screw propulsion, the construction of ships of iron and steel, and the opening of the Suez Canal in 1869. This event triggered an enormous expansion of seaborne trade, which in turn led to the building of larger and faster ships, their more efficient handling in ports developed for the purpose, and the growth of large steamship companies serving every continent along defined, internationally organized routes. There is no limit to the type of cargo modern ships move, but the greater part has always consisted of basic raw materials, such as coal, oil, minerals, and fertilizers, and foodstuffs, such as grain, sugar, rice, vegetable oils, fruit, meat, and dairy produce. But over a period, as technological discoveries are made and new demands arise from them and as sources of supply are exhausted and others developed, the proportions of given commodities within the overall total steadily change, and directional flows are altered. Since World War II, oil has to a considerable extent replaced coal as the chief source of power; fresh territories have been developed, and new countries are emerging, adding to the volume of international trade and influencing its pattern.

To cope with the expansion of trade, the shipping industry has had to grow and develop new techniques and methods. The broad aim of carrying larger bulk loads more speedily has involved the speeding of loading methods. One way of achieving this has been by the construction of cellular container ships designed to carry cargoes in sealed boxes of standard size that can be transported from their point of origin, loaded, shipborne, unloaded, and transported to their final destination by other transport modes with the load unbroken. Faster and larger than the conventional cargo liner and with far faster turnaround, container ships greatly increase efficiency and economy. Roll-on, roll-off vessels, transporting trucks, trailers, and automobiles, serve a similar purpose. Tankers and other bulk carriers have increased both in size and in the list of goods they carry in unbroken loads. The traffic of the orthodox tramps and scheduled cargo-liner services has been eroded by the growing fleets of specialized ships. Only in the range of small and high-priced goods has air transport successfully competed with sea, though passenger traffic has largely passed to the air.

With vessels expensive to construct and requiring special handling equipment, the so-called container revolution has brought in its train changes in the organization of the shipping industry. Many of the long-established liner shipping companies have cooperated among themselves to form consortia to operate long-distance routes across the Atlantic, to the Far East, and to Australia, while the oil companies have built their own tanker fleets, which they supplement by chartering. This trend toward larger ships carrying greater loads of cargoes in ever growing variety seems likely to characterize water transportation in the 1970s.

The sections that follow do little more than outline the history of the movement of people and goods by water and trace the development of the shipping industry through sail to steam and down to the shape of the industry today. The history of ships themselves is dealt with in the article SHIP. Inland waterways are treated in CANALS AND INLAND WATERWAYS (see also such articles as HARBOURS AND SEA WORKS; SAILS AND SAILING SHIPS; MARITIME LAW; and MATERIALS HANDLING). The article is divided into the following sections:

I. History of water transportation
Early history
Later developments
From sail to steam
Technological progress
Specialization of carriers
Improvements in ports and harbours
Influence of Suez and Panama canals
Safety at sea
Advances in the 20th century

Problems of the shipping industry

I. History of water transportation

EARLY HISTORY

Travel by water was among man's earliest and best means of extending the range of his activities, broadening his horizon, and improving his living standards by securing raw materials and exchanging goods. The Egyptians used watercraft during the 4th millennium BC; early seafarers from Crete and the Aegean sailed westward to the Mediterranean islands and Spain and penetrated as far as Ireland, Wales, and Brittany. Over the centuries this mode of transport developed to meet the differing needs of fighting and trading. Whereas early war vessels were galleys carrying sails but propelled by oars, trading vessels took more generally to sail, and those of the Greeks and Romans carried a square sail that was deep and wide in contrast to those of the narrower men-of-war. With sailing ships, trade routes were opened up, among the earliest known being one from Elath at the head of the Gulf of Aqaba through the Red Sea to Ophir on the Arabian Sea. Because ships were able to carry only small quantities of goods and journeys were long and slow, water transport was expensive, and only luxury goods were carried. Cargoes of precious metals were brought by water in Solomon's day, while from Palestine shipping moved by established routes to southern and western Europe.

Fighting and trading vessels

Considerable trade was carried over water by the Romans between the Mediterranean and their northern territories; by the end of their occupation of Britain (5th century AD) some 800 ships were in service carrying cereals between Britain and Gaul, and large quantities of wool were being exported to the south. In northern waters ships developed more slowly, but in the Middle Ages Viking trading vessels were venturing far from their Scandinavian homelands to pioneer sea routes to Greenland and Iceland, to trade in cloth between Flanders and the Baltic, and to trade with Constantinople through Russia by the river Dnepr to the Black Sea. The timber products, furs, and slaves of the North were exchanged for the spices, textiles, and wines of the southern and eastern Mediterranean.

In the 10th and 11th centuries the Venetians were responsible for a great trade expansion along the routes they developed through the southern seas to Constantinople and the Middle East. Wheat, wine, timber, and salt were carried from the north Adriatic to exchange for the products of the East carried from Indian ports to the Persian Gulf and through the Red Sea. Sailing through the Bay of Biscay, the Mediterranean traders also established themselves in Flanders, leading to the growth of the Dutch carrying trade. Wool was transported from Britain by sea to the Mediterranean. The Genoese pioneered sea routes to the North Sea and the Baltic, where the Hanseatic League flourished in the 13th century. Centred on Lübeck, the league was a federation of

north German trading cities engaged in general trade along the river routes to southern Germany, Poland, and central Europe and from the Baltic to Britain, to trade northern products for wool and metals.

The Age of Discovery

The great Age of Discovery, with its voyages of exploration, was largely motivated by the search for gold and silver to pay for goods imported to Europe from the Middle and Far East. The sea route to India and the Far East was established, America discovered, and the Pacific reached. The seas were infested with buccaneers, however, and faster ships were wanted to outsail them. Larger vessels able to carry bigger cargoes were also needed to make the long voyages worthwhile. With the opening of the sea route to India, the Portuguese built merchantmen as large as men-of-war and took full advantage of the great new trade route. Portugal established trading posts in India, South China, and East Africa, thereby creating a monopoly of trade with India and the East that it held for nearly a century. In 1592, however, Britain founded the Levant Company, with a monopoly of eastern Mediterranean trade, and established the East India Company in 1600. Fierce competition followed, with the French and Dutch helping to break Portugal's monopoly. The Dutch established trading posts in the East Indies, whereas Britain opened up trade with northern Europe as far as the White Sea.

With colonization of the Americas, trade flowed across the Atlantic. Routes sailed in order to take advantage of the prevailing winds were necessarily long and often involved triangular or even quadrangular voyages; *i.e.*, by way of Africa and the West Indies, thence to North America or the Caribbean, and back by the North Atlantic route. As a result, cargoes were collected and exchanged en route, metalware being traded in Africa for slaves and ivory to be left in the West Indies for sugar, rum, and cotton, with return cargoes from America of tobacco and skins. There were many routes, varying according to cargoes and seasons. In addition to the European countries, especially Britain and The Netherlands, the American colonies built up their own merchant fleet, at first principally to carry fish.

The British East India Company

The British East India Company's trade influenced ship design throughout the 16th and 17th centuries. Ships of heavy construction were built by the East India Company similar to men-of-war, the largest being 1,200 tons, 165 feet (50 metres) long and 42 feet (13 metres) wide, built for maximum capacity rather than speed. Reduction of the British tea duty at the end of the 18th century greatly increased trade and stimulated the construction of even larger and more efficient vessels. With the ending of the company's monopoly in trade with India in 1813, competition was renewed, and speed became important. The Americans, who had always built for speed, made the fastest time on the Far East runs. The great trade revival that followed the ending of the Napoleonic Wars and the American War of 1812 made faster speeds and prompter deliveries necessary to ensure profitable operations. Atlantic packets were thus built for speed to facilitate regularly scheduled services; these achieved surprising regularity despite their dependence on weather. On the China run, especially in shipping opium to evade both pirates and government junks, speed was of the essence; this led to the development of the clipper with its raking stern and stern posts. When the East India Company's monopoly of the China trade ended in 1833, intense rivalry followed; the Americans took full advantage, attaining remarkable speeds from China to New York and Boston. These were the days of the great tea races, with the American clippers outpacing the British. In mid-19th century, America quit the China trade for the more lucrative one of carrying passengers to San Francisco for the gold rush.

LATER DEVELOPMENTS

From sail to steam. Technological advances in the late 18th and early 19th century, particularly the coming of steam and the building of ships of iron and, later, of steel, brought about changes in propulsion and construction that were to lead to the emergence of the world's merchant fleets as they existed up to World War II. Early in the 19th century the successful harnessing of steam to ship propulsion was exploited by traders, who were quick to realize the advantages of speed provided by steam over sail; one trade followed the other in turning to this new power unit. Yet the advantages of sail for long voyages, on which steamships had to be able to carry large amounts of fuel, kept a considerable sailing cargo fleet alive into the 20th century. World War I was the final blow to sail.

Steam power

Initially, steam was used mainly for passengers and mails. One of the earliest passenger steamship services was in Russia between St. Petersburg (now Leningrad) and the Kronstadt fortress; a regular service also operated on the River Neva. In Britain steam packets were used for postal services to Ireland in the 1820s. In the United States large and speedy steamboats operated on the Hudson River; a 1,000-ton vessel accommodated 600 passengers and made 20 knots (nautical miles) per hour. Steamships also carried thousands of immigrants from Europe to the New World. Claims for the first regular crossings under steam across the Atlantic are disputed between the "Savannah" and the "Sirius." The "Savannah," built in New York, crossed in 1819, but because it was under steam for only 80 hours of its 25 days at sea, the "Sirius" claims the honour with her voyage in 1838 using a paddle wheel most of the way. The "Sirius" voyage stimulated interest in regular steam passenger service. The "British Queen," of 2,400 tons, inaugurated an Atlantic passenger service for the British and American Steam Navigation Company in April 1839, carrying 500 passengers and 80 tons of cargo. The first truly regular service, however, was operated by the Cunard Steam-Ship Company, Ltd., which obtained the British contract for mails and built four sister ships, paddle steamers with 740-horsepower engines raising 8½ knots. Inaugurating the service, the "Britannia," starting from Liverpool on its maiden voyage, made Boston in 14 days and eight hours, including a 12-hour stop at Halifax, Nova Scotia, to unload mails and take on coal. Several steamship lines were soon established to exploit the profitable Atlantic routes.

First Atlantic steamship crossings

Concurrently, the shipping companies turned to steam on the India and Far East routes, the first voyage from England to India being completed by a 470-ton paddle steamer in 113 days, including coaling en route. Regular services began in 1834, starting in England, stopping at Spanish and Portuguese ports, Malta, and Alexandria, then shipping cargo and passengers overland to Suez to connect with the East India Company steamers to Madras, Calcutta, and later, Hong Kong and Shanghai. The first steam mail services to Australia were established in 1852 by the Royal Mail Steam Packet Company, which, with the aid of a government mail subsidy, also operated services via Mexico to the Caribbean, Rio de Janeiro, and the Río de la Plata. Services to Australia via the Atlantic were inaugurated with overland connections across the Isthmus of Panama. The importance of the coastal trade within the United States led to high-speed steamers carrying mails, passengers, and cargo from New England to the southern states. Finally, in 1875, Japan turned to steam for trade among her islands.

The steamship, combined with the Industrial Revolution, vastly extended world commerce, with the main emphasis on exchange of manufactured goods for raw materials and foodstuffs; at the same time the development of steam power caused a worldwide demand for coal, of which Britain was the chief exporter. Steamship companies rapidly increased in number and size.

Technological progress. The great increase in world trade contributed to the development in ship construction, design, and propulsion. Despite fears of the skeptics that iron would not float, that ships hulls would become fouled, and that metal would render the magnetic compass inaccurate, experiments in the construction of iron ships were carried on from the late 18th century. By the early 19th century the endurance of iron vessels had been proved, a surface composition had been developed for protecting the hull, and means had been found for correcting the compass. Cunard introduced its first iron ship, the "China," on its North Atlantic service in 1862, and

from then on iron progressively replaced wood. Early steamboats were all paddle vessels, but the inefficient engines not only took up much space themselves but also required huge bunkers to feed their furnaces. This led to problems of payload and the operation of refuelling points. One early solution to the problem was a small auxiliary engine and collapsible paddles for use only when there was no wind to fill the sail. For better propulsion, screw propellers were developed to replace the paddle wheel. One of the earliest screw-propeller vessels, the British engineer Isambard K. Brunel's "Great Britain," completed in 1843, was of iron construction, had a four-cylinder steam engine supplemented by sail on six masts, and achieved 11 knots.

The screw propeller

Savings in space and the opportunity to move the engines to the stern so that the more comfortable midships section could be used for passengers brought an end to a quarter of a century of paddle-liner operation. During that time the paddle vessels had not only grown larger and faster but more elegant as well. Cunard's last ocean paddle steamer was a handsome two-masted brig, the "Scotia," an iron vessel of 3,871 gross tons, which cost the company £170,000 and broke both the eastbound and westbound speed records. In addition to accommodations for 240 passengers, the "Scotia" could carry 1,400 tons of cargo and earn about £6,000 from freight on each voyage.

With the screw replacing the paddle and the fitting of water tanks for ballast and the great increase in coal-bunkering stations along the trade routes, the type of services provided by shipowners underwent a change. Heretofore the steamship had been built for definite, regular scheduled services operating on defined sea routes, whereas bulk cargoes were mainly carried by ships chartered for the purpose. To these liner and chartered services a third was now added—tramping. The tramp cargo ship became available to transport cargoes between ports as required on a negotiated contract basis. Though engine development in response to demands for economy on long voyages to the Far East, Australia, and New Zealand was rapid, ship operators responded rather slowly to other innovations until the last part of the 19th century. Increased carrying capacity was achieved by replacing iron with steel in ship hulls, strengthening them and reducing their weight. Though some steel-hulled ships were built in the 1870s, it was not until shortages of the metal were overcome in the 1880s that steel successfully supplanted iron.

The first tramp ships

Specialization of carriers. With changes in the types and quantities of goods carried, there arose a need for ships specially adapted to different purposes, of which the chief types were refrigerated vessels for perishable foodstuffs and bulk carriers for oil and grain. Although the importance of refrigeration was realized only slowly, early trials were initiated in the 1870s; and the first refrigerated ship was the French "Frigorifique," in which ammonia was used to produce low temperatures. Shortly afterward compressed air was employed on the British "Strathleven"; in 1880 this ship delivered a sound cargo of frozen meat from Australia to London. Compressed-air machines were latter replaced by carbon dioxide and ammonia systems. Refrigeration was now generally accepted and by the end of the 19th century a number of refrigerated ships were entered in *Lloyd's Register of Shipping*.

Oil tankers

Though oil had previously been transported in barrels aboard ships, it became advantageous to carry it in bulk as demand grew, thereby lowering handling costs. Accordingly, in 1886, three British vessels, forerunners of the modern tanker, commenced operation. Two of these employed the outer shell of the ship as the skin of the tank, and the third carried oil up the underside on the weather deck.

Improvements in ports and harbours. The changing conditions in ship operation necessitated the provision of new facilities at the world's ports and harbours to accommodate the greatly increased size and variety of shipping. Efficient services for docking, loading, discharging cargoes, warehousing, and transit of goods from ports were developed. With increases in their draft, steamships required deeper channels and better docking arrangements.

The traditional quay wall berth, parallel to the shore, was not easy to adapt to large vessels. The lineal quay, built perpendicular to the shore, overcame this disadvantage; additional length of quay could always be added and the berths thus adapted to accommodate larger ships. In the 19th century considerable port construction was undertaken; docks were dredged deeper, wharves extended outward, and quays lengthened. There were new developments in construction technology, often aided by new materials, such as portland cement, which replaced stone in seawalls (see HARBOURS AND SEA WORKS).

Influence of Suez and Panama canals. With the opening of the Suez Canal in 1869 and the shortening of the sea route to India and the Far East by some 3,500 miles (5,600 kilometres), a great stimulus was given to world trade. Shorter voyages, combined wtih the reduction in distance between bunkering stations, enabled more of a ship's capacity to be given over to cargo. Consequently, one-third more traffic could be carried by the same vessels. As their coal-bunkering costs fell, steamers were able to challenge the clipper successfully.

Shipowners were slow at first to take advantage of this new route, but by the 1880s the Suez Canal had a substantial impact; by shortening the route to India and thereby lowering transport costs, it made Indian cotton competitive with American cotton in the markets of Europe. Britain, with the world's largest merchant fleet and with readily available coal for export (which ensured return cargoes), predominated in the use of the canal. During 1870, Suez' first full year of operation, 437,000 shipping tons traversed the canal, of which 66.25 percent was British. By 1880 this total had risen to more than 3,000,000 tons (2,700,000,000 kilograms), of which 79.33 percent was British. In 1913, 20,000,000 tons, 7.5 percent of the world's total, passed through Suez, of which 60.16 percent was British. In 1892 the first oil tanker passed through the canal. In 1966, the last full year before the canal was closed by the Arab-Israeli War, total transits were 241,900,000 tons, of which 175,800,000 tons were oil and 66,100,000 tons dry cargo.

Britain and the Suez Canal

The Panama Canal, opened in 1914, shortened the distance from the Atlantic to Pacific by 7,000 to 9,000 miles (11,000 to 14,000 kilometres) and had as great an effect as Suez on world trade routes. The average annual traffic during the Panama's first five years was 1,691 ship transits and 5,900,000 tons of cargo. After World War I, transits and cargo rose, averaging in the ten years 1920–29, 4,443 transits and 21,600,000 tons of cargo. During the decade up to World War II traffic continued to rise, averaging 5,253 transits and 25,300,000 tons. By 1960 they had nearly doubled to 5,448 transits and 48,100,000 tons. The traffic flow through the Panama Canal is greater from the Atlantic to the Pacific than in the reverse direction, and the cargoes differ. The closing of the Suez Canal greatly increased traffic through Panama to the Far East; in the United States fiscal year 1971, 74,344,000 tons of cargo were transported through the canal to the Pacific, of which half was petroleum products, coal, and coke. Of the 44,283,000 tons traversing the canal in the other direction, ores and lumber constituted about one-quarter of the total, with a great miscellany of commodities making up the other three-quarters. Asia-bound traffic accounted for the greater part, with Japan the predominant destination, whereas the second largest tonnage was carried from the west coast of South America to the east coast of the United States and the third largest amount was destined for Europe from South America.

Safety at sea. With the expansion of steam navigation, the greater variety of cargo carried, the growth in size of merchant fleets, and the increase in number of countries taking part in shipping, rules for ensuring safety at sea have needed frequent adaptation. The earliest steps to establish international standards were taken by a London group of marine underwriters who in 1760 cooperated to establish, assess, and classify ships' conditions. From this beginning, the Lloyd's Register of Shipping was to evolve and its classification to be accepted the world over.

Lloyd's Register of Shipping

Lloyd's took the lead in seeking rules for safety at sea; when in the mid-19th century unscrupulous operators bought old ships, insured them, and sent them to sea speculating on their loss, public opinion was aroused, and a Merchant Shipping Act was enacted by the British Parliament. As revised in 1876, it defined proper methods of dealing with different types of cargo and required every ship to carry on her sides a mark showing the maximum depth to which she might be loaded in saltwater. This "Plimsoll line," named for Samuel Plimsoll, the promoter of the bill, was accepted internationally. The British rules on navigation at sea of ships in relation to one another were also adopted internationally, and a series of international conventions were negotiated and adopted by most seafaring countries (see the section *Maritime law* below).

ADVANCES IN THE 20TH CENTURY

Developments after World War I. At the beginning of the 20th century the world steamer merchant fleet was less than 25,000,000 tons; 6,500,000 tons of sail were still engaged in trading. During the 14 years before World War I, steamship tonnage doubled and subsequent wartime losses were replaced by new building, largely by United States Liberty ships. During the interwar years world seaborne trade rose by 1929 to 35 percent above 1913 but declined during the Depression of the early 1930s. Seaborne trade did not recover to the 1929 level until 1937. During the period, important technological changes had taken place, including conversion from coal to oil burning and the development of diesel motor ships. Despite much experimentation in the late 19th and early 20th century the use of oil as fuel did not come into use on a large scale until after World War I. Conversion was then rapid. Whereas in 1914, 96.6% of the world merchant fleet tonnage was coal burning and only 2.9% oil, the balance being internal-combustion-powered motor ships, by 1939, 45.3% used coal, 30% burned oil for steam, and 24.7% were motor ships. The first oceangoing, diesel-engined ship, the "Selandia," was built in 1912; by 1939 one out of four ships was motor driven; the turbine and the diesel engine competed for speed and economy. Turbines were favoured for greater speed for long voyages, but diesel was preferred for intermediate and short distances. Other substantial economies and improvements contributed to greater shipping efficiency, including increases in size of ships, new bow designs reducing wave formation and water resistance, and better safety equipment, with radar an outstanding innovation.

Developments after World War II. After World War II shipping underwent several major changes resulting from rapid technological progress in ship construction and port handling and in the greater development of specialized ships, including the cellular vessel, built or adapted to carry cargo in standard containers. World trade expanded and with it the volume of goods and the variety shipped, accompanied by changes in their directional flow. Shipping routes were altered to meet the new requirements. With competition from the air, passenger traffic declined sharply, particularly on the North Atlantic and on the long voyages to the Far East. Of all these changes, the most significant were the strides made in the construction of special-purpose vessels for specialized trades to handle the widening range of commodities often carried in entire shiploads. The multipurpose dry bulk carrier was developed to transport new cargoes, such as iron and steel products, forest products, fertilizers, and automobiles, in addition to the traditional bulk commodities, such as grains, coal, phosphate, sugar, and timber. Specially designed combination vessels carried dry and liquid bulk cargoes in either the same or adjacent holds, the basic combinations being crude oil and mineral ores or other bulk solids. A major change in general cargo carriage was the development of cellular bulk cargo ships, which rapidly eroded the traffic of conventional liners. The first container ships were converted cargo ships or tankers, but the great economies offered by containerization led to the building of special-purpose cellular ships. The United States built the first such vessels with special handling equipment, employing them on domestic routes and to offshore islands, but the introduction in 1966 of the first successful international deep-sea container service across the North Atlantic heralded the container revolution. Other countries entered the container trade, and by the 1970s services were operating on most of the long-distance routes serving Europe, North and South America, Japan, Africa, and Australia, with feeder lines serving minor peripheral ports from transshipment points. One advantage of containerization is that it provides through-transit of containers from point of origin to final destination, the continuous process being facilitated by the establishment of inland clearance centres with customs facilities enabling containers to be shipped direct to the vessel. Because of the ease and speed of loading and unloading, the time ships spend in port is reduced up to 75 percent. Fewer ships are needed to offer the same frequency of service, up to 70 percent less, for example, on the North Atlantic run. A further development in special-purpose vessels was the so-called roll-on, roll-off ship designed to carry trucks, trailers, and automobiles driven onto the ship through side or interdeck ramps in the bow or the stern. Another unit load system involved loading cargo on pallets (small, light frameworks, usually of wood), to be lowered into the hold or carried on deck and offloaded on the pallets at their destination. Roll-on, roll-off services were first developed in the United Kingdom for short sea routes to Ireland and nearby European ports but have become so numerous that many goods are carried overland in this way rather than being sent by sea. Oceangoing roll-on, roll-off ships for general cargo on the longer sea routes were coming into service in the early 1970s on the North Atlantic route. With these developments, the proportion of goods shipped by bulk carriers increased greatly in the 1960s and was continuing to increase into the 1970s. In 1960 bulk carriers took only 16% of the five major bulk commodities and 7% of total dry cargo, but by 1969 the figures were 74% and 36%, respectively.

Roll-on, roll-off ship

The economies obtainable through large-scale operation also brought increases in the size of ships, limited only by draft and available port facilities. During the 1960s the average size of tankers rose from 23,000 tons to 38,000 tons, that of bulk carriers from 18,000 tons to 30,000 tons. In the dry-cargo field, tramps ranged from 8,000 to 15,000 tons deadweight, but the specialized bulk carriers capturing much of their cargoes weighed 100,000 tons or more. Tankers of over 300,000 tons deadweight were coming into service in the early 1970s.

Before World War II, Britain, the United States, Japan, and the nations of western Europe collectively owned 90 percent of the world's fleet; by the end of the 1960s total fleets had trebled in tonnage, and these countries owned only 60 percent, although through flags of convenience (see below) they owned another 20 percent. The fleet of the Soviet Union has grown fastest; tonnage rose from 1,200,000 to approximately 15,000,000 between 1945 and 1970. Ship registration under the flags of convenience of such countries as Liberia, Panama, Cyprus, Singapore, Somalia, and Lebanon has also grown quickly. These countries, whose combined gross tonnage totalled over 41,000,000 in 1970, or one-fifth of the world fleet, allow ownership or control of vessels by noncitizens, permit easy transfer, give taxation exemption, and have few or no governmental or international regulations.

Decline of passenger traffic

Government subsidies or requirements regarding use of national vessels represent another influence on ownership. Few countries subsidize their shipping directly, an exception being the United States, which pays subsidies to operators up to the level of costs of competitors on all routes of national importance. Furthermore, government-financed cargo is reserved to national flag vessels. Japan also subsidizes shipping operators, and Italy, France, and Spain grant payments for specific purposes. Government assistance is also given by some countries for new ship construction.

After World War II, shortages in countries devastated by war influenced seaborne trade, but by the end of the 1950s definite trends had emerged resulting from the growth of the world population, expansion of industriali-

Changing trade patterns

zation, changes in sources of supply for raw materials, and the demands of the developing nations. The main sources of power shifted from coal to oil, for example, and some nations such as Britain began to import iron ore for steelmaking. The net result of the postwar changes in trade was more than a doubling of world international seaborne trade between 1960 and 1969, from 1,110,000,000 tons to 2,280,000,000 tons. Oil transport grew rather faster than dry-cargo shipments during this period, increasing from 49 to 54 percent of total world trade. The three principal bulk dry commodities—iron, coal, and grain—accounted for about 35 percent of all movements. Generally speaking, more manufactured goods were imported by the three important regions of North America, western Europe, and Japan during this period, while fuel and raw materials imports to Europe and North America fell, rising slightly in Japan. In the early 1970s Japan was becoming the second most important region in terms of seaborne import tonnages, although its total imports by value were far behind those of North America.

II. Modern water transportation

SPECIALIZATION IN SHIPPING

The liner and the tramp ship. The two main types of ships are the liner, operating regular, scheduled services on a predetermined trade route, charging advertised rates, and the tramp ship, prepared to carry any suitable cargo from any port to any other on a negotiated contract basis. Liner services are of particular value for passengers and mails and for traders not dealing in entire shiploads of commodities. The bulk shipper finds it more economical to purchase transport services on the open market, offering his business to the lowest bidder. Thus tramp ships usually carry homogeneous cargoes, whereas liners transport small consignments of many different kinds of goods.

The principal bulk cargoes have varying characteristics. Liquids, for example, require specially designed ships and are considered as a separate branch of the industry. The normal dry-cargo tramp ship is designed for flexibility so that it can carry, as the occasion arises, commodities as different as iron ore, coal, grain, sugar, cotton, or copra. Because of the difference in stowage factors (cubic capacity required per ton of cargo), for example, a ship large enough to carry 10,000 tons of coal might be loaded to its maximum draft with less than 5,000 tons of ore; and if it were to carry grain, interior partitions would be necessary to prevent the cargo from upsetting the stability of the ship by shifting when the ship rolled.

Loading and unloading

Different methods are used for loading and discharging different types of cargo. Cargoes shipped in cases, bales, or bags must be handled by the ship's derricks or by shore cranes, and the same applies to cargoes of commodities like timber, steel, or scrap. Iron ore and coal are discharged by grab and grain by elevators or suction pipes. Bulk solids are gravity loaded by conveyers and chutes. Oil is often pumped from tankers directly into pipelines connected to storage tanks and refineries. With the trend toward larger bulk carriers, the installation of self-discharging gear has increased. A number of systems are in use, including various forms of conveyers and elevators.

Specialized carriers. Specialized ships such as ore carriers may still be divided into the two categories of liner and tramp. Some are constructed by tramp shipping companies to be hired out or chartered on a long-term basis to shippers or importers of ore, whereas others are built and operated by the shippers or consumers of ore themselves, mainly the large steelworks. Several other industrial consumers of raw materials in bulk, such as major importers of sugar, newsprint, molasses, gypsum, and chemicals, operate their own fleets of bulk carriers in a similar fashion and also hire ships from tramp shipowners on the open market.

Barge tows and barge carriers. Barges towed by high-powered tugs are another recent development; some of the units now being built are high-capacity carriers of around 10,000 tons. The tug and barge concept is mainly valuable when voyages are short; one tug can sometimes serve three barges—one loading, one discharging, and one in transit—providing the best possible utilization of the high-cost power unit and the labour required to man it.

Lighter aboard ship system

Even further advances in utilization have been made with the adoption of a so-called lighter aboard ship (LASH) system, which involves a mother ship carrying nests of lighters that are loaded and discharged by powerful stern cranes. This system permits the preloading and assembling of the cargo in the lighters and can be a particular advantage if the point of origin or destination of the cargo is not approachable by a larger vessel. Such ships now operate across the North Atlantic.

Tankers. The transport of petroleum products by sea has vastly expanded in the 20th century, particularly since World War II. In 1939 the world tanker fleet totalled 11,568,000 tons gross, comprising 16.9 percent of the total tonnage of all merchant ships. By 1970 the tanker fleet had reached a total of 86,140,000 tons gross, representing as much as 37.9 percent of the total world fleet. Accompanying this growth of total tonnage was a remarkable advance in the size of individual tankers, up to 300,000 tons deadweight, over 1,000 feet (300 metres) in length, 130 feet (40 metres) in breadth, and drawing up to 64 feet (20 metres) of water.

Tankers must be subdivided into compartments in order to restrict the movement of the cargo by the motion of the ship. No shipborne cargo-handling facilities are required; the oil is pumped on board and off.

Before World War II the greater part of the world tanker fleet was owned and operated by the major oil companies, operating as industrial carriers. Tramp tankers occasionally supplemented these vessels. After World War II, however, and despite the expansion of their own fleets, the oil companies came to rely also on tramp tankers. A particular feature of the tanker trade is that it is almost entirely a one-way traffic; since tankers are not suitable for carrying any other type of cargo without structural alterations, the outward journey must be made in ballast. An exception to this rule is made for iron ore. Sweden, an ore-exporting and oil-importing country, has evolved ships capable of carrying an inward cargo of oil and an outward cargo of ore. As a result of the exploitation of the Labrador ore fields, this combined oil and ore carrier was increasingly built after World War II. In the winter season, when the ore-loading ports of Labrador are closed by ice, these specially designed ships find alternative employment as oil carriers. Other liquid cargoes, such as molasses, caustic soda, asphalt, and wine, are also carried in bulk at sea.

Coastal and short-sea shipping. Most oceangoing ships have their smaller scale counterparts in coastal shipping, the function and extent of which varies in different parts of the world according to geographical conditions. Coastal shipping, sometimes referred to as cabotage, is a separate branch of the shipping industry, generally confined to the coastal waters of a particular country. In those with continental coastlines, such as the United States, Australia, and India, coastal shipping differs little operationally from oceangoing shipping; and in the United States the term is even extended to include the intercoastal trade between the Pacific and Atlantic coasts via the Panama Canal and the noncontiguous trade between continental America and outlying areas such as Hawaii. In Europe, where national coastlines are comparatively short, coastal shipping has a more international character.

British coastal trade

In the United Kingdom there can be distinguished the purely coasting trade, plying among the islands and along the coast of Great Britain; the home trades, which ply between the United Kingdom and the continent of Europe within the limits of Brest, France, and Hamburg; and the short-sea trade, between the United Kingdom and Scandinavia, the Baltic Sea, and the Mediterranean. Some shipping companies operate liners, tramps, or tankers in all of these trades, while others may specialize in any one.

In the coasting and short-sea trades there are also many specialized vessels, such as cross-channel passenger ships, train ferries, ramp-loading or roll-on, roll-off motor vehi-

cle transport ships specially designed for container traffic, as well as colliers and tankers. These tend to be operated by companies specializing in particular routes over which traffic is heavy but localized. As these services often form sea links between, or extensions of, railway systems, the railway companies often operate them. Indeed, the coastal shipping industry may be regarded as complementary to the inland system of transport communications as well as a link with neighbouring countries; a useful characteristic of the coastal ship is its ability to load cargo directly from the oceangoing vessel for transshipment along the coast and distribution to smaller ports whose depth of water or lack of facilities precludes the direct approach of the larger ship.

Ancillary services. At the port, where the sea transport and inland transport systems meet, many ancillary services must be provided for ships. These include towage, stevedoring, warehousing, replenishment of stores, repair, and maintenance. Practice varies widely among different ports, the various services being provided by independent contractors, by the port authority, or by the shipping companies. In many ports, particularly those in which large liner companies operate, the companies have their own subsidiary organizations to provide such services not only for their own ships but also for others. Some of the larger shipping groups operate or control fleets of tugs, loading and discharging facilities and labour, warehouses and refrigerated stores, lighterage and land transport, and even provide for the building, repairing, equipment, and maintenance of ships for themselves and for other shipowners.

SHIP OPERATION

As the carrying performances of liners and tramps differ, so do the operational organization and methods of the companies that run them.

Liner operation. The operator of a liner service has special interests in the particular trade route on which he travels. The design and performance of his ships is directed toward fulfilling the requirements of shippers using his services in the most economical way possible. Since a liner may carry cargo from dozens or even hundreds of individual consignees, the company must maintain extensive facilities and staff, both at the loading port and at the port of discharge. In less active ports these functions may be carried out by agents acting for one or more liner companies. Furthermore, passengers and cargo must be solicited from inland centres often quite distant from the ports of shipment, and it must always be possible to arrange for the transshipment or onward movement of cargo and passengers from terminal ports to ultimate destinations.

The conference system. Liner companies provide regular and frequent carriage of all kinds of cargo in consignments large and small, at advertised fixed charges. They are enabled to do this by the liner conference system, which was first tried out on the Britain–Calcutta trade in 1875. The object of the conference system is to regulate uneconomic competition. Shipping companies of different ownership and nationality that service the same range of ports form a conference agreement to regulate rates for each type of freight; in some cases the agreement also allocates a specified number of sailings to each company. Coupled with this agreement there is generally a deferred-rebate system, by which regular shippers of goods by conference vessels receive a rebate of a percentage of the tariff freight rate, payable after a period of proved loyalty, provided they use conference vessels exclusively.

The shipping conference system has sometimes come under attack as tending to create a monopoly and to restrain competition against the public interest. It is, however, generally agreed that evidence is in favour of this system: it has been concluded that no realistically possible combination of shipping companies can force unreasonable rates and that shipping companies that provide regular sailings with good ships and maintain staffs and organizations in ports to handle and dispatch cargoes, irrespective of whether trade is good or bad, are entitled to some protection against the casual vessel that picks up an occasional cargo at cut rates. Advocates agree that through the system, the shipper can rely on a well-managed service, running vessels that will carry any desired quantities of his goods at predetermined rates.

Ship brokering and chartering. As mentioned above, tramp-ship sailings and rates are determined by negotiation. Most of the world's tramp-ship chartering business is carried out in the Baltic Mercantile and Shipping Exchange in London, commonly known as the Baltic Exchange. This exhange had its origins in the 17th century, when merchants and ships' captains were accustomed to meet in coffeehouses to arrange cargoes for ships. The Baltic and the Jerusalem were the two coffeehouses chiefly patronized by merchants and captains until the business was concentrated in the Baltic tavern in 1810. In 1823 the first rules and regulations of a "Baltic Club" were drawn up, limiting membership to 300 and providing for accommodations and refreshments. At that time tallow was the principal commodity in the Baltic trades, but with the repeal of the British protectionist Corn Laws in 1846, the buying and selling of grain cargoes became one of the chief activities.

The Baltic Exchange

On the floor of the Baltic Exchange brokers circulate daily, some of them representing the shippers of cargoes, such as grain, coal, or ores, who require shipping space for their movement, and others representing the owners of tramp ships wanting employment. When seeking a ship for the carriage of a cargo, the broker naturally looks for a ship of the right size and specifications, ready at the right time and in the right port and prepared to carry the cargo at the cheapest possible rate. Conversely, the owner's broker must attempt to anticipate the charterer's requirements by having his ship at the right place at the right time but must also try to obtain the highest freight rate possible without running the risk of losing the contract to a competitor. This constant interplay of supply and demand, of ships as well as of cargoes, has the effect of reducing sea transport costs to a minimum, although tramp rates fluctuate frequently and widely at times.

These fluctuating rates also offer opportunities for speculation, as on a stock exchange. The shipper of grain, for example, may decide to charter a ship at what he considers to be a cheap rate even before he has sold the cargo, which he attempts to dispose of in the best market while it is still afloat. In this case the ship is chartered for a voyage from, say, the Río de la Plata to the English Channel "for orders," freight rates having been previously arranged to cover a variety of alternative destinations. Again, a shipper or owner may agree to charter a ship for a period of time at a certain rate, in the hope that he will later be able to "rent it" to another owner or shipper at a higher rate if the market improves. A good deal of "forward" chartering may also occur, in which a contract is entered into for performance at some specified time at a predetermined rate that both owner and hirer hope will prove favourable, according to their estimate of future market conditions.

The four principal methods of chartering a tramp ship are voyage charter, time charter, bareboat charter, or on a contract or "lump sum" basis. The voyage charter, in which a ship is chartered for a one-way voyage between specified ports, with a specified cargo at a negotiated rate of freight, is most common. The charterer agrees to provide the cargo for loading within an agreed range of dates. Once the cargo has been delivered at the port or ports of destination, the ship is free to further employment at the owners' discretion. Sometimes, however, the arrangement is for a series of consecutive voyages, generally for similar cargoes over the same route. The freight rate is expressed in terms of so much per ton of cargo delivered.

On time charter, the charterer undertakes to hire the ship for a stated period of time or for a specified round-trip voyage or, occasionally, for a stated one-way voyage, the rate of hire being expressed in terms of so much per ton deadweight per month. Whereas on a voyage charter the owner bears all the expenses of the voyage (subject to agreement about costs of loading and discharging), on

time charter the charterer bears the cost of bunkers and stores consumed. On bareboat charter, which is less frequently used in ordinary commercial practice, the owner of the ship delivers it up to the charterer for the agreed period without crew, stores, insurance, or any other provision, and the charterer is responsible for running the ship as if it were his own for the period of the contract.

Contracts can also be arranged on a lump-sum basis, when an owner agrees to ship a given quantity of a stated cargo from one port to another for a stated sum. Sometimes large quantities of cargoes such as coal are arranged for on a contract basis. The shipowner agrees to undertake the shipment of a given quantity over a given period at a fixed price per ton of cargo, but not necessarily in any specified ship, although he generally uses his own ships if they are available. The question of substituted ships, however, often leads to disputes, and the terms of the contract may make special provisions for this eventuality. Once the owner's broker and the charterer's broker have agreed on the terms of contract, the ship is "fixed," although by word of mouth alone. The motto of the Baltic Exchange is "our word is our bond," and that code of ethics is observed by ship brokers throughout the world, whether they are members of the Baltic or not, for the simple reason that any ship broker who does not abide by it would be unable to transact further business. Legally, however, the final contract is the written "charter party," which for most transactions is accepted as a standard document and is agreed to by all parties normally concerned in a tramp-ship "fixture" for a particular trade. The standard form of a charter party covers all the main points that experience has shown might lead later to misunderstanding or disputes about the liabilities of each party, while the variable details, such as the particulars of the voyage, cargo, ship, loading and discharging conditions, ports, and rate of freight, can be inserted in accordance with the prior verbal agreement. The charter-party document is subject to scrutiny and interpretation by a court of law in the event of dispute, but in practice most disputes are submitted to arbiters (generally independent ship brokers appointed by each participant) for settlement, unless an important legal precedent is involved.

"Charter party"

Among the most important clauses in any charter party are those that lay down the number of days allowed for loading or unloading and those that determine who is to bear the expense involved. Normally a certain number of days are allowed for loading, and if the charterer fails to finish loading in the time specified, the shipowner is entitled to compensation. Quite often, on the other hand, the charterer receives dispatch money if the cargo is loaded in less than the time agreed in the charter party. Similar conditions usually apply in the port of discharge.

Many tankers, ore carriers, or other specialized bulk-cargo carriers are operated by an oil company or a steel company or an ore exporter exclusively on company business, whether on a regular schedule or not, or they are owned by an independent tramp shipowner and taken on charter by an oil or steel company to fulfill its marginal transport requirements on terms similar to those employed in the dry-cargo tramp shipping market.

Shipowners' and seamen's associations. Shipowners are organized on a national and a regional basis, generally in Chambers of Shipping or their equivalent. The chambers deal with policy issues, recruitment, and training of seafarers and the supply of crews. Such associations have sections to look after the special interest of subgroups in the industry, such as tankers, liners, tramps, and bulk carriers. Chambers consult governments on matters of high policy and are concerned with a wide range of issues affecting the industry as a whole, such as port organization, international relations, technical research, marine safety, radio and navigation questions, marine pollution, maritime law, marine insurance, information, and fiscal policy. The chambers are the voice of the industry and the forum for discussing and deciding policy on whatever (except labour relations) affects the well-being of shipping.

On the international level, the chief shipowning organizations include the International Chamber of Shipping and the International Shipping Federation, whose offices and secretariats are housed in London. Formed in 1921, the International Chamber of Shipping excluded state shipping organizations of any kind. The ownership of the national fleet or of a substantial part of it had to be vested in private individuals or companies. Though the International Chamber of Shipping was suspended during World War II, shipowners representing 14 nations met in London in 1946 to reconstitute it, and in 1970 it had 19 member countries. To avoid the overlap of its functions with those of other organizations and to preserve the principles of private enterprise, it drew up a broad definition of its own purpose: to promote internationally the interests of the shipping industry; to coordinate expert advice on technical questions, in particular, with standards of safety and technical and scientific progress; and to provide a medium for the exchange of views and information on questions affecting the industry internationally.

To deal with more routine matters, other international shipping organizations exist. Prominent among these is the Baltic and International Maritime Conference, started in Copenhagen in 1905 as the Baltic and White Sea Conference to curtail cutthroat competition among tramp shipowners engaged in the Baltic and White Sea trades. The conference was organized primarily to secure minimum freight rates and negotiate uniform chartering terms between shipowners of different flags and the charterers. By 1969 the Baltic and International Maritime Conference consisted of shipowner and ship broker members from 75 different countries representing some 71,000,000 tons gross of shipping. The conference now embraces many kinds of trades in all parts of the world, and one of its principal functions is to inform members of changes in port expenses, in costs of loading and discharging cargoes, and in port labour conditions; but perhaps the most valuable part of its work consists of the drawing up of standard forms of charter party for use in a wide variety of tramp-shipping trades. There is also an International Committee of Passenger Lines and a Comité Maritime International and, on a regional basis, a Committee of European Shipowners, Committee of European National Shipowners' Association, and a Committee of Liner Operators: South America.

Government regulation agencies

On the governmental level, in the United States the Federal Maritime Commission carries out regulatory activities, as do government departments in most countries. Of the international governmental organizations, the United Nations' specialized agency, the Inter-Governmental Maritime Consultative Organization, is one of the most important and in the early 1970s was very much concerned with problems of oil pollution. Other bodies include the United Nations Conference on Trade and Development–Committee of Shipping and the Maritime Transport Committee of the Organization for Economic Cooperation and Development.

INTERNATIONAL MARITIME LAW

International conventions. Ships operate in an international field, the high seas, and are subject not only to the laws of the country in which they are registered and to the laws of the country in whose territorial waters they may be but also to a series of international conventions, the principles of which are incorporated into the domestic legislation of most maritime countries. There has grown up, particularly in the years since the expansion of steam navigation, a body of international maritime law —"the common law of the sea"—that has been developed through international agreement. Nearly all the world's maritime nations, for example, have adopted the International Regulations for Preventing Collisions at Sea, originally based on British rules formulated in 1862 and made internationally effective after a series of international meetings culminating in a conference at Washington, D.C., in 1889. These rules specify in great detail how ships must navigate in respect of each other, what lights must be shown and what signals must be given in accordance with circumstances; any infringement of this international code of conduct is accepted in all maritime courts of law as prima facie evidence of liability in case of collision.

Similarly, the internationally accepted requirements for the protection and safety of life at sea, as far as the ship and its equipment are concerned, are embodied in the International Convention for Safety of Life at Sea. The sinking of the liner "Titanic" in 1912 gave rise to a general desire to raise the standards of safety of life at sea. Although a convention was drawn up in 1914 requiring certain minimum standards for passenger ships, it did not become fully operative because of the outbreak of World War I. A second Safety of Life at Sea Convention, drawn up in 1929, determined minimum standards for the construction of passenger ships engaged in international voyages and for the provision of lifesaving appliances and extended its rules for the safety of navigation to all ships on all voyages. The provisions regarding radio equipment were extended to cover cargo ships of more than 1,600 tons gross.

Improved techniques led to the convening of a third Safety of Life at Sea Conference in London in 1948, after which a third International Convention for Safety of Life at Sea was adopted. This convention came into force on November 19, 1952, having been ratified one year previously by the following countries in order of acceptance: United Kingdom, New Zealand, the United States, France, The Netherlands, Sweden, Norway, South Africa, Iceland, Portugal, Canada, Pakistan, Denmark, Yugoslavia, Italy, Belgium, Israel, Japan, and the Philippines. The scope of the 1929 convention was again extended to include, in several matters, cargo ships of 500 tons gross and above. Minimum requirements were laid down for construction of ships, provision of watertight bulkheads, closing of openings in hulls, lifesaving appliances, fire appliances, radio equipment and direction finders, grain divisions in ships carrying grain cargoes, precautions in carriage of dangerous goods, and emergency musters and drills. The 1948 convention also embodied the recommendations of governments associated with the World Meteorological Organization and provided for the continuance of the International Ice Patrol maintained by the United States Coast Guard in the North Atlantic. This convention was again revised in 1960. Whereas the Safety of Life at Sea Convention deals with the construction of ships from the safety point of view, particularly in respect of passengers and crews, the International Load Line Convention deals with the strength and seaworthiness of ships in normal operating conditions. This convention emerged from the British Merchant Shipping Act, 1875, providing the Plimsoll load line on the ship's side, indicating the maximum depth to which a ship could legally be loaded. In order to protect the competitive position of British ships, the Merchant Shipping Act of 1890 required all foreign ships leaving British ports to comply with the load-line regulations. This led to the adoption of load-line rules by most maritime countries, and the International Load Line Convention of 1930 was ratified by 54 nations. A new International Convention on Load Lines, drawn up in 1966, came into force in July 1968 and allowed for a smaller freeboard (vertical distance between the water and the deck) for large ships while calling for more stringent protection of openings in decks and superstructures.

International Load Line Convention

In 1958 the Inter-Governmental Maritime Consultative Organization, a specialized agency of the United Nations, came into existence. The purpose of this advisory organization is to promote international cooperation in maritime navigation. By mid-1971, membership had grown to 73 nations.

Commercial legislation. International agreements and international law are also concerned with the business dealings between maritime countries. In this connection, the International Maritime Committee (Comité Maritime International) and the International Law Association did invaluable work. Delegates to the International Conference on Maritime Law held at Brussels in 1922 recommended to their respective governments the adoption of a set of rules, known as The Hague Rules, which establish the responsibilities, rights, and immunities of carriers under bills of lading (documents acknowledging receipt of cargo for shipment and proving entitlement to the goods). The Hague Rules, which are generally also incorporated into the terms of a charter party, were given widespread legislative sanction by maritime countries.

The Hague Rules

Legislative sanction is not necessary to secure international agreement or observance. The York-Antwerp Rules of General Average, for example, differ in some respects from English law relating to marine insurance and contracts of affreightment. They were formulated by delegates from various maritime countries meeting at York, England, in 1864 and at Antwerp in 1877 and were revised at Stockholm in 1924 and at Amsterdam in 1950. They were so widely adopted by the maritime nations that for all practical purposes they have the force of law.

Ship classification. To ensure compliance with the various international safety and load-line and other maritime conventions as well as with the requirements of national legislation concerning the registry and construction of merchant ships, most maritime nations require ships to be built under the supervision of government surveyors or of surveyors belonging to recognized classification societies and in accordance with their standards.

Lloyd's Register of Shipping. The leading classification society, operating in almost every country in the world, is Lloyd's Register of Shipping, which began its work long before any national legislation existed for the performance of its purposes. The history of Lloyd's Register of Shipping can be traced back to 1760. The society was reconstituted in 1834 and again in 1914. The shipping community maintains it voluntarily, and its principal work is to supervise the survey and classification of merchant ships of all nationalities according to rigid standards. Through a worldwide organization of surveyors, initial classifications are made when ships are built, and maintenance surveys of such items as the hull, machinery, boilers, and refrigerating plant are carried out periodically or whenever the ship has suffered damage from collision or from any other cause. Lloyd's Register surveyors test and approve, during its manufacture, the steel intended for use in the ship's structure or in its engines and boilers; survey refrigerating machinery at sea or on land; supervise the testing of chains, anchors, and pressure vessels; and are competent authorities for the assignment of freeboard to all classes of ship in accordance with the provisions of merchant shipping acts or the load-line regulations.

The society publishes an annual multi-volume register book, which contains full details of all merchant ships in the world of more than 100 tons gross; this is kept up-to-date by means of regular supplements. Separate registers are kept of British and American yachts. The society also publishes annual and quarterly statistical summaries of shipping registered or under construction in the world.

Lloyd's Register of Shipping operates in most maritime countries, often in cooperation with classification societies established by other nations. These include the American Bureau of Shipping, originally established in 1867 and resuscitated as a result of the large volume of merchant ships built in the United States during World Wars I and II; the Bureau Veritas, which was founded in Antwerp in 1828 but moved its headquarters to Paris in 1832; the Norske Veritas, established in Norway in 1894; Germanischer Lloyd, founded in Germany in 1867; and Registro Italiano Navale, founded in Italy in 1861. Most of these and other national classification societies work in close conjunction with Lloyd's Register of Shipping.

Tonnage measurement. Classification societies largely agree on the strength requirements of different types of ship; the technical, legal, or commercial enactments of the conventions are almost universally accepted. On the other hand, complete international agreement on methods of interpreting the term tonnage measurement was slow to develop. The two chief reasons for this were, first, the possibility of interpreting the term tonnage itself in several senses and, second, the fact that a ship's tonnage is calculated by one of several methods, according to the standard of measurement required. In speaking of shipping, the term ton may be used not only to name a unit of weight in the usually accepted sense but also to name a unit of volumetric capacity.

Displacement tonnage and deadweight tonnage

As far as weight is concerned, the ton is the long ton of 2,240 pounds avoirdupois (1,016 kilograms, almost identical with the metric ton); this is used to measure the weight of the ship and its contents. According to Archimedes' law, the weight of a floating vessel and its contents is equal to the weight of water that it displaces. This weight is known as the displacement tonnage, and the term is used most commonly in comparing the size of warships. In a cargo-carrying ship it is obvious that the displacement varies according to the amount of cargo, bunkers, and stores that are in the ship; and as it is important to determine the amount of cargo that can be carried, the ship's displacement must be calculated both when it is in light condition and when it is loaded to find the difference, which represents the weight of cargo that can be carried. The lightweight displacement tonnage is equivalent to the weight of water displaced by the ship's hull, machinery, and equipment plus the weight of the crew and their effects, when no cargo or bunkers are carried. When the maximum admissible weight of bunkers and cargo is added, the ship has reached its full displacement tonnage. The difference between the full displacement tonnage and the lightweight displacement tonnage is called the deadweight tonnage, and this corresponds to the maximum weight of cargo and bunkers the ship can safely carry. Deadweight tonnage is the measurement ordinarily used to describe and compare the sizes of dry-cargo ships and tankers.

In many procedures, such as the assessment of harbour dues and canal transit dues, a different system of tonnage measurement, based on the volumetric ton, is required. The volumetric ton is a measure of the capacity of the enclosed space in a ship, one ton equalling 100 cubic feet (about three cubic metres) of enclosed space. The volume of the ship up to the tonnage deck (which is generally the uppermost continuous deck), excluding certain exempted spaces, such as the double-bottom tanks, the steering-gear compartments, the galley, and other spaces not used for the carriage of cargo, is called the underdeck tonnage and is expressed in terms of tons of 100 cubic feet. The internal volume of between-deck spaces and deck erections used for the carriage of cargo is added to the underdeck tonnage to give what is called the gross tonnage, again in terms of tons of 100 cubic feet. In merchant shipping statistics the gross registered tonnage is usually given. It is also given for passenger ships, whose deadweight tonnage is relatively unimportant as a means of comparing them in size. For the purpose of assessing dues payable for port, canal, pilotage, lighthouse, and other services, the freight-earning capacity of the ship is usually accepted as the criterion of measurement; this is commonly computed by deducting the space devoted exclusively to such items as machinery, bunkers, crew accommodation, and navigating quarters from gross tonnage, in order to calculate the net registered tonnage. It is apparent that the final tonnage measurement of a ship according to the volumetric reckoning depends much on the definition of the spaces exempted from computation.

The British system of tonnage measurement is the one most used by maritime nations, but in certain areas, notably the Suez and Panama canals, there are different systems of measurement for the assessment of tonnage on which dues are payable, and all ships have to be specially measured for the assessment of their dues when passing through these areas.

The measurement ton

For the purpose of assessing freight rates on cargo, yet another form of volumetric tonnage is employed, known as the measurement ton, which is equivalent to 40 cubic feet (about one cubic metre) of capacity. This term has no connection with the tonnage measurements used for registration and for the assessment of dues. It derives from the fact that the charge made for carrying cargo is normally based either on the weight of the cargo or on the amount of space it occupies. Freight rates cannot all be fairly assessed by weight alone; a ton of feathers would occupy a far greater amount of the ship's hold than a ton of coal. Similarly, heavy machinery, although occupying much less space than coal, would prevent the extra space being used for the carriage of more cargo, for such a deadweight cargo would bring a ship down to its load-line limits with much of the cubic capacity of its holds still unfilled. Hence liner freight-rate tariffs are generally expressed in terms of so much per ton weight or measurement, the measurement ton being the equivalent of 40 cubic feet of capacity and the rate paid being the higher of the two.

WORLD SHIPPING ROUTES AND FLEETS

Trade routes. Over the years a comprehensive pattern of worldwide liner services has been built up for both passengers and freight, linking all continents and countries, supplemented by the random movement of goods from one part of the world to another as occasion and demand has arisen. Despite the directional changes in world trade with the development of new areas, exploitation of new sources of supply, and different demands arising, these major routes have remained largely the same for the last century. An outstanding addition of new routes has been those served by the modern tankers, including those from the Persian Gulf to the United Kingdom and Europe; from the Persian Gulf to Japan; from the Caribbean to the United Kingdom and Europe; from the Caribbean to North Africa and Europe; from the Middle East to Japan; and from the Middle East to Europe and North America. While the worldwide trade routes are operated by liners and tramps, in the 1970s container services were extending further into the major deep-sea trade routes. Apart from the North Atlantic routes, which experienced the greatest expansion of capacity and hence intense competition, container services were operating between Japan and Australia and New Zealand; from the United Kingdom to Australia and New Zealand, the United States, and the Far East; between the United States and Australia; and on many short sea routes, such as between the United Kingdom and Ireland; the United Kingdom and near continental and Scandinavian ports; between Scandinavian and Baltic ports; and in United States coastal waters.

Merchant fleets of the world. By 1939, before the outbreak of World War II, world merchant shipping totalled 69,404,000 tons gross. Despite the enormous war losses, the world fleet reached 80,292,000 tons by 1948 and by 1955 exceeded 100,000,000 tons gross for the first time. In 1971 the world merchant fleet totalled 247,203,000 gross registered tons, over one-third (96,141,000 tons) of which consisted of tankers. Ore and bulk carriers totalled 53,797,000 tons and the fully cellular container tonnage 2,780,000 tons gross.

A significant feature of the development of the world merchant fleet after 1920 was the growth of the number of ships propelled by diesel engines. A simultaneous development was the replacement of coal by oil as fuel for steamships, a movement that reached its peak just after World War II. Motor ships totalled 145,425,000 gross registered tons and steamships 82,065,000 tons, of which only a negligible part was coal burning.

British Commonwealth. Among the merchant fleets of the world, the world's largest, that of the British Commonwealth, has declined steadily in importance in percentage terms. In 1886 the Commonwealth owned 63.6 percent of the mechanically propelled fleet of the world, but by 1939 this share had fallen to 30.7 percent. By 1970, though total tonnage amounted to more than 36,000,000 tons gross, making combined British and Commonwealth shipping still the largest fleet in the world, its proportion of world tonnage had fallen to about 16 percent.

Though most of the British-registered tonnage is owned and operated by the United Kingdom, significant numbers of vessels are owned in such Commonwealth countries as Australia, Canada, Hong Kong, India, Malaysia, New Zealand, and the West Indies. A general movement toward flags of convenience began in 1956, with a consequent increase in ships registered in Bermuda and the Bahamas. Of the privately owned United Kingdom merchant fleet, about half the vessels are oil tankers and whaling factory ships, while an additional third consists of passenger and cargo liners, the largest fleet of passenger ships in the world. Of special interest are the

refrigerator cargo liners that carry agricultural products from Commonwealth nations, such as Australia, and New Zealand, and to Britain.

Western Europe. Among western European nations, Denmark, France, Germany, Greece, Italy, The Netherlands, Norway, and Sweden have important merchant fleets. Though Danish shipping suffered severe losses during World War II, by 1950 its strength had more than recovered. By 1971, over 1,200 ships flew the Danish flag, comprising over 3,500,000 tons gross, of which about 36 percent (in terms of tonnage) were tankers. Most Danish ships were propelled by diesel engines; there is substantial ferry traffic between Denmark and neighbouring countries.

French shipping

The principal activity of the French mercantile marine is the carrying of trade from metropolitan France to parts of the French Union and its former members, notably to North Africa, West Africa, and the West Indies, and to former French-controlled territories in Southeast Asia. By 1971 the French flag fleet amounted to over 7,000,000 tons gross, including a high proportion of specially designed banana carriers and fruit ships and a significant number of passenger liners.

German shipping suffered heavily in World Wars I and II but recovered rapidly; the West German fleet totalled over 2,800 vessels of 8,678,000 tons gross by 1971. Roughly similar tonnage groups are employed for tramping and bulk cargoes, amounting in each case to about one-fifth of total tonnage, while regular shipping services account for about one-third. The German merchant fleet also runs a passenger service. The transportation activities of the German merchant fleet take the form mainly of import and export via German ports and in so-called cross trade between foreign ports, which in 1971 accounted for 40 percent of carryings. Tankers account for about one-fifth of German sea transportation; Germany's refrigerated shipping, with over 70 units, is the most efficient of its kind. German firms have also entered the container trade, carrying cargoes between Bremerhaven and Australia.

After World War II, Greek shipowners purchased large numbers of war-built United States Liberty ships to replace vessels lost during the conflict. Thereafter, a decline set in, with many Greek owners preferring to register their ships under flags of convenience. In the 1950s more favourable Greek maritime legislation brought about a large-scale repatriation of Greek-owned tonnage to the national flag, and in 1971 the Greek flag fleet totalled 2,056 vessels of just over 13,000,000 tons gross. Owners of Greek nationality achieved a predominant position in world dry-cargo and tanker tramping after World War II, operating mainly from London and New York.

Though Italy lost an enormous percentage of its merchant fleet during World War II, by 1953 the prewar total was exceeded, and by 1970 the Italian flag fleet exceeded 8,100,000 tons gross. A state-owned liner group built several large passenger liners, fast cargo liners, and specialized ships, while private firms engaged in liner, tramping, and tanker operations.

The Netherlands' shipping industry consists of oceangoing passenger and cargo liners, tankers owned by the major oil companies, and coasting and short-sea vessels engaged mainly in trade with the United Kingdom and neighbouring and Baltic Sea countries. The granting of independence to Indonesia caused the Dutch liner companies to lose much of their traditional network of services, but they established themselves in other trades, notably to the Great Lakes in North America, to Australia, and to the Far East. In 1971 the fleet totalled over 5,200,000 tons gross.

Although the overseas trade of Norway itself is not sufficient to maintain a large merchant fleet, Norwegian shipping grew to large proportions through the enterprise of Norwegian shipowners in the worldwide tramping trades. A number of liner groups developed, operating worldwide services, but the recovery and expansion of the fleet after World War II to 21,720,000 tons gross in 1971 (almost half being tankers) was again due to the enterprise of tramp-tanker owners.

In 1971 the Swedish merchant fleet amounted to almost 5,000,000 tons gross, of which about 35 percent were tankers. In addition to a substantial coasting and short-sea traffic and a fair-sized oceangoing tramp fleet, Sweden has a number of well-established liner groups. Iron ore is a major Swedish export; a large fleet of ore carriers exists to carry this trade, many of the larger units being able to carry iron-ore exports on the outward voyage and cargoes of imported oil products on the return trip.

Japan. The geographical situation of Japan is favourable to the natural development of a large shipping industry; in 1971 that nation's fleet was the second largest in the world, totalling over 30,000,000 tons gross, and was expected to double by 1975. Though 60 to 70 percent of shipping is in the liner trades, the tramper side was expanding more rapidly, and Japan's world share of the three most important raw materials carried by tramps—iron ores, coking coals, and cereals—increased from 18 percent in 1963 to 40 percent in 1969. Japan has entered the container trade with the formation of five shipping firm groups operating services in the Pacific between Japan and the Pacific coast of the United States and between Japan and Australia.

Japanese tramping

Liberia and Panama. Liberia and Panama are both flags of convenience; in 1971 the Liberian fleet was the largest single-flag fleet in the world, totalling 38,552,000 tons gross. The Panamanian flag flew over 6,260,000 gross tons. Of the Liberian fleet, nearly 55 percent consists of tankers, with the remainder dry-cargo ships or bulk carriers engaged in international tramping. Nearly 60 percent of the Panamanian fleet is also tankers.

Eastern Europe. Poland and the Soviet Union have the largest merchant fleets in eastern Europe, with the Polish fleet comprising 606 ships, with a total of 1,760,000 tons gross in 1971. Container ships were being operated by the Polish Ocean Lines between Polish and British ports, and services were planned on the Baltic and North Atlantic and Far East routes to start in 1974, when a large number of container ships under construction would be in service. During 1971 East Germany's merchant fleet topped 1,000,000 tons gross for the first time.

The merchant fleet of the Soviet Union registered a phenomenal growth after World War II, amounting in 1971 to 16,194,000 gross tons, of which over one-quarter was tankers. Though the Soviet fleet included no container ships, some 600,000 tons were transported in containers on conventional ships in 1970, and a program was announced in 1971 for construction of container ships for both international and coastal trade. The Soviet Union is experimenting with gas-turbine-engine ships; one, the 11,800-horsepower "Paris Commune," built in 1968, had by 1971 successfully sailed more than 70,000 miles (110,000 kilometres) and carried 150,000 tons of cargo across the Atlantic.

Soviet gas-turbine ships

People's Republic of China. The fleet of China exceeded 1,000,000 tons gross for the first time in 1971.

United States. By mid-1971 the total seagoing merchant fleet of the United States comprised over 3,300 ships, totalling 16,265,000 tons gross. Of the oceangoing fleet, 345 vessels, totalling 4,644,000 tons gross, were tankers, container ships totalling over 1,000,000 tons. One of the largest container shipping lines operated 45 vessels in 1971, carrying containers to 48 ports in 23 countries around the world. Another specialized container line operates across the North Atlantic with especially fast ships including two gas-turbine models capable of 28 knots. United States shipping on the Great Lakes reached a peak in 1934 and nearly matched that total in 1956. Thereafter, prospects began to decline with the decrease of iron-ore deposits in the area and with the completion of the St. Lawrence Seaway, which opened the Great Lakes to intense competition from oceangoing foreign flag vessels.

PROBLEMS OF THE SHIPPING INDUSTRY

As shipping entered the 1970s it faced a number of new problems, largely caused by the changing pattern and continual growth of world trade and the technological advances that brought larger, speedier, and otherwise improved vessels. The volume of cargo moving in interna-

tional trade doubled between 1900 and 1950 and quadrupled between 1950 and 1970, from 500,000,000 tons to 2,000,000,000. During the same period—1900 to 1970—the merchant fleet increased sevenfold, most of it in the last 20 years. If past rates of increase in population, trade, and shipping are maintained, by the year 2000 the world fleet required to carry the seaborne proportion could be six times the level of today, or about 1,200,000,000 tons. Faced with this prospect, shipowners have striven for greater size, efficiency, and diversification. Shipping has become more specialized and more capital intensive. In the bulk trades, the trend has been increasingly away from spot charter of general-purpose ships toward long-term contracts, in which owners undertake to carry large volumes of a particular cargo over a period of years. This has led to owners cooperating in consortia to accumulate the necessary finance, tonnage, and management resources and to building specialized ships to meet the requirements of shippers. Between 1960 and 1970 the typical bulk-carrier size shot up from about 15,000 to 20,000 tons. For oil tankers the growth has been even greater, with the typical supertanker rising from about 50,000 tons in the late 1950s to 250,000 tons in the 1970s, with vessels up to 3,500,000 being constructed and vessels of 500,000 to 1,000,000 tons planned. Specialization in the carriage of liquid cargoes, such as chemicals and liquefied gas, to meet the growing demand has also required more costly and sophisticated ships. In general cargo, the major change has been in the development of containerization, with its certain advantages of speed, reliability, and control. But all these developments create new technical problems for the industry—in handling at sea and in port, in threatened pollution of the oceans and seacoasts, in an imbalance between the conventional liner and tramps and the bulk, unit load, container, and roll-on, roll-off ships. New international regulations are required, including those on pollution. This imbalance was particularly noticeable at the beginning of the 1970s, with an overcapacity of container ships, particularly on the North Atlantic routes, where container capacity exceeded cargo availability by some 50 percent. This led to withdrawal of some of the consortia from the trade. Equally, the ports of the world competing for the container trade were constructing the necessary facilities far in excess of requirements. At the same time the industry faced rising costs both in ship construction and operation. To help to meet these higher operating costs, automatic controls are being applied at every stage of a journey and the randomness of operation is being eliminated at the same time as the ratio of manpower to vessel size is being reduced.

Overcapacity problems

The passenger trade faced a more serious and longer lasting problem. Competition from air, particularly on the longer sea voyages, had drastically reduced demand for passenger accommodations. On the North Atlantic routes, in 1970, scheduled and chartered flights carried 2,202,000 passengers between North America and Europe, while ships carried only 249,000. To meet this challenge, growing with the advent of the jumbo jet, the passenger shipping companies were turning to car ferries and cruises. Their future appears to lie in the leisure and holiday field.

Meanwhile, many of the older problems of the shipping industry remain. Despite the large measure of international agreement and cooperation achieved in the shipping industry, competition among merchant fleets persists. Current problems and developments have driven several major lines to merge nationally or to cooperate through consortia at the international level.

The shipping industry is unique in that it has an economic and strategic as well as a commercial importance and is rarely free from political or strategic interference by governments. For internal political reasons, some states consider shipping services as a state monopoly. In practice, however, this is difficult to achieve since a state's jurisdiction does not extend beyond territorial waters. Nevertheless, various practices are observed from time to time to protect the domestic shipping industry and to discriminate against other flags. Higher port dues may be charged to foreign ships, or national flag ships may be favoured. In bilateral trade agreements it is sometimes stipulated that a fixed proportion of the cargoes must be carried in ships of the national flag. A common method of assisting the domestic shipping industry is to reserve coastal shipping to ships of the national flag, a policy that greatly assisted the expansion of the British mercantile marine until the policy was abandoned with the repeal of the Navigation Acts in 1849, except for the coastal trades, which were not brought into line until 1854. Several other nations, notably the United States, still follow this practice and strictly reserve their coastal trade for their own vessels. Assistance in the form of tax exemptions, preferential credit terms, direct subsidy of shipbuilding, or operating costs is often given to protect national fleets.

Although operating costs are much the same for ships of all flags, the rates of taxation vary, and after World War II heavy taxes, combined with a sharp rise in shipbuilding prices, caused the registration of more and more shipping companies under flags of convenience. Some 40,000,000 gross tons, over one-fifth of world tonnage, were so registered in the early 1970s.

Despite problems, the shipping industry has always proved itself resilient and, particularly in recent years, ready to adopt new technological aids to efficiency. Thus, it can be expected to meet the challenge of competition and changes in economic conditions. Its adaptation may be less through the increase of vessel sizes and the resultant economy of scale than through even greater specialization, rationalization of existing structures, and innovations through new types of vessels and services.

Transport Phenomena

The subject of transport phenomena in physics is generally understood to deal with the movement of various entities, such as mass, momentum, or energy, through a medium, fluid or solid, by virtue of nonuniform conditions existing within the medium. Variations of concentration in a medium, for example, lead to the relative motion of the various chemical species present, and this mass transport is generally referred to as diffusion. Variations of velocity within a fluid result in the transport of momentum, which is normally referred to as viscous flow. Variations in temperature result in the transport of energy, a process usually called heat conduction. There are many similarities in the mathematical description of these three phenomena, and, hence, it is advantageous to group them together as one subject. Furthermore, the three phenomena often occur together

physically, as in combustion, where a flowing, viscous, fluid mixture is undergoing chemical reactions that produce heat, which is conducted away, and that produce various chemical species that interdiffuse with one another.

Transport phenomena include not only the transport of mass, momentum, and energy but also the transport of angular momentum, electrical charge, entropy, and other quantities. The mechanism for transport of the various entities can involve neutrons, ions, photons, colloidal particles, macromolecules, and other particles. This article is restricted for the most part to transport of mass, momentum, and energy in fluids composed of molecules.

Varieties of transport phenomena

Transport phenomena can be studied at various levels of description, all the way from the molecule level, where one deals with the transport occurring by virtue of molecular collisions, to the industrial-equipment level, where one is concerned with mass, momentum, and energy relations for large pieces of apparatus.

Kinetic molecular theory of transport properties. The transport properties to be considered are viscosity (a measure of the resistance to flow), thermal conductivity (a measure of the ability to conduct heat), and diffusivity (a measure of the tendency to interdiffuse); these properties are characteristic for each substance, and they depend in general on the temperature, pressure, and composition of the substance. Fluids that flow sluggishly (*i.e.*, fluids with high viscosity), such as molasses, are more difficult to shear or distort than are fluids with low viscosity; or, to phrase it differently, momentum is transferred more rapidly in fluids of high viscosity than in fluids of low viscosity. Thermal conductivity is a measure of the ability of a material to conduct heat; copper has a high thermal conductivity and transfers energy by conduction quickly, whereas wood has a low thermal conductivity and transports energy by conduction slowly. The diffusivity of a two-component mixture is a measure of the tendency of the two species to intermingle or diffuse into one another; a high diffusivity indicates that the mass of one species is transported quickly relative to the motion of the mixture, whereas a low diffusivity indicates that the mass will be transported slowly. Viscosity, thermal conductivity, and diffusivity, therefore, are associated with the transport of momentum, energy, and mass, respectively.

Theoretical physics has developed kinetic theories (that is, theories based on the motion of the molecules and the dynamics of their collisions) that enable the prediction of transport properties from the properties of the individual molecules making up the material. Although the theories are highly mathematical and the details quite tedious, the final results are simple and easy to use.

Idealized molecular models

Because of the complexity of these theories it is necessary to introduce some kind of idealization (or model) for the molecules that make up the matter under consideration; for example, nonpolar molecules (*i.e.*, molecules with negligible dipole moment—the dipole moment being defined as the product of the distance between two poles and the charge on one pole; examples of nonpolar molecules are methane and nitrogen) are sometimes approximated as rigid spheres; polar molecules (molecules with a non-negligible dipole moment such as water and ammonia) are considered to be rigid spheres with an embedded dipole (*i.e.*, they have a positive and negative pole built in). Very long molecules may be approximated as ellipsoids, and macromolecules or polymers may be pictured as beads interconnected with springs. These idealizations or simplifications are generally referred to as models. The reason such models are needed when, in fact, so much is known today about molecular structure is twofold: first, most transport properties are not terribly sensitive to details of molecular structure, and, second, the kinetic-theory calculations would be prohibitively difficult if they were to include all of the information about molecular structure. In the molecular model, therefore, only such information is included as seems intuitively to be essential for describing the properties that are to be calculated.

Gases. In calculations for gases consisting of nonpolar molecules, the idealization that they are rigid spheres is often useful. For viscosity of a pure gas, thermal conductivity of a pure gas, and diffusivity of a binary mixture of gases equations can be developed that show how the transport properties depend on the absolute temperature, the pressure, the molecular weight, and the diameter of the rigid sphere. Based on the rather crude rigid-spherical model, these equations give the essential behaviour of the transport properties of gases: the increase of viscosity, thermal conductivity, and diffusivity with temperature; the fact that viscosity and thermal conductivity are independent of pressure; and the fact that diffusivity is inversely proportional to pressure. These results also show that the transport properties are all inversely proportional to the square of the diameter of the molecules; *i.e.*, the larger the molecule, the smaller the value of the transport property. The formulas have been considerably refined by using more realistic molecular models that take into account the attractive and repulsive forces between molecules, their shape, and their dipole moments. With these equations, the transport properties of gases can often be estimated within 1 or 2 percent of the experimental values over rather wide ranges of temperature and pressure.

Realistic molecular models

Liquids. For liquids, the kinetic theory has not yet been developed to as high a degree of utility as it has been for gases; the problem with liquids is orders of magnitude more difficult because the molecules are in a continual state of multiple collision, whereas for dilute gases only binary, or two-body, collisions have to be considered. Although considerable work has been done, the most useful formulations at present employ a very rough picture of the liquid state. These rough theories lead to the following widely used results: the Eyring equation for viscosity, the Bridgman equation for thermal conductivity, and the Stokes-Einstein equation for diffusivity; these equations relate the transport properties to Avogadro's number (number of molecules in one mole of the substance), Planck's constant, Boltzmann's constant, the molar volume, the absolute temperature, the boiling point, the velocity of sound, the radius of the diffusing species, and the viscosity of the solvent. Until rigorous theories have been worked out and the concomitant numerical analysis completed, the above-mentioned equations are useful as rough approximations.

Suspensions. For suspensions and other kinds of two-phase materials (consisting of any two phases of matter; *e.g.*, gas–liquid or liquid–solid), the transport properties of the composite, or mixture, can sometimes be computed in terms of the properties of the individual phases. The most famous of these is Einstein's formula for the viscosity of a dilute suspension of rigid spheres in a viscous liquid, obtained by methods of classical hydrodynamics; this gives the suspension viscosity in terms of the viscosity of the solvent, the radius of the suspended spheres, and the concentration of the spheres. Einstein's work has been extended to emulsions (suspensions of liquid droplets in a liquid), suspensions of deformable spheres, suspensions of ellipsoids, and other, more complicated kinds of two-phase fluids.

Models for polymeric molecules

Polymers. For polymer solutions (a polymer is a macromolecule formed by joining together chemically thousands of small molecules called monomers), various bead–spring or bead–rod models have been used. These models consist of many beads joined together by rods or springs, with freely rotating joints. These pearl necklaces, as they are sometimes called, are imagined to be suspended in a solvent in which they are subjected to hydrodynamic drag forces and Brownian-motion forces (the movement imparted to particles of larger than molecular size by bombardment of the liquid molecules). The simplest model of this type is the rigid dumbbell—two beads connected by a rigid rod. For this model it is possible to obtain an expression for the viscosity in terms of the concentration (number of dumbbells per unit volume), solvent viscosity, temperature, and a time constant which depends on the drag coefficient of the bead and the length of the dumbbell. The result is interesting because it shows that the viscosity decreases with increasing velocity gradient (or, to put it another

way, with rate of shear), a phenomenon that is well-known in polymer solutions (often called non-Newtonian viscosity or shear thinning). The time constant that appears in the expression is also interesting because it is related to the rate at which stress relaxation, recoil, and other time-dependent phenomena occur in polymer solutions. Many more complicated models have been used for polymer kinetic theory, and the theory is highly developed and mathematically rather complicated.

Phenomenological expressions of transport. *Rate equations in simplified cases.* To make the connection between the transport properties and the rates at which momentum, energy, and mass are transported, equations for the fluxes (flow per unit area per unit time) are introduced. These mathematical expressions, which define the transport properties can be discussed in terms of three simple "thought," or imaginary, experiments.

"Thought" experiments

To understand viscosity and momentum transport, a fluid is imagined to be placed in the region between two parallel plane surfaces separated by a known distance, and the lower plane, or plate, is imagined to be moving with a constant velocity while the other remains stationary. The force per unit area that has to be supplied to the lower plate is postulated to be directly proportional to the velocity of the plate and inversely proportional to the distance between the plates (that is, the farther apart the plates, the smaller the force). This is Newton's law of viscosity, and the proportionality coefficient, found by measurement of the other factors, is called the viscosity of that particular fluid.

For describing thermal conductivity and energy transport, a material is imagined to be placed in the region between two parallel plates with a known separation, as before. The top plate is held at a fixed temperature, whereas the bottom plate is maintained at a higher temperature. It is reasonable to expect, then, that the rate of heat flow upward will be proportional to the temperature difference and inversely proportional to the plate separation. This is Fourier's law of heat conduction, and the proportionality constant in the equation that relates the various quantities is called the thermal conductivity of the substance.

For describing diffusivity and mass transport, a mixture of two substances, A and B, is imagined to be placed between the two parallel plates, again as before. The concentration of A at the upper plate may be expressed as the mass fraction (the mass of A per unit volume, divided by the mass of the mixture AB per unit volume), and the concentration at the lower plate is at a higher concentration. It would be expected that the rate of movement of A would be proportional to the difference between the two concentrations and inversely proportional to the distance between the plates. This is to a good approximation Fick's (first) law of diffusion, and the proportionality constant is conventionally taken to be the product of the density and the diffusivity.

The description above shows that the elementary experiments used to relate the transport properties and the fluxes, or rate of transport, are quite similar and that the three formulations that describe the fluxes have a similar mathematical form that may be written: (flux) = (transport property) × (driving force).

Similarity of three formulations

These laws of Newton, Fourier, and Fick are generally written as differential expressions that give linear relationships between the fluxes and the gradients. The laws written in this way are valid for unidirectional transport. When one considers the more general situation that the velocity, temperature, and concentration depend on all three directions in space and on the time, then the phenomenological relations have to be generalized. The generalizations for the energy and mass fluxes (which are vectors, quantities that associate a scalar with each coordinate direction) are straightforward; but the generalization for the momentum flux (which is a tensor, a quantity that associates a scalar with each ordered pair of coordinate directions) is somewhat more complicated. In fact, in the process of generalizing Newton's law, which contains the viscosity, one obtains an expression with two physical properties: the viscosity and the dilatational viscosity. The latter property is much less well-known; it describes the resistance to flow in which an expansion or contraction of the fluid occurs.

Exceptions and qualifications. There are further generalizations: (1) For multicomponent mixtures the generalization of Fick's law is rather complicated; if the number of chemical species present is designated by N, then there will be N times N–1 diffusivities required to describe the diffusional processes occurring. (2) Even for binary mixtures, Fick's law is incomplete; if there is a thermal gradient in the system, there may be a flow of matter (*i.e.*, a mass flux) associated with this gradient, known as thermal diffusion, or the Soret effect; the effect has been exploited for separating isotopic mixtures (isotopes of an element are atoms with identical chemical properties but different mass) in a device called the Clusius–Dickel column. If there is a pressure gradient in the system, there will be a flux of mass, and such a phenomenon is called pressure diffusion. The effect is used in centrifugation, the technique of whirling or spinning mixtures at enormously fast speeds, causing the heavier components to concentrate in the container farthest from the axis of rotation. In addition, if the diffusing mixture contains ions, then an electric field can bring about an ionic flux, and such a phenomenon is termed forced diffusion. (3) Fourier's law is valid only for a pure substance. For mixtures there may be flow of energy, or an energy flux, associated with a variation in concentration; this is termed the diffusion-thermo effect, or the Dufour effect. The Dufour and Soret effects and other "cross effects" have been studied from the viewpoint of the thermodynamics of irreversible processes. (4) The various phenomenological laws discussed above embody the idea that the fluxes are directly proportional to the gradients. For energy and mass transport this kind of relationship has been found to be satisfactory, and for momentum transport in gases and chemically simple liquids the linear relationship is also satisfactory. For structurally complex fluids, however, notably polymers, it is found that Newton's law of viscosity is totally inadequate; such fluids are termed non-Newtonian fluids, and they exhibit some remarkable flow properties. Not only does the viscosity become dependent on the velocity gradient (*i.e.*, the viscosity changes as the rate of shear is increased) but, in addition, even in steady shear flow the normal stresses are not zero, and they, too, depend on the velocity gradient. Furthermore, in generalizing from steady-state to unsteady-state flows, additional information about the time-response properties of the fluids (*i.e.*, the time it takes for the fluid to respond to changes imposed on it) have to be included. This requirement leads to the construction of rather complex mathematical expressions for the momentum flux needed to describe such nonlinear effects of viscosity and elasticity. The subject is generally treated under rheology, the science of deformation and flow.

Energy transport by radiation. All the fluxes discussed so far have been associated with molecular phenomena. For energy transport an important additional mechanism must be discussed; namely, energy transport by radiation, a type of transport that can occur through a vacuum. The simplest case deals with the energy emitted from what is called a black body, and it is given by the celebrated Stefan–Boltzmann law, an equation that relates the energy flux to the absolute temperature, the Boltzmann constant, the speed of light, and Planck's constant. This formula is extremely useful in physics, but it applies only to energy transport across a vacuum. The problems of radiant-energy transport through moving, absorbing fluids are exceedingly difficult to deal with.

Hydrodynamic aspects of transport. *Equations of change.* In many situations one wishes to obtain what are called the profiles or distributions of velocity, temperature, and concentration—*i.e.*, the dependence of these quantities on position and time. This problem is solved by combining the equations for the fluxes given in the previous section with the equations of change or conservation equations, which express the laws of conservation of mass, momentum, and energy for a continuous medium. The equations for conservation of mass for the

The momentum-conservation equations

various species are often called the equations of continuity. The three momentum-conservation equations, usually called the equations of motion, result from applying Newton's second law of motion to the fluid (*i.e.*, mass times acceleration equals the sum of the pressure and of viscous and gravity forces). The energy equation is the statement of the first law of thermodynamics applied to the flowing fluid (that is, the energy increase is equated to the heat added minus the work done). These equations form the starting point for theoretical hydrodynamics, the rheology of viscoelastic fluids, heat transfer, diffusion, and the fluid dynamics of reacting fluids. In order to use the equations of change for calculating the velocity, temperature, concentration, and pressure distributions, one must insert the expressions for the fluxes in terms of the transport coefficients.

The solution to the equations of change is no easy task. Considerable attention has been given to the analytical and numerical solutions since their formulation in the middle of the 19th century. Thousands of solutions for appropriately simplified boundary and initial conditions have been tabulated in the literature and are widely used in science and engineering. Furthermore, the equations are the starting point for many fields of study, including hydrodynamics, heat transfer, diffusion, acoustics, aerodynamics, lubrication theory, viscoelastic flow, boundary-layer, turbulence, and reactive-gas dynamics.

Transfer coefficients at boundary surfaces. For many applications there is no need for detailed velocity, temperature, and concentration profiles—only for the rate at which momentum, energy, and mass are transferred at some bounding surface. This situation leads to the definition of transfer coefficients that can be calculated if the profiles are known. For very complex situations the transfer coefficients are often obtained experimentally and then correlated by means of dimensional analysis, a practical method for summarizing the results of many experiments.

The friction factor

First the transfer of momentum is considered at solid surfaces, leading to the definition of the friction factor, or drag coefficient. A fluid flowing through a duct or around a submerged object will exert a force on the duct or object. This force will contain two parts: the force that would be exerted even if the fluid were stationary and the additional force associated with the fluid motion. (The discussion is restricted to flows that result in a simple force on the solid but with no torque, or twisting effect.) It is then customary to define the friction factor as the proportionality constant between the force associate with the fluid motion and the product of a characteristic area and a characteristic kinetic energy per unit volume. For flow in conduits, the area is taken to be the wetted inside surface area, and the kinetic energy is taken to be the average velocity inside the conduit. For flow around submerged objects, the area is taken to be the area obtained by projecting the solid onto a plane perpendicular to the velocity of approach of the fluid, and the kinetic energy is taken to be the approach velocity of the fluid at large distances. For flow in circular tubes, for example, the friction factor is given separately for laminar flow and for turbulent flow. The laminar-flow equation is merely a restatement of the Hagen-Poiseuille law for laminar flow in circular tubes, and it may be derived by solving the equations of motion and continuity for an incompressible fluid. The turbulent-flow-friction-factor equation is only approximate and is obtained essentially from experimental data.

For flow around spheres, the friction factor (drag coefficient) can be obtained for creeping flow and for noncreeping flow. The creeping-flow equation, or expression, is merely a restatement of the Stokes law for creeping (*i.e.*, very slow) flow around a sphere; the second expression, for noncreeping flow, is empirical and designed to fit the experimental data over a wide range.

The transfer of energy at solid–fluid boundaries is usually discussed in terms of the heat-transfer coefficient. It is defined as the proportionality coefficient between the wall heat flow and the product of the heat transfer area and the temperature differences. The expression obtained for the heat loss from a heated object shows that the heat loss increases as the velocity of the surrounding fluid increases. An equation of this type is the basis for the wind-chill temperature, which accounts for the heat loss from the human body in a cold wind.

The heat-transfer and mass-transfer coefficients

Finally, the transfer of mass at solid-fluid boundaries is usually expressed in terms of a mass-transfer coefficient. The mass-transfer coefficient (for small concentrations and small mass-transfer rates) is defined as the proportionality constant between the molar flow of one species into the fluid across the solid surface and the mass-transfer area and the concentration difference. The results for the heat transfer may be taken over for isothermal mass transfer simply by changing the nomenclature. The great similarity between the results for heat and mass transfer stems basically from the fact that, when the proper assumptions are made, the differential equations describing the two processes are identical. Considerable use is made in engineering of this analogous behaviour.

Transport in macrosystems. For the description of pieces of industrial equipment or portions thereof, it is customary to use integrals of the equations of change known as the macroscopic balances. These are relations among the input quantities (that is, various quantities pertaining to fluid streams entering the equipment), the output quantities, and the quantities describing the interaction of the system with its surroundings; the various transfer coefficients discussed in the preceding section are used.

The general results of the integration of equations for multicomponent reacting mixtures are too complicated to present here, but for pure fluids the integration of the equations of change over the volume of the system may be described schematically thus (the integration of an equation is designed by $\int$):

- $\int$ (equation of continuity) $\rightarrow$ macroscopic mass balance
- $\int$ (equation of motion) $\rightarrow$ macroscopic momentum balance
- $\int$ (velocity times equation of motion) $\rightarrow$ macroscopic mechanical energy balance
- $\int$ (position vector times equation of motion) $\rightarrow$ macroscopic angular momentum balance
- $\int$ (equation of energy) $\rightarrow$ macroscopic energy balance

The resulting balances are rather simple in form if one makes the following assumptions concerning the whole system: (1) it is in a steady state, (2) it has flat velocity profiles at input and output, and (3) it has no swirling of the fluid at input and output.

Transuranium Elements

The transuranium elements are so called because they all lie beyond uranium; that is, they are elements with atomic numbers higher than 92 in the periodic table (see Figure 1). Thirteen elements, up to and including atomic number 105, have been discovered. All are unstable, decaying

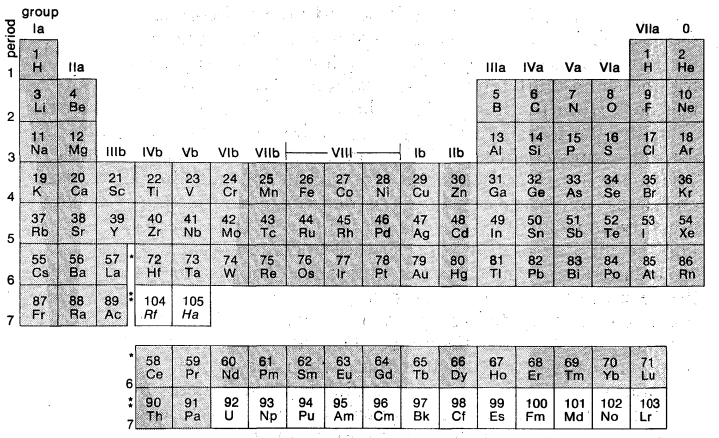

Figure 1: Transuranium elements in the periodic table.

radioactively, with half-lives that range from tens of millions of years to fractions of a second. Since only two of the 13 have been found in nature, and those only in trace amounts, the synthesis of these elements through nuclear reactions is an important source of man's knowledge about them. That knowledge has expanded man's understanding of the fundamental structure of matter and makes it possible to predict the existence and basic properties of elements much heavier than element number 105; *i.e.*, the "superheavy" elements with atomic numbers from around 110 to 126. Since it is predicted that these should have significant nuclear stability and, therefore, may exist in nature, some of them are being sought. Elements with atomic numbers even higher, around 164, are also predicted, but with lesser stability; and present theory suggests that the maximum atomic number will be found to lie somewhere between 170 and 210. All these still unknown elements belong to the transuranium group.

Although the first transuranium element was found only in 1940, some have already become useful, for example as fuel in the generation of electricity from nuclear fission. Isotopes (see below) of transuranium elements are used in the diagnosis and treatment of disease and in control methods in industrial processes. They may also become useful in cancer therapy and in chemical analysis.

DISCOVERY OF THE FIRST TRANSURANIUM ELEMENTS

General atomic structure. To understand the subject of transuranium elements, a knowledge of atomic structure is necessary. Here, only a brief and very general summary of atomic structure can be given. The basic structure of atoms was understood by the early 1930s. Every atom consists of a massive nucleus surrounded by electrons, each with negligible mass. The nucleus is composed of two particles (called nucleons and bonded together), the neutron and the proton, of about equal mass, but with a positive electrical charge on the proton. All the atomic nuclei of a particular element have a fixed number of protons and, therefore, a fixed positive charge (*e.g.*, uranium has 92), and this is called its atomic number, symbolized as Z. The number of neutrons bonded to any Z, however, is not fixed. In fact, every element has several species of atoms each with the same number of protons with different numbers of neutrons. The sum of neutrons and protons, called the atomic mass number, is symbolized as A. All the species of an element are called its isotopes. Some nuclei are unstable and decay in any of several ways, the process producing other nuclei with different Z and A. A nucleus bombarded by neutrons may absorb one and become another isotope of that element—the A having changed, but the Z remaining the same—and become unstable (that is, radioactive), so that it will decay into the isotope of a different element. If large enough, the nucleus that captured the neutron may split (fission) into two more or less equal parts, each being an isotope of an element. Since the bonding forces in a nucleus involve extremely high concentrations of energy, any sort of nuclear change produces exceedingly large energy changes, relative to the energy changes that accompany chemical reactions; the latter involve only the orbiting electrons, and their energy changes are ignored when nuclear reactions are discussed.

Atomic structure in the 1930s

First synthesis. The first attempt to prepare a transuranium element was made in 1934 in Rome where a team of Italian physicists headed by Enrico Fermi and Emilio Segrè bombarded uranium nuclei with free neutrons. Although transuranium species may have been produced, the results of the experiment were ultimately interpreted by the German physical chemists Otto Hahn and Fritz Strussman in terms of nuclear fission. Not until 1940 was a transuranium element first positively produced and identified by two American physicists, Edwin Mattison McMillan and Philip Hauge Abelson, who, in California, exposed uranium oxide to neutrons from a cyclotron target. The resulting element was found to have an atomic number of 93. It was named neptunium.

Transformations in atomic nuclei are represented by equations that balance all the particles of matter and the energy involved before and after the reaction. The above transformation of uranium into neptunium may be written as follows:

$$^{238}_{92}\mathrm{U}(n,\gamma)^{239}_{92}\mathrm{U} \xrightarrow{\beta^-} {}^{239}_{93}\mathrm{Np}$$

In this equation, the atomic symbol of the particular isotope reacted upon, in this case U for uranium, is given with its mass number (sum of neutrons and protons, or A) at upper left and its atomic number (protons, or Z) at lower left: $^{238}_{92}\mathrm{U}$. The symbols within the parentheses indicate, first, the species of matter or of energy (here n for neutron) reacting with the nucleus and, second, the species (here γ, for a quantum of energy called a gamma ray) emitted by the nucleus during the reaction.

The resulting isotope is shown next, with its changed mass at the upper left ($^{239}_{92}\mathrm{U}$). Together, these symbols represent the transformation of a single uranium-238 nucleus, reacting with a neutron and releasing gamma radiation, to produce the isotope uranium-239. The next event is represented by an arrow showing a spontaneous loss of a beta particle (symbolized β), an electron with very high velocity, from the nucleus of uranium-239. What has happened is that a neutron within the nucleus has been transformed into a proton, with the emission of a beta particle which carries off a single negative charge; the nucleus, therefore, now has one more positive charge than it had before the event, when its atomic number was 92. The resulting isotope, as a result, has an atomic number of 93 but, because the beta particle has negligible mass, the mass number of the nucleus has not changed. It is still 239. The nucleus resulting from these events is an isotope of the element neptunium, atomic number 93, and mass number 239. The above is called negative beta-particle decay; a nucleus may also emit a positron, or positive electron, resulting in beta-particle decay. (In another type of decay the nucleus, instead of emitting a β-particle, "captures" or absorbs one of the electrons orbiting the nucleus, thus reducing the positive charge by one.)

Equations for nuclear transformations

The usual manner of writing nuclear reactions drops the atomic number from the symbol for the element and this rule will be followed in the rest of this article.

The discovery of the next element after neptunium followed rapidly. Early in 1941 three American chemists, Glenn T. Seaborg, J.W. Kennedy, and Arthur C. Wahl, first produced and chemically identified element 94, named plutonium (Pu). In 1944 after further discoveries, Seaborg hypothesized that a new series of elements called the actinide series, akin to the lanthanide series (elements with atomic numbers 58–71) was being produced, and that this new series began with thorium (Th), atomic number 90. Thereafter, discoveries were sought, and made, in accordance with this hypothesis.

For further information on discoveries of transuranium elements, see Table 1.

SYNTHESIS OF TRANSURANIUM ELEMENTS

The most abundant isotope of neptunium is neptunium-237 that, with a half-life of approximately 2×10^6 years for decay by the emission of alpha particles (composed of two neutrons and two protons, actually the very stable

*Mass number of longest-lived isotope. †Mass number of more available isotope. ‡Proposed by U.S. scientists, not yet approved by Commission on Atomic Weights of International Union of Pure and Applied Chemistry. §Proposed by U.S.S.R. scientists, not yet approved by Commission on Atomic Weights of International Union of Pure and Applied Chemistry.

nucleus of helium), is formed in kilogram quantities as a by-product of the large-scale production of plutonium in nuclear reactors. This isotope is synthesized from the reactor fuels, uranium-235 and uranium-238, by the following reactions:

$$^{238}U(n,2n)^{237}U \xrightarrow{\beta^-} {}^{237}Np$$

$$^{235}U(n,\gamma)^{236}U(n,\gamma)^{237}U \xrightarrow{\beta^-} {}^{237}Np$$

In the first reaction, uranium-238 captures one neutron but emits two, reducing the mass number by one. Plutonium, as the isotope plutonium-239, is produced in ton quantities in nuclear reactors by the reaction:

$$^{238}U(n,\gamma)^{239}U \xrightarrow{\beta^-} {}^{239}Np \xrightarrow{\beta^-} {}^{239}Pu$$

The plutonium isotope plutonium-238, which is of secondary importance, is produced in kilogram quantities by the reaction:

$$^{237}Np(n,\gamma)^{238}Np \xrightarrow{\beta^-} {}^{238}Pu$$

The production of transuranium elements by a process of continuous, intensive irradiation with slow neutrons is illustrated in Figure 2, in which the heavy line indicates the principal path of neutron capture and negative beta-particle decay that results in successively heavier elements and higher atomic numbers. The lighter lines show subsidiary paths that augment the major path. The major path terminates at an isotope of fermium (fermium-257), because the short half-life of the next fermium isotope (fermium-258), for radioactive decay by spontaneous fission (360 microseconds), precludes its production and the production of isotopes of elements beyond fermium

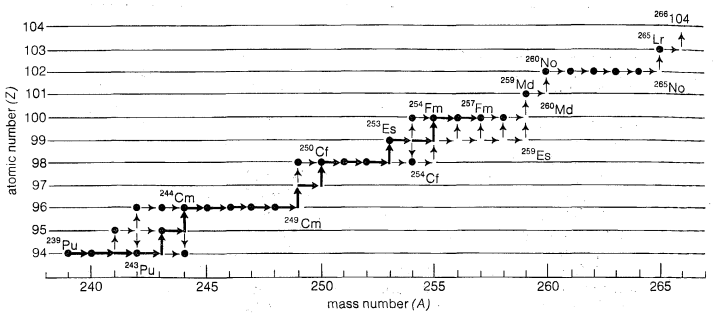

Figure 2: Nuclear reactions for the production of heavy elements by intensive slow neutron irradiation (see text).
From G. Seaborg, "Elements Beyond 100, Present Status and Future Prospects," *Annual Review of Nuclear Science*, vol. 18, p. 119 (1968)

by this means. The lighter lines beyond indicate predictions only.

Heavy isotopes of some transuranium elements are produced in nuclear explosions. Since 1965, underground detonations of nuclear explosive devices have resulted in the production of significant quantities of einsteinium and fermium isotopes, which are separated from rock debris by mining techniques and chemical processing. Again, the heaviest isotope found is that of fermium-257. Why this is the case is not yet completely understood.

An important method of synthesizing transuranium isotopes, currently as well as historically, is by bombarding heavy element targets with charged particles, rather than neutrons, from accelerators. For the synthesis of elements with atomic numbers of 101 or greater, so-called heavy ions (*i.e.*, charged particles heavier than the helium nuclei, mentioned above as alpha particles) have been used.

Accelerators for superheavy elements

New accelerators, or modifications of existing ones, are necessary in order to accelerate the heavy ions needed to produce the superheavy elements. Targets and projectiles relatively rich in neutrons are required so that the resulting superheavy nuclei will have sufficiently high neutron numbers; too low a neutron number renders the nucleus extremely unstable and unobservable because of its resultingly short half-life.

NUCLEAR PROPERTIES OF TRANSURANIUM ELEMENTS

Isotopes of the transuranium elements are radioactive in the usual ways: they decay by emitting alpha particles, beta particles, gamma rays; and they also fission, or break up, spontaneously. In Table 2, significant nuclear properties of certain important isotopes are listed. Only the principal mode of decay is given, though in many cases other modes of decay also are exhibited by the isotope. In particular, with the isotope californium-252, alpha-particle decay is important because it determines the half-life, but the expected applications of the isotope exploit its spontaneous fission decay that produces an enormous neutron output. Other isotopes, such as plutonium-238, are useful because of their relatively large thermal power output during decay (given in Table 2 in watts per gram). Research on the chemical and solid-state properties of these elements and their compounds obviously requires that isotopes with long half-lives be used. Isotopes of plutonium and curium, for example, are particularly desirable from this point of view. The discovery of the mendelevium isotope, with a half-life of 54 days (for the emission of alpha particles) has raised hopes that all elements, at least through atomic number 101, will have some isotopes with half-lives long enough so that some of their macroscopic properties can be measured. In Table 2, the specific activities, such as disintegrations per minute per unit weight, are given for those elements that can be produced in nuclear reactors (formerly called atomic piles). Beyond element 100 the isotopes must be produced by charged-particle reactions using particle accelerators, with the result that only relatively few atoms can be made at any one time.

Table 2: Nuclear Properties of Selected Transuranium Element Isotopes

name and mass	principal decay mode	half-life	specific activity	
			d/m/μg*	watts/gram
Neptunium-237	alpha	2.14×10^6 years	1.56×10^3	2.07×10^{-5}
Plutonium-238	alpha	86 years	3.86×10^7	0.570
Plutonium-239	alpha	2.44×10^4 years	1.36×10^5	$\sim 1.91 \times 10^{-3}$
Plutonium-242	alpha	3.8×10^5 years	8.63×10^3	1.13×10^{-4}
Plutonium-244	alpha	8×10^7 years	39.7	4.93×10^{-7}
Americium-241	alpha	433 years	7.59×10^6	0.114
Americium-243	alpha	7.4×10^3 years	4.24×10^5	6.45×10^{-3}
Curium-242	alpha	163 days	7.30×10^9	122
Curium-244	alpha	17.6 years	1.79×10^8	2.83
Curium-247	alpha	1.6×10^7 years	1.96×10^2	$\sim 2.8 \times 10^{-6}$
Curium-248	alpha	4.7×10^5 years	8.34×10^3	5.32×10^{-4}
Berkelium-249	beta (minus)	314 days	3.71×10^9	0.358
Californium-249	alpha	360 years	9.06×10^6	0.152

Nuclear structure and stability. Although the decay properties of the transuranium elements are important with regard to the potential application of the elements, these elements have been studied largely to develop a fundamental understanding of nuclear reactions and nuclear and atomic structure. Study of the known transuranium elements also helps in predicting the properties of yet undiscovered isotopes and elements as a guide to the researcher who can then design experiments to prepare and identify them. As shown in the allegorical Figure 3,

From G. Seaborg, *Proceedings of The Robert A. Welch Foundation Conference XIII: Transuranium Elements* (November 17, 1969)

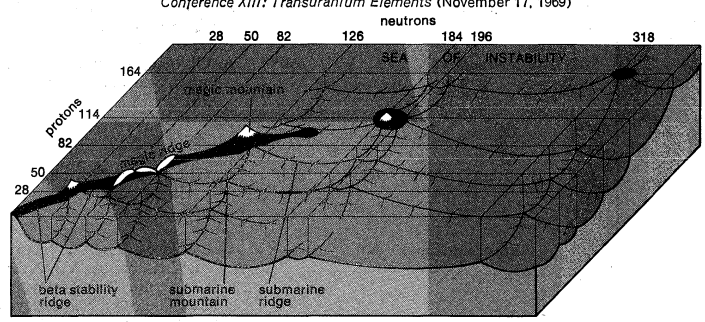

Figure 3: Known and predicted regions of nuclear stability, surrounded by a "sea" of instability.

the known isotopes of the elements can be represented graphically with the number of protons in the nucleus along the left-hand axis and the number of neutrons plotted on the axis along the bottom. The relative stabilities of the isotopes are indicated by their relative heights. In such representation, the known isotopes resemble a peninsula rising above a sea of instability. The most stable isotopes, appearing as mountain tops, occur at specific values called magic numbers.

Magic numbers

The magic numbers derive from calculations of the energy distribution based on the theoretical structure of the nucleus. According to theory, neutrons and protons (collectively, nucleons) are arranged within the nucleus in shells that are able to accommodate only fixed maximum numbers of them; when the shells are closed (*i.e.*, unable to accept any more nucleons) the nucleus is much more stable than when the shells are only partially filled. The number of nucleons in the closed shells yields the magic numbers. As the proton and neutron numbers depart further and further from the magic numbers, the nuclei are relatively less stable.

As the highest atomic numbers are reached, decay by alpha-particle emission and spontaneous fission sets in (see below). At some point the peninsula is terminated. With experimental methods available in the early 1970s, it appeared that the point at which the peninsula of stability disappeared lay in the vicinity of the element with atomic number 108. There was, however, considerable speculation, based on a number of theoretical cal-

culations, that two islands of stability might also exist. The first was expected to extend from about element 110 to element 126, while the second would be centred on element 164. With heavy-ion accelerators, experimenters might be expected to find such islands, especially the first.

Processes of nuclear decay. The correlation and prediction of nuclear properties in the transuranium region are based on systematics (that is, extensions of observed relationships) and on the development of theoretical models of nuclear structure. The development of structural theories of the nucleus has proceeded rather rapidly, in part because valid parallels with atomic and molecular theory can be drawn. At the same time, systematics has been successfully used in the case of alpha-particle decay by noting regularities in experimental alpha-particle decay energies and half-lives as a function of mass and atomic number. Similarly, for beta-particle decay, nuclear thermodynamics gives useful results. Half-lives for spontaneous fission also can be predicted by the application of systematics.

Alpha-particle decay. A nucleus can decay to an alpha particle (helium nucleus) plus a daughter product if the mass of the nucleus is greater than the sum of the mass of the daughter product and the mass of the alpha particle; *i.e.*, if some mass is lost during the transformation. The amount of matter defined by the difference between reacting mass and product mass is transformed into energy and is released with the alpha particle. The relationship is given by Einstein's equation: $E = mc^2$, in which the product of the mass (m) and the square of the velocity of light (c) equals the energy (E) produced by the transformation of that mass into energy. It can be shown that because of the inequality between the mass of a nucleus and the masses of the products, most nuclei beyond about the middle of the periodic table are likely to be unstable because of the emission of alpha particles. In practice, however, because of the reaction rate (*i.e.*, speed of reaction), decay by ejection of an alpha particle is important only with the heavier elements. Indeed, beyond bismuth (element 83) the predominant mode of decay is by alpha-particle emission, although at californium (element 98) an alternate process, called spontaneous fission, becomes possible (as a result of changes in energy balances) and begins to compete favourably with alpha-particle emission. In addition, with a number of transuranium nuclei, a third process, beta-particle decay (emission of a negative electron by the nucleus or the capture by the nucleus of an orbital electron) is of considerable importance.

Predicted half-lives

The regularities in the alpha-particle-decay process that have been noted from experimental data have been used to predict half-lives of as yet undiscovered isotopes. Such predicted half-lives are essential for experiments designed to discover new elements and new isotopes, because the experiment must take the expected half-life into account. The regularities in alpha-particle-decay energies can be plotted in a graph and, since the alpha-particle-decay half-life depends in a regular way on the alpha-particle-decay energy, the graph can be used to obtain the estimated half-lives of undiscovered elements and isotopes.

Beta-particle decay. In elements lighter than lead, beta-particle decay—emission of either negative electrons (usually called simply electrons) or positive electrons (positrons)—is the main type of decay observed. In the transuranium elements, alpha-particle decay and spontaneous fission occur, in addition to decay, by emission of negative electrons or by capture of orbital electrons. (Positron emission has not been observed in transuranium elements.) When the beta-particle decay processes are absent in transuranium isotopes, the isotopes are said to be stable to beta decay.

Decay by spontaneous fission. Regularities also are observed for spontaneous fission in the very heavy element region. If the half-life of spontaneous fission is plotted against the ratio of the square of the number of protons in the nucleus (symbolized by Z) divided by the mass of the nucleus (symbolized by A)—*i.e.*, the ratio Z^2/A—then a regular pattern results for nuclei with even numbers of both neutrons and protons (even–even nuclei). Although this uniformity allows very rough predictions of half-lives for undiscovered isotopes, the methods actually employed are considerably more sophisticated. Nuclei with odd numbers of neutrons or protons exhibit longer half-lives for spontaneous fission than those shown in the figure.

The results of study of half-life systematics for alpha-particle, negative beta-particle, and spontaneous-fission decay in the near region of undiscovered transuranium elements can be plotted in graphs for even–even nuclei, and for nuclei with an odd number of protons or neutrons, and for odd–odd nuclei (those with odd numbers for both protons and neutrons). These predicted values are in the general range of experimentally determined half-lives and correctly indicate trends, but individual points may differ appreciably from known experimental data. Such graphs show that isotopes with odd numbers of neutrons or protons have longer half-lives for alpha-particle decay than do neighbouring even–even isotopes.

Odd–odd and even–even isotopes

Nuclear structure and shape. *Liquid-drop models.* From the theoretical point of view, spontaneous-fission half-lives are generally treated by assuming that the nucleus has the properties of a liquid drop whose interior is inhomogeneous. The inhomogeneity arises from the fact that the neutrons and protons within the nucleus are more likely to be found inside rather than outside certain regions of the nucleus, called shells. This circumstance requires that a shell correction be applied to the ordinary homogeneous liquid-drop model of the nucleus. Nuclei with the exact number (or close to the exact number) of neutrons and protons dictated by closed shells (magic numbers, see above) have spherical shapes.

Since many transuranium nuclei have numbers of neutrons and protons different from the magic numbers and thus are nonspherical, considerable theoretical work has been done to describe the motions of the nucleons in their orbitals outside the spherical closed shells. These orbitals are important in explaining and predicting some of the nuclear properties of the transuranium and superheavy elements.

Nuclear-shape isomers. The mutual interaction of fission theory and experiment brought about the discovery and interpretation of fission isomers. At Dubna, U.S.S.R., in 1962, americium-242 was produced in a new form that decayed with a spontaneous-fission half-life of 14 milliseconds, or about 10^{21} times shorter than the half-life of the ordinary form of that isotope. Subsequently, more than 50 other examples of this type of behaviour were found in the transuranium region. The nature of these new forms of spontaneously fissioning nuclei was believed, in the early 1970s, to be explainable, in general terms at least, by the idea that the nuclei possess greatly distorted but quasi-stable nuclear shapes. The greatly distorted shapes are called isomeric states, and these new forms of nuclear matter are consequently called shape isomers. As mentioned earlier, calculations relating to spontaneous fission involve treating the nucleus as though it were an inhomogeneous liquid drop, and in practice this is done by incorporating a correction for shells in the homogeneous liquid-drop model. The theorist found an apparently reasonable way to amalgamate the shell and liquid-drop energies. The remarkable result obtained through the use of this method reveals that nuclei in the region of thorium through curium possess two energetically stable states with two different nuclear shapes. This theoretical result furnished a most natural explanation for the new form of fission, first discovered in americium-242.

Two stable states for each nucleus

This interpretation of a new nuclear structure is of great importance, but it has significance far beyond itself because the theoretical method and other novel approaches to calculation of nuclear stability have been used to predict islands of stability beyond the point at which the peninsula of Figure 3 disappears into the sea of instability.

EXTENSION OF THE PERIODIC TABLE: THE SUPERHEAVY ELEMENTS

Possible existence of superheavy elements. According to these calculations, islands of stability will occur over the region of atomic numbers from approximately 110 to

126 and also at around 164. The so-called superheavy elements that exist at these islands of stability are predicted to have neutron numbers ranging from about 184 to 318. The nucleus most stable against all forms of decay is thought by many to be element 110, of mass 294, although the assignment of a specific atomic number and mass number is speculative. This particular nuclide (isotopic species) may have an overall half-life (although unlikely) of 10^8 years. Other hypothetical nuclides that are predicted to have exceptional stability are those with atomic numbers 114 and 124; when the neutron number of 184 is added to these numbers of protons, mass numbers of 294 and 308, respectively, are obtained. If these projections are correct, it is considered possible that superheavy elements exist in nature and many scientific groups were looking for such elements.

The possibility of natural occurrence depends not only on the length of the half-life, but also on whether they were created in the first place. The discussion of the possible manufacture of these elements is as difficult and speculative as the discussion of their half-lives. At any rate, in the late 1960s, astronomers first observed a new kind of celestial object called a pulsar. It was thought that the most reasonable model for a pulsar was a rapidly rotating neutron star. The rapidly rotating electromagnetic and electrostatic fields associated with such a star should be able to accelerate charged particles to the velocities found in cosmic rays. If cosmic rays should originate in neutron stars, their composition might include superheavy elements. Unconfirmed evidence suggesting that elements in the atomic number range of 105 to 110 exist in cosmic rays was reported in 1968.

The existence of superheavy elements in meteorites or in terrestrial minerals depends on the probability of their having been formed by the same fundamental processes that created the other elements. Consequently, it is worthwhile to look for superheavy elements in meteorites and terrestrial minerals, since their presence or absence may tell something about the origin of the universe. In the early 1970s, searches had uncovered certain anomalies that might be attributed to superheavy elements, but the results could not be said to furnish proof of their existence.

Superheavy elements and their predicted properties. The postulated nuclear islands of stability are important to chemistry. The periodic table of the elements classifies a wealth of physical and chemical properties, and study of the chemical properties of the superheavy elements would show how far the classification scheme of the table could be extended on the basis of nuclear islands of stability. Such studies would shed new light on the underlying properties of electrons orbiting the nucleus because it is these properties that produce the periodic system. The positions of superheavy elements in the periodic table ultimately would be determined by the characteristic energies of the electrons of their atoms, especially those called the valence electrons, which are involved in chemical reactions. In all known atoms these valence electrons can be considered to be arranged around the nucleus in a variety of orbit-like paths that are designated as *s*, *p*, *d*, *f*, and *g* orbitals. The orbitals are arranged in shells numbered 1 to 8, each shell having *s* orbitals, and the larger also *p*, *d*, *f*, and *g* orbitals. Thus, an electron is identified by the position it has taken up (*e.g.*, 1*s*, 2*s*, 4*p*, 7*s*). Complex calculations have predicted meaningful distribution of electrons in orbitals for a number of superheavy elements. Results for elements 104–121 are given in Table 3, the configurations being those that the atoms have when they are at their lowest energy level, called the ground state.

Electronic structure of atoms

Elements 113 and 114. These calculations of electronic structure permit predictions of detailed physical and chemical properties of some superheavy elements. If, for example, the structure of the periodic system (Figure 4) remains predictable to higher atomic numbers, then element 113 will be in the same group of elements as boron, aluminum, gallium, indium, and thallium; and element 114 will be in the group with carbon, silicon, germanium, tin, and lead. Element 113 usually is called ekathallium, and element 114 is called ekalead. If they ever are discovered, of course, these elements will be given proper names of their own. Computer calculations of the character and energy levels of possible valence electrons in the atoms of these two superheavy elements have substantiated the placement of the elements in their expected positions. Extrapolations of properties from elements with lower numbers to elements 113 and 114 can then be made within the usual limitations of the periodic table. In Table 4, the results of such extrapolations are given. Although, in many cases, theoretical calculations are combined with extrapolation, the fundamental method involved is to plot the value of a given property of each member of the group against the appropriate row of the periodic table. The property is then extrapolated to the

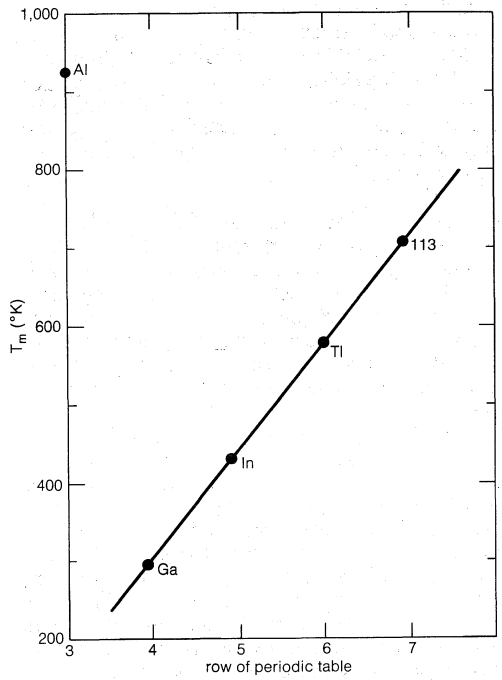

Figure 5: Melting points (Tm) in degrees Kelvin (°K) of Group III elements extrapolated to element 113 (see text).

Bonding properties

The bonding property of an element can be expressed by the energy required to shift a bonding, or valence, electron. This energy can be expressed in various ways, one of which is a relative value called the oxidation potential. The relative stabilities of possible oxidation states of an element represent what is probably that element's most important chemical property. The oxidation number of the atom of an element indicates the number of its orbiting electrons available for chemical bonds or actually involved in bonds with other atoms, as in a molecule or in a crystal. When an atom is capable of several kinds of bonding arrangement, using a different number of electrons for each kind, it has that many oxidation numbers, or oxidation states. The number is indicated in roman numerals following the name or symbol of the element, as copper (II), meaning copper in its oxidation state of two, and copper (I), oxidation state of one. Oxidation states may be positive or negative to indicate that the electrons involved may be considered as lost or gained, respectively. The prediction of oxidation states can be illustrated with element 114, ekalead, which occurs in Group IVa of the periodic table. The outstanding periodic characteristic of the Group IVa elements is their tendency to go from a +4, or tetrapositive, oxidation state, to a +2, or dipositive state, as the atomic number increases. Thus, carbon and silicon are very stable in the tetrapositive state, whereas germanium shows a weak dipositive state in addition to its strong tetrapositive state. Tin chemistry is characterized by about equal stability in the tetrapositive and dipositive states, and lead chemistry is dominated by the dipositive state—the element showing only weak tetrapositive properties. Extrapolation in the periodic table to the seventh row, then, results in a predicted most stable dipositive oxidation state for element 114. This result is supported by valence bond theory and by extrapolations of thermodynamic data.

Other superheavy elements. Less detailed predictions have been made for other superheavy elements. Element 117, for example, is expected to be a member of the halogen series, the group composed of fluorine, chlorine, bromine, iodine, and astatine. Solid elemental 117 should be metallic in appearance, as is astatine, but it is expected that instead of the minus one (−1) oxidation-state characteristic of the natural halogens, it will show +3, +5, and +7 oxidation states. It should also form stable interhalogen compounds with fluorine, chlorine, and bromine.

Computer calculations of element 118

Computer calculations suggest that element 118 should have the closed-shell electronic configuration of the noble gas elements helium, neon, argon, krypton, xenon, and radon. The element should be the most electropositive of the noble gases and, therefore, the existence of a (partially ionized) difluoride of the element 118 is predicted. A tetrafluoride and an oxide of the type formed by xenon (XeO_4) are also expected.

Although detailed predictions of the chemistry of element 119 have not as yet been completed, it is expected to be a typical alkali metal with a plus one (+1) oxidation state. The energetic properties of its valence electron, the 8*s* electron, suggest that its first ionization potential will be higher than the oxidation potential predicted by simple extrapolation, so that the element may be more like potassium than cesium in its chemistry. This higher energy will cause the metallic and ionic radii to be smaller than simple extrapolation would indicate.

Element 120 would be expected to be a typical alkaline-earth element. As with element 119, the ionization potentials should be raised to higher level than the normal family trend would indicate and, also, should make the metallic and ionic radii smaller. These changes should make the chemistry of element 120 similar to that of calcium and strontium.

Element 121 should be similar in its chemical properties to lanthanum and actinium, but detailed properties have not been predicted.

Superactinide series. It is probable, in a formal sense at least, that element 122 will begin another series of elements in which each successive electron is added to a deep inner orbital, in a manner similar (see Figure 4) to that found in the lanthanide and actinide series (see RARE-EARTH ELEMENTS AND THEIR COMPOUNDS; ACTINIDE ELEMENTS AND THEIR COMPOUNDS). Such a series, which would be listed under the actinide series in the periodic table, should consist of 32 elements, ending in the neighbourhood of element 153 and resulting primarily from the filling of the 5*g* and 6*f* inner electron shells (shell 5 orbital *g*, and shell 6 orbital *f*). Since the number of elements proposed for this series is much greater than the number of elements in the actinide series, the new series might be called the "superactinide" series. This nomenclature is equivalent to suggesting for element 121 the name "superactinium" in recognition of the prediction that it would be the approximate prototype for the 32 elements that follow it.

Not every element of this new series would correspond to an actinide (or lanthanide) element on a 1:1 basis, and prediction of the chemistry of the members of the series is a very complex problem. The difficulty arises partly because of uncertainty of the exact point at which the energetically similar 5*g* and 6*f* orbitals begin to fill, and partly because calculations indicate that the 8*p* and 7*d* orbitals may be very close in energy to the 5*g* and 6*f* orbitals. (The number 8 shell is outermost from the nucleus and in each shell the *s* orbital is the innermost.) These orbitals

may all be filled, then, in a commingling fashion, resulting in a series of elements that show multiple, barely distinguishable oxidation states. The electronic basis for the periodicity shown in Figure 4 will then no longer be present.

As shown, element 153 will be the last member of the superactinide series, at least in a formal sense. The prediction of properties on the basis of an orderly extrapolation appears to be of doubtful validity, however, in this heavy-element region of the periodic table. In still higher elements, the closely spaced energy levels are expected to make multiple oxidation states the rule. The placement of the elements in the heaviest portion of the periodic table as shown in Figure 4 is, therefore, probably also of only formal significance.

End of the periodic table. At some point the stability of the orbital electrons in the ordinary sense must be destroyed as more and more protons are added to the nucleus. There is, therefore, in the ordinary chemical sense, a critical atomic number, or range of atomic numbers, which represents the end of the periodic table. This end, it should be noted, is separate, at least philosophically, from the question of stability of the nucleus itself; *i.e.*, nuclear stability is not the same as stability of the electron shells. The maximum atomic number, according to current theories, lies somewhere between elements 170 and 210, as indicated above.

Maximum atomic number

CHARACTERIZATION AND IDENTIFICATION OF THE TRANSURANIUM ELEMENTS

Two important factors provided the key to the discovery and identification of many of the transuranium elements: one was knowledge of the lanthanide series coupled with the concept that it could be paralleled in the actinide series, and the other was the technique of separating elements with similar properties from a mixture by using the principle of ion exchange (see ION-EXCHANGE REACTIONS). Ion-exchange reactions depend on the fact that some complex molecules have a charge that will attract ions of the opposite charge, hold them, and then exchange them for other ions of the same charge when brought in contact with them. The actinide concept, proposed in 1944, stated that the transuranium elements were part of a series of elements that started at thorium and that the chemistry of the series would be similar to that of an earlier transition-element series, the lanthanides. By the use of ion-exchange reactions that are highly specific, many of the transuranium elements have been separated and identified. The tripositive ions of the lanthanides and actinides are eluted (washed) from a cation-exchange resin (a resin that has a negative charge and will hold positive ions or cations) using a particular organic ion, alpha-hydroxyisobutyrate. The striking similarity between elution patterns of the two groups constitutes strong support for the actinide concept. A certain measure of stability of the dipositive state for nobelium was predicted by the actinide concept. A position was predicted for lawrencium (Lr), but for this element the yields have been so small and the half-lives so short that its positive identification by ion exchange has not been achieved. The tripositive state of lawrencium has been confirmed by a very rapid solvent-exchange experiment in which the lawrencium displayed the behaviour of the tripositive actinides and not that of the dipositive nobelium or radium, again in accord with the predictions of the actinide concept.

Non-chemical identification and separation

When the yields of a new element are small and its half-life is short, chemical identification and characterization are frequently not possible. In such cases the atomic number is deduced from the method of production through nuclear reactions, from the parent-daughter relationship of the new element to known elements of lower atomic number resulting from its nuclear decay, and from its nuclear-decay systematics that cannot be attributed to any known nuclides. Additionally, the variation in the yield of the new element is noted when the bombarding energy is changed or when the target or projectile or both are changed.

Separation of the product nuclide from the target has been accomplished in the discoveries of elements 101 through 105 by a recoil collection method. When the target nucleus is struck by a heavy ion projectile, the product nucleus recoils out of the very thin target and is either attracted to a substrate by an electrostatic potential or is swept onto a substrate by a jet of helium gas. The new element is then in a position to be observed and characterized by suitable detection techniques, essentially free of the parent isotope.

It is desirable, though not essential, that the mass number of the new element be established by evidence related to its mode of production, or to its parent-daughter relationship through radioactive decay to a radioactive isotope of known mass number. When weighable quantities of a transuranium element are available, more extensive characterization experiments can be performed. The most important of these experiments is the preparation of the metal, frequently done by high-temperature reduction of the fluoride of the transuranium element with an alkali or alkaline-earth metal. Another method used for preparation of larger (gram) quantities of high purity is electrolytic reduction of the chloride of the transuranium element. Physical characterization of these metal samples includes determination of the density, melting point, vapour pressure, boiling point, hardness, and other properties. X-ray diffraction measurements permit the determination of the crystal structure and calculation of the metallic radius and metallic valence. Chemical characterization includes a determination of the reactivity of the metal with other substances and the chemical stability of the compounds formed. Also of importance are the oxidation states and chemical-bonding properties of the elements in its compounds.

PRACTICAL APPLICATIONS OF TRANSURANIUM ISOTOPES

Three transuranium isotopes, of plutonium, americium, and californium (plutonium-238, americium-241, and californium-252), have demonstrated substantial practical applications. One gram of plutonium-238 produces approximately 0.56 watt of thermal power, primarily from alpha-particle decay, and this property has been used in space exploration to provide energy for small thermoelectric-power units.

Thermoelectric power

The most noteworthy example of this latter type of application is a radioisotopic thermoelectric generator left on the moon. It produced 73 watts of electrical power to operate the scientific experiments of the Apollo lunar exploration, and was fuelled with 2.6 kilograms (5.7 pounds) of the plutonium isotope in the form of plutonium dioxide, PuO_2. Americium-241 has a predominant gamma-ray energy (60 keV) and a long half-life (433 years) for decay by the emission of alpha particles, which make it particularly useful for a wide range of industrial gauging applications and the diagnosis of thyroid disorders. When mixed with beryllium it generates neutrons at the rate of 1.0×10^7 neutrons per second per gram of americium-241. The mixture is designated ^{241}Am–Be and a large number of such sources are in worldwide daily use in oil-well logging operations; *i.e.*, to find how much oil a well is producing in a given time span, as a day. Californium-252 is an intense neutron source: one gram emits 2.4×10^{12} neutrons per second. This isotope is being tested for applications in neutron activation analysis, neutron radiography, and portable sources for field use in mineral prospecting and oil-well logging. Both plutonium-238 and californium-252 are being studied for possible medical applications: as a heat source for use in heart pacemakers and heart pumps and as a neutron source for irradiation of certain tumours for which gamma-ray treatment is relatively ineffective.

Transvaal

The Transvaal is the northernmost and second largest province of the Republic of South Africa. With an area of 109,621 square miles (283,917 square kilometres), it is bordered by Botswana and Rhodesia to the north, Mozambique and Swaziland to the east, the provinces of Natal and the Orange Free State to the south, and Cape Province to the west. Almost 76 percent of its 8,744,000 population is black, and about 22 percent is white. Many of the whites are descendants of the Afrikaners who in the earlier 19th century migrated north over the Vaal River, which now forms part of the province's southern boundary, thus giving the province its present name—Transvaal, "across the Vaal."

Rich in mineral resources, including gold and uranium, as well as in power resources, the Transvaal is South Africa's industrial heartland and also an important agricultural region in its own right. Pretoria, the provincial capital, is also the administrative centre of the republic. The province also contains Johannesburg, the largest city in South Africa. (For a related physical feature article, see VELD; see also the city article JOHANNESBURG; for general historical background, see SOUTHERN AFRICA, HISTORY OF.)

History. In the early 19th century the land between the Vaal River in the south and the Limpopo River, which today forms the northern border, was inhabited by agricultural Bantu tribes who were skilled in metalworking. They became unsettled in the 1820s and 1830s by invasions of refugee Bantu tribes fleeing south and west from the warring Zulu. Between 1837 and 1838 seminomadic pastoral Afrikaner farmers, the voortrekkers, moving northward to avoid British rule, crossed the Vaal River and entered the area, where they settled in isolated farms. More white settlers arrived when the United Kingdom annexed both Natal and the Orange River Sovereignty in the 1840s. In 1852 the independence of the Afrikaners in the Transvaal was recognized by the United Kingdom with the conclusion of the Sand River Convention. In 1857 the new Transvaal state was formally proclaimed as the South African Republic; its authority, however, was virtually limited to the southwest of the present Transvaal. In 1877 the republic was annexed by the United Kingdom, but the Afrikaners resorted to arms to maintain their independence, which they regained—subject to certain provisos—in 1881 after the British forces had been overwhelmed at the Battle of Majuba Hill. The discovery of gold in the Witwatersrand area in 1886 resulted in a tremendous influx of fortune seekers, primarily English and Germans, which caused new problems for the Afrikaner republic. Tension with the United Kingdom increased when an English adventurer, Leander Starr Jameson, led an abortive raid across the frontier of the South African Republic in an attempt to provoke an internal uprising. War between the republic and the United Kingdom subsequently broke out in 1899. Defeated by superior arms and numbers, the republic, together with its ally the Orange Free State, lost its independence when peace was concluded in 1902, after which the Transvaal became a British crown colony. In 1907 it regained self-government, and in 1910 became a province of the Union of South Africa, a status that was maintained when the Union became the Republic of South Africa in 1961.

Settlement by the voortrekkers

Landscape. *Physiography.* There are six distinct physiographic regions in the province—the Highveld, the Bushveld Basin, the Waterberg Plateau, the Pietersburg Plain, the Limpopo Valley, and the Lowveld. In the south, the altitude of the Highveld ranges between 4,000 and 6,000 feet, declining slightly from east to west. The eastern area is covered by horizontal sandstones and shales (laminated clays) that produce gray, claylike acidic prairie soils with a leached upper layer that merges into lateritic (leached, reddish, iron-bearing) soils farther to the north and west. The relief is undulating but changes into a rugged landscape in the vicinity of the Witwatersrand Ridge, where older rocks have been bared. To the west of Johannesburg, the Highveld is monotonously even, being composed of water-bearing limestone and lavas. The region is drained by the Vaal River and its tributaries.

The six regions

The central part of the province is occupied by the Bushveld Basin, formed by a large substratum of rock that has been solidified from the molten state. The peripheral ridge-and-valley landscape is composed of quartzites and intervening shales that dip toward the centre. These ridges are known as the Western Bankeveld around Pretoria and the Eastern Bankeveld near the Drakensberg Mountains. North of Pilgrimsrest, water erosion on the Eastern Bankeveld has created the spectacular canyon of the Blyde River. The black clays of the basin are associated with norite (a granular, mineral-bearing rock solidified from the molten state) and basalt, and are of exceptionally high fertility, as they are at the Springbok Flats.

The Waterberg Plateau rises from 3,500 to nearly 7,000 feet in altitude to the northwest of the basin. Few of its grass- and bush-covered sandstone areas are suitable for cultivation. To the northeast the Pietersburg Plain is almost entirely composed of a granite surface. It is bounded by the Strydpoort Mountains in the south and the Soutpansberg Mountains in the north.

The Limpopo Valley forms the northern border with Rhodesia. It cuts mainly into old granite in a bushy area covered by the sandy soil of the nearby Kalahari, and a red-brown unleached subtropical sandy soil to the east. Farther east, this sandy soil extends into the Lowveld, a bush-clad plain, generally below 2,000 feet in altitude, that gently slopes towards the Lebombo Mountains on the Mozambique boundary. On the slopes of the Great Escarpment—the ridge that separates the plateau from the Lowveld—thick, red, iron-bearing earths support dense plantation growth. The whole of the northern, and most of the eastern, Transvaal is drained by the Limpopo River and its tributaries, which include the Crocodile, Mogalakwena, Letaba, and Olifants rivers.

Climate. Temperatures are directly related to the altitudes of the region. Rainfall is unreliable and varies from year to year. Almost exclusively a summer phenomenon, it normally arrives as thunderstorms and showers. Hailstorms that frequently are destructive may be expected about five times a year, while the great amount of sunshine results in extensive evaporation.

The Highveld is warm and temperate, with mean annual surface temperatures of 57° F (14° C) in the east and 65° F (18° C) in the southwest. Rainfall varies from 40 inches in the east to 18 inches in the west. Frost is common from mid-May to mid-September, but its duration decreases to the north and east. North of Pretoria, the climate becomes subtropical and semi-arid, with an annual average rainfall ranging from 28 inches on the Waterberg Plateau to 16 inches in the Sand River Valley, which is the driest part of the Transvaal. The subtropical Lowveld is warm and oppressive except during the winter. The mean annual surface temperature is 74° F (23° C), and rainfall increases from 19 inches in the northeast to more than 72 inches on the Drakensberg slopes, where mist and drizzle are frequent.

Vegetation and animal life. The natural vegetation of the Highveld and part of the Bankeveld consists of successive sweet, mixed, and sour grassland toward the east, the extent of each zone depending upon the climate and type of soil. The whole of the Lowveld and the greater part of the country to the north of the Bankeveld carries a parkland type of vegetation, with acacia types predominating and tall grasses and scrubs forming the undergrowth. Where rainfall is high in the mist belt, true timber forests with dense undergrowth are found, but they have suffered severely from the hand of man.

Animal life has been severely decimated, except in conservation areas. Kruger National Park—covering some 8,000 square miles in the eastern Lowveld—supports a wide variety of primates such as monkeys and baboons; insect-eaters such as hedgehogs and ant bears; carnivores such as lions, cheetahs, jackals, and hyenas; and hoofed animals such as rhinoceroses, hippopotamuses, giraffes, buffalo, koodoos, blue wildebeests, and impalas. There are many species of birds. Crocodiles and several species of snakes are found, as well as freshwater fish.

Kruger National Park

Population. *Ethnic composition.* There are four main population groups in the Transvaal, which in 1970 to-

gether totalled 8,744,000. The whites number 1,892,000; the Coloureds (racially mixed), 152,000; the Asians, 81,000; and the Bantu, 6,619,000. In terms of simple densities, the total averages about 80 persons per square mile. More than 55 percent of the population is urbanized.

About 61 percent of the white population is Afrikaans-speaking and 33 percent is English-speaking. The balance are of German, Dutch, and other European origin. Approximately 80 percent of the whites are urban-centred, being concentrated in the Pretoria–Witwatersrand–Vereeniging metropolitan complex. The adjacent rural areas have a density of roughly 12 whites per square mile, the remainder of the province less than 4. The Afrikaners, once overwhelmingly engaged in farming, live increasingly in the cities; by 1960, 80 percent were urbanized.

The Bantu population, in spite of a broad cultural solidarity, is diversely grouped in numerous tribes and clans. The main groups are the Sotho, Nguni, Tsonga, and Venda. Since few members of the main groups can understand each other's language, a lingua franca called Fanagalo has developed, especially among the Bantu gold miners. The majority of the Bantu still live in rural areas, where the average density normally exceeds 20 persons per square mile, and reaches more than 60 per square mile in the Tswanaland area northwest of Pretoria.

The Coloureds are about 92 percent urbanized and are concentrated mainly in the Witwatersrand area and in the larger towns. They speak both Afrikaans and English. The Asians are also predominately urban; they consist mainly of Indians, although there is also a Chinese minority.

Religion. More than half of the white population are members of the three Afrikaans churches—the Nederduits Gereformeerde and the Nederduits Hervormde (both Dutch Reformed churches), and the Gereformeerde (Reformed Church of South Africa)—and 25 percent are members of the three main English churches—Anglican, Methodist, and Presbyterian. There is also a small Jewish community. Because of strong missionary activity, almost 90 percent of the Coloureds are Christian. Many of the Bantu have accepted Christianity, but they tend to form independent sects; 20 percent of the Bantu belong to more than 1,000 separatist churches. The Asian community has retained its affiliation with Hinduism and Islām.

Rural and urban settlement. Because of large, individually owned farms, rural settlement among whites is dispersed, with long distances separating neighbours. The pattern in the Bantu areas differs totally because their communal ownership and communal land use results in the appearance of rural villages separated by open stretches of cultivated and grazing lands.

Towns are generally small and few in number, having evolved as mining, marketing, or administrative centres. Over 130 of them have a population of less than 10,000, while 37 of them have between 10,000 and 200,000 inhabitants, and only Johannesburg, Pretoria, and Germiston exceed 200,000. Although the towns were founded by whites, they are numerically dominated by the Bantu.

South Africa's urban heartland

The highly built-up Witwatersrand region covers about 200 square miles, and supports more than 2,000,000 people. Johannesburg, Pretoria, and the Vereeniging–Vanderbijlpark complex—in fact, the whole of the southern Transvaal—forms the mining, industrial, commercial, and financial heart of South Africa. In the west, the gold-mining complex of Klerksdorp–Stilfontein–Orkney, and in the east the Witbank–Middelburg coalfields and industrial area, are important. Other important centres are Pietersburg, Nelspruit, Ermelo, and Lichtenburg, all with populations of between 10,000 and 50,000.

Administration and social conditions. *Administration.* Provincial authority is delegated by the Parliament of the Republic of South Africa to the Provincial Council, the 73 members of which are elected every five years. Taxation for provincial purposes is under provincial control, and local administration is provided by some 50 city or town councils, various local boards, village councils, health committees, and a peri-urban area health board. There are 62 magisterial districts with responsibility for the administration of justice as well as for some functions of other government departments. Bantu Territorial Authorities function under the control of the Bantu affairs commissioner in internal matters of administration and finance.

Social conditions. There are some 57 provincial hospitals; together with private hospitals, they provide about 13,000 beds for whites, and about 20,000 for nonwhites. There are also mine hospitals and hospitals for leprosy, mental illness, and tuberculosis. The provincial authority maintains field services to combat malaria, plague, typhus, tuberculosis, trachoma, and other diseases. Indigent whites and most nonwhites receive free medical attention from the provincial hospitals. The biggest hospital on the African continent, and one of the biggest hospitals in the world specializing in the treatment of a wide range of diseases, is Baragwanath, a hospital for nonwhites near Johannesburg.

Elementary and secondary education and the training of teachers are administered by the provincial government. Schooling is compulsory for whites between the ages of 7 and 16, and for Coloureds and Asians between 7 and 14 where the demand justifies the establishment of facilities. School attendance for the Bantu is not yet compulsory, but Bantu literacy has risen to 85 percent for the group between 7 and 20 years old. Six universities—the universities of South Africa, Pretoria, the Witwatersrand, Potchefstroom, Rand Afrikaans University, and the University of the North for the Bantu—are subsidized by the federal government but remain autonomous. They provide a wide range of teaching and research facilities.

Welfare activities are undertaken by voluntary organizations and by the Ministry of Social Welfare. From 1960 onward, in order to clear the so-called squatters' camps that resulted from a rapid industrialization that was accompanied by an unprecedented influx of Bantu into urban areas in the southern Transvaal, more than 100,000 houses were built; provision was also made for schools, parks, community halls, and other facilities.

Economy. The Transvaal contains one of the greatest known concentrations of mineral deposits, both in variety and quantity. Employing 280,000 nonwhites and 31,000 whites, and producing large quantities of gold and uranium, the mines of the Witwatersrand, Klerksdorp, and eastern Transvaal have stimulated the growth of a large complex of industries and economic activities. Gold purchased for industrial purposes had by 1968 reached the level of total world output of newly mined gold. Diamond output amounted to 2,550,000 metric carats in 1968. Enormous reserves of platinum, as well as of chromite, tin, and nickel, are associated with the Bushveld. Reserves of coal are estimated at 75,000,000,000 tons. Other mineral deposits include iron ore at Thabazimbi, copper at Messina and Phalaborwa, asbestos, vermiculite (a micaceous mineral), antimony, corundum (crystals used industrially as abrasives), and limestone. An ever-growing need for explosives for mining has resulted in the development of a large chemical industry.

Gold, uranium, and diamonds

Agriculture is productive, having adopted modern methods of conservation, irrigation, and fertilization. Products include maize, wheat, peanuts (groundnuts), sunflower seeds, cotton, sugar, tobacco, and potatoes and other vegetables, as well as a wide variety of fruits. Beef and dairy cattle are important, and there is some sheep ranching. Huge plantations of eucalyptus and coniferous trees in the mist belt comprise 37 percent of South Africa's total acreage of plantations.

The demand for water for mining, industry, power stations, and irrigation has exceeded the supply available from the Vaal River, 97 percent of which is already in use. Planners are seeking supplementary supplies from the Tugela River of Natal, and from the desalinization of seawater.

Transportation and communications. Total railway track mileage amounted to about 3,604 miles in 1969, of which almost 2400 miles were electrified. An underground pipeline from the port of Durban in Natal Province con-

veys petroleum products to the Witwatersrand over a distance of 450 miles. There were 7,000 miles of bituminous-surfaced national and provincial roads in 1969. South Africa's main international airport, Jan Smuts, is situated near Johannesburg. Post office services and the telecommunication system have expanded steadily to cope with increasing demands. There are national radio broadcasting stations at Johannesburg, Pretoria, and Pietersburg. The Voice of South Africa transmits to other countries from Bloemendal in ten languages for 182 hours weekly. Radio Highveld broadcasts continuously in Afrikaans and English. Television is to be installed in 1974.

Cultural life. The Transvaal's population diversity has resulted in a variety of different cultures. "White" Transvaal is culturally comparable to any Western country. Its well-known hospitality can be traced back to the rough environment and hard life of past decades, which stimulated mutual dependence and a close family life. There is a strong desire to preserve objects of historical significance; Afrikaner attachment to national tradition is symbolized by the Voortrekker Monument near Pretoria, which honours the first pioneers.

The Transvaal has attained international recognition for its contributions to art, music, and ballet. Opera is presented regularly, and the Aula at Pretoria and Johannesburg Civic Theatre are well-known cultural centres. A wealth of literature and folk song has accumulated, but there is little if any traditional architecture.

Bantu tribes are normally comprised of a number of clans whose members are related. A strong recognition of the power of the tribe's chief prevails, and traditional medicine has considerable influence. The Bantu are renowned for their music and dancing, of which the "Domba," or snake dance, of the Venda is an example.

The climate lends itself to outdoor living, and sports are extremely popular. Motoring vacations over large distances are common, and an exodus to the beaches of Natal is a holiday phenomenon at all seasons.

Tree

Although the concept of a tree as a growth form is useful and generally well understood, it is not possible to provide a precisely delimiting definition of a tree. There is an imperceptible merging of plants that obviously are trees into shrubs and of woody plants into herbaceous plants. To qualify as a tree a plant must be a perennial (*i.e.*, a plant that renews its growth each year); in addition, trees usually have a single self-supporting trunk that contains woody tissues. The trunk generally is dominant for some distance above the ground and commonly produces secondary limbs, called branches; in some species, however, the trunk divides at a low, sometimes even at ground, level into two or more trunks. Most palms have no branches. Although height is often considered a factor in defining trees—minimum limits of 15 or 20 feet (five to seven metres) being most commonly accepted—limits are an arbitrary measure of convenience; woody plants, like all others, are greatly influenced by environment, and the same species, and even specimens propagated by cuttings or some other means from the same stock of one species, may vary tremendously in size depending upon where they grow and the treatment they receive. Pines, spruces, birches, and many other trees, although reduced in size—in some cases to no more than a few inches tall—at the northernmost limits and the highest altitudes of their occurrence, may still have single woody trunks. Specimens of many species grown under adverse conditions of soil, moisture, exposure to wind, and other environmental factors may be similarly dwarfed. The Japanese, by manipulating natural factors that affect growth and by skillful pruning, practice the art of bonsai, in which species that would be forest trees in nature are so dwarfed that they never exceed a few inches to three feet or so in height; such trees develop the proportions and appearance of their fully developed counterparts, however.

TREE TYPES AND DISTRIBUTIONS

Botanical classification of trees. In 1948 the British botanist John Hutchinson, following a trend that had been gaining acceptance for several years, divided the traditionally recognized flowering plant class Dicotyledoneae into two classes: the Lignosae (containing all trees and shrubs as well as clearly related herbaceous plants) and the Herbaceae (all herbaceous plants in addition to some obviously related woody ones). This system stresses the woody characteristic of trees and shrubs more than do other modern systems of plant classification but is still very different from the arrangement put forward by the Greeks about 300 BC and accepted for 1,000 years; they separated plants according to their forms into such major groups as trees, shrubs, and vines.

Ancient system of classifying plants

An important objective of modern botanical classification has been to arrange species, genera, and other recognized groups phylogenetically; that is, according to their probable evolutionary lines of development and genetic relationships. In attempting such a classification, many factors are considered other than those concerned with plant form and gross morphology; *e.g.*, evidence from cytology, genetics, ecological behaviour, and indications of probable population migrations. Because of vast gaps in the knowledge of the actual evolutionary development that led to the Earth's present flora, phylogenetic systems of plant classification are based to a considerable degree on conjecture; in none of these systems, however, are trees treated as a discrete group.

Trees are represented in the major divisions and subdivisions of the plant kingdom called pteridophytes, gymnosperms, and angiosperms. To the first belong the tree ferns; to the second the cycads, the ginkgo, and the conifers; and to the third all flowering plants.

Tree ferns, which belong to the fern families Dicksoniaceae and Cyatheaceae, account for more than 300 of the approximately 10,000 species of ferns. Many attain heights of 20 to 30 feet (seven to ten metres); some are 50, 60, or occasionally 80 feet in height. These graceful trees, which are natives of humid mountain forests in the tropics and subtropics and of warm-temperate regions of the Southern Hemisphere, have huge lacy leaves; they are the remnants of a vastly more numerous flora that populated much of the Earth 280,000,000 to 345,000,000 years ago (the Carboniferous Period).

Cycads compose the Cycadaceae, a family consisting of nine genera and approximately 100 species. Natives of warm regions of the Eastern and Western Hemispheres, they also are remnants of a much larger number of species that in past geologic ages dominated the Earth's flora.

Ginkgo is the only living representative of the family Ginkgoaceae (order Ginkgoales). It is a relic that has been preserved in cultivation around Buddhist temples in China and elsewhere since the mid-18th century; the tree probably no longer exists in a wild state. It is believed to represent the last of a group of related genera that were most abundant in the Jurassic Period, some 165,000,000 years ago.

Conifers include trees and shrubs in seven families and more than 500 species. Familiar representatives are araucarias, cedars, cypresses, Douglas firs, firs, hemlocks, junipers, larches, pines, podocarpuses, redwoods, spruces, and yews.

Angiosperms, or flowering plants, dominate the Earth's present flora; they are divided into about 300 families and approximately 220,000 species, among which are the majority of the world's trees. Angiosperms are divided on the basis of a group of characteristics into two classes: the Monocotyledoneae, or monocotyledons, and the Dicotyledoneae, or dicotyledons. The most numerous of the monocotyledonous trees are palms; others include agaves, aloes, dracaenas, screw pines (*Pandanus*), and yuccas. By far the greatest number of tree species are dicotyledons; they are represented by such familiar groups as apples, birches, elms, hollies, magnolias, maples, oaks, poplars, willows, and a host of others.

Popular tree classification systems. For nonscientific usage, trees have been grouped in various ways, some of which more or less parallel their scientific classification; *e.g.*, softwoods are conifers and hardwoods are dicotyledons. Hardwoods are also known as broadleaf trees. It is important to note, however, that the designations softwood, hardwood, and broadleaf do not indicate with precision the characteristics they imply. The wood of some hardwoods—for example, certain willows and poplars, and the softest of all woods, balsa—is softer than that of some softwoods; *e.g.*, the longleaf pine (*Pinus palustris*). Similarly, some broadleaf trees (tree heaths, *Erica*, and some kinds of *Tamarix*) have narrower leaves than do those of certain conifers (*Podocarpus*).

Evergreen and deciduous trees

A popular and convenient grouping of trees is evergreens and deciduous. This is most useful at the local rather than the worldwide level: whether a particular species retains its foliage throughout the year and thus qualifies as evergreen may depend on climate. At the northern limits or, in the Southern Hemisphere, the southern limits of their occurrence and at high elevations, species that under more favourable circumstances retain their foliage may become leafless for a period. Many tropical and subtropical species that in uniformly humid climates are never without foliage are deciduous in regions in which dry and wet seasons alternate. In northern North America the term evergreen is often used as a synonym for conifer and thus excludes foliage-retaining angiosperms. But five coniferous genera—*Larix* (larch), *Metasequoia* (dawn redwood), *Pseudolarix* (golden larch), *Taxodium* (swamp cypress), and *Glyptostrobus*—are composed of or include deciduous species.

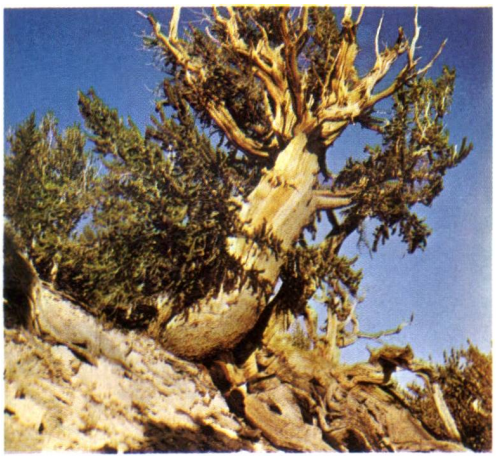
Other tree groups are popularly recognized: tree ferns as tree ferns, palms as palms, and, among desert plants, the tree forms of agaves, aloes, cactuses, euphorbias, and yuccas. Sometimes the layman includes as trees plants that botanists cannot accept as such; for example, the banana. Such confusion arises from the fact that what appears to be the trunk of the "banana tree" is actually leafstalks rolled tightly around each other. The banana plant is entirely herbaceous, has no true trunk, and thus is not a tree.

The distribution of trees. The occurrence of trees in nature is largely determined by the length of the growing season and the availability of water. In areas in which the time between the thawing of the ground in spring and its freezing in fall is insufficient for woody plants to develop and mature their season's growth and to produce seeds, trees are not part of the natural vegetation. Except for a few desert and semidesert species, trees are less successful than many other plants in regions in which rainfall is scanty. In such regions, trees, for the most part, give way to grasses and other herbaceous plants or to low shrubs (chaparral), succulents (fleshy plants such as the cactuses), and other desert-adapted plants. Factors such as inhospitable soils, persistent winds, agricultural practices, and repeated burning of vegetation may also be responsible for the absence of trees. Trees usually inhabit regions in which the annual rainfall exceeds 30 inches.

Northern cold-region evergreen forests consisting chiefly of conifers occupy a broad belt, occasionally extending northward to latitude 72° north, across North America, Europe, and Asia and with southward extensions in mountainous areas into the tropics. A moist temperate forest of chiefly conifers extends from central California to Alaska. In comparison with northern cold-region evergreen forests, this western North American forest experiences higher average temperatures and less violent seasonal changes. Temperate deciduous forests occupy or once occupied vast areas with marked seasonal changes of temperature in eastern North America, Europe, Australia, and southern South America. In parts of the Northern Hemisphere in which winter and summer temperatures are less extreme, subtropical broadleaf evergreen forests are found; they merge, wherever rainfall is adequate, into tropical rain forests, such as those that occupy vast areas in the Amazon and Orinoco drainage systems in South America; those of the Congo, Niger, and Zambezi rivers in Africa; and those in Madagascar, the Indo-Malayan region, Borneo, and New Guinea. Trees also occur as scattered individuals and groups in the savannas of South America, Africa, Australia, and elsewhere.

Forests of broadleaf evergreen trees

THE IMPORTANCE OF TREES TO MAN



Forests are of immense importance in soil stabilization and erosion control, especially in mountainous and hilly regions; they also protect and conserve water supplies and prevent floods. Small groups of trees and even single trees have a similar role locally in preventing washouts and in holding stream banks. Trees can be considered guardians of soil and water; where they predominate, loss by erosion is compensated by the production of new soil resulting from the weathering of rocks and the accumulation of organic debris. Trees not only provide shelter, homes, and food for many animals but also, like all green plants, help to purify the atmosphere by absorbing carbon dioxide and releasing oxygen.

Economic importance. Without trees the world would be bleak, and life as it is known impossible. Carbonized and fossilized wood (coal) supplies fuel for the energy needs of man; other fossilized products of trees include amber, which is formed from the gum of pines, and kauri gum, the product of *Agathis australis*. From earliest times man employed wood for such purposes as homes, rafts, canoes, fuel, and weapons. Too often, however, so-called advanced civilizations have wantonly destroyed trees; great forests of cedars of Lebanon, for example, were virtually eliminated in lumbering operations during early historic times for such purposes as the construction of King Solomon's great temple and palace. Forests that covered much of the Mediterranean region and Middle East were extravagantly exploited by the Assyrians, Babylonians, Greeks, and Romans. Primitive peoples were dependent on trees for many materials in addition to wood. Fruits and nuts of many kinds were important foods for both man and animals. Leaves of palms and other trees were used for thatching roofs. Tapa cloth and woven fabrics made from bark, leaves, and other tree parts were used for clothing. Utensils were fashioned from calabashes, coconuts, and other fruits. Medicines, including quinine, the properties of which were long known to South American Indians, were obtained from trees, as were dyes, tanning materials, and spices. Seeds and other tree parts were used as charms and ornaments.

Modern man is no less dependent upon trees. Although substitutes now are commonly used for some tree products—concrete, steel, glass, and plastics; synthetic drugs and dyes; and synthetic substitutes for natural rubber—the demand for tree products has vastly increased in the manufacture of newsprint, for example, and in the manufacture of other papers as well as cardboard and similar packagings. The modern plywood industry converts immense numbers of trees into useful building materials and, in so doing, makes more complete use of good lumber than can be done by other means.

Wood products

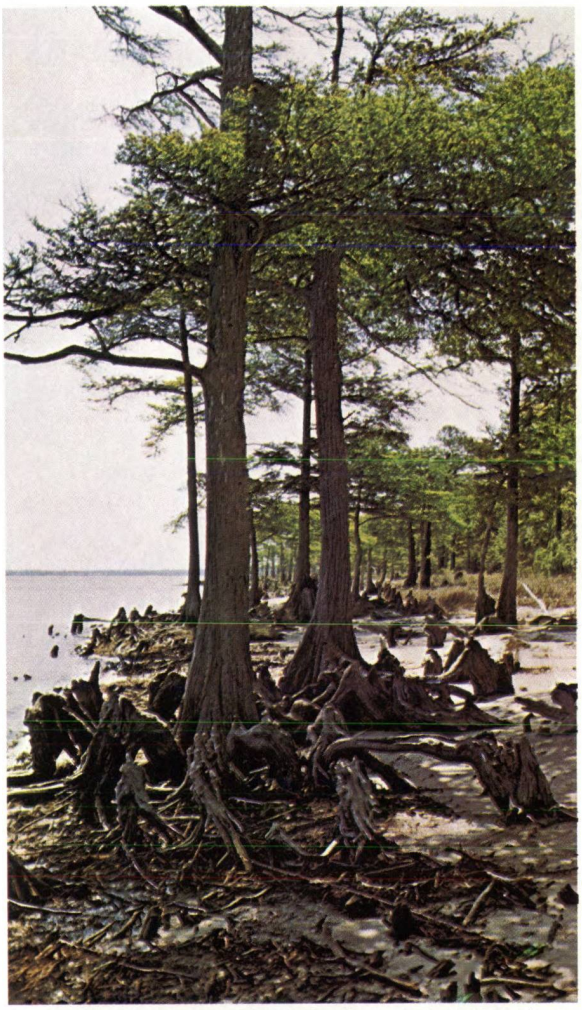
Many products other than wood and its derivatives are important to modern man. Edible fruits produced by trees include apples, cherries, peaches, pears, and others in temperate climates; avocados, figs, persimmons, and

Bristlecone pine *(Pinus aristata)*, among the oldest known trees.

Cedars of Lebanon *(Cedrus libani)*, known throughout ancient art and literature as symbols of power and longevity.

Tree ferns *(Alsophila australis)*, the largest of all ferns.

General Grant tree, a giant sequoia, or big tree *(Sequoiadendron giganteum)*, among the largest trees in total bulk.



Leaves and fruit of the female ginkgo, or maidenhair tree *(Ginkgo biloba)*.

Cycas media, a treelike cycad that produces large terminal seed cones.

citrus fruits in warm-temperate and subtropical regions; breadfruit, coconuts, jackfruit, mangoes, and mangosteens in tropical regions; and the important fruit of desert regions—the date. The coconut (*Cocos nucifera*), the oil palm (*Elaeis guineensis*), and the olive (*Olea europaea*) are important sources of oils and fats used as food and for other purposes. From trees come such spices as cinnamon, cloves, and nutmeg; substances used in beverages, such as chocolate, coffee, and kola nuts; and chicle, the basis of chewing gum. Nonedible tree products exploited commercially include rosin, turpentine, tanbark, creosote, cork, and kapok fibre.

The aesthetic values of trees are generally appreciated. They are admired in their natural settings in forests, savannas, and along river courses; they are planted and cared for in gardens, parks, parkways, cemeteries, and city streets. They serve as screens to secure privacy and to reduce noise levels, and they provide shade.

Unusual trees of special interest. Mangroves, which consist not of one genus or species of tree but several, colonize tidal shores and brackish waters in the tropics and subtropics. In so doing they not only stabilize shore lines but also create new land by trapping debris, silt, and mud among their interlacing roots. Mangroves spread out into the water by sending from their branches roots that reach into the mud and develop into sturdy supporting props. A distinctive feature of mangroves is their large fruits, the seeds of which germinate and grow into sturdy seedlings before they leave the parent plant. When the seedlings fall, they either become fixed in the mud or float away, to be washed up at some site at which the opportunity to become established may occur.

Mangroves are not the only trees that spread by dropping prop roots from their branches. The habit is well developed in several tropical figs (*Ficus*), including one popular in small sizes as a houseplant—the rubber plant (*F. elastica*). Most noteworthy of the group is the banyan tree (*F. benghalensis*) of India; its numerous prop roots develop into secondary trunks that support the widespreading head of massive, constantly extending branches. One specimen 2,000 feet (600 metres) in circumference has been estimated as being capable of sheltering 20,000 people. The wonderboom (*F. pretoriae*) of Africa grows in a similar manner; a specimen at Pretoria has a spread of 165 feet. Because of their unusual growth habits these tropical ficuses are called strangler figs. Often they begin life high in a palm or some other tree in which a monkey, bat, or bird that has fed on the fruits deposits seeds that have passed through its alimentary tract. The seeds germinate, the roots growing into organic matter collected in crotches or crevices of the host tree. Under humid conditions the seedlings grow rapidly, sending roots down along the trunk of the host tree. Upon reaching the ground the roots branch and establish themselves. Above the ground the roots thicken until they form an interlacing cylinder around the trunk of the host.

Strangler figs

The ombu (*Phytolacca dioica*) is a remarkable South American relative of the pokeweed. A tree capable of attaining heights of 60 feet (20 metres) and a spread of 100 feet, it has a wide trunk; the branches contain as much as 80 percent water and very little wood tissue. From its base radiates a circle of rootlike outgrowths wide enough for a man to sit upon.

The traveller's tree of Madagascar (*Ravenala madagascariensis*) has a palmlike trunk up to 30 feet tall topped by a huge, symmetrical fan of long-stalked, paddle-shaped leaves often much shredded by wind. The vernacular name alludes to the leaves having hollow bases from which, it has been reported, travellers could obtain potable water.

The talipot palm (*Corypha umbraculifera*) of tropical Asia may live as long as 75 years before it flowers and fruits just one time, then dies. The huge panicle (many-branched cluster) of creamy white blooms arises from the centre of the cluster of fan-shaped leaves topping the trunk, which may be 80 feet tall and three to four feet in diameter. Another palm of special interest is the double coconut (*Lodoicea maldivica*); a native of two tiny islands of the Seychelles group in the Indian Ocean, it has fruits that require about ten years to mature, weigh up to 50 pounds (20 kilograms), and have the appearance of a pair of coconuts joined together. Long before their source was known, these fruits were washed up by the sea in India, and magical properties were ascribed to them.

The tallest trees are Pacific Coast redwoods (*Sequoia sempervirens*) specimens of which exceed 350 feet (105 metres) in height in an impressive grove in Redwood Creek Valley, California. The species is confined to a narrow coastal belt extending from southern Oregon to California. The next tallest trees are the Australian mountain ash (*Eucalyptus regnans*), specimens of which in Victoria, Australia, exceed 300 feet (90 metres), the greatest heights known for nonconiferous trees. A close relative of the redwood, the giant sequoia (*Sequoiadendron giganteum*) develops the greatest total bulk of wood, but not the biggest girth, among trees. This tree, which attains heights in excess of 300 feet and may have a trunk diameter of about 25 feet some distance above its flaring base, is restricted to a strip about 280 miles long and less than 20 miles wide in the region of the Sierra Nevadas, in California.

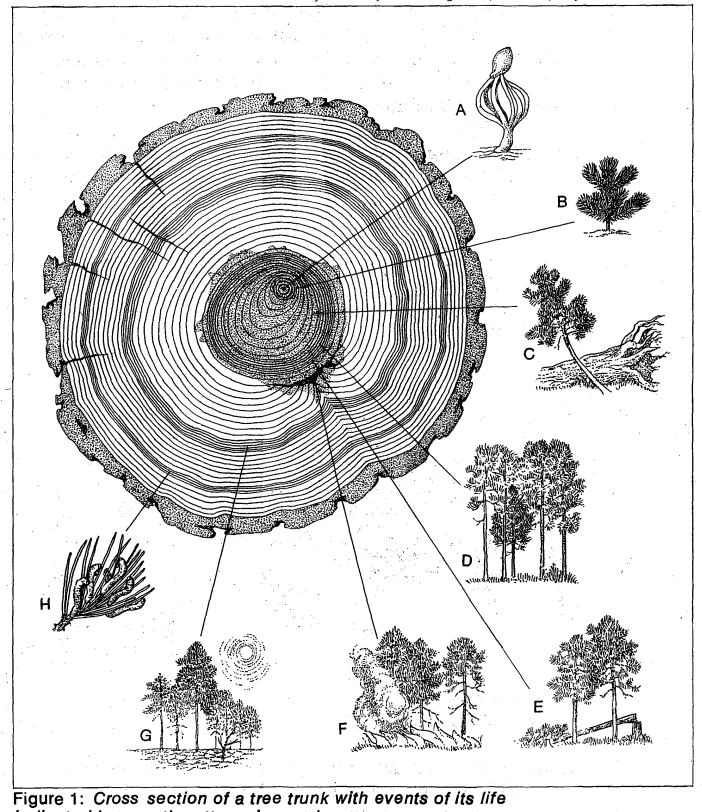

Figure 1: *Cross section of a tree trunk with events of its life indicated by growth patterns in wood.*
(A) A loblolly pine is born; (B) growth is rapid forming relatively broad, even rings; (C) "reaction wood" is formed to help support tree after something fell against it; (D) growth is straight but crowded by other trees; (E) competing trees are removed and growth is again rapid; (F) fire scars the tree; (G) narrow rings probably caused by prolonged dry spell; (H) narrow rings that may have been caused by an insect.

Records for tree girth are held by the baobab (*Adansonia digitata*) of Africa and the Mexican swamp cypress (*Taxodium mucronatum*). The baobab attains a maximum height of about 75 feet; its barrel-shaped trunk may be more than 25 feet in diameter a few feet above the ground. The most famous specimen of Mexican swamp cypress is "El Gigante," located at Tule, Oaxaca. The trunk of this massive tree is buttressed and not circular; if the bays and promontories of the buttresses are followed, the basal circumference is 150 feet.

The oldest living tree is a bristlecone pine (*Pinus aristata*) in Nevada; it has been reliably reported to be about 4,600 years of age. The species rarely exceeds a height of 35 feet.

The role of trees in religion

Trees have been worshipped as gods, accepted as the dwellings of good and evil spirits, and revered. In some parts of the world some of these practices still exist. Sacred trees and holy groves have existed and still exist. The Bible makes early reference to the tree of knowledge, and the pomegranate was long held in reverence by Jews and Persians as the biblical forbidden fruit. The name of the Druid priests of ancient Britain is derived from that of the oak tree they venerated. The use of holly, the leaves of *Ilex* trees, is traceable to the pre-Christian practice of the Druids, who decorated altars with it in winter. The asoka, or sorrowless tree (*Saraca indica*), and the bo tree (*Ficus religiosa*) are held sacred by Buddhists, the first as the tree under which Gautama Buddha was born, the other as the one under which he meditated and received enlightenment. The Hindu divinity Viṣṇu is also said to have been born under the bo tree. The banyan tree (*Ficus benghalensis*) is held sacred by Hindus, who believe that Brahmā was transformed into a banyan.

THE STRUCTURE AND GROWTH OF TREES

External growth forms. In outward form trees vary greatly according to species, and individuals sometimes differ in response to the environment. Because of inherent similarities within related groups, recognition of species and even varieties is often possible from distances too great for observation of the distinctive characteristics upon which botanical separations are based. The method of branching, for example, is highly significant. In some trees, including most conifers, the trunk forms a well-defined, dominant main axis, and the lateral branches are secondary in size and importance. Such a branching pattern, called excurrent, is characteristic of firs, spruces, larches, and most pines. In contrast is the decurrent, or deliquescent, branching pattern characteristic of many angiosperms, in which the trunk forms a well-defined central axis for the lesser part of the height of the tree and then divides and redivides as it forms a head of branches, or crown, of approximately equal dimensions. The decurrent pattern is characteristic of many oaks, the honey locust (*Gleditsia triacanthos*), the silver linden (*Tilia tomentosa*), and the American elm (*Ulmus americana*).

Drawing by M. Pahl

Figure 2: Principal growth forms of trees. Left to right: columnar, deliquescent, and excurrent.

The angle from the horizontal assumed by branches can usually be strongly associated with species or variety and, together with the pattern of branching and comparative length of branches to trunk, is chiefly responsible for the form of the crown. The crown is usually strongly modified in trees growing in the forest as compared with those growing in open areas and thus not impeded by neighbours. In the consideration of tree forms presented here, specimens growing in the open are described. The Lombardy poplar (*Populus nigra* variety *italica*) is an upright form of strikingly columnar outline, very different from the vase-shaped American elm (*Ulmus americana*). The heads of both are shaped differently from that of the pin oak (*Quercus palustris*), which typically has a well-defined central trunk with downsweeping lower branches, horizontal middle branches, and upward-angling high branches. Globular or billowy globular heads are characteristic of many trees, including the Chinese scholartree (*Sophora japonica*), the horse chestnut (*Aesculus hippocastanum*), the London plane (*Platanus acerifolia*), the Norway maple (*Acer platanoides*), the saucer magnolia (*Magnolia soulangeana*), and the white oak (*Quercus alba*). Others, such as the sugar maple (*Acer saccharum*), have more oval heads. A very common form, usually called pyramidal, is more correctly described as conical; it is characteristic of the various types of conifers.

Distinctive landscape patterns are provided by "weeping" trees, the best known of which is the weeping willow (*Salix babylonica*). In weeping trees the younger and often the older branches are pendulous or markedly downsweeping. There are many others, however, most of which are horticultural varieties of species that typically are more upright in their branching, such as the weeping beech (*Fagus sylvatica* variety *pendula*).

Tree bark

A characteristic feature, useful in the identification of many trees, is the protective layer of bark covering the trunks and branches. Bark varies from smooth, copper-coloured covering of the gumbo-limbo (*Bursera simaruba*) to the thick, soft, spongy bark of the punk tree (*Melaleuca leucadendron*). Other types of bark include the commercial cork of the cork oak (*Quercus suber*) and the rugged, fissured outer coat of many other oaks; the flaking, patchy-coloured barks of sycamores (*Platanus*) and the lacebark pine (*Pinus bungeana*); and the rough shingle-like outer covering of shagbark hickory (*Carya ovata*).

The trunks of some tropical trees, such as the silk-cotton tree (*Ceiba pentandra*), are supported by great flange-like buttresses. The presence of thorns is often an identifying characteristic of trees, as are the arrangement, form, shape, texture, and colour of leaves, flowers, and fruits.

Growth and internal structure. The life-spans of trees, like those of all organisms, are limited. They originate in the fertilization of a female egg cell (ovule) by a male reproductive cell (pollen grain), and eventually they die. During their life-spans trees respire and carry on photosynthesis and other physiological processes, including growth. Except in their early years, trees usually produce reproductive bodies (seeds or, in the case of ferns, spores). Growth, which includes elongation throughout life, is commonly most rapid in young trees; it slows markedly after maturity and in old age may be almost infinitesimal. Nevertheless, as long as a tree lives, its stems lengthen each year, and those of conifers and angiosperms increase in diameter.

Structurally, trees consist of three systems of vegetative organs—roots, stems, and leaves—and, in addition, reproductive organs. The latter include flowers, fruits, seeds, and spores. Roots (except for small feeder roots) and stems are permanent for the life of the tree. The other organs are transient, remaining for periods ranging from a few hours to a few years. Even leaves of evergreens fall and are replaced.

Roots provide firm anchorage for the aboveground parts and absorb practically all water and essentially all of the required nutrients except carbon dioxide, which is obtained from the air. The stems (trunks, branches, and branchlets) serve as a framework to support and dispose the leaves advantageously to the light needed in the process of photosynthesis; they also dispose and expose the reproductive parts to wind, insects, and other pollinating and dispersing agents. Also important is the pipeline function of stems by which water containing dissolved nutrients is moved from the roots to other parts, usually the leaves but sometimes leafless stems, in which photosynthesis takes place. Foods elaborated as a result of photosynthesis are translocated, or moved, to growing and storage tissues. The upward flow of water and solutes in conifers and angiosperms is almost exclusively through

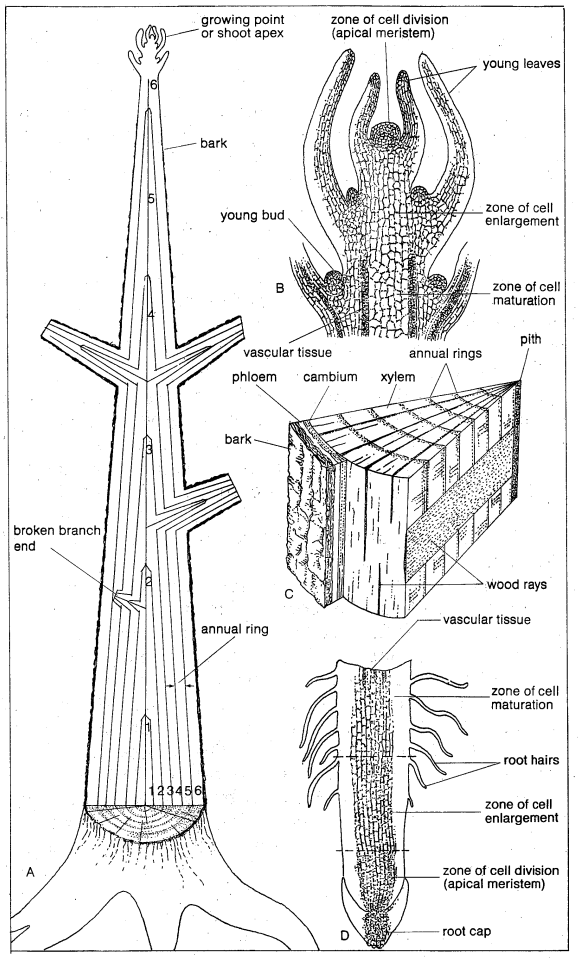

Figure 3: *Growth regions of a tree.*

the tubular cells of the living xylem, or sapwood; the downward movement is through the phloem, or bast, which is a tissue layer that lies just beneath the bark.

Growth regions in trees

Increase in the size of trees results from the production of new cells, the enlargement of old ones, and sometimes the enlargement of the spaces between cells. New cells are formed by meristem tissues, regions of rapid cell division, which are located at the tips of stems and roots, and in secondary meristems, called cambium layers, which form a thin cylinder between the wood and the bark in conifers and dicotyledons; cambium occurs to a lesser extent in some monocotyledons and cycads. The meristems at the tips of stems and roots are responsible for increases in length and height, the secondary meristems for thickening. Tree ferns have no cambium; hence, no secondary thickening of the trunk takes place. In conifers and dicotyledons, the successive layers of wood, usually one each year, that are laid in concentric rings around previously developed wood comprise the annual rings so clearly seen when a trunk or branch of a tree is cut. The cells of the annual rings usually live for several years. During the time the cells are alive, the tissues they compose are called sapwood. As the tree ages, the older, inner portions of the sapwood undergo chemical changes and are infiltrated by oils, gums, resins, tannins, and other compounds. When the cells die, the sapwood has been converted to heartwood. Heartwood is often much darker in colour, denser, and contains less moisture than sapwood. Heartwood, although dead, persists for the life of the tree and affords structural strength unless invaded by disease organisms.

Trees that inhabit arid regions employ various devices to conserve moisture. Thick, succulent, water-storage tissues form a large bulk of the leaves of tree aloes and agaves and of the stems of tree cactuses. As additional protection from desiccation these parts are often coated with wax. Yuccas, including the Joshua tree (*Yucca brevifolia*), have tough, leathery foliage that transpires (loses water by evaporation) only to a limited extent. Some desert inhabitants, such as the tree euphorbias of Africa, the great columnar cactuses of North and South America, the boojum tree (*Idria columnaris*) of Baja California, and the paloverde (*Cercidium torreyanum*) of western North America, either have such meagre foliage—often in evidence only for short periods—or none, that it is not sufficient to photosynthesize the food they need. This deficiency of leaves is met in part or entirely by the chlorophyll-containing outer layers of the trunks and stems, which carry on photosynthesis. The roots of a few trees, notably the swamp cypress (*Taxodium distichum*) and mangroves, which live in watery habitats, produce pneumatophores, or "knees," that rise above the water level. It has been postulated that they are devices that ensure a supply of air to the cells of the roots, but this is by no means certain.

THE ORIGIN AND EVOLUTION OF TREES

Coal-age forests

After the initial invasion of land by plants, perhaps 500,000,000 years ago, the evolution of the first trees began; not until the Devonian Period (345,000,000 to 395,000,000 years ago) did the first vascular plants, including some treelike forms, appear. The Devonian was succeeded by the Carboniferous Period (280,000,000 to 345,000,000 years ago), during which the climate of most of the world was uniformly warm and moist. It favoured the growth of trees, and numerous kinds, many of gigantic size, evolved and populated the vast forests characteristic of that period. These trees formed the great accumulations of decaying organic matter that, after being innundated, buried under mud and silt, and subjected to immense pressures, were transformed into coal. The extent and thickness of the coal deposits of the world, some covering thousands of square miles, give silent evidence of the almost unbelieveable lushness, extent, and persistence of the Carboniferous forests. It has been estimated that 1½ inches (four centimetres) in the thickness of a seam of coal represent on the average 1,000 years of forest growth; some coal seams are hundreds of feet thick. A change in climate ended the vast Carboniferous forests and most of its plant forms, with the exception of a few descendants now called horsetails, club mosses, and ferns. The Permian Period (225,000,000 to 280,000,000 years ago) that succeeded the Carboniferous was by comparison cold, dry, and unfavourable to tree growth over much of the Earth.

None of the early trees had flowers or seeds. They reproduced, as ferns and other lower plants still do, by spores. Toward the end of the Devonian Period seed plants appeared. They were the seed ferns, which are now extinct; contemporary seed-producing plants now constitute by far the greatest portion of the vegetation of Earth. Seeds in effect are embryonic plants packaged with starter supplies of food. They enabled trees to colonize areas less moist and humid than those essential for the development of plants from spores. Seed ferns of tree dimensions became abundant during the Carboniferous Period. But they, too, vanished and were replaced, about 200,000,000 years ago, by a new breed of trees now called gymnosperms. Of the 750 species that survive, some—the cycads, ginkgo, and conifers—are abundant. None has flowers as that term is commonly accepted. Not until the latter part of the Cretaceous Period (65,000,000 to 136,000,000 years ago) did the first flowering plants appear, but their development and rise to ascendancy was re-

markably rapid. The first flowering trees, having many of the characteristics of magnolias, appeared about the time the dinosaurs were becoming extinct.

Trevithick, Richard

Richard Trevithick, English mechanical engineer and inventor, was one of the major contributors to the development of the steam engine. By successfully harnessing high-pressure steam, he reduced the size and weight of engines and so made steam locomotion possible. His technical achievements were an important factor in the rise of the Industrial Revolution.

Trevithick, oil painting by John Linnell, 1816. In the Science Museum, London.

Early life in Cornwall's tin-mining district

Born on April 13, 1771, at Illogan in the tin-mining district of Cornwall, Trevithick attended the village school, where the master described him as "disobedient, slow and obstinate." His father, a mine manager, considered him a loafer, and throughout his career, Trevithick remained scarcely literate. Early in life, however, he displayed an extraordinary talent in engineering. Because of his intuitive ability to solve problems that perplexed educated engineers, he obtained his first job as engineer to several Cornish ore mines in 1790 at the age of 19. In 1797 he married Jane Harvey of a prominent engineering family. She bore him six children, one of whom, Francis, became locomotive superintendent of the London & North Western Railway and later wrote a life of his father.

Since Cornwall has no coalfields, high import costs obliged the ore-mine operators to exercise rigid economy in the consumption of fuel for pumping and hoisting. Cornish engineers, therefore, found it imperative to improve the efficiency of the steam engine. The massive engine then in use was the low-pressure type invented by James Watt. Inventive but cautious, Watt thought that "strong steam" was too dangerous to harness; not so Trevithick. He soon realized that by using high-pressure steam and allowing it to expand within the cylinder, a much smaller and lighter engine could be built without any less power than in the low-pressure type.

In 1797 Trevithick constructed high-pressure working models of both stationary and locomotive engines that were so successful that he built a full-scale, high-pressure engine for hoisting ore. In all, he built 30 such engines; they were so compact that they could be transported in an ordinary farm wagon to the Cornish mines, where they were known as "puffer whims" because they vented their steam into the atmosphere.

Trevithick built his first steam carriage, which he drove up a hill in Camborne, Cornwall, on Christmas Eve, 1801. The following March, with his cousin, Andrew Vivian, he took out his historic patent for high-pressure engines for stationary and locomotive use. In 1803 he built a second carriage, which he drove through the streets of London, and constructed the world's first steam railway locomotive at Samuel Homfray's Penydaren Ironworks in South Wales. On February 21, 1804, that engine won a wager for Homfray by hauling a load of ten tons of iron and 70 men along ten miles of tramway. A second, similar locomotive was built at Gateshead in 1805, and in 1808 Trevithick demonstrated a third, the "Catch-me-who-can," on a circular track laid near the Euston Road in London. He then abandoned these projects, because the cast-iron rails proved too brittle for the weight of his engines

Successful applications of steam engines

In 1805 Trevithick adapted his high-pressure engine to driving an iron-rolling mill and propelling a barge with the aid of paddle wheels. His engine also powered the world's first steam dredgers (1806) and drove a threshing machine on a farm (1812). Such engines could not have succeeded without the improvements Trevithick made in the design and construction of boilers. For his small engines, he built a boiler and engine as a single unit, but he also designed a large wrought-iron boiler with a single internal flue, which became known throughout the world as the Cornish type. It was used in conjunction with the equally famous Cornish pumping engine, which Trevithick perfected with the aid of local engineers. The latter was twice as economic as the Watt type, which it rapidly replaced.

Trevithick, a quick-tempered and impulsive man, was entirely lacking in business sense. An untrustworthy partner caused the failure of a London business he started in 1808 for the manufacture of a type of iron tank Trevithick had patented—bankruptcy followed in 1811. Three years later, nine of Trevithick's engines were ordered for the Peruvian silver mines, and, dreaming of unlimited mineral wealth in the Andes, he sailed to South America in 1816. After many adventures, he returned to England in 1827, penniless, to find that in his absence other engineers, notably George Stephenson, had profited from his inventions.

Shortly before his death, he wrote:

> Mr. James Watt said . . . that I deserved hanging for bringing into use the high pressure engine; this so far has been my reward from the public: but should this be all, I shall be satisfied by the great secret pleasure and laudable pride that I feel in my breast from having been the instrument of bringing forward and maturing new principles and new arrangements, to construct machines of boundless value to my country.

He died in poverty at Dartford, Kent, on April 22, 1833, and was buried in an unmarked grave.

Triassic Period

Triassic Period is the name given to that interval of geological time from about 190,000,000 to 225,000,000 years ago, during which the rocks of the so-called Triassic System were formed. It is the earliest period of the Mesozoic Era (65,000,000 to 225,000,000 years ago).

The term Trias, later modified to Triassic, was proposed in 1834 for a sequence of strata in central Germany lying above Permian (Zechstein) and below Jurassic (Lias) rocks of marine origin. The name refers to a threefold division of the strata into a lower unit of nomarine red-coloured sediments (Bunter, or Bundsandstein), a middle unit of marine limestone, sandstone, and shale (Muschelkalk), and an upper unit of nonmarine rocks (Keuper) that are similar to the lower division. This sequence is typical of Triassic strata of northern Europe, France, Spain, and north Africa; it is commonly known as the Germanic facies (the term facies refers to all aspects of the rocks involved, particularly to any lateral gradations or changes in characteristics that may occur). In contrast to the predominantly continental Germanic facies, there is in the Alps a complete marine fossiliferous sequence covering all of Triassic time that is commonly called the Alpine facies and that, with the addition of units in the lower beds from southern Asia, forms the primary standard sequence of stages and zones.

The standard divisions and correlation of the Germanic and Alpine units (descending from the most recent) plus the main zones, identified by ammonites (a type of cephalopod, a marine invertebrate animal), are shown in the Table. It should be noted that French geologists define the term Keuper in more restricted fashion than do the German geologists; the French apply the name Keuper to the middle part of the German sequence (Gipskeuper) and refer the Rhaetian (Rhät) to the Jurassic and the Lettenkohle to the Middle Triassic (Muschelkalk). In the French literature the German terms have been translated in ascending order, as *Grès bigarré* (Bunter), *Calcaire conchylien* (Muschelkalk), and *Marnes irisées* (Keuper restricted). An additional but minor variation is the use of Virglorian for Anisian and Werferian for Scythian.

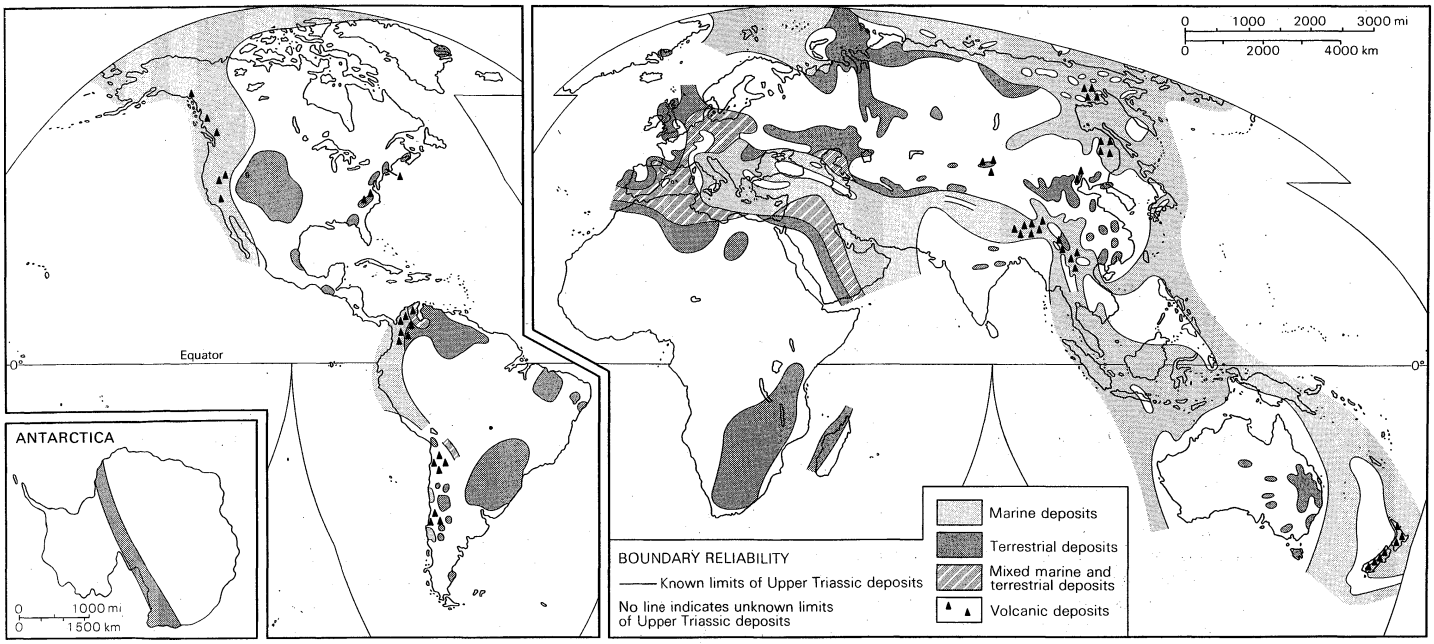
Triassic System Correlation Table

Germanic facies			series	stage	Alpine facies zones*
Keuper	Rhät	Rhaetian	Upper Triassic	Rhaetian	*Choristoceras marshi*
	Gypskeuper	Keuper of French geologists (Marnes irisées)		Norian	*Sirenites argonautae* *Pinacoceras metternichi* *Cyrtopleurites bicrenatus* *Cladiscites ruber* *Sagenites giebeli* *Discophyllites patens*
				Karnian	*Tropites subbullatus* *Carnites floridus* *Trachyceras aonoides* *Trachyceras aon*
	Lettenkohle			Ladinian	*Protrachyceras archelaus* *Protrachyceras reitzi*
Muschelkalk (Calcaire conchylien)			Middle Triassic	Anisian (Virglorian)	*Paraceratites trinodosus* *Paraceratites binodosus* *Nicomedites osmani* *Neopopanoceras haugi*
Bunter or Bundsandstein (Grès bigarré)			Lower Triassic	Scythian (Werferian)	*Prohungarites–Subcolumbites* *Owenites–Anasibirites* *Gyronites–Prionolobus* *Otoceras–Ophiceras*

*Indexed by the ammonite fossils.

Research in recent years on rock sequences and ammonoid faunas indicates that the zonal scheme shown in the Table is far from final. A new proposal of ammonoid zones for North America has illustrated some of the inconsistencies involved in the Alpine sequence. The stage names for the Middle and Upper Triassic have remained unchanged since their introduction; that for the Lower Triassic (Scythian) is under attack. Provincial stage names for this segment of time have been introduced in New Zealand and Japan. In the Soviet Union a two-name nomenclature for this segment of time has been adopted, the Induan below and the Olenekian above. On the basis of ammonoid sequences known from Arctic Canada, a fourfold nomenclature has been introduced, namely (from bottom to top) the Griesbachian, Dienerian, Smithian, and Spathian. These proposals reflect greatly increased study of this segment of geological time, but no consensus has yet been reached.

Major features of the Triassic



The Triassic Period is of special interest in Earth history because fundamental changes took place in the evolutionary pattern of the continents and of life. The preceding Permian Period was a time of great extinctions, especially among marine invertebrate life. During the Triassic, however, greatly renewed evolutionary radiation occurred. Among land animals the great radiation of the reptiles that so characterizes the subsequent Jurassic and Cretaceous periods became well established, and the first mammals made their appearance. The Triassic was also a period of great continentality (large areas of land emerged from beneath shallow seas), and most advocates of continental drift consider it to have been the period of initial breakup of the original supercontinent. Unlike most other geologic periods, it was not a time of formation of significant economic deposits. Triassic coal deposits are known in the Arctic islands of Canada, in various localities in Siberia, China, and Japan, in Queensland, and in Antarctica, but none of these is large or of economic importance. The same generalization applies to petroleum.

Dealt with in this article are the rocks, life forms, and environments of the Triassic Period. For comparable information on the prior and subsequent intervals of geological time see PERMIAN PERIOD and JURASSIC PERIOD, respectively. See also MESOZOIC ERA for an overview of Earth history that began in Triassic time and the articles FOSSIL RECORD; STRATIGRAPHIC BOUNDARIES; and PALEOGRAPHY for relevant information on stratigraphy and paleontology and the principles that underlie determination of ancient environments.

TRIASSIC ROCKS

Geosynclinal and shelf sea deposits. Triassic rocks are widely distributed in former geosynclinal belts (major depositional troughs in the Earth's crust) and on continental platforms and, to a much lesser extent, in former shallow marine shelf areas. The geosynclines are those of Tethys (an east–west belt extending from Spain to Indonesia) and the circum-Pacific region. In the Tethys belt a wide assortment of thick sequences of Triassic rocks occurs in the Alpine region, Turkey, Iran, Afghanistan, West Pakistan, and the Himalayas. In the western Pacific geosynclinal belt, extremely thick sequences of Triassic rocks are present in New Zealand and are well represented in Japan. In the eastern Pacific belt Triassic rocks of great thickness are known from Alaska, British Columbia, and the western United States and in Colombia, Ecuador, Peru, and Chile.

Sediments laid down in shelf seas, on the other hand, are

Distrbution of land, sea, and volcanic areas during Upper Triassic time.

of more limited distribution. Along the northern margin of central and western Tethys, two conspicuous, large embayed regions were periodically occupied by shelf seas that spread outward. One is east of the Alps, occupying much of the Balkan region; another covered much of the area of the present Caspian Sea. Part of South China was also occupied by a shelf sea during Early Triassic time; this sea merged into Tethys. Deposits of shelf seas are also known along the southern margin of Tethys in Algeria, Libya, the Dead Sea region, Saudi Arabia, and in the Salt Range of West Pakistan. Shallow seas occupied a few very limited embayments along the west coast of Australia and a single area along the east coast of Australia in Queensland. The northwestern part of Madagascar was also occupied by shelf seas at least during Early Triassic time. Vladivostok, in eastern Siberia, was at the approximate centre of an embayment of shallow sea during parts of Early and Middle Triassic time. In the western United States shallow seas spread eastward over parts of Utah and Wyoming from the adjoining geosyncline only briefly during Early Triassic time. Much of the circum-Arctic region was occupied by shelf seas during the Triassic. Fairly thick deposits of primary clastic facies (sandstones and shales, in contrast to chemically precipitated sedimentary rocks) are present along northern Siberia from the Sea of Okhotsk to the Lena River. Similar kinds of rocks are a conspicuous part of the geologic record of Spitsbergen. Along the coast of eastern Greenland, Lower Triassic rocks of marine origin were laid down in a north–south embayment that opened to the Arctic Ocean but was closed at about 70° north latitude. The Canadian Arctic has very thick sequences of Triassic rocks in the Sverdrup Basin, and similar but much less well-known sequences are present in northern Alaska.

Red beds and evaporites

Continental deposits. Continental sediments, especially of red-bed facies often associated with evaporite deposits, are especially widespread and characteristic of the Triassic. Throughout Eurasia north of Tethys, such rocks are a conspicuous part of the rock record. In northwest Europe these are the strata of the Germanic facies previously mentioned, and they include the New Red Sandstone of Great Britain. Vast areas of these continental sediments are present west of the Urals and in many scattered areas eastward across the remainder of Eurasia. South of Tethys continental sediments are the predominate sediment type. In peninsular India very thick deposits of Triassic age, all of nonmarine origin, are known. In Australia, as already noted, marine strata are very greatly restricted, but nonmarine red-bed formations representing stream, lake, and playa deposits are widely distributed in Queensland and New South Wales. In South Africa the major part of the Karroo System is composed of Triassic formations, all of continental origin. Only a few of these formations are of red-bed facies; the variety of depositional environments represented by the Karroo includes streams, lakes, and deserts. East of the Andes in South America, there are several vast basins containing continental sediments of Triassic age. One is in the northwest over much of Colombia and Venezuela, and two are in northeastern Brazil; the largest, however, is in the Paraná Basin of southern Brazil, northern Argentina, and parts of Uruguay and Paraguay. In Antarctica no marine Triassic rocks have yet been identified, but in the Transantarctic Mountains there are extensive deposits of nonmarine sandstones of that age containing fossil plants, amphibians, and reptiles. Finally, in western North America, Triassic continental rocks compose much of the spectacular scenery of Utah, Wyoming, and Colorado. Many of these formations are stream, lake, and playa deposits and are red in colour. Others are vast sand dune deposits.

Overview of rock types. The Triassic is represented by a great variety of sedimentary rocks. Limestone is confined mainly to the middle latitudes (including Tethys and western United States) and is represented by a great variety of carbonate facies, including reefs. One of the more interesting aspects is that no true reefs of Early Triassic age have yet been recognized; in fact, no corals are known from Lower Triassic formations. Scleractinian corals (a type that comprises the Mesozoic to Recent coral reef faunas) do not appear until the Middle Triassic and did not form true reefs but lived on banks. True reefs appeared in the Upper Triassic, and Triassic limestone formations are widely distributed in Tethys. Such formations are extremely thick in the Alps, Iran, and the Himalayas.

In the circum-Pacific geosyncline, graywacke (a type of sandstone containing a muddy matrix and a high proportion of rock fragments), sandstone, shale, and volcanic rocks predominate. In New Zealand the whole Triassic is made up of such facies, and the sequences are extremely thick. In the shelf areas of the circum-Arctic region, the Triassic formations are almost entirely sandstone, siltstone, and shale.

Volcanic activity

Extrusive and intrusive igneous rocks are not conspicuous in Triassic history. The eugeosynclinal belts (deep-sea depositional troughs) of the circum-Pacific region include varying amounts of volcanic deposits, as is usual for such depositional regions. Large areas of Siberia were covered by basalt flows during the Triassic. The coastal

region of Queensland was also a centre of active volcanic activity at this time. Such activity was also conspicuous in the Chilean Andes and adjoining regions of Argentina. In the downfaulted grabens (blocks that subside between fracture zones in the Earth's crust) that formed in the Appalachian Mountain region during the Upper Triassic, there were several phases of outpourings of basalt.

TRIASSIC LIFE

The geologic eras were first recognized by differences in the total fossil life. The Triassic Period is the harbinger of the Mesozoic Era, and its fossil record contrasts markedly with that of the preceding periods and sets the stage for the remainder of Mesozoic time. The evolution of life during earth history is punctuated by episodes of large-scale extinctions. That which took place toward the end of the Permian Period around 225,000,000 years ago was the most severe and widespread. Thus, the whole aspect of the Lower Triassic fossil record largely reflects this phase of Late Permian extinctions.

Invertebrate faunas. Paleozoic marine strata are generally characterized by an abundant and very diverse fauna of invertebrate animals. Even to the nonspecialist this is evident on examination of these strata in the field, because the fossil record of the Lower Triassic strata has an impoverished aspect. The predominant invertebrate fossils are ammonites. These are not only abundant and diverse but extremely widespread. Bivalves and brachiopods are second and third in abundance but much less abundant than the ammonites. All other major invertebrate groups are rare, extremely rare, or absent in the Lower Triassic fossil record. It is worthwhile to document these points. Foraminifera are an extremely abundant and common fossil group from the Late Paleozoic to the Recent (the Holocene Epoch, or last 10,000 years). In the Lower Triassic, however, only 28 genera have been recorded to date. No corals have yet been recorded from Lower Triassic strata, and there is only a single record of a Bryozoa, a new genus of Trepostomata from Lower Triassic strata on Ellesmere Island, Arctic Canada. Though brachiopods are fairly well represented in the Lower Triassic record, they are difficult to interpret because there has been no study of the group in the 20th century. The latest compilations show 34 genera as being present in the Lower Triassic. According to the American paleontologist G. Arthur Cooper, the foremost authority on brachiopods, "The whole Triassic is a critical time in brachiopod history but a kind of never-never land between the Permian and the Jurassic." Among the most interesting new discoveries are Permian-type brachiopods in strata believed to be lowermost Triassic in the Salt Range of West Pakistan and at Guryul Ravine near Srinagar, West Pakistan. These are believed to be short-lived survivors of Permian-type brachiopods into Triassic time, but there is some disagreement on this interpretation. Bivalves are a fairly common element in Lower Triassic formations, but well-preserved specimens are rare. Some of the genera are worldwide in distribution. The relationship of Lower Triassic bivalves to Permian forms is poorly understood. The gastropods are exceedingly poorly represented in the Lower Triassic fossil record. For both the bivalves and gastropods there are relatively few genera recorded from the Lower Triassic. In each group greatly increased evolutionary radiation does not take place until the Late Triassic.

Remains of Echinodermata are important components in the composition of some Lower Triassic formations, but reasonably complete fossils are extremely rare. Among echinoids the only known is *Miocidaris*, a survivor from the Permian, whose fragmental remains are important in the composition of the lowest Triassic beds in the Salt Range of West Pakistan; ophiuroids and stelleroids are likewise extremely rare. Crinoids are only known from isolated columnals, which are abundant locally. Nautiloids are present in Lower Triassic formations but cannot by any means be considered as common. What is of particular interest in the nautiloids is that there is no change in pattern or mode of evolution of this group across the Permian–Triassic boundary.

The ammonites are the most conspicuous and prominent of all Lower Triassic faunal groups. In the Lower Triassic Scythian Stage, 136 genera of ammonites are known, ample testimony to the evolutionary vitality of this group.

Expansion of ammonites

There is no general consensus as to the cause of the Late Paleozoic phase of extinction. There has, however, been a great number of suggested causes, including changes in ocean salinity, climatic change, changes in geomagnetic polarity, cosmic radiation, changes in supply of nutrients, orogenies (mountain building), and regression of the seas off the continents. Whatever the cause or combination of causes, the result was a strange and impoverished Lower Triassic fauna. It has been tempting to examine the sedimentary facies as a corollary factor to explain the particular composition of Lower Triassic faunas. On careful analysis of the rock record, this explanation is not tenable. Lower Triassic formations include nearly a complete spectrum of marine rock types; the only major facies that is not present are true reefs.

In the Middle and Upper Triassic the ammonites maintained their predominance in the composition of marine invertebrate faunas. The bivalves increased, but nearly all other invertebrate groups were generally uncommon except in exceptional circumstances. The close of the Triassic was marked by the near extinction of the ammonites.

Vertebrate faunas. The history of vertebrate life during the Triassic contrasts greatly with that of invertebrate life. In the first place, the phase of extinction toward the close of the Permian is not nearly as marked. Permian tetrapod faunas included labyrinthodont amphibians; cotylosaurs, primitive reptiles not far removed from their labyrinthodont ancestors; the eosuchians, a restricted group of small reptiles; the thecodonts (derived from an eosuchian ancestry); the araeoscelids or proterosaurs, another restricted but rather persistent group of reptiles; and the therapsids, or mammal-like reptiles. Of this group of tetrapods, only the labyrinthodonts, cotylosaurs, and therapsids are abundantly represented in sediments of Late Permian age. At the close of the Permian, one order of labyrinthodonts came to the end of its evolutionary line; all the remaining groups suffered great reduction in numbers of families at the close of the Permian, but others did survive into Triassic time. Tetrapod faunas of the earliest Triassic are dominated by these surviving groups from the Permian. Very soon, however, and progressively through the remainder of the Triassic, a number of new tetrapod orders appeared. The new orders were the proanurans (ancestors of the frogs), the chelonians or turtles, the lizards, the rhynchocephalians, the crocodilians, the saurischian dinosaurs, the ornithischian dinosaurs, the marine sauropterygians, placodonts, and ichthyosaurs, and the first mammals. The first lizards appeared in the Late Triassic, as did the first crocodilians and two orders of dinosaurs, the latter three groups being derived from thecodont ancestors. Turtles, arising from cotylosaurian forebears, evolved during Middle and Late Triassic time; and the rhynchocephalians, having arisen in the Early Triassic, went through a considerable range of evolutionary development during the Middle and Late Triassic. In the Late Triassic the first mammals appeared, as descendants from certain therapsid reptiles. The tetrapod invasion of the seas by the sauropterygians or nothosaurs and plesiosaurs, by the mollusc-eating placodonts, and by the fishlike or porpoise-like ichthyosaurs took place during Early and Middle Triassic time. There were 17 orders of tetrapods in the Triassic Period, as contrasted with seven orders in Late Permian time. Thus, as a result of evolutionary development following tetrapod extinctions that marked the end of Paleozoic history, the air-breathing vertebrates of Triassic time became more varied and, what is especially important, attained greater potentialities for future evolution along widely diverse lines than had been the case among tetrapods of Late Permian time. By the close of Triassic time, the whole character of tetrapod faunas had changed, and the stage was set for the even greater evolutionary radiation of the group in the following periods.

Dominant tetrapod faunas

Late Permian extinctions had little significance in the

evolutionary history of fish. The two or three families of sharks that existed in the Late Permian continued into the Triassic. The same is true for one family of coelacanths and one of lungfishes. Among the 18 genera of chondrostean families, eight persisted into the Triassic.

The floral record. Triassic floras are distinctive because they are dominated by gymnospermous types and thus contrast with the preceding Permian floras. Ferns, conifers, cycads, and ginkgos are the most common forms. The fossil floral record for the Triassic is not well documented, and this in part may be a reflection of widespread aridity for the period. At the same time large forests did exist, as illustrated by the Petrified Forest of Arizona. In the Gondwana areas, mainly the southern continents, Permian floras were dominated by *Glossopteris-Gangamopteris* elements. These were abruptly replaced by a new assemblage dominated by the pteridosperm genus *Dicroidium*.

STRATIGRAPHIC-BOUNDARY PROBLEMS

In the type area of the Triassic, in Germany, most of the system comprises clastic formations of continental origin that are very poorly fossiliferous. The lower division, the Bunter, rests unconformably on the underlying Upper Permian Zechstein. The upper division, the Keuper, is unconformably overlain by marine shales of earliest Jurassic age.

The Permian–Triassic boundary. The first sequence of zones for the marine Triassic "pelagic facies" was proposed in 1895; the term pelagic refers to floating or freely swimming marine organisms, and the rocks in this facies are characterized by the fossil remains of such organisms. The sequence of zones for the Middle and Upper Triassic was based on Alpine data, whereas that for the Lower Triassic was based on Salt Range and Himalayan faunas.

Otoceras and *Ophiceras* as index fossils

The lowest Triassic zone was named *Otoceras woodwardi*. It was soon recognized that in Tethys, wherever the lowest Triassic strata were present, the ammonite genus *Ophiceras* was associated with *Otoceras* and in much greater abundance. This lowest zone is now generally called that of *Otoceras-Ophiceras*. In the circum-Arctic region *Otoceras* appears first in the record, followed later by *Ophiceras*. The presence of Permian-type brachiopods with these index fossils in the Salt Range of West Pakistan and at Guryul Ravine, near Srīnagar, Kashmir, has prompted some specialists to consider this zone as of Permian age. This viewpoint, however, has received little support.

The nature of the Permian–Triassic boundary has been a subject of intense debate for a century. There are few places in the world where latest Permian strata are overlain conformably by youngest Triassic strata: there are the regions of Kap Stosch, eastern Greenland; Soviet Armenia and Azerbaijan and adjacent areas of northwest Iran; central Iran; the Salt Range of Pakistan; Kashmir; and Kwangsi Province, South China. At all of these localities there are small thicknesses of strata at the Permian–Triassic boundary that contain a mixture of Permian-type and Triassic-type faunal elements. The interpretation of these strata has been the crux of the problem. Much study has been concentrated on these areas in recent years. The Permian-type faunal elements associated with Triassic-type faunal elements in the Salt Range of Pakistan and in Kashmir are believed to be true survivors for a short period into Triassic time. In Soviet Armenia and Azerbaijan and adjacent northwestern Iran, the strata with the so-called mixed fauna have been conclusively shown to be of Late Permian age. The immediately overlying strata in Soviet Azerbaijan contain a rich and diverse *Ophiceras* fauna. In eastern Greenland the Permian-type faunal elements found in strata with *Otoceras* have been shown to be derived from outcrops of Permian rocks. The primary problem in definition of the Permian–Triassic boundary is not so much recognition of what is earliest Triassic but what represents latest Permian time.

The Triassic–Jurassic boundary. Definition of the upper boundary of the Triassic System has not been without difficulties. In the mid-19th century when the geological time scale was being established, marine strata were recognized in England and in Europe north of the Alps containing the bivalve *Rhaetavicula contorta* resting on the nonmarine New Red Sandstone and the Keuper. These strata were overlain by very fossiliferous shales and limestones of the Lias. Because these strata represented an abrupt change from continental to marine deposition, it was natural to recognize this contact as the Triassic–Jurassic boundary. In the Alps, however, these same strata with *Rhaetavicula contorta* later yielded a small fauna of ammonites of Triassic affinity. These beds were given the name Rhaetic. The lowest zone of the overlying Lias beds is identified by the appearance of the ammonite *Psiloceras planorbis*, which is of nearly worldwide occurrence, with an accompanying molluscan fauna. At the present time stratigraphers in most countries except France include the Rhaetic in the Triassic.

TRIASSIC PALEOGEOGRAPHY

Distribution of land and sea. The Triassic Period was characterized by general emergence of land areas as a consequence of long continuing orogeny (uplift and mountain building) during the Late Paleozoic. In this process the Uralian Geosyncline, a north–south mobile zone separating Eurasia into two distinct areas of greater stability, underwent its final orogenic episode. The mobile belt of the geosynclinal region in eastern and southern North America also underwent its final orogenic phase. The same applies to the Tasman geosynclinal belt of eastern Australia.

Geosynclines and mountain building

Geosynclinal areas are confined to Tethys and to the circum-Pacific region. Shelf seas bordered the circum-Arctic region. Probably at no other time during the Paleozoic and Mesozoic were the world continents in such an emergent state.

At the same time, diastrophism (mountain-making movements) was areally restricted. During the Late Triassic the Appalachian Mountain region from Nova Scotia south to the Carolinas underwent faulting, forming deep subsiding grabens wherein many thousands of feet of terrestrial clastic sediments accumulated. In Nevada orogenic activity (thrust faulting) continued along the Antler orogenic belt in a north–south trend through central Nevada. Along the Pacific coastal margin from California to southern Alaska, no Lower or Middle Triassic formations are found. In fact, Upper Triassic formations are very widespread and tend to overlie Permian and older formations. It is believed that in the intervening time the area was emergent and undergoing orogeny. On the opposite side of the Pacific, a pronounced orogeny took place in late Middle Triassic time (Ladinian) in the inner zone of southwestern Japan. Throughout the Paleozoic, China had been subjected to periodic marine transgressions, northward out of Tethys, and these continued until Middle Triassic time. In the Late Triassic much of China underwent orogeny, ending all further marine transgressions. Triassic sediments in eastern Australia are primarily nonmarine intermountain-basin deposits, and these were gently folded at the close of Triassic time.

The hypothesis of continental drift (*q.v.*) is advocated by the majority of earth scientists and is strongly supported by evidence from the ocean floors (see ROCK MAGNETISM; SEA-FLOOR SPREADING). The problem is much too complex to be discussed here, but a few general comments, insofar as they pertain to the Triassic, are in order. One of the strongest arguments for drift is the geological fit of the opposing coasts of South America and Africa and the fact that there are no marine deposits of Triassic age on either side of the South or North Atlantic south of Spitsbergen. A great many different reconstructions of the continents have been proposed, and more can be expected in the future. There is considerable difference of opinion as to when the supercontinent began to break up, but Triassic time is favoured by a number of specialists. Most of the proposed continental reconstructions are based on physical criteria, such as fit of continental margins, similarity of rock facies and sequence, and paleomagnetic data from the ocean floor. The distribution of

fossil animals, especially amphibians and reptiles, is also used to support the hypothesis. Specialists on these groups, however, do not agree on the interpretation of the data. Among marine invertebrates there does appear to be a pronounced north–south faunal gradient, but lack of marine deposits along the Atlantic inhibits any statement on east–west movements that is based on paleontological evidence.

Indications of warm temperatures

Triassic climates. Beginning in mid-Permian time, approximately, widespread aridity became a major factor in world climatic patterns. This tendency increased through Late Permian time and set the pattern for Triassic climates. The fossil and rock record for Triassic time suggests highly homogeneous climatic conditions lacking extremes. For instance, there are no known continental glacial deposits of Triassic age. This contrasts greatly with pre-Triassic conditions. The most widespread continental deposits are red beds of sandstone and shale, in many places associated with evaporite deposits. There is no simple explanation for the origin of all these continental red-bed deposits, but most were probably not products of deposition in a fully arid climate. Many contain abundant fossil plants, fish, and tetrapods. These deposits were most likely formed in warm areas of seasonal rainfall and periods of drought.

Climatic interpretations on the basis of lithologic character of marine rocks are more difficult to make. The fact that there are essentially no limestones of Triassic age in the circum-Arctic region probably has some climatic significance, but the precise nature is difficult to establish. The absence of limestones may be a result of nothing more than an abundance of clastic sediments in the shelf seas adjoining the circum-Arctic region throughout much of Triassic time.

Geographic distribution of animal and plant life adds significant insight to the problem. Modern amphibians and reptiles are ectothermic, or "cold-blooded," animals having no internal-temperature-regulation mechanisms and are therefore more or less controlled by the temperature of the environments in which they live. It is assumed that the same factors existed in the past. The great majority of modern amphibians, for example, are inhabitants of the tropics or subtropics. Some have adapted to live in higher and lower latitudes, but these are small forms with very special habits. Caution, of course, is required in application of this principle, but plots of distribution of Triassic amphibians and reptiles yield provocative data. Lower Triassic amphibians and reptiles are known from as far north as 80° north latitude to about 30° south latitude. Of special interest is that the faunas of the higher and lower latitudes are made up of individuals of smaller size than those from the intervening zone. This is interpreted by some authorities as reflecting the influence of lower temperatures. In contrast to this pattern, Upper Triassic amphibians and reptiles have the same approximate latitudinal distribution, but large-size forms are found throughout the range. Again, this is interpreted as a reflection of equitable climatic conditions over much of the globe.

Temperature appears to be one of the most important factors controlling the distribution of marine invertebrates. Among modern shelf faunas, there are larger numbers of genera and species in tropical seas than in the Arctic seas. Much work in recent years has involved assembling data on faunal diversity for various periods of geologic time. One example for the Triassic illustrates the method. In one zone (the uppermost) of the Lower Triassic, 73 genera of ammonites are known, 64 of which lived in Tethys and only 22 in the circum-Arctic region; the intermediate zone has 32 genera. This is interpreted as a clear-cut faunal diversity gradient that probably reflects some temperature difference between the low and high latitudes. Although there is no reason to believe that the differences were great, they were probably sufficient to control the distribution of these marine invertebrates.

Tribal Religious Movements, New

Encounters between tribal peoples and higher civilizations

In the last five centuries, the tribal peoples of the world have had more extensive and disturbing encounters with the religions and cultures of highly sophisticated and powerful civilizations than ever before. Such encounters have been brought about by the expansion of the European peoples across the world, except in Asia and the Islāmic areas of North Africa and the Middle East. On a much smaller scale, the tribal peoples marginal to the Hindu and Buddhist societies in India and Southeast Asia have experienced the renewed impact of these dominant cultures and religions (*e.g.*, the reform movements among the Bhil tribes of western India under the influence of Hinduism and the cults among the Karen tribes of Burma under the influence of Buddhism).

In the encounters between large, powerful, highly organized, and literate societies and small, weak, and nonliterate tribal peoples, the latter have responded by developing a vast proliferation of religious movements. These movements owe something to the religions of both their own and the newly introduced cultures, without being completely identified with either the old tribal or the new invasive religions. They are, in this sense, new religious creations, and the similarity of the situations in which they arise, of their characteristic features, and of the variety of their forms makes it possible to consider them in the aggregate as a new development in the history of religions.

NATURE AND SIGNIFICANCE

The problem of descriptive terminology. During the middle and latter part of the 20th century many different terms have been used to designate these movements. Those concerned with their political implications, especially in colonial situations, have spoken of revolutionary cults, rebellious prophets, or protonationalist movements. Their psychological aspects have been stressed in such terms as crisis or deprivation cults and reformative or revitalization movements. Sociologists may refer to separatist or independent sects or to voluntary religious societies and popular movements; and cultural anthropologists speak of adjustment or acculturation or of nativistic, perpetuative, revivalistic, or transformative movements. Their religious features appear when they are called, on the basis of certain distinguishing characteristics, heretical, syncretistic, or prophet movements; eschatological (with an emphasis on the end time), millennial (with an emphasis on a final reign of the saved elect), or messianic (with an emphasis on a salvatory figure or group) cults; or pentecostal (spiritual or charismatic) or visionary sects. This wide range of terms indicates the rich variety of the phenomena as well as the many disciplines interested in their study.

Only a few of these terms might apply to all such movements; they could perhaps be identified as independent syncretist adjustment movements. These terms, however, like all the others mentioned above, also apply to movements outside the phenomena being examined and thus

do not provide a distinguishing description. Certain widely used terms would seem to be better avoided. "Nativistic," a term from the early 1940s, is suggestive of the tribal reference; but its regressive suggestions exclude many dynamic and creative movements, and it may be used elsewhere for movements within Western or other societies. The terms millennial and messianic have been seriously overworked because comparatively few such movements are messianic in the strict sense; and many are no more millennial than are most religions with some conception of a blessed future (see MESSIAH AND MESSIANIC MOVEMENTS; MILLENNIALISM). The term revitalization movements, though it was widely adopted in the 1950s, remains useful but is rather redundant because the concern with the renewal of vitality from the divine source lies near the centre of most religions.

Differences from folk religions

These movements should be distinguished from folk religions, which do not arise in an encounter situation of the kind described but occur among rural and urban masses as unsophisticated popular religions in a symbiotic relationship with a more sophisticated and classic form. Also excluded from consideration are most of the New World Negro religions, some of which are regarded as forms of folk religion.

General basic characteristics. *Religious nature.* The first basic characteristic of these new tribal movements is their religious nature. Because of the integration of the secular and the religious in these societies, they have often appeared as predominantly political, economic, or social movements. Colonial governments, therefore, frequently regarded their religious concerns as fronts for subversive activities. The religious dimension has, however, usually persisted and continued to develop after the more secular concerns and functions have declined or have been taken over by political parties, trade unions, cooperatives, or social and cultural societies.

Acculturative processes. The second basic feature is the rise of these movements in situations provided by encounters of tribal societies with the more powerful and complex cultures associated with one of the major religions—usually with Western culture and Christianity and in a colonial setting. The interaction between the two cultures changes them both; but the subordinate, or tribal, culture is usually much more drastically affected. This is known as the acculturation process, although the changes may be either towards assimilation of selected features from the dominant culture or toward rejection of this culture by reassertion of the weaker culture in new forms. In either case, the process commonly (but not always) issues in new religious movements as bearers and formulators of the acculturative response.

Mere contact, however, no matter how extended, is not necessarily sufficient. West Africans had long contact with Europeans before the first series of new movements began in the 1880s. The Aborigines of northern Australia had met the more sophisticated Indonesians, Japanese whalers, and the earlier Europeans; but it was only when they were caught up in the activities of World War II and in postwar tourist developments and new government policies that the syncretistic Elcho Island movement appeared in Arnhem Land about 1958. It was founded by Buramara, a mission-influenced Aborigine. The scale or the suddenness of the encounter, and especially the degree of pressure or interference from the dominant culture by way of control, exploitation, or colonialization, usually precipitates the acculturative religious response.

Sensitivity to contacts with more sophisticated cultures

Some tribal peoples, on the other hand, have proved to be exceedingly sensitive to slight and indirect contacts that have contained features capable of being given important meanings in local cultural terms. Thus, isolated New Guinea highlanders, beyond the reach of government agents or missions, have developed incipient cargo cults (*e.g.*, Zona [Ghost] wind cults) after steel tools and cloth goods were filtered through their ordinary trading channels, along with stories of mysterious whites, who were probably first seen in connection with airplanes from about 1930 on. These whites were interpreted to be the long-awaited spirits of the ancestors now returning with abundant material wealth according to the hopes expressed in the tribal myths. For the highlanders this was a sudden and dramatic development requiring a new religious response that went beyond the gradual changes normally occurring in religions.

The acculturative religious movements are new in relation to the religious traditions of both the local and the invasive cultures. Their followers tend to be rejected by and to reject both those who seek to conserve the old traditions without change and those who make a complete conversion to the new religion of the dominant culture. The sources of the new movement, however, lie in the local and the invasive religions; and by various degrees of syncretism there emerges a new pattern of cultic and social forms, a new symbolic system, and a reforming ethic and distinctive ethos. As a working definition, new tribal religious movements can be described as

> a historically new development arising in the interaction between a tribal society and its religion and one of the higher cultures and its major religion, involving some substantial departure from the classical religious traditions of both the cultures concerned, in order to find renewal by reworking the rejected traditions into a different religious system.

The stages of the religious acculturative process

The term new development includes all forms and stages of the religious acculturative process—the embryonic stage of new ideas, the incipient stage of an individual with a new religious formulation but without followers, and the more explicit identifiable movement whereby a whole group transforms the old religious system, whether in a short-lived or local manner or in a more permanent and widespread fashion.

General causative factors. Earlier studies tended to explain the origin of these movements in terms of one or two major causes, usually drawn from those dealt with in the discipline of the scholar concerned or by one single general cause—extreme psychological, social, or cultural strain. It is now recognized, however, that a large number of factors may be at work in complex situations that may vary considerably from one area to another. Four kinds of causal factors may conveniently be considered: the situational or acculturative; the contributing; the precipitative; and the enabling factors.

The situational or acculturative factor. The matrix, or the general situation within which the appearances of new religious movements occur, has already been described, including the disturbing effects on a tribal people of interaction with a dominant society. This is a necessary but not a sufficient cause because not all people in such situations react in this particular way.

Contributing factors. Several contributing factors are significant in the rise of the new religious movements. (1) The psychological stress and conflict felt by individuals in unfamiliar or rapidly changing situations may cause them to be confused, powerless, and frustrated, especially if they are able or ambitious. (2) Because of the cultural and social disintegration experienced in tribal life, the new movements provide members of new social groups with a strong sense of belonging and with new ways of life. (3) Moral conflicts between the traditional and invading systems, with their different values and codes, are often resolved by the formation of new moral systems drawn from both cultures and sanctioned by the new religions. (4) Political domination, whether oppressive or paternalistic, in which traditional political structures have been eroded or replaced, are often countered by new religious movements, which provide alternative opportunities for organization and leadership, and, on occasion, a basis for political action. (5) Economic deprivation or exploitation, such as the loss of land, has contributed to the emergence of new religious movements among the peoples of North America, South Africa, Rhodesia, and New Zealand. The change from subsistence to wage-labour economies, the use of forced or migrant labour, and the creation of a new range of wants have all added their disturbing effects. (6) The colonial situation as such, which usually contains most of the above fea-

tures, has been regarded as a major contributing factor, whether or not it was oppressive or more enlightened.

No close correlation, however, exists between any or all of these contributing factors and the rise of new religious movements. Ghana, for instance, has been one of the most prosperous of black African nations, with no white settlers, and has been politically independent since 1957; yet new religious movements appeared there in the 1960s more extensively than ever before.

Precipitative factors. Precipitative factors, such as severe personal crises or the traumatic effects of sudden epidemics (*e.g.*, a worldwide influenza epidemic in 1918), have provoked the appearances of new movements in situations that are already affected by the operation of deeper causes. A crisis precipitating the rise of a new religious movement may derive from new taxes or from severe economic depression, both of which were operative in the later Aladura ("prayer" people), prophet-healing groups in West Africa, in the early 1930s. In Melanesia, contact with the affluence of American armed forces in World War II precipitated a number of cargo cults; *i.e.*, groups that thrived on expectations of arrivals of special cargoes from supernatural sources. Elsewhere a movement might be touched off by the disciplining of a mission agent; casual contact with a nonwhite visitor, such as a Negro from an independent church in the United States; a miracle of healing, or the emergence of a charismatic individual with some special religious experience.

Types of crises that precipitate new religious movements

Enabling factors. The features of the two cultures involved that finally determine whether or not a new religious movement will appear and what shape it will assume may be called enabling factors. Among the major religions, Christianity seems to possess a peculiar potentiality for arousing new tribal religious movements. This potentiality has been attributed to Christianity's traditional appeal to the poor and the oppressed. Tribal peoples throughout the world have identified themselves with the suffering peoples of the Old Testament and their leaders with its great figures, especially the prophets Moses and Elijah. Biblical eschatology (doctrine of the last times) has provided a framework for the hope of a better future or a new world; and the tension between the Christian religion and Western culture has enabled tribal movements to draw upon the former in its conflicts with the latter. The dominant religion must, therefore, possess features suitable for application to and reinterpretation by the tribal peoples; and the religion of the latter requires beliefs and practices that can be reworked in the light of the invasive religion.

VARIATIONS AND FORMS

Any of the factors noted above may help to explain why only some peoples in the acculturative situation produce new religious movements, why different types of movements appear to characterize certain areas, or why a new movement in one tribe is accepted or rejected when it seeks to spread to others. New movements have proliferated in the West African peoples of the Ivory Coast, Ghana, Dahomey, and Nigeria, for example, but they have been rare or late in appearing in Sierra Leone, Liberia and Cameroon. The Ghost Dance of 1890, a North American Indian messianic movement, spread rapidly to more than 30 tribes of the Plains Indians but was ignored by the Navajo and the Hopi of the Southwest. Though cargo cults are characteristic of Melanesia, they are absent from the Trobriand Islands and New Caledonia and are rare in Polynesia, where the social system has much in common with that of these two areas of Melanesia. In the case of the cargo cults, the more developed Polynesian-type societies, with ranked social classes and either hereditary chiefs or a centralized political authority, have been better able either to oppose the invasive culture or to deal with it in its own terms and accommodate to it. Again, a psychological rather than a sociological reason has been suggested for the contrast between the dramatic cargo cults of the Melanesians, with their alleged proneness to ecstasy and violent movement and their ready loss of conscious control, and the new movements of the Plains Indians of the United States. The Plains Indians were marked by a striking degree of self-control; they had to struggle for unconsciousness and trance or visions; and when the vision was achieved there were no physical excesses but only peaceful receptions of the revelations.

Geographical variations

Some scholars have suggested that Protestant rather than Roman Catholic Christian missions have contributed to the appearance of new movements; and there appears to be some truth in this, connected especially with the Protestant policy of providing vernacular translations of the Bible. On the other hand, in the earlier centuries (*e.g.*, 16th–18th) there were many such movements in Latin America; and notable movements (*e.g.*, Maria Legio, or Legion of Mary, an independent church that arose in the 1960s) have emerged in recent times from a Catholic milieu in Africa.

Variations of incidence and of form are more likely to be connected with the different ways in which the various tribes have had contact with Westerners and Christian missions, and especially with the sequence in which the various aspects of Western culture have been encountered. Much depended on whether the earliest or the major contact was with traders, miners, ranchers, or farmers, with missionaries, with government officials, or with the military or the police. The missionaries might have been authoritarian or egalitarian, hostile to indigenous culture or appreciative of it, confined to one major Christian tradition or divided among many Christian denominations, concerned more with secular development, as were the early Quakers in North America who influenced the Seneca Indians, or with the rescue of souls before the imminent return of Christ, as was the case with many early missionaries in the Pacific.

Many tribal peoples who had made an initial mass response to Christianity involving a dramatic rejection of tribal religion later experienced various kinds of disappointments, and therefore turned to their own attempts at a new religion. Reactions and attempts of this kind include various themes or forms: (1) Because the return of Christ, the resurrection of the dead, and the new age failed to occur, tribal peoples produced their own millennial, messianic, or cargo cults. (2) Because the Bible did not prove to be the revealer of all the secrets of Western power and knowledge, cults arose around a prophet with his own new revelation or even with no more than a piece of paper with marks or diagrams or an alleged new book that was never publicly produced. (3) When it was discovered that the denominational Christianity first encountered was the religion of only one nation or that it was no older than the 16th or some later century, there began a search for the true original Christian church (*e.g.*, the African Greek Orthodox Church) or an attempt to create such themselves, as among many Aladura in Nigeria. (4) When Western medicine introduced by missionaries failed to show that it dealt with the spirit causes of sickness and was inadequate in many sicknesses, especially in psychic disorders and in epidemics such as that of 1918 (influenza), healing by other and more spiritual means figured prominently in new religious movements all over the world. (5) When second-generation Christians, who lacked the psychological rewards of intimate relationships with missionaries and the dramatic break from the past enjoyed by their fathers, discovered that they had only the administrative and financial responsibilities of church membership as replacements, they turned to their own churches with more immediate spiritual rewards and simpler organizational demands.

Reactions to Christianity that led to new religious movements

CHARACTERISTIC FEATURES

In spite of the diversity of movements and tribal backgrounds, it is possible to identify a wide range of characteristic features.

Origin in mystical experiences. The usual origin of those movements is a mystical experience of some contact with the spirit world through a dream, trance, coma, or apparently fatal sickness. Prophets often report having died and met the supreme God, Jesus, or the angels, or

the ancestors or culture hero in heaven. After being instructed in a new way of life and religion, they returned equipped with a new teaching, perhaps a new sacred book or its equivalent, special rituals, songs, and dances, or the power to work miracles, especially healing.

Emphasis on a supreme and personal God. The spirits and divinities that operated in the traditional religions are likely, in the new religions, to be ignored, demoted, or reinterpreted as angels or even as the devil; and the emphasis will be on a single supreme and personal God. This Being, or his agents, is viewed as being responsible for the call and commission of the founder and for the charter and sanctions of the new movement.

The nature of charismatic leaders

Charismatic leadership. An individual leader who has had some such experience often possesses charismatic qualities. His peculiar nature and experience place a distinctive stamp upon the movement, whether he be primarily a prophet, preacher, messiah, healer, wonderworker, remote mystic, or one with political gifts. Especially notable is the extent to which women have been founders and leaders (*e.g.*, the Lumpa Church in Zambia, the Aladura churches in West Africa, or the Maria Legio in East Africa).

Institutional leadership. The charismatic leader has often been balanced sooner or later by others with organizational gifts who have institutionalized the movement or even redirected it into more secular channels for political action. The husband of Alice Lenshina, the leader of the Lumpa ("higher") Church of Zambia, and elders of that church seem to have played some such role from an early stage.

Rejection of traditional ways. A selective but dramatic rejection of many of the traditional ways has been a prelude to a radically new order that comes to be expected. Members of cargo cults may kill the pigs, destroy the food stores, and cease gardening. Followers of Siberian religious movements have burnt the shaman's drums, and those of North American movements have thrown away the medicine bags. In most cases there is strong hostility to the continued employment of magic and a sustained attack on witchcraft. Other traditional practices, such as polygamy and reliance upon dreams, however, have been defended against Christian criticisms.

Missionary zeal. The new way may be confined to a single tribe but it often transcends ethnic boundaries and offers a universalistic faith. This is expressed in a remarkable missionary zeal that was quite unknown in the original tribal faith and may result in the religion spreading from contact areas to pre-contact areas, as was the case with new religions that were carried to the Nunamiut Eskimos in the Brooks Range in Alaska by traders who had met Quakers on the coast.

Moral reform. Prominence is given to moral reform in the face of the breakdown of traditional codes and sanctions. The moral teaching may reinforce tribal practices or borrow new elements from the invasive culture, such as an insistence upon monogamy. Common features are: a stress upon love, peaceableness, sexual discipline, and industry. There is often a strong ascetic aspect, with a prohibition against tobacco and, especially, alcohol.

New symbolic forms. New rituals, symbolisms, and forms of worship appear, drawing upon the resources of both of the religions involved and sometimes showing considerable liturgical creativity.

New voluntaristic organizations. New organizations of a voluntary type are developed, with new roles filled by many officials with titles, ranks, and uniforms or insignia. This new community replaces or transcends the old tribal groups and may range from amorphous, loosely associated groups, such as the Native American Church that uses peyote (a part of a cactus that produces hallucinogenic effects), to highly integrated Western-style bodies, like some of the larger African independent churches.

Promise of definite blessings. In the new religions there is an offer of definite concrete blessings—either here and now in the form of healing, revelations or "messages," personal success, and protection from evil powers, or else in the nearer future in a new order (promising plenty, health, peace, and freedom from oppression) that will appear through some cataclysmic event. This new order may be either a recovery of lost lands or resources, an earlier state of sinlessness and freedom, or the inauguration of a great improvement in which members of the new religion will share all of the blessings and powers of the invasive group or even transcend these in some future paradise.

The forms of rewards to those who participate

Dependence on a transcendent being and compliance with moral and ritual requirements. The securing of these new blessings depends upon the action of someone from the spirit world, ancestors or culture heroes, guardian angels, Jesus, the spirit, or the deceased founder returning from the dead. It also depends, however, on faithful observance of the moral and ritual requirements of the new religion.

Concern for renewal and acceptance. Throughout these movements there also runs a deep concern for personal and spiritual renewal and for the assumption of full spiritual autonomy, responsibility, and dignity in the eyes of the world. One strand in this may separate into political forms of rebellion or nationalism and into attitudes that are anti-white or anti-Christian; but another element looks to the contribution that the tribal peoples may make even to the sophisticated peoples of the dominant culture and thus to the whole world.

CLASSIFICATION AND TYPOLOGIES

Since the first classification of the new religious movements among tribal peoples as "nativistic movements" (in 1943), social scientists have endeavoured to improve on this term in their search for a general theory that would also include movements outside the kind of acculturative situation here described. In the 1960s this attempt was criticized as premature and somewhat artificial, and it was suggested that it is better for each discipline to classify the movements according to its own categories and for its own purposes and to include nontribal phenomena as it sees fit, without attempting a single all-purpose definitive system. Thus, sociology can explore the relation of the movements to tribal social and kinship systems, or to the sect-church classification, and endeavour to classify such various forms as inchoate prophet or mass movements, clienteles dealing with a specialist practitioner (such as a healer), congregational or churchlike organizations, or new communities and holy cities. Yet, some of the anthropologists' terms remain useful for descriptive purposes ("nativistic," "reformative," "revivalistic") in particular cases; other terms may be useful in a regional context (such as "cargo" in Oceania or "Zionist" and "Ethiopian" in southern Africa). One attempt to secure a working classification for a whole culture area, Africa, was forced to fall back on a mixed system of religious and historical categories.

Forms of classification

The simplest classification may be derived from the relation of the new movement to the two religions concerned. Thus, it would be possible to envisage a continuum embracing various degrees of syncretism in the range of possible types between a traditional tribal religion and an indigenous church that, for example, represents some form of Christian orthodoxy. New movements would then fall between these two poles, with neo-traditional movements (new forms of traditional indigenous religions) at the tribal end of the spectrum, followed by various degrees of syncretism in moving toward so-called Hebraist bodies (identifying with Israel; *i.e.*, the Hebrews or the Jews, such as the Ras Tafarians, a Jamaican-based Negro group that believes that the blacks are the true Jews) and independent churches at the other end. As an alternative response, at the tribal end, in cases in which traditional religion has been eroded, there may be a revival of magical procedures or of new witch finding movements. At the church end of the spectrum, the alternative responses are to be seen in the separation of various secular organizations from the original matrix of the religious movement.

Alongside this type of continuum and, in general, in step with it, there is another continuum representing the relation to the acculturative process. The two poles here are: total rejection, represented by complete indifference or

withdrawal into isolation, and total acceptance, or complete assimilation. Pure forms of either polar situation probably do not occur; but approximations to such forms are found, for example, in the conservatism of the Tewa and Hopi Indians of New Mexico and Arizona and the Seri Indians of Baja California and, at the other extreme, the assimilation of individual Indians to Western culture or the *évolués* ("assimilated ones") in French-speaking Africa. Along the intervening spectrum there are stages that can be called contra-acculturative (also regressive, nativistic, or revivalistic), which correspond to neo-traditional religious movements, followed by various degrees of semi-acculturation corresponding to degrees of religious syncretism, and then examples of pro-acculturation (also progressive, acceptive, or assimilative) represented by Hebraist movements and independent churches.

This religio-cultural method of classification is for descriptive and comparative purposes only. New movements may commence at any point on these continua, may change gradually or by mutations of form, and may move toward either pole. The overall tendency, however, especially for those that continue for a generation or more, is to move from the traditional to the more fully acculturated and invasive religion's position, as may be noted, for example, in the later introduction of the Bible into some Indian Shaker churches of the U.S. Pacific Northwest and into peyote groups, and in the Ringatu, a New Zealand Maori tribal prophetic movement, and into moves toward leadership training and association with the older churches by the African independent churches and movements.

HISTORY OF NEW MOVEMENTS IN MAJOR CULTURAL AREAS

Latin America and the Caribbean. *Latin America.* Approximately 40 identifiable new religious movements have been recorded among the South American Indian population, and others probably have escaped notice. The figure does not include the millennial movements among the Tupí-Guaraní in the interior of eastern Brazil, who have travelled over vast distances in search of their mythological "land-without-evil"; these migrations have occurred periodically since before white contact and into the present century and are a traditional and not a new acculturative phenomenon, even though they may have been aggravated by the advent of the whites. The "land-without-evil" theme, however, was emphasized in many of the millennial, syncretistic, and anti-white movements that appeared in the 16th century among Indians in more continuous contact with Europeans as slaves, mine or plantation workers, or converts.

The "land-without-evil" theme

The earliest recorded new religious movement was in 1546 in Colombia, followed by others in 1576, 1603, and 1613, when a cult of Luiz Andrea combined the worship of Christ and John the Baptist with the local divinity Buciraco. Among the Chiriguano Indians in what is modern Bolivia a young man known as Santiago seems to have led a reforming movement about 1571–73. In nearby Paraguay there were large numbers of "man-gods" and messianic movements reported by the Jesuit missionaries of the 16th and 17th centuries. The most fully recorded movement was one led by Obera, a Guaraní chief much influenced by Christianity, who claimed to be the divine son of a virgin. He rebaptized his followers and exhorted them to sing and dance rather than work for future blessing and in 1579 led an unsuccessful revolt.

Similar movements are recorded as early as 1578 in the Bahia region of Brazil among the semi-Christianized Tupinambá Indians. A most remarkable early movement occurred around 1583, with a church organized in imitation of the Jesuit missions, complete with hierarchy under an Indian pope, priests hearing confessions and conducting mass, schools with imitation books made from bark, and missionaries spreading the movement to other tribes. Traditional millennial beliefs included the return of the ancestors by ship to destroy the Portuguese oppressors. There were few Brazilian movements in the 17th and 18th centuries, when Indian slaves had been replaced by Negro slaves and had subsequently retired beyond white contacts to the Amazonian forests. When white settlers began penetrating the Brazilian interior in the mid-19th century, further millennial movements appeared; the "Christs" were reincarnated culture heroes, the Christian features in the syncretism were slender, and all were eventually suppressed.

In contrast to the Santiago movement of the 16th century, later examples in Bolivia, especially among the Chiriguano, took the form of religiously inspired revolts with messianic (salvatory figure) features. The first was reported in 1778 and the last in 1892, when a young prophet named Apiawaiki assured his followers that the Bolivian soldiers' bullets were mere water. In Peru the earliest such movement precipitated a Quechua (Inca) revolt of 1565, but the most remarkable was one led in 1742 by Juan Santos Atahualpa, who was educated and had been to Angola (in Africa) and Spain. Returning to Peru, he called himself after the Inca emperor Atahualpa and declared that God had sent him to restore the Inca Empire and free the Indians from Spanish oppression; in the new era there would be an Indian Catholic Church with native clergy. The Spaniards failed to defeat the movement, which lived on for some time in the remote highlands.

The movement of Atahualpa

In Central America, somewhat similar movements of revolt inspired by a new religious formulation have occurred ever since a messiah arose among the Quiché of Guatemala in 1530. One of the most notable revolts was led by a young Tzeltal prophetess in Mexico, Maria Candelaria, as a result of her vision of the Virgin Mary in 1712; but after initial wide success the movement was crushed by the Spanish.

The Caribbean area. Since about 1846 the Cariban-speaking tribes in the hinterland of Guyana have produced a series of messiahs or prophets who have claimed to have visited heaven and returned with a new religion. One of these movements, the Hallelujah religion—first reported in 1884—can be traced to a certain Bichiwung, who had probably visited England. The religion continued in the 1970s as a syncretistic system with a strong moral discipline and has been treated by the Anglican mission in the area as an ally in facing social disruption and as a potential prayer tradition within the Anglican Church.

The complex acculturative and syncretistic religious history of the Caribbean culture area is perhaps better studied in terms of folk religion. Some movements are primarily survivals of African religious and magic systems, perhaps with occasional Caribbean Indian elements: the former Nyame cult in Jamaica and similar cults among the bush Negroes of Surinam, or current "Obeah" magic (based on the Ashanti *obi* ["priest"] practices of removing evil spirits from, or placing them on, people) in Jamaica, the Bahamas, and the Black Caribs of Honduras. Others are best described as Afro-Christian syncretisms: in Jamaica, the older spirit Myallism, now almost extinct, the Pocomania and Revival Zionism cults since the Great (Christian) Revival of 1861–62, the spirit-possession Convince and Kumina cults connected with the Maroons ("runaway slaves," from the Spanish *cimarrones,* living in the Blue Mountains of eastern Jamaica), and the more recent Ras Tafarians; the Shango cult of Trinidad and Grenada; and the Rada (Dahomean-Catholic) cult of Trinidad; voodoo in Haiti; and Santería in Cuba. Others again are somewhat Africanized forms of mission or revival Christianity, such as the Jamaica Native Baptist Free Church of Alexander Bedward, a 19th– 20th-century nearly illiterate labourer, the so-called Jumpers of the Church of God in the Bahamas, or the many prophet and healing cults.

North America. *Eastern and central United States.* The tribal peoples of the North American continent have produced approximately 100 distinguishable religious movements since the advent of the whites, most of these being in what later became the United States. The first firm evidence of such movements shows a whole series of prophets among the Delawares after they had been thoroughly demoralized by the invasive culture. In 1745 David Brainerd, the first missionary among them, was impressed with what seemed to be "like true religion"

in a nameless prophet who sought to stem alcoholism and reform his people on the basis of a new revelation from God. Other prophets followed: Papoonan, with a similar basis for his town in 1758; an old prophet at Assinisink in 1760 with some booklike equivalent of the Bible; and, in the Ohio country, Neolin, "The Enlightened," who won converts from many tribes and gave spiritual support to Pontiac, an Ottawa chief, in his attack on Detroit in 1763. After Pontiac's War, the Delaware Indian Wangomend claimed to be God's preacher to the Ohio Indians, from 1766 to the 1790s; he was influenced by the Moravians but rejected white religion and also white customs, such as rum drinking and enslavement of Negroes, in favour of his own movement. In the decade 1800–10, when the Delaware nation was attempting to restore its shattered life in Indiana, a former Moravian prophetess named Beade had a series of visions in 1805 and initiated religious reforms.

Various leaders of American Indian new religions

The Delaware were also involved in the widespread movement of tribes on the Midwest frontier when the great chief Tecumseh sought to unite them against the Americans in 1805–12, supported by his brother the Prophet, or Tenskwatawa, whose message included rejection of shamanism (a belief system centring on the psychic transformation and healing powers of certain religious personages), magic, and the old healing ways, and also of white religion and culture, in favour of a new strict morality. Tecumseh died and the end of the Prophet's influence occurred in the War of 1812.

At about the same time (*i.e.*, the late 18th and the early 19th centuries) a Seneca prophet, Ganioda'yo (Handsome Lake), was establishing a revitalizing and modernizing religion that syncretized both old and Christian beliefs and encouraged limited adoption of white ways; this remains the religion of some 5,000 Iroquois. A similar adoption of animal husbandry and agriculture from the whites, together with a strong moral code rejecting alcohol, marked the syncretistic teaching of the Indian prophet Kennekuk, who transformed a section of his Kickapoo people in Illinois and Kansas from 1827 until his death in 1852; a small Kennekuk church still existed in Kansas in the 1950s.

As the frontier of white settlement moved west in the 19th century, other new movements appeared among the Winnebago in Iowa (those of Wabokieshiek in 1832 and of Patheske in 1852–53), the Potawatomi (1883–*c.* 1890), and the Crow of Montana (1887). The Ketoowa Society, an Oklahoma Cherokee movement, led by Redbird Smith from 1896 until he died in 1918, was remarkable as a nativistic religious movement with neither prophet nor visions.

Northwestern United States. In the plateau and coastal areas of the Northwest the background of many new movements was the indigenous "prophet dance," which waxed and waned as different leaders were inspired through visions. The central rite was a circular dance that, it was believed, would hasten the imminent return of the dead and renewal of the world. From the 1820s, Christianized forms appeared among the Flathead, the Nez Percé, and other tribes of the Pacific Northwest; and by the mid-19th century there arose cults such as that of Smohalla (the Preacher) and the prophet dance of the Umatilla prophet Luls. The latter's cult met on Sundays and advocated a strict morality and monotheistic faith without millennial features, in contrast to the shamanism and individual vision quests that were persistent features of the traditional indigenous religions. Millennial forms, however, appeared in the famous Ghost Dances that spread from the Northern Paiute in Nevada; the first instance of this phenomenon penetrated westward in 1860–73 and the second, inspired by Wovoka "the messiah" (who died in 1932), spread eastward through the Plains tribes in the late 1880s, culminating in the defeat of the Sioux Indians at the Battle of Wounded Knee in 1890.

The rise of the Ghost Dances

Christian elements appear in differing degrees in the Indian Shaker Church (unconnected with the white Shakers) of the Northwest derived from John and Mary Slocum, Squaxon Indians, in 1881–82, and in the Native American Church that has grown out of the peyote cults since the 1880s and is now the largest of the new movements ever to have appeared in North America (see also PHARMACOLOGICAL CULTS).

Southwestern United States. In the Southwest the Apache produced the cult of militaristic medicine man Nokadelklinny in 1881, the Dahgodiyah (They Will be Raised Up, *i.e.*, the dead) movement of 1903–07 begun by the medicine man Oaslahdn, which was also millennial but not anti-white, and the Holy Ground Religion, founded by Silas John Edwards in 1921. This last movement blends traditional and Christian symbolism and ritual, emphasizes morality and monotheism, and has absorbed Jesus into one of the mythological figures (Naiyenesgani) of the Apache; it has also survived the imprisonment of its founder from 1924–54. In the 19th century the Papago of Arizona and northern Mexico developed their own cult of St. Francis, quite independently of the Catholic Church, and this spread widely between 1890–1910. In 1906 a Papago group inspired by Protestant evangelists called themselves "Israelites," and some of these waited for the expected end of the world.

Most of the above movements may be placed in terms of classification nearer to the nativistic or neo-traditional end of the spectrum; but the 20th century has witnessed the emergence of Indian independent churches akin to those common in Africa. In Oklahoma there are a number that are Baptist in type; in Arizona the Hopi Mission Church and the Pima Independent Church and, in Florida, the Miccosukee Independent Indian Church emerged from Baptist missions; in Arizona the Mohave Mission Church derived from Presbyterian work, and the San Carlos Apache Independent Church from that of the Lutherans. The only earlier example of this type is the independent church of the Narraganset Indians in Rhode Island, which has remained a force for tribal identity since the 1740s.

In general, movements in the United States have tended to move from resistance with violence towards peaceful co-existence, from millenarian to nonmillenarian forms, and from nativistic to more Christian forms as in the independent churches.

Canada, Alaska, and Greenland. In Canada there have been over 20 indigenous movements reported, beginning with imitations of Roman Catholic missions among the Micmac of the east in the late 17th and 18th centuries. Others, mostly in the west, appeared throughout the 19th century and into the 20th century and derived from prophets with some visionary experience who then introduced ideas of a single supreme God and a few Christian symbols or rituals. The best recorded is Bini, a medicine man of the Carrier people, who introduced the sabbath, public confession, the sign of the cross, and went about preaching until his death about 1870. Two movements have taken the form of independent churches: that of the shaman Albert Tritt among the Kutchin of Alaska, from about 1910 until the 1930s; and the Christian Band of Workers, early in the 20th century, at Fort Simpson, Canada. The major movements in the United States have spread into Canada—Handsome Lake, the Ghost Dance (minimally), the Shaker, and Native American churches; Canadian movements have mostly been local and more short-lived.

This has also been true of the movements among the Eskimo, starting from the "great revival" of the prophet Habbakuk in a south Greenland Christian community at Evighedsfjörd, in 1790. Another nativistic Greenland movement, that of Matthew "the great sage" at Fredericksdal in 1853, expected the end of the world. In Alaska new religious forms appeared in the 1890s and 1900s among the Nunamiut, and later in the Hudson Bay area there was a nativistic prophet, Uming, from 1919 to 1922, and the millennial movement on the Belcher Islands from 1941 to *c.* 1942, both of these being influenced by access to the Bible.

Eskimo nativistic movements

Africa. In 1968, according to one estimate, some 6,000 movements had arisen in Africa since the 1880s, even excluding the neo-traditional forms. The concentration of these movements in sub-Saharan Africa raises the

question as to why there seems to be almost no corresponding effect in the tribal encounter with Islām, unless it be found in such West African movements as postwar Hamallism, founded by Ḥamāllāh (died 1943), which is anti-Arab and has translated the Qur'ān into an African vernacular—a noteworthy action. Yorubaland in Nigeria raises the question: there, Western Christian and Arab Islāmic cultures penetrated about the same time and with equal success; the only reported new Islāmic movement is a conservative attempt to restore orthodox Islāmic life with no signs of African syncretism, though the same area has proliferated with new Christian syncretisms or independent churches. Certain features of Christianity may explain this situation, but the question awaits fuller examination.

South Africa. The earliest movements go back to the Portuguese period in the old Kingdom of the Congo in the 17th century; of these, the best known is the Antonian sect of a prophetess, Béatrice, that sought to become the national church of a restored and independent Congo. Béatrice, however, was burned alive in 1706. White settlement in South Africa was responsible for the next developments: the millennial prophecies of the Xhosa prophets Ntsikana and Nxele in the first decades of the 19th century and those of the later prophet Mhlakaza, which led to the near extinction of the Ndhlambe tribes when they destroyed their cattle and cereals in anticipation of the millennium in 1857. In South West Africa, Hendrik Witbooi, a Christian convert, became a prophet for the Nama people and was killed in conflict with the Germans in 1905. A similar tragedy attended the South African prophet Enoch Mgijima's "Israelites" when they defied the South African government in 1921. In movements like these and others in Bechuanaland (now Botswana), there was a strong nativistic and millenarian and anti-white emphasis, but the movements were gradually replaced by the more churchlike and often more Christian Ethiopian (independent all-African) and Zionist (all-African pentecostal type) bodies that continue today. By 1970 there were probably about 3,000,000 members in some 3,000 bodies of this kind in South Africa, with smaller but substantial numbers in Rhodesia and the other southern territories.

West Africa. In West Africa the developments have been much more peaceful and less millennial or messianic, as well as more concerned with reforming and applying Christianity in African terms. Neo-traditional movements have been a minority, the most outstanding being the National Church of Nigeria, which sought to restore worship of "the God of Africa" from 1948 and, in 1964, united with a similar Edo National Church, or Aruosa cult, founded in 1945 by the *oba* ("king") of Benin City.

Tendencies toward independent churches

Most movements, however, have been independent churches corresponding to the South African Ethiopian or Zionist types. The Ethiopian type appeared in 1888 in Ghana and especially in Nigeria, where churches of this kind form a well-established group known as "the African Churches," centred in Lagos. Since the 1920s, the main growth has been in the Zionist type, with emphasis on healing and revelations; these are known in Nigeria as the Aladura and in Ghana and elsewhere as the "spiritual churches"; in the Ivory Coast they are called Harriste (Harris) churches because most of these groups owe something to the influence of a mass movement aroused by the Liberian prophet William Wade Harris around 1913–15. The following estimates of numbers of distinct West African bodies applied early in the 1970s: a few in Sierra Leone but probably over 50 in Liberia, scores in the Ivory Coast, as many as 500 in Ghana, and some hundreds in Nigeria.

Central Africa. Considerable variation has developed in the incidence of movements in Central Africa: in the Cameroon a few fairly orthodox independent churches since the Native Baptist Church of 1888; in Chad and the Central African Republic some secessions—mostly small and short-lived—from Protestant missions since the 1950s; in Gabon the syncretistic Bwiti cult among the Fang, which has been moving to a more Christian content, since the 1890s; in Angola Simon Toco's Church of Our Lord Jesus Christ (also known as the Red Star Church) has been a substantial body since 1949. In Zaire (formerly the Belgian Congo) the early movements were strongly nativistic, anti-white, and prone to violence, as was the case of the Epikilipikili cult of 1904. Later movements in Zaire generally arose under the influence of the prophet Simon Kimbangu and his healing revival of 1921 and, to a lesser degree, of the Salvation Army after its arrival in 1935, such as the Khaki Church, or Église des Noirs (Church of the Blacks), of Simon-Pierre Mpadi, founded in 1939. The least syncretistic and most organized groups are now gathered in the Kimbanguist Church that became a member of the World Council of Churches in 1970. A total of some 400 distinct groups has been estimated for Zaire. In the Congo (Brazzaville) the Amicale movement of André Matswa, a successor of Simon Kimbangu, began in the 1920s with social and political concerns but developed in a more religious and messianic direction after his death in prison in 1942. In Zambia there was the Ethiopian Church of Barotseland as early as 1900 and the Kitawala, or Watch Tower movement, from 1908. The Watch Tower movement stemmed from the American body of this name (also known as Jehovah's Witnesses) and has had an extensive influence through Central Africa ever since. Among over 20 other groups in Zambia, the most famous has been the Lumpa Church, founded by the charismatic leader Alice Lenshina (*i.e.*, "Queen"), which has been in conflict with the government since 1964.

Eastern Africa. Of the areas in eastern Africa, Malawi is notable for the complex interaction of foreign and indigenous influences: the white missionary Joseph Booth, American Negro churches, the Watch Tower Bible and Tract Society, and South African Ethiopianism. In the earlier nationalist phases, a 1915 uprising against the British was influenced by the evangelist John Chilembwe and Elliott Kamwana's Watch Tower movement, which had been initiated in 1908. New bodies in Uganda have been comparatively few, partly because of the influence of the indigenous evangelical revival movement within the Anglican Church. The largest was the Society of the One Almighty God, which opposed Western medicine and claimed over 100,000 adherents by 1921 but has now virtually disappeared; the other notable movement is the African Greek Orthodox Church founded in 1929 by Reuben Spartas, an Anglican influenced by an American black nationalist, Marcus Garvey. Kenya shared in the Uganda movements but has produced a large number of movements of its own since 1929. Some have been nativistic revivals mixed with political nationalism, such as Dini ya Msambwa (Religion of the Ancestors); many others have stressed healing, like the Maria Legio; others again resemble their parent churches, such as the African Brotherhood Church (60,000 members in 1970), derived from the Africa Inland Mission and the Salvation Army in 1945, or the Church of Christ in Africa (about 75,000 members), derived from the Anglican Church in 1957. New religious movements in Tanzania and Mozambique have been smaller and much less numerous, but in Madagascar, where a short-lived syncretistic movement founded by Rainitscandavaka (a Merina tribesman) arose in 1833–34, there have been some 20 movements of the independent church form since the first in 1894.

Interaction of foreign and indigenous influences

Europe and Asia. Only one clear example of a new religious movement among tribal peoples is reported from Europe; the "Big Candle," or Kuga Sorta, a nativistic and millenarian movement among the Cheremis (a Finno-Ugric people) of the Upper Volga area from the 1870s. The main instance from Asian Russia is the millennial Burkhan (from the Mongolian word for Buddha) movement among the Altai Mountains Kalmyks. Founded in 1904 by the prophet Chot Chelpan, the Burkhan movement was anti-Russian and anti-Christian but with Christian elements; members burned the shamans' drums and rejected animal sacrifices but preserved traditional taboos and an indigenous term for its single divinity. In India there have been many examples of new religious movements since the late 18th century, chiefly among the hill tribal peoples, in response to a closer encounter with

New religious movements based on contacts with Hinduism or Buddhism

Hindu culture and religion or to a Western Christian influence. These have usually begun from a reforming prophet and have moved away from the tribal religion towards a monolatrous (worship of a single deity) form with a strict morality; some have been messianic and have led to revolts and violence.

Similarly, the marginal hill tribal peoples of Southeast Asia have produced a number of new religious movements. Ten or more with a Buddhist background, and sometimes with Christian elements, also have been reported among the Karen (a variety of tribal peoples) of Burma since the 1820s; at least two, the Leke (a messianic cult), founded by an unnamed couple, and Telakhon (Fruit of Wisdom), founded by Con Yu, have continued since the 1860s, and another new religious movement from this period took the form of an independent Karen Baptist Church. Among the Chin (a group of Mongoloid tribes inhabiting the mountain ranges separating Burma from Assam, India), a new religion, named after its founder Pau Cin Hau, in the 19th and 20th centuries replaced *nat* (spirits) worship and its expensive feasts with a more Christian form. In the 1950s the alleged inferiority of the aborigine Khmu people to the Lao people and Westerners in Laos was expressed in an embryonic millennial and cargo cult in which it is believed that ritual acts, including the killing of livestock, would enable the culture hero, Cûang, to return with fabulous wealth.

In the past century, as colonial administrations and Christian missions have penetrated the more intact tribal cultures of the Indonesian areas, new religions have arisen. The Pormalin movement, continuing from the 1870s into the 1960s in Sumatra, is a syncretistic movement with Christian elements. The Mejapi ("to hide oneself," *i.e.*, withdraw from a village) movements, reported in 1902, 1908, and the 1960s in Sulawesi, have been millennial; and at one period members abandoned farms and animals in expectation of joining the ancestors in the spirit world. Other apocalyptic movements, based on a belief in an intervention of the divine in history with accompanying cataclysmic events, have been the Parhudamdam religion among the Bataks in Sumatra around 1915–20, the Samin cults (founded by a peasant named Samin) at various times in central Java since the turn of the century, and the Njuli (Resurrection from Death) movements in southeast Borneo after World War I. All these were millennial and most came into contact with the government; only in the Njuli cults were there any Islāmic influences, in this case combined with Christian elements; these were also evident in the reforming Bungan movement from 1948 in Borneo, with its trinity of God Almighty, a saviour son, and Bungan, a divine wife or mother.

New religious movements in the Philippines

The Philippines exhibit all types of movements. There have been revised forms of traditional religion with a new moral emphasis, such as the Paluy cult founded by the prophet Angsui about 1896–98 among the Igorots ("non-Christian" mountain peoples of northern Luzon); syncretistic reform and accommodative movements, such as the Sapilada (founded by the reformer Pedro Degan), seeking economic improvement for the Igorots, from 1899 until the 1950s; and unsophisticated millenarianisms, especially the succession of such movements on Mindanao since the Tungud movement (founded by Mapakla, a Manobo tribesman) swept the area in 1908–10. A whole range of strongly nationalistic and often messianic movements opposed first to the Spanish and then to the American regimes: the Katipunan, or Highest and Most Respectable Society of the Sons of the People, founded by Andres Bonifacio (1892); Pulahan, a group of religio-political peoples who were identified by their red (*pula*) dress or turbans (1894); Colorum, a movement founded (1841) by Hermano Puli, also known as Apolinario de la Cruz, before the movement assumed its name (1897, with later revivals); Guardia de Honor, a peasant movement led by a certain Baltazar who founded a holy city known as Cabarvan (1897–*c.* 1919); and a host of messianic Rizalist cults (from 1897), based on a belief in the return of José Rizal, a hero martyred by the Spanish in 1896. Independent churches, such as the Iglesia ni Kristo founded in 1914 by Felix Manalo and hundreds of smaller bodies of varying degrees of syncretism, have increased even faster after Philippine independence in 1946.

Oceania and Australia. In the Pacific area, the most distinctive form of the new religious movements is found in Melanesia, where scores of millennial cargo cults hold a belief that an imminent new order is to be inaugurated by the arrival of a cargo of goods from supernatural sources. Among the better known examples are the "Vailala Madness" (1919) in Papua, the anti-white John Frum and Naked cults of the 1940s in the New Hebrides, the Buka cult of the 1930s, founded by the prophet Pako and his successors, and the more modernizing Masinga (Brotherhood) Rule after World War II in the Solomon Islands, and the Tuka (cult of immortality) apocalyptic movement of the 1870–80s in Fiji, founded by the prophet Ndungumoi. Other movements have been millennial but non-cargo, such as that founded by the nativistic anti-white prophet Tokeriu of Milne Bay in the 1890s; or neither millennial nor cargo, such as transtribal Taro cults founded by the prophet Buninia after 1914 in Papua, who promised easier growing of taro, the staple food, and especially the movement of the Paliau in the Admiralty Islands. The Paliau cargo cult began in 1946 as a modernizing utopian independent Christian community and has moved toward economic and political concerns, with its leader, Paliau, a member of the House of Assembly by the 1970s and a member of the Order of the British Empire (OBE). The main independent church type is the Christian Fellowship Church, formed about 1959 by Silas Eto as a somewhat heretical secession from the Methodists in the Solomon Islands.

Cargo features have occasionally appeared in Polynesia, as in the Mamaia (Flock of God) movement of 1826–40s in Tahiti or the brief Kapuvai cult, founded by the prophetess-healer Kapuvai, of 1947 in the Cook Islands. Mamaia was primarily an example of a nativistic millennial reaction to the early mass Christian conversions, and influenced the similar cult of the prophet Joe Gimlet, or Siovili, in Samoa in the 1830–40s. Among the Maori people of New Zealand the best known movements include the 19th-century prophet Papahurihia, the reformative but nationalistic King movement from the 1850s, the nativistic Pai Marire (Good and Peaceful) or Hauhauism (based on the Maori battle cry "Hau! Hau!" when the movement became militant) during the Maori wars from 1862, in contrast to Te Whiti's (a minor chief of the Taranaki tribe) millennial but modernizing and peaceful Parihaka community from 1869, the Ringatu religion from 1867, and the Ratana independent church, founded by the Maori prophet and healer Tahupotiki Ratana, from 1919. In Hawaii there were nativistic reactions, such as the prophetess Hapu cult about 1825, and King Kalakaua's more sophisticated attempt to revive traditional religion in 1886; otherwise there has been a range of indigenous independent churches.

Australian aborigines have produced a few embryonic nativistic movements in the 20th century and several in more developed form, such as the transtribal Kurrangara cult since the 1900s, the anti-white millennial Worgaia (poison) movement, with Jesus as a culture-hero, since the 1950s, and the peaceful Elcho Island adjustment movement from about 1958.

NEW RELIGIOUS MOVEMENTS AMONG TRIBAL PEOPLES TODAY AND FUTURE PROSPECTS

Areas in which new religious movements continue to appear

In some areas the main growth has passed or even ceased, but in others new movements continue to appear, especially in Africa and the Philippines. Their study is likely to increase and to become more systematically multidisciplinary and comparative across the cultural areas. More attention will be given to the historical setting and background, and to analysis and interpretation in terms of the phenomenology and history of religions. The movements themselves will inevitably learn more about one another and this will provide an inter-movement stimulus and critique.

Governments and development agencies may take a more positive interest in the potentiality of these popular and mass movements for modernization, for even the most nativistic movements have usually made some significant breach in the traditional order, and others have shown a capacity to operate transtribally and to initiate new social forms and economic projects as a religious voluntary society distinguished from politics and the state.

In areas where the dominant religion involved is Christianity, local older churches and missions have often changed since the 1950s from their traditional indifferent or hostile attitudes and now make serious attempts at understanding the new religious movements. In some cases the independent church forms have been admitted to Christian councils or are being assisted in training their leadership and in Bible study. Those concerned with mission policies have begun to learn from the successes and the failures of the new tribal movements, and there may be a growing interrelationship rendering Western theology less culturebound as it takes account of new modes of apprehension and forms of expression in other cultures. That many new nativistic or neo-traditional movements will appear does not seem likely, and those still at this end of the spectrum will probably either disappear or move towards the other more acculturated pole.

In general, the more sophisticated and developed societies no longer dismiss these movements as the fanatical mass hysterias of ignorant backward peoples. They are coming to appreciate such movements as signs of the dynamic, creative, and revitalizing capacities of tribal societies, which are able to produce their own leaders and reformers and their own transitional forms between the culture of the past and the invasive culture.

(H.W.T.)

Tribological Phenomena

Tribology is the study of the interaction of sliding surfaces. It includes three subjects: friction, wear, and lubrication. There is a difficulty in that friction is generally characterized as a branch of physics or mechanical engineering, wear is part of material science or metallurgy, while lubrication is a branch of chemistry. Tribology is thus a complex interdisciplinary subject and has suffered the same neglect as have other such subjects.

Definitions. The phenomena considered in tribology are among the most fundamental and most common of those encountered by man in his interaction with his largely solid environment. Many manifestations of tribology are beneficial and, indeed, make life possible as we know it. Many other effects of tribology, however, constitute serious nuisances, and careful design is necessary to overcome the inconvenience arising from excessive friction or wear. On an overall basis friction uses up, or wastes, a substantial amount of the energy generated by mankind, while much of his productive capacity is devoted to replacing objects made useless by wear. It is this waste of resources that induced at least one government in the middle 1960s to undertake a systematic effort to increase research and education in this area. The term tribology was introduced to characterize this activity.

Friction as a factor

Friction is the resistance to sliding of a solid when the resistance is produced by a contacting body. It is, therefore, a vital factor in the operation of most mechanisms. High friction is needed for the satisfactory functioning of nuts and bolts, paper clips, and tongs, as well as in the familiar processes of walking, gripping objects manually, and building piles of sand or of apples. Low friction, however, is desired in objects that are designed to move continuously, like engines, skis, and the internal mechanism of watches. Constant friction is required in brakes and clutches, as otherwise unpleasant jerky movement would be produced.

Friction has been studied as a branch of mechanics for many hundreds of years and its laws, as well as satisfactory methods of estimating the magnitude of friction, have been known for nearly two centuries. The mechanism of friction, namely, the exact process by which energy is lost as two surfaces slip past each other, is understood only in an incomplete way.

Wear is the removal of material from a solid surface as a result of the mechanical action exerted by another solid. It is such a universal phenomenon that rarely do two solid bodies slide over each other or even touch each other without measurable material transfer or material loss. Thus, coins become worn as a result of continued contact with human fingers; pencils become worn after sliding over paper; and rails become worn as a result of the continued rolling of train wheels over them. Only living things (*e.g.*, bone joints) are in general immune to the permanent damage caused by wear because only they have the property of healing through regrowth. And even a few living things do not heal themselves (*e.g.*, teeth in humans).

The systematic study of wear has been severely hampered by two factors: first, the existence of a number of separate wear processes, which has led to much confusion, especially in terminology; second, the difficulties caused by the small amounts of material involved in wear processes. These difficulties were greatly alleviated when radioactive isotopes of the common engineering metals (iron, copper, chromium, etc.) became available in the 1940s; tracer techniques using these radioisotopes permit measurements of wear, even in small amounts, while it is occurring. This has made it possible to identify types of wear and discover the laws of wear.

The use of lubricants

The use of lubricants, namely, substances introduced into the interface between sliding surfaces to diminish friction, is an ancient practice, and Egyptian pictures dating back 4,000 years show the application of lubricants to reduce the friction involved in dragging heavy monuments. In modern lubrication practice, the main concern is to reduce the wear that accompanies sliding and, at the same time, to design lubrication systems that will operate for long periods without inspection or maintenance.

A large number of different lubricants are in use at any one time, (a single major oil company may market many hundreds of different varieties), and no aspect of tribology receives as much attention as the development and testing of improved lubricants.

Parameters that influence friction. In almost all cases the friction force F, defined as the force required to produce or maintain sliding, is proportional to a force L which is normal to the surface, so that if a force smaller than F is applied to stationary surfaces no sliding occurs. The constant of proportionality, equal to the ratio of the two forces F/L, is called the coefficient of friction f or μ. This coefficient is a convenient way of characterizing a sliding situation, and thus the effect of various variables on friction is best discussed in terms of their effect on the friction coefficient.

The friction coefficient is independent of the area or the shape of the interface, that is, of the apparent region of contact. Indeed, the real contact is made over only a few small patches or junctions whose extent is not determined by the size of the apparent contact area.

The friction coefficient is nearly independent of the sliding speed (see Figure 1). In some situations, it takes a larger coefficient to initiate sliding (the static coefficient) than to maintain sliding (the kinetic coefficient).

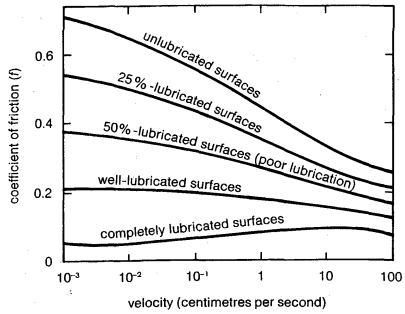

Figure 1: Plot of friction coefficient as a function of sliding velocity for low-carbon steel surfaces in various states of lubrication. Only for well-lubricated surfaces does the friction go up as the velocity goes up. In other cases the slopes are negative, thus allowing stick-slip to occur.

From E. Rabinowicz, *Friction and Wear of Materials* (©1965); John Wiley and Sons, Inc.

The friction coefficient is nearly independent of the surface roughness, although this fact might be hard to accept. The lowest friction is generally given by a surface with a fairly smooth but matte finish. Highly polished surfaces give somewhat higher friction because increased adhesion occurs, while very rough surfaces also give higher friction because there is some interlocking of surface high spots. Rough surfaces display relatively moderate friction because, while some of the contacts are sliding uphill, others are moving downhill.

Variation of friction with materials

Typical clean, unlubricated surfaces give friction coefficients in the range of 0.3 to 0.4, and this is true for metals, for inorganic nonmetals, and for organic polymers. The exceptions consist of a number of miscellaneous categories: (1) high friction coefficients (0.8 to 1.5) are given by clean, soft metals (*e.g.*, lead) and organic elastometers (*e.g.*, rubber); (2) low friction coefficients of about 0.2 are given by hard nonmetals (*e.g.*, diamond, tungsten carbide); (3) very low friction coefficients (0.1 to 0.05) are given by substances with layer lattice structures, (*e.g.*, graphite), by substances with low adhesion properties (*e.g.*, teflon), and by self-lubricating substances (*e.g.*, ice near its melting point when it is lubricated by a film of water). When different clean surfaces are brought into contact, the friction coefficient is generally that of the softer one. When surfaces of different extent of lubrication are combined, the surface with the larger extent of lubrication controls the friction. For walking, friction coefficients of 0.2 or more are required. It will be seen from the above tabulation, and it is confirmed by experience, that rubber makes a good shoe material while ice makes a poor walking surface.

Lubricants and contaminants

Lubricants often have a profound effect on the friction coefficient, surpassing other influences. Lubricants may be liquid or solid, but it has been found that a good liquid lubricant often forms a solid layer of molecular thickness on a sliding surface. Good lubricants in several categories (*e.g.*, metallic soaps, graphite films) are able to reduce the friction coefficient to as low as 0.05, but no lower. More typical values for liquid lubricants are in the range of 0.08 to 0.15.

Contaminants are lubricants that are not deliberately applied to a surface but are already present as a result of the manufacturing process or of previous handling. Typically, they reduce the friction to about 0.2, and sliding surfaces must generally be carefully cleaned to give friction coefficients above the 0.2 level when lubrication is not desired.

Effect of temperature

For unlubricated surfaces, friction is independent of temperature unless heating causes melting, oxidation, or other such drastic changes. Circumstances are far different, however, in the case of lubricated surfaces, since lubricants are generally effective only up to some definite limiting temperature (see Figure 2). Above that point they cease to function and the friction rises to the value applicable to unlubricated surfaces. This transition temperature is about 250° F for a bicycle oil, 350° F for an automobile engine oil, and 450° F for a jet engine lubricant.

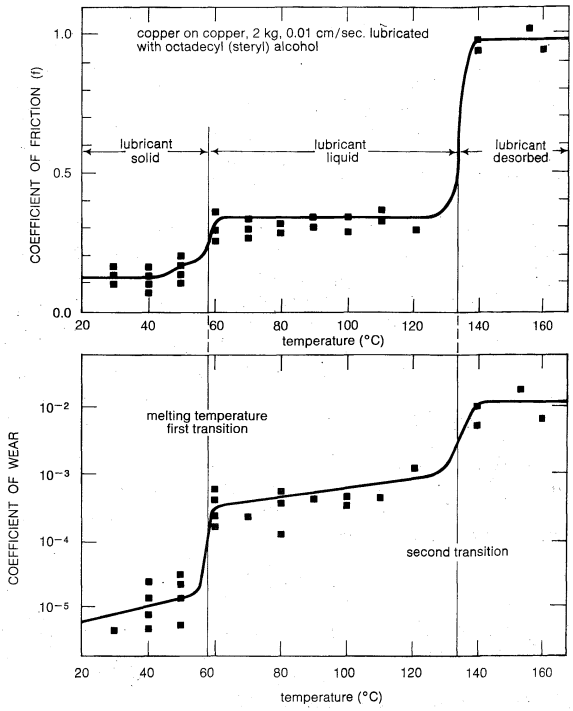

Figure 2: Plot of friction and wear as a function of temperature for copper surfaces lubricated by steryl alcohol (a long chain hydrocarbon with polar ending). There is an increase in friction and wear at the melting point of the lubricant (59° C); the lubricant completely loses its usefulness at a higher temperature (135° C). Above this temperature the friction and wear resemble those of unlubricated copper surfaces.
From E. Rabinowicz, *Friction and Wear of Materials* (© 1965); John Wiley and Sons, Inc.

Consequences of friction. A number of different phenomena occur as the results of frictional energy dissipation during sliding. Although some of these phenomena may have a limited degree of usefulness, they are classified essentially as nuisances.

The energy that must be applied in friction appears as a heat input to the sliding surfaces. Formerly, this frictional heat found use in the lighting of fires by rubbing sticks together, and the same mechanism is still encountered in the striking of matches. Most manifestations of frictional heat, however, constitute a severe nuisance since the sliding surfaces often become too hot if left unprotected, and cooling fluid must be circulated through the system to prevent surface damage.

Types of wear. Four types of material loss are associated with sliding surfaces. Each has different causes, proceeds in a different manner and, if not desired, is cured in a different fashion. They are listed here in order of diminishing importance.

Adhesive wear, the most common removal process, arises from the strong adhesive forces that are generated at the interface of two solid materials. It occasionally happens during sliding that the junctions at the interface are broken not at the original interface but inside one of the two bodies and, consequently, a wear particle is formed. The wear particle sticks initially to the surface to which it was transferred, later it may be retransferred to its original surface, but eventually it will come off in loose form and constitute a loss of material from the sliding system. A surface undergoing adhesive wear is easily characterized under high optical magnification by the irregular-appearing particles adhering to the surface.

The mathematical formulation for adhesive wear states that for any pair of sliding materials there is a probability that the breaking up of a junction will lead to formation of a wear particle, and the linear dimensions of the particle are assumed to be of the same magnitude as those of the junction. Thus, the volume (V) of wear particles formed on sliding a distance is derived by multiplying the distance moved (x), the applied load (L), and the probability factor (k), and dividing by the penetration hardness of the softer material (p):

$$V = \frac{kLx}{3p}.$$

The constant k is often referred to as the coefficient of adhesive wear. (It is found empirically for any two surfaces.)

Unfortunately, high accuracy in computing wear rates is not possible because adhesive wear depends greatly on the exact state of surface cleanliness and repeat experiments designed to produce exactly the same surface conditions often give wear rates that differ by factors of two or even three. Typical values of wear constant for a number of sliding situations are shown in Table 1. If two materials of different hardness are slid together, Table 1 gives the wear of the softer material. It is found that the harder material also undergoes wear, usually at a rate between one-tenth and one-hundredth that of the softer material.

Table 1: Values of Wear

materials combination	value of k*
Carefully cleaned surfaces	
Metal on similar metal	5×10^{-3}
Metal on dissimilar metal	2×10^{-4}
Nonmetal on metal or on nonmetal	10^{-5}
Indifferently lubricated surfaces	
All categories	10^{-5}
Very well lubricated surfaces	
Metal on metal	10^{-7}
Nonmetal on metal or nonmetal	10^{-6}

*Value of the softer of two dissimilar metals.

Abrasive wear arises when a hard rough surface slides over a softer surface. The hard material penetrates below the surface and during sliding scratches a groove. Some of the material originally in the groove is pushed aside and the remainder is lifted by the cutting action above the surface and is removed in the form of a chip. A similar form of wear involves two soft surfaces and hard abrasive grains. The grains adhere momentarily to one of the surfaces and abrade material from the other. A surface that has undergone abrasive wear shows characteristic sharp scratches in the sliding direction.

Abrasive wear is governed by the same basic equation as that for adhesive wear: the volume worn away is directly proportional to the normal load, the distance slid, and the inverse of the hardness. The constant of proportionality k in this case is a function of the surface roughness and the roughest surfaces produce the highest abrasive wear rates. Typical values of k are shown in Table 2. If the file or abrasive paper is well worn, the abrasive wear drops by about a factor of ten.

Table 2: Typical Values During Abrasive Wear

process	value of k
Filing (sharp file)	2×10^{-1}
Lapping or sandpapering (fresh abrasive paper)	5×10^{-2}
Damage caused by loose abrasive grains	5×10^{-3}
Polishing	5×10^{-4}

Normally, when a surface corrodes, the products of corrosion tend to stay on the surface, thus slowing down further corrosion. But if sliding takes place, the sliding action removes the surface deposits continuously and corrosion takes place more rapidly. Thus, metal surfaces sliding at high temperatures in air are often subject to corrosive wear, because, as the oxide layer is removed during sliding, naked metal is exposed and further corrosion takes place. A surface that has experienced corrosive wear generally has a relatively smooth, matte appearance.

Surface-fatigue wear is observed during repeated sliding or rolling over the same surface. The repetition may cause surface or subsurface fatigue cracks to form. Eventually this leads to the breakup of the surface with the formation of large fragments, leaving large pits in the surface. A ball bearing, for example, may operate for some millions of revolutions without any external evidence of wear until,

suddenly, a fragment separates from the surface. Soon other fragments are formed and the surface of the bearing and of the balls becomes completely destroyed.

Surface fatigue wear is the main form of wear for rolling elements, such as bearings and gears, since they are relatively immune to other forms of wear. For sliding surfaces, adhesive wear usually proceeds sufficiently rapidly so that there is no time for fatigue to occur.

Stick-slip oscillations. It has been pointed out that friction coefficients are nearly independent of sliding velocity and, in a typical case, increasing the sliding speed by a factor of 10 may raise or lower the friction coefficient by 5 or 10 percent. If the friction is reduced as the sliding speed increases (a so-called negative characteristic) then frictional oscillations, often called stick-slip, can arise. Musical instruments of the violin family produce their sound only by means of friction oscillations, and treatment of the violin bow with rosin is necessary to maintain the negative friction characteristic. Other manifestations of stick-slip are less tuneful, being the creaking, squeaking, and groaning noises often produced by sliding systems.

Well-lubricated systems do not squeak, while poorly lubricated ones frequently do. Thus, if the lubricant in a sliding system disappears or degrades, stick-slip will frequently set in, indicating that relubrication is in order.

Frictional electricity. The fact that two nonconducting surfaces become oppositely charged electrically during sliding has been known for a long time, and indeed this was the earliest method for generating electrical charge. Nowadays, frictional electricity exists mainly as a minor annoyance sometimes encountered by people walking on carpeted floors in winter, who generate a spark on touching a grounded object like a doorknob. Occasionally, sparks of this type are produced in chemical plants or in oil transportation facilities and have been known to start fires or even explosions.

Historical development of theories of friction. The first research study on friction was carried out by Leonardo da Vinci in the 15th century but his results were not published. Credit for discovering the laws of friction is given to G. Amontons (1699). His work was concerned only with static friction, or the friction of objects at rest, and it was only after Newton's laws of motion were enunciated that the friction of moving bodies was analyzed.

Early workers, most prominently Coulomb (1781), realized that there are two possible explanations of friction, that is, that it is due either to adhesion between the contacting surfaces or to the interlocking of surface protuberances. In fact, they wrongly chose the roughness theory because they felt that friction should be proportional to the area of the bodies in contact, which it is not. Widespread public belief in the roughness theory still persists even though the adhesion theory has been generally accepted by researchers in tribology since about 1945.

Adhesion theory

Modern research has adopted the adhesion theory because it explains why friction is largely independent of surface roughness, since even smooth surfaces often give very high friction, and because a mode of analysis published around 1940 by several groups of workers explains why friction is independent of the contact area. It is hypothesized that the interface between contacting solids consists of two types of region, one being a small number of highly stressed spots or junctions where the surfaces come into intimate contact (their atoms touch one another), the other being all the rest of the contacting area where there is no interaction between the surfaces. Friction originates only at the junctions, whose total area is independent of the apparent area of contact.

If two surfaces are pressed into contact, the pressure at the junctions is normally so high that deformation occurs and continues until the real area of contact A_r reaches a value given by L/p, in which L is the load and p the penetration hardness of the softer of the two materials in contact. In order to undertake sliding, the junction must be sheared, and the force F to do this is given by sA_r in which s is the shear stress of interface. In most unlubricated situations, s is the bulk shear stress of the softer material at the interface. The friction coefficient, f, is then derived by

$$f = \frac{F}{L} = \frac{sA_r}{pA_r} = \frac{s}{p}$$

and is seen to be the ratio of two quite similar plastic properties of the softer material. Not involved in the equation are parameters such as the load, the surface area, the sliding velocity, and the surface roughness and, in fact, the friction coefficient is largely independent of them.

Surface energy theory

One of the main problems associated with the adhesion theory is that it predicts essentially the same friction coefficient for all unlubricated solids because the ratio s/p is a constant for all solids, whereas, in fact, there is a range in values from about 2.0 for a very soft metal on itself to about 0.2 for a very hard nonmetal on itself.

A number of modifications of the adhesion theory have been suggested to allow facts such as this to be explicitly accommodated. One in particular is the surface energy theory according to which the area of contact between sliding surfaces is determined not only by plastic deformation at the junctions but also by adhesive forces between the two surfaces. An expression for the friction coefficient has been derived in the form

$$f = \frac{s}{p} + C\frac{W_{ab}}{p}$$

in which W_{ab} is the energy of adhesion of the interface, while the parameter C is a constant whose value is determined by the surface geometry. This equation has given good agreement with experimental values. The surface energy theory also gives a value for the diameter d of wear particles formed during adhesive wear, the relevant equation being

$$d = \frac{60{,}000\ W_{ab}}{p}$$

Lubrication, the reduction of friction. The lowest friction combined with an absence of wear occurs in cases of full fluid lubrication in which a thick, continuous film of fluid separates the sliding surfaces. To enable such a film to form, fresh lubricant has to be guided continually into the interface, the overall pressure has to be kept low, the sliding speed high, the lubricant should have a high viscosity, and the sliding surface should be smooth. In the bearings of rotating machinery, fluid lubrication is highly desirable because then the energy loss is small (typical friction coefficient values are as low as .001), and the only wear that takes place does so during start-up and slowdown. Occasionally, fluid lubrication occurs when it is unwanted, as between the tires and ground for an airplane landing on a smooth wet runway, so that a rough runway to prevent this is desirable.

For surfaces operating at high pressures, for example within a gear or a ball bearing, lubrication is often by a somewhat different mechanism, one in which sizeable elastic deformation of the sliding surfaces occurs, thus increasing the area of contact until a full fluid film can remain at the interface. This is known as elastohydrodynamic lubrication. The most important property of a lubricant that determines its ability to perform under hydrodynamic as well as elastohydrodynamic conditions is its viscosity, or resistance to shear.

In boundary lubrication, which takes place at high loads and low speeds, the lubricant layer is only one or two molecules thick and, in fact, there will generally be a few patches where solid–solid contact occurs. In this case, the adhesive bonds between the lubricant and the underlying surface become important. The earliest boundary lubricants were animal fats and vegetable oils. The molecules of these lubricants consist of a long hydrocarbon chain with one polar end that hooks firmly into the surface to form a structure like a carpet. Materials of this type are still used as lubricants for metal deformation processes such as wiredrawing, and as additives in mineral oil intended for light service, such as a bicycle lubricant. The two disadvantages of these lubricants are that they lose their effectiveness at relatively low temperatures and are readily oxidized and degraded by bacteria.

Boundary lubricants cannot reduce the friction coefficient below 0.05. If lower friction is required, then the

system must be redesigned either to operate within the region of hydrodynamic lubrication or else rolling contact devices such as ball bearings must be used. These generally give friction coefficients of about .003.

Most modern lubricants are based on mineral oils derived from petroleum. The intrinsic lubricating ability of such oils is augmented by additives, which are frequently tailored to the intended application. For service under severe conditions, reliance is placed on synthetic lubricants, which give good performance even at very high temperatures.

Current research in tribology. Current research efforts are focussed in a number of areas. Some investigators are trying to improve the theoretical understanding so that tribology problems can be solved without resort to the present time-consuming empirical testing techniques. A second group is trying to overcome problems involving new applications, for instance, sliding systems to operate at the high temperature of a rocket engine or in the high vacuum of outer space. A third group is trying to devise new materials and new systems that will allow sliding to occur more cheaply, more effectively, and more reliably.

Trichoptera

Caddisflies are insects that comprise the order Trichoptera. The mothlike adult, attracted to light at night, often lives near lakes or rivers. Because fish feed on immature, aquatic stages and trout take flying adults, caddisflies are used as models for fishermen's "flies."

General features

Adult caddisflies are commonly 3 to 15 millimetres in length; their anterior wings range from 4 to 20 millimetres in length, providing wing spans of 8 to 40 millimetres. The wings at rest are folded rooflike over the body. One family (Hydroptilidae), commonly known as microcaddis, are only 1.5 millimetres in length, with anterior wings of 2 to 5 millimetres. Caddisfly wings are either covered with hairs or have hairs on the veins; the posterior pair are often broader than the anterior.

Caddisflies are widely distributed in freshwater habitats throughout the world. The larva of one marine species, *Philanisus plebeius*, occurs in intertidal zones of New Zealand and southern Australian coasts. The larva of one terrestrial European species, *Enoicyla pusilla*, lives in damp moss under trees, while one or two other species occur in brackish water. Approximately 7,000 species of caddisflies are known.

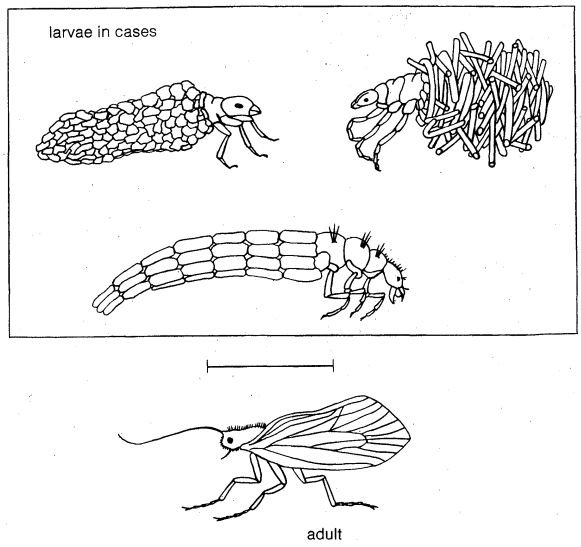
Natural history. *Life cycle.* Caddisflies undergo complete metamorphosis. Males generally have complicated external genitalia. Spermatozoa are transferred either directly or in spermatophores (capsules transferred to females). In the females of some species the terminal segments of the abdomen are modified to form a long ovipositor. Eggs, in masses numbering up to 800, are laid within a jelly that swells on contact with water. A female may wash off a partially extruded egg mass by dipping her abdomen into water during flight, or she may place the mass on stones in the water or on aquatic plants just above the water.

Young larvae, crawlers with strong legs, hatch within a few days and feed on vegetable material or algae. In some species the larvae form webs of debris for protection; others form a funnel-like web between stones in running water to catch food. Some protect their bodies with cases;

Larval cases

others spin protective lairs or are free-living. Larvae may be herbivorous, carnivorous, or omnivorous. They produce silk from glands on the lower lip (labium), and many herbivorous species spin tubular protective cases, open at both ends, that enlarge as the larvae grow; sand grains or vegetable debris, added to cases, provide protection and rigidity. In casebearing forms the head and thorax protrude from the case, which is pulled along by the abdomen. Larvae of one species (*Triaenodes bicolor*) swim by means of long, slender, hair-fringed posterior legs, dragging their cases through the water. Undulating movements of the enclosed larvae circulate water to provide oxygen for respiration.

Prior to the last molt before the pupal stage, the larva fixes the case to some solid object and closes both ends for further protection, leaving only water circulation holes. The larva pupates inside the larval case (which then becomes a cocoon) or inside a specially constructed cocoon. After two or three weeks the pupa bites its way out of the cocoon and swims or crawls to the water surface, using its hair-fringed middle pair of legs; then the winged caddisfly adult emerges and lives several weeks. Adults sometimes emerge in large numbers, often forming swarms. Caddisflies usually mate on vegetation or rocks surrounding water. There is generally one complete life cycle per year.



Ecology. Essentially, caddisflies are aquatic insects associated with a wide range of freshwater habitats. Oxygen concentration, associated with water velocity, is important to their larvae, as is the chemical content of the water. In fact, certain species have been used as indicators of pollution. Larvae feed on aquatic plants, algae, diatoms, or plant debris; a few are predatory on other aquatic insects, crustaceans, and mollusks; some are omnivorous. The larvae, often numerous, play an important role in the aquatic community, reducing plant growth and disposing of animal and plant debris; they use vegetation and debris in casemaking and for food. Most adult caddisflies, incapable of feeding on solids, imbibe liquids (*e.g.*, nectar) from flowers; one species pollinates an Alpine flower as it feeds.

Sponges and algae grow on the protective cases, and protozoans and mites grow on the larvae of some species. Two hymenopterans parasitize caddisflies; the parasitic wasp seeks its host underwater and lays it eggs inside the caddisfly larval case. The parasitic larva devours the caddisfly larva and remains inside the case to pupate; the adult parasite overwinters in the case and emerges in the early summer. Caddisflies are important as food for other animals. Freshwater fish, particularly trout, and eels feed on larvae and swimming pupae; trout, birds, lizards, frogs, spiders, dragonflies, and bats feed on adults. Day flight of caddisflies includes stationary swarming usually off some obvious object on the shore, or mobile swarming, in which the swarms move haphazardly. Most species fly at night, however, and are strongly attracted to light. Night flight may be bimodal, continuous, or intermittent. Warm moist nights are particularly conducive to caddisfly flight.

Form and function. Trichopteran adults are characterized by four wings that bear hairs on the membrane or prominent veins, or both. The head and thorax are also usually hairy. The many-jointed antennae, usually about the length of the anterior wing, may be longer than the wingspan. Mouthparts have nonfunctional mandibles but well-developed maxillary and labial palpi (or sensory appendages); the hypopharynx is modified to form a sucking tongue for imbibing fluids. Various sensory and scent organs may occur on the head or wings. Each of the three thoracic segments bears a pair of walking legs. Several of the ten abdominal segments may bear lateral filaments (or cerci), often with complicated external genitalia terminally in males, sometimes with prominent ovipositors in females.

Mouthparts

Evolution and paleontology. The caddisflies were long classified in the order Neuroptera; the two groups are now thought, however, to represent different evolutionary lines. Ancestral Mecoptera (scorpionflies) probably gave rise to the Neuroptera (lacewings), Trichoptera (caddisflies), and Lepidoptera (moths, butterflies). The closely related Trichoptera and Lepidoptera may have arisen from a common offshoot. Early aquatic trichopterans may have diverged from the terrestrial line in the Late Triassic Period (about 200,000,000 years ago). The earliest known trichopteran fossils are from the Early Jurassic Period

General structure of caddisflies, larvae and adult; line indicates approximate size of adult.

(about 185,000,000 years ago). A few fossil wing prints from the Cretaceous Period (about 65,000,000 to 136,000,000 years ago) are known; many fossils in Oligocene Baltic amber (about 26,000,000 to 38,000,000 years ago) belong to or are related to living genera. Later fossil wing prints occur in Miocene deposits.

Classification. *Distinguishing taxonomic features.* Caddisflies are mothlike insects with two pairs of hairy wings (sometimes a few scales) folded rooflike over the abdomen. Antennae are long and many jointed with a large basal joint. Large compound eyes are present; simple eyes (ocelli) number three or are absent. The number of maxillary palpal joints usually is five but varies between two and six. Posterior wings are broader than anterior; the pattern of veins is generalized and sometimes reduced. Legs are long and slender, tarsi five-jointed; tibial leg segments may bear variable numbers of spurs. Male genitalia, often complex, have been used for specific identification; female genitalia are of increasing taxonomic significance. Another system relies on the internal characters (*e.g.*, internal head skeletal structures, known collectively as the tentorium). Larvae are essentially aquatic. Campodeiform (elongated and flattened) larvae are free-living or net forming; eruciform (caterpillar-like) larvae are casebearing. In some groups head capsules, functional mandibles, thoracic shields, abdominal gills, abdominal prolegs or hooks, and types of nets or cases are distinct; in all groups antennae are short, and spiracles absent. Pupae have functional mandibles, free limbs, and hook-bearing dorsal plates.

Annotated classification. The number of living families has recently increased. Nineteen were listed in 1953 and 34 (based on a different method of classification) in 1967. The following is based on the later scheme.

ORDER TRICHOPTERA (caddisflies)
Insects with 2 pairs of wings held rooflike over the body in repose; the wing membrane or veins with hairs, or both; wing vein pattern generalized; tibiae usually with spurs, tarsi 5-jointed; larvae and pupae aquatic, with functional mandibles; larvae with terminal abdominal hooked prolegs or hooks, free-living, net spinning, or casemaking, pupate in larval case or cocoon.

Suborder Annulipalpia
Terminal segment of maxillary palpi annulate (with ringed appearance) or subdivided; larvae, net spinners.

Superfamily Hydropsychoidea. Antennae usually anterior wing length or less.

Family Philopotamidae. Ocelli medium to small; larval head elongated.

Family Stenopsychidae. Closely related to Philopotamidae; ocelli large or absent; larval head elongated.

Family Xiphocentrionidae. Closely related to Psychomyiidae; ocelli absent.

Family Psychomyiidae. Ocelli absent.

Family Polycentropodidae. Ocelli absent.

Family Dipseudopsidae. Closely related to Polycentropodidae.

Family Hydropsychidae. Antennae mostly about anterior wing length or slightly longer; ocelli absent; larvae with many-branched ventral abdominal gills on most segments.

Suborder Integripalpia
Terminal segment of maxillary palpi undivided; larvae free-living or case makers.

Superfamily Rhyacophiloidea. Antennae shorter than anterior wing length.

Family Rhyacophilidae. Ocelli present; larvae free-living, produce a single line of silk.

Family Glossosomatidae. Adults similar to Rhyacophilidae; larvae, saddle case makers with modified terminal prolegs and hooks.

Family Hydroptilidae (microcaddis). Ocelli present or absent; wings reduced, narrow, with long hair fringes; larvae purse case makers or tube case makers in last larval stage; earlier stages free-living.

Superfamily Limnephiloidea. Larvae, tube case makers.

Limnephilid Branch

Antennae about anterior wing length; ocelli usually present; adult mandibles reduced or lost.

Family Limnocentropodidae. Primitive articulating mandibles.

Family Brachycentridae. Maxillary palpi 3-jointed in male.

Family Phryganeidae. Maxillary palpi usually 4-jointed in male.

Family Phryganopsychidae. Male maxillary palpi 4-jointed.

Family Goeridae. Ocelli absent; maxillary palpi of male 3-jointed.

Family Thremnidae. Closely related to Limnephilidae.

Family Limnephilidae. Maxillary palpi of male 3-jointed.

Family Plectrotarsidae. Closely related to Limnephilidae; specialized elongated mouthparts.

Family Lepidostomatidae. Ocelli absent; maxillary palpi 3-jointed in male.

Family Rhynchopsychidae. Closely related to Lepidostomatidae, but mouthparts elongated.

Leptocerid Branch

Antennae about anterior wing length or less, except Leptoceridae; ocelli absent.

Family Pisuliidae. Male maxillary palpi 3-jointed.

Family Calocidae. Maxillary palpi 5-jointed.

Family Pycnocentrellidae. Anterior arms of tentorium spread anteriorly; maxillary palpi 5-jointed.

Family Beraeidae. Corporotentorium atrophied; maxillary palpi 5-jointed.

Family Sericostomatidae. Male maxillary palpi 3-jointed or less.

Family Helicophidae. Maxillary palpi 5-jointed, both sexes.

Family Philanisidae. Maxillary palpi 5-jointed in both sexes; larvae only in marine littoral zone.

Family Antipodoeciidae. Apparently related to Odontoceridae; male maxillary palpi 3-jointed.

Family Odontoceridae. Maxillary palpi 5-jointed.

Family Molannidae. Maxillary palpi 5-jointed; claws specialized.

Family Philorheithridae. Maxillary palpi of males 5-, 4- and 3-jointed, basal joint with nodule.

Family Helicopsychidae. Maxillary palpi of male 2-jointed; larval cases look like small snail shells; very small in size, traditionally placed in Sericostomatidae; many adult characters reduced or absent; relationships uncertain.

Family Calamoceratidae. Maxillary palpi 5- or 6-jointed.

Family Leptoceridae. Antennae longer than wingspan; maxillary palpi 5-jointed; anterior wings elongated; vein pattern reduced.

Critical appraisal. Many species of caddisflies have been described from male characteristics, particularly genitalia, only, family characters being assumed. Work in recent years on female characters, internal adult characters, and larval characters has revealed new sources of taxonomic information. Further progress in classification depends upon these detailed studies. The classification used above reveals the extent of progress thus far.

Trinidad and Tobago

Trinidad and Tobago are two islands in the southernmost part of the Caribbean Sea that constitute an independent unitary state. Forming the two southernmost links in the Caribbean chain of islands, they lie close to the South American continent, northeast of Venezuela and northwest of Guyana. They have a combined area of 1,980 square miles (5,128 square kilometres).

Trinidad, the larger island, comprises 1,864 square miles (4,828 square kilometres). The island fits snugly into the South American coastline, its northwestern and southwestern peninsulas separated from Venezuela by two channels—the Dragon's Mouth (Boca del Dragon) and the Serpent's Mouth (Boca de la Sierpe)—12 and 9 miles wide, interspersed with small islands and rocks.

Tobago, the smaller island, with an area of about 116 square miles (301 square kilometres), lies in the Atlantic, 21 miles to the northeast of Trinidad, together with Little Tobago, also called Bird of Paradise Island. Little Tobago is noted for the bird by the name, originally introduced from the Pacific islands of New Guinea. Tobago, lying diagonally from southwest to northeast, is about 26 miles long and is more than 7 miles wide at its widest point; it is cigar shaped but has an indented coastline and tapers to the southwest.

The population of the islands was estimated at about 1,027,000 in 1970. The capital, Port-of-Spain, Trinidad, in the northwest, has an estimated 74,000 inhabitants.

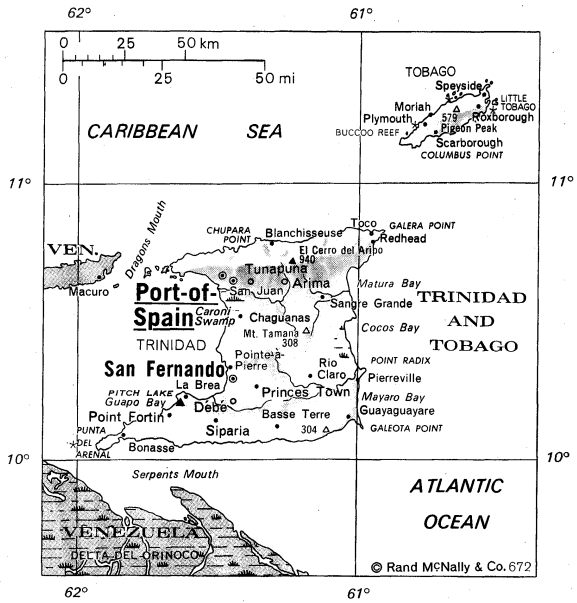
Trinidad and Tobago achieved independence from the United Kingdom in 1962 and subsequently obtained membership in the British Commonwealth, the Organization of American States (OAS), and the Caribbean Free Trade Association (Carifta). The country has a Cabinet system of government, patterned on that of the United Kingdom. Exports include petroleum. The gross national product (GNP), which averaged about $890 per capita in 1969, was the highest of the Caribbean states (see also CARIBBEAN SEA). (A.N.R.R.)

History. Christopher Columbus reached Trinidad in 1498 on his third voyage. The island remained a Spanish possession for almost 300 years, until it surrendered to a British naval expedition in 1797. During most of these three centuries the island was neglected. Not until 1530 did Spain appoint a governor; no effective possession took place until the early 17th century and no effective development until the late 18th century. The right to trade with the Spanish colonies was restricted to the port of Seville, and in 1662 the complaint was made that no authorized Spanish ship had visited the island for 30 years, while trade was openly carried on with English, French, and Dutch vessels. The main commodity produced at this time was tobacco. In the 1720s, however, cocoa became important, though after a disastrous crop failure in 1727 cocoa did not again become of major importance until the 1820s.

The Spanish era

The original Amerindian population was worked to death on the Spanish plantations, and African slaves were brought in to replace them. As the Spanish had difficulty in populating the island, the King of Spain in 1783 encouraged Roman Catholic settlers to immigrate, bringing their slaves with them. This resulted in an influx, mainly of French planters, from neighbouring islands. In 1797 the last Spanish governor surrendered the island to a British naval force.

The British were reluctant to import more slaves from Africa to develop Trinidad as a sugar colony: there were objections from influential planters in Barbados and Jamaica who feared competition; there was growing opposition to slavery itself; and there had been a black uprising in Haiti in the 1790s. Early in the 19th century attempts were made to attract white settlement, and in 1802 Chinese immigration was tried; most of the Chinese, however, soon left the island.



Early in the 19th century, civil wars on the South American mainland brought an influx of Spanish immigrants. In 1845 a system of apprenticeship was introduced on the plantations, in order to try to compel workers to remain on the estates after the abolition of slavery, which was proclaimed in 1833, although full emancipation did not occur until 1838. In 1844, in order to provide labour needed by the plantations, the British began to subsidize Indian immigration, which continued until 1917.

While Trinidad experienced three centuries of Spanish rule, Tobago—also discovered by Columbus in 1498—was the subject of continual dispute between England, France, Spain, and Holland. Not until 1721 was there any attempt at settlement (by the British); development began only in 1781, after the French captured the island. Tobago was essentially a sugar colony, although nutmeg and cotton were also cultivated. England acquired the island in 1802, and Tobago subsequently had its own bicameral legislature, which it retained until 1874, though in 1833 Tobago, together with the other Caribbean islands of Grenada and St. Vincent, was put under the jurisdiction of the governor of Barbados. In 1889 the island was amalgamated with Trinidad, while retaining its own legal and fiscal systems; in 1899 it became a ward of Trinidad, uniting with it to form one colony.

Progress to independence

In 1923 a tentative move toward self-government occurred when seven elected members replaced seven nominated members in the colony's Legislative Council. From 1937 to 1938, a strike occurred in the Trinidad oil fields that ultimately affected labour relations throughout the Caribbean. Universal suffrage was introduced in 1945, and elected members of the Legislative Council began a gradual assumption of power. In 1956 Eric Williams, leader of the People's National Movement, won a victory at the polls. In 1962 the colony attained independence, while continuing to bear the marks and the burdens of a colonial economy. Popular mass demonstrations, resulting in part from widespread unemployment, led to the proclamation of a state of emergency, which was lifted in 1971. (C.L.R.J.)

The landscape. *Relief.* Physiographically, the islands represent an extension of the South American mainland. The outstanding physical feature of Trinidad is its Northern Range of hills (the counterpart of the Cadena Del Litoral Oriental in Venezuela), which runs from west to east at an average elevation of 1,500 feet rising to 3,085 feet (940 metres) at the Cerro Aripo, the nation's

TRINIDAD AND TOBAGO

highest peak. The Northern Range is the site of many waterfalls, the most spectacular of which are the Blue Basin and the Maracas Falls, both 298 feet (91 metres) high. On the southern side of the range, foothills with an elevation of about 500 feet descend to the Northern Plain.

Running across the centre of the island, from southwest to northeast, is the Central Range, the highest point of which is Tamana Hill (1,009 feet, or 308 metres high). A third row of hills, the Southern Range, adds further variety to the mostly flat or undulating surface of Trinidad.

These three mountain ranges determine the island's drainage pattern. The average length of the rivers is about 21 miles; none exceeds 50 miles in length. About 13 swamps occupy parts of the low-lying areas, among them the Caroni Swamp in the northwest.

An oil-bearing belt occupies an area of about 800 square miles in the south of the island, extending from northwest to southeast. Gas and water seepages give rise to mud volcanoes of various types, the most famous of which is the Devil's Woodyard.

In the southwest of the island is the famous sedimentary volcano known as the Pitch Lake, which contains about 10,000,000 tons of asphalt.

Tobago's topography

Tobago is physiographically an extension of the Venezuelan or Caribbean coast range and the Northern Range of Trinidad. Its dominant feature is the Main Ridge, which runs from northeast to southwest, rising to a height of 1,899 feet (579 metres) at Pigeon Peak in the northeast. The ridge slopes more gently to the southwest onto a coral plain. The coral formation has given rise to a number of reefs, one of which, Buccoo Reef, is world famous for its marine life and sea bathing.

Climate, vegetation, and animal life. The climate of Trinidad and Tobago is tropical; there is a high degree of humidity. The coolest months are January and February, when the average minimum temperature is about 68° F (20° C). Warmest months are April, May, and October, which have an average maximum of about 89° F (32° C). In general, mean temperatures range between 77° F (25° C) in February and 85° F (29° C) in April. Temperatures vary significantly between day and night, and the climate is tempered by sea breezes.

There is a major dry season from January to May, and a short dry season (Petite Carême, or Indian Summer) in October. The prevailing winds are the northeast trades. The islands are outside the main hurricane zone, but Tobago has twice in a century—in 1867 and 1963—been struck by disastrous hurricanes.

Vegetation zones are well marked on both islands. In general, the highest areas coincide with the most luxuriant vegetation. Cultivated estates or small settlements are established in clearings on the hills. In the dry season, the hills are beautiful with the orange flowers of the mountain immortelle (a large flowering tree, growing to a height of about 80 feet) and the gold flowers of the poui.

Sugar, the main agricultural crop, is grown on the Central Plain. The Caroni Swamp is frequented by flocks of white flamingo and egret as well as the scarlet ibis—a national bird.

The forests on both islands are hunting grounds for small game, the most sought after being the lappe. Other kinds include agouti (a short-haired, short-eared, rabbit-like rodent), quenk or peccary (wild hog), tattoo (an armadillo), and iguana (a large lizard).

There are four main groups of reptiles: snakes, lizards, turtles, and crocodiles (one kind, the caiman, related to the alligator). Most of the 37 types of snake are harmless; the poisonous snakes include the fer de lance, common coral snake, and large coral snake.

The landscape under human settlement. Soils, climate, and vegetation have all influenced the pattern of local settlement. Villages stretch ribbon-like along the major roadways. In Trinidad, though not in Tobago, villages are so diverse that it would be difficult to call any typical.

Even in the sugar belt of the Central Plain, with its mainly, though not exclusively, East Indian population, patterns vary. Kinship tends to be the important structural element in the life of the East Indian villager; caste may also have a localized influence, as may the Praja relationship (which implies a reciprocal obligation between one who needs and another who bestows a favour), in which a kind of boss exercises various kinds of influence. Religious festivals, such as Dīwālī (Festival of Lights) and various forms of Puja (ceremonial offering), are important events. Houses vary in size and architecture from the simple thatched hut to the well-built two-storied dwelling, brightly painted and ornamented, and roofed with corrugated iron.

The East Indian villages

A somewhat different life-style prevails in villages inhabited by people predominantly of African descent, though many villages have both Indian and African characteristics. Because of the conditioning of the slave system, traditional African culture has undergone considerable mutation or reinterpretation. The family unit is nuclear rather than extended and may be based upon marriage or upon a stable extralegal relationship. The main institution is the Christian Church, which may be Roman Catholic, Anglican, or Fundamentalist. Steel band and calypso music is heard everywhere in preparation for carnival, the national festival.

These different rural cultural streams converge on the capital, Port-of-Spain. This city, with its mixed population, its Spanish influence (particularly in architecture), and French Creole flavour, is one of the most cosmopolitan in the world. San Fernando, the second town, occupies the southwestern foothills of the Central Range in the heart of the oil belt. Arima, the smallest Trinidadian municipality, is the oldest and least opulent. Scarborough, the chief town in Tobago, is an administrative centre and market town.

People and population. The original inhabitants of Trinidad were chiefly Arawaks. Although there are inhabitants of the town of Arima who claim descent from Carib royalty, there is doubt that the land was also settled by Caribs. Tobago was frequently visited by Amerindians but was not settled before the arrival of Columbus. As described above, Spanish, French, African, English, East Indian, and Chinese have all contributed to the ethnic composition of the islands' population. The various immigrant groups brought with them their languages, culture, and religion.

Protestantism gained a foothold in its various forms (Anglican, Methodist, Moravian, and Baptist) with the advent of the British. Roman Catholicism, then the official religion, was strengthened by French immigration, which also introduced the patois dialect, while the East Indians brought with them their languages and their Hindu and Muslim religions. Further diversification followed with the immigration of Syrians and Lebanese.

Between 1901 and 1960, the population trebled, rising from 274,000 to 834,000. The annual rate of increase between 1946 and 1960 was 2.9 percent; this high rate was

Demographic trends

a result of an increasing birth rate, a declining death rate, and a sharp increase in immigration in 1958 and 1959, when Trinidad belonged to the now defunct Federation of the West Indies. The birth rate peaked in the mid-1950s at 4.2 percent but, by 1970, had declined to 2.4 percent. The death rate remained fairly constant. A sharp change in migration trends also occurred during the 1960s. There was an influx of 2,500 persons a year in 1962 and 1963, which changed to a net outflow of about 2,000 in 1964, rising to more than 15,000 in 1969. The rate of population increase for 1966 to 1970 was 1.1 percent.

The economy. *Components of the economy.* Principal features of the economy are a dependence on the petroleum industry and a high level of unemployment. In the period 1965–70, petroleum accounted for roughly 25 percent of gross domestic product, 30 percent of government recurrent revenues, and 83 percent of gross exports (or 60 percent of net exports). The petroleum industry, however, employed only 7 percent of the working population. By contrast, agriculture, while contributing only 8 percent of the gross domestic product, accounted for 22 percent of employment.

Oil production is both land and sea based and in 1969 was about equal from both sources, though the prospects for sea-based production are much better from 1972 onward because of new discoveries. Trinidad is also a major refining centre; crude petroleum is imported from Colombia and Saudi Arabia for refining.

After petroleum, agriculture accounts for the bulk of the country's traditional exports. Since 1964, however, the three major export crops—sugar, cocoa and coffee—encountered problems because of fluctuating export prices and difficulties in expanding supply. In addition, sugar may face loss of protection because of the entry of the United Kingdom into the European Common Market. Other agricultural products include citrus fruits, poultry, vegetables, and domestic food crops.

Manufacturing

Manufacturing output, apart from petroleum products, increased during the 1960s, partly as a result of the policy of encouraging local manufacturing to reduce dependence on imports and partly because of the stimulus of membership in the Caribbean Free Trade Association. Industrial plants are engaged in the assembly of consumer durables, (including motor vehicles) and in the manufacture of fertilizers, cement, furniture, garments, and processed foods.

Tourism, which is somewhat unstable owing to social and political conditions, is potentially the fastest growing industry; it is based particularly on Tobago and on Trinidad's northwest peninsula.

The principal instruments employed for management of the economy have been import duty and income-tax concessions; quota restrictions on imports; credit and subsidies to agriculture, manufacturing, and tourism; and budget deficits financed by internal and external loans.

Transportation and communications. The islands are served by a fairly well-developed network of main and local roads, but there is heavy congestion in urban areas. The traffic accident rate is high. Taxis are a prominent feature of traffic in Trinidad.

Two small ships and a domestic airline connect Tobago to Trinidad. Piarco International Airport on Trinidad has links with New York, North and South America, and the Caribbean. Crown Point Airport on Tobago is, so far, used almost exclusively for interisland travel.

Port-of-Spain is the chief commercial port, accommodating vessels with drafts of up to 32 feet; petroleum exports are handled in ports in the south, such as Pointe-à-Pierre and Brighton, while sugar is exported at Goodridge Bay and cement at Claxton Bay. There are proposals for the development of an industrial estate and extensive port facilities at Point Lisas on the west coast about 10 miles north of San Fernando. The islands are served with a dial-telephone system.

Administration and social conditions. *Governmental structure.* A constitution, promulgated as a British Order in Council (1962), provides for a governor general appointed by the queen; a Cabinet, consisting of the prime minister and not more than 11 other ministers appointed by the governor general on the advice of the prime minister; a bicameral legislature consisting of a Senate and a House of Representatives; an attorney general; a Supreme Court; and commissions dealing with judicial, public, and police services.

The country is divided into 11 local government areas including nine rural counties (one of which is Tobago), which have county councils, and the three municipalities of Port-of-Spain, San Fernando, and Arima, which have municipal councils.

A constitution reform commission was appointed in 1971 to review the entire structure of government.

Health conditions

Health, housing, and social welfare. Health conditions had deteriorated in the late 1960s and early 1970s; the death rate was about 7 per 1,000 and the infant mortality rate (1970) was about 40 per 1,000. In 1968, however, there was only about one doctor for every 2,320 people —one of the lowest such ratios in the Western Hemisphere. This low rate was principally a result of the emigration of doctors.

In housing, it was estimated in 1968 that some 3,000 more houses than provided per year are needed; the unemployment rate in the construction industry is 25 percent—well above the average rate of 15 percent for all industries. "Squatter" housing (erected on land that does not belong to the builders) has become a characteristic feature in and around the towns.

State provision for social security takes the form of noncontributory old-age-pension and public-assistance schemes, noncontributory government employee-pension schemes provided out of public revenues, and workmen's compensation compulsorily paid by employers. Proposals have been published to establish a national-insurance scheme.

Education. Education, the main requirement for upward social mobility, is free at primary and secondary levels. There has, however, been a growing disparity between school places and children of school age, particularly at the secondary school level. Three faculties of the University of the West Indies—engineering, agriculture, and liberal arts—are situated on the university campus at St. Augustine about 8 miles east of Port-of-Spain. There are two technical institutes, one in Port-of-Spain and the other in San Fernando.

A new education plan, which provides for a three-tier system—primary, junior secondary, and senior secondary schooling—would meet the deficiency in primary schools by providing 109,000 new places between 1969 and 1983; it faces, however, financial and other problems. The provision of physical facilities for junior secondary and vocational schools is assisted by loans from the Inter-American Development Bank (IADB).

Prospects for the future. Trinidad and Tobago as a unitary state occupies a position of major importance in the Caribbean. This is a result of its strategic location, its mixed population, its cultural diversity, and its underlying economic strength. The extraordinarily high rate of economic growth that the country experienced just before independence, from 1955 to 1961, however, levelled off sharply from 1962 to 1965; another period of growth from 1966 to 1968 also levelled off abruptly in 1969.

The principal task facing the country is the deployment of its human and natural resources to ameliorate growing social problems stemming mainly from a persistently high rate of unemployment, especially among the young. Civil disorders have periodically resulted in the proclamation of a state of emergency.

The causes lie deeper, however, in the structural weaknesses that are a feature of an inherited form of economic organization and in the tensions arising from attempts—or failures—to transform this structure. In this respect, Trinidad and Tobago share a common experience with many of their Western-Hemispheric neighbours, as well as a common need to participate in a closer form of regional cooperation. Tripura

Tripura, the smallest of the five states of the northeastern arm of India, is bordered on the north, west, and south by Bangladesh, on the east by the union territory of Mizoram, and on the northeast by the Indian state of Assam. Its area of 4,035 square miles (10,451 square kilometres) is about equal to that of Lebanon but is half the size of nearby Manipur state, India. The population of some 1,557,000 early in the 1970s was less than one-fourth that of greater Calcutta. The capital city of Agartala is the only urban area in the state with more than 55,000 inhabitants. Tripura is basically an agricultural area in which rice is the major crop. Since the 1960s the Indian government has fostered the growth of small-scale industries.

History. Tripura was an independent Hindu kingdom for more than 1,000 years before it became part of the Mughal Empire in the 18th century. At the height of its power, its suzerainty extended over much of Bengal, Assam, and Burma. Tripura acceded to India in 1947 and was designated a union territory in 1956. Upon the administrative reorganization of India's northeastern territory in 1972, it acquired full status as a state.

The landscape and environment. The state can be divided physiographically into the four northern valleys—Dharmanagar, Kailāshahar, Kamalpur, and Khowai—and the southern plain of Agartala. The easternmost valley of Dharmanagar is bordered on the east by the long ranges of the Jamrai Tlang, which rise to between 2,000 and 3,000 feet (600 and 900 metres) above sea level, and on the west by the Sakhon Tlang, which rise to between 1,000 and 2,500 feet. It is drained by the northward-flowing Deo River in the south and the Juri River in the north.

The northern valleys

West of the Sakhon Tlang is the Kailāshahar Valley, which, like the Dharmanagar Valley, runs the full length of the state. Its western limit is defined by the Langtarai Range, which rises to more than 1,500 feet above sea level. The northward-flowing Manu River and its tributaries drain the valley, which is much dissected and forested in its southern half. The northern half of the valley is more open and even marshy.

Between the Langtarai Range on the east and the Atharamura Range, which rises to more than 1,400 feet on the west, lies the Kamalpur Valley. The valley is drained by the northward-flowing Dhalai River; the south is covered with forests, and the north is largely marshy rice fields. West of the Atharamura Range lies the Khowai Valley, which is bordered on the west by the low Deotamura Range. The valley is drained by the northward-flowing Khowai River; its western hills do not rise much above 800 feet in elevation.

The southern half of Tripura is more open and contains an extensive plain to the west of the Deotamura Range. The region is drained by a number of rivers of which the Gumti is the largest. The Gumti receives several southward-flowing streams and cuts across the ranges in a steep-sided valley from east to west before emerging from the hills near Rādhākishorepur.

Climate

Over 80 in. (2,000 mm) of rainfall occurs during the monsoon season from June to September. Temperatures are hot in the valleys and cooler in the mountains.

Natural vegetation consists largely of evergreen forests, much of which have been cleared for cultivation. The remaining forests contain valuable trees including the sal, an East Indian timber tree that yields hardwood, second in value only to teak. Animal life includes tigers, leopards, jackals, and wild dogs. The Asiatic elephant is fairly common, and there are wild boar, the gaur—the largest of the world's wild oxen—the gayal ox, and wild buffalo.

The people. Tripura had a population in 1971 of about 1,557,000, less than 10 percent of which could be classified as urban. The average population density was 386 persons per square mile (149 persons per square kilometre); the most densely populated areas were the Dharmanagar and Khowai valleys.

Of the total population, more than 246,000 persons belong to scheduled castes and scheduled tribes, groups outside the traditional Indian caste system. More than half the population speaks Bengali; other important languages are Tripuri and Manipuri. More than 50 percent of the population are Hindus. There are more than 121,000 Muslims and more than 34,000 Buddhists.

Towns are concentrated on the southern plain, where the state capital of Agartala, Sonāmura, Udaipur, Amarpur, Belonia, and Sabrūm are located. The four towns for which the northern valleys are named all serve as local marketing centres.

Administration and social conditions. There is a common governor and high court for the five states and two union territories of northeastern India. In the early 1970s a Northeastern Council composed of representatives of the states and territories was proposed. The council would discuss common problems and coordinate development programs. Within the state, the government is headed by a chief minister and a Council of Ministers. There is also a unicameral 33-member Legislative Assembly.

Education and health services

Educational facilities in the late 1960s included 1,400 primary, 192 middle, and 81 higher secondary schools. There was one agricultural school, one nurses-training centre, and four industrial training centres, as well as seven professional and technical schools. The state's seven colleges offered general studies and curricula in music and engineering. To raise the literacy rate (only 31 percent), there were over 400 adult education centres.

Health services included 11 hospitals, 22 public health centres, and 124 dispensaries in the late 1960s. There were nine specialized clinics for the treatment of leprosy, venereal diseases, and diseases of the eyes, chest, and teeth. There were also 32 family-planning centres.

The economy. Tripura is primarily an agricultural area. The major crop is rice, which is chiefly grown in the northern marshy section of the Kailāshahar Valley. Other cash crops include jute (an East Indian plant that produces fibres used in the manufacture of sacking, burlap, and twine), cotton, tea, and fruit. Sugarcane, rape (a European herb of the mustard family that produces oilseeds), mustard, and potatoes are among the minor crops. Livestock includes cattle, buffalo, sheep and goats,

horses, pigs, and poultry. Forestry activities produce timber, firewood, and charcoal. Manufacturing is largely on a small scale and includes many cottage industries, such as weaving, carpentry, basketry, and pottery manufacture. There are small units for the production of tea, sugar, sawn timber, bricks, tin articles, canned fruit, agricultural implements, and footwear; larger establishments include a spinning mill and plywood factory.

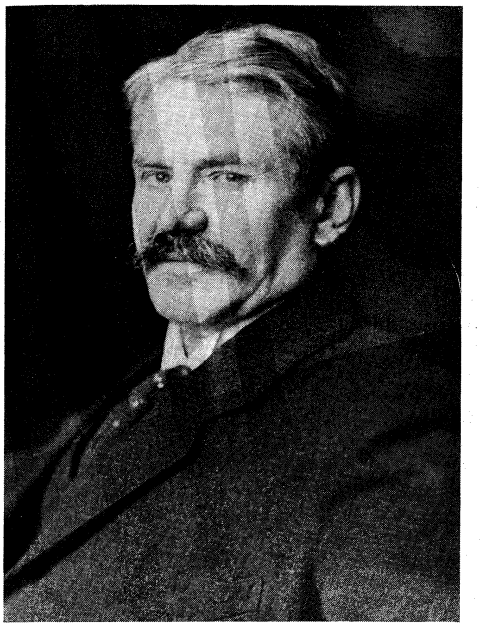
Financial services include one state cooperative bank and one land mortgage bank. There are also numerous service, agricultural, and marketing societies.

Power plants

Energy is provided by diesel-powered thermal power stations at Agartala, Ambāsā, Khowai, Dharmanagar, Kailāshahar, Udaipur, and Bogafa. The total installed capacity was 2,886 kilowatts in the late 1960s; power is also purchased from Assam. A hydroelectric power scheme was begun on the Gumti River in the late 1960s.

Transport. Tripura's topography has rendered communications difficult, and transport outside of the state is made difficult by the surrounding foreign territory of Bangladesh. There are about 1,000 miles (1,600 kilometres) of roads, of which more than 400 miles (700 kilometres) are paved. Two main roads link Agartala with Assam and with Sabrūm. There is also a railway link from Dharmanagar to Kalkalighat, Assam. Most of the rivers carry boat traffic, especially during the rainy season. Long-distance travel is most convenient by air, and there are three airstrips and one airport (in Agartala).

Cultural life. The major factor in Tripura's cultural life is its isolation from the nations around it. The members of the secluded tribes live in the hills and are divided into numerous groups speaking a variety of languages and dialects. Most of the population, adhering to Hinduism and speaking Bengali, seem to have cultural links to the rest of India, while the smaller Muslim population seems closer in culture to Bangladesh.



(S.P.C./Ed.)

Troeltsch, Ernst

Ernst Troeltsch was an influential German scholar (1865–1923) whose writings span the disciplines of theology, social history and theory, philosophy of religion, and the philosophy of history. His important contributions to the theory and methodology of sociology began to be recognized only long after his death, and in theology many now believe that his works prepared a kind of revolution in Protestant thought, anticipating what the 20th-century German theologian Dietrich Bonhoeffer (1906–45) was later to call "man's coming of age."

Troeltsch was born Feb. 17, 1865, near Augsburg in Bavaria (Germany). His father, a medical practitioner, early instilled in his son a passion for scientific observation and led him to see problems of history and civilization within a framework of the development of the sciences. After Troeltsch's school years at the Augsburg Gymnasium, where he acquired a solid grounding in classical languages and literature, he decided to study theology, which, according to an autobiographical sketch, seemed to him at that time the only study in which his historical, philosophical, and social interests could meet in the investigation of a worthwhile subject matter. He studied Protestant (Lutheran) theology at the universities of Erlangen, Göttingen, and Berlin, becoming in turn *Privatdocent* (lecturer) at Göttingen, extraordinary associate professor at Bonn (1892), and ordinary (full) professor in the chair of theology at Heidelberg (1894). He married in 1901, and an only son was born in 1913.

During 21 years at Heidelberg he published, besides his *Grundprobleme der Ethik* (1902; *Fundamental Problems of Ethics*), a large number of articles on a variety of subjects thematically linked with the development of the Christian Churches. Many of these were later integrated into his best known work, *Die Soziallehren der christlichen Kirchen und Gruppen* (1912; *The Social Teachings of the Christian Churches*, 1931). In that work he explored the relationships between and within social and cultural groups in the context of the social ethics of the Christian Churches, denominations, and sects. In 1915, realizing that his strength lay more in the philosophy of religion than in orthodox theology, he moved to a chair of philosophy at Berlin, a post he held until his death in 1923.

Troeltsch, *c.* 1919.

The problem of "historicism"

Troeltsch had a considerable influence on younger theologians of his time, especially through his insistence that the church must drastically rethink its attitude toward "absolutist" claims made for the truth of its doctrines. He was both fascinated and troubled by "historicism" (historical relativism): the view that whatever is valued, pursued, conceived, or achieved at any given time or place is relative to, and only understandable in the context of, the conditions of that time or place. Although the view seemed to him in important respects inescapable, he surmised that it applied inadequately to the norms—whether legal, religious, or ethical—that govern human conduct. If consistently applied, the historicist view would, he thought, make any present understanding of past ages impossible. The polymorphous, historically changing dogmas of the church had to be reconciled with the absolute aspects of revealed truth interpreted anew by every generation. Despite this, many theologians have seen in Troeltsch only a critic of the certainties of Christianity. Paul Tillich (1886–1965), a distinguished German philosopher and theologian, for example, accused him of sacrificing the absolute to the purely relative in religion (*Kant-Studien*, 1924).

Troeltsch's thought, never purely abstract, is always based on extensive knowledge of historical and factual data. His work has been influential precisely in those aspects that reveal his dislike of very general terms of reference—in its pioneering study of small social units or groups, such as the family, the guild, and the individual state, church, or sect, and also in its advocacy of the comparative approach to religious studies. Within Protestantism, he made important contributions to the study of the genesis of Lutheranism and Calvinism and their differing social ethics and social impact. Here he was in close sympathy concerning the nature of Protestant ethics with his friend the German sociologist and economist Max Weber (1864–1920). Troeltsch was familiar with the Marxist approach to sociology, and found its perspective on the socioeconomic substructure of civilization exciting and superior to the then current Hegelian view of history as the forward march of an inevitable dialectical process. Yet he rejected Marxism in favour of a more flexible conception of the interaction of cultural, social, and economic factors. This preoccupation with the problems of historical relativity and what he called the logic of historical development found expression in a late but important work, *Der Historismus und seine Probleme* (1922; *Historical Relativism and its Problems*).

Sociologist of culture and religion

Troeltsch had more than an academic interest in social and political affairs. He was a member of the Baden Upper House during his years in Heidelberg, and later, in Berlin, a member of the Prussian Landtag (the provincial legislature) and, for a number of years, undersecretary of state for religious affairs. Pondering the reasons, in the aftermath of World War I, for Germany's disastrous estrangement from the ethical, political, and social thought of the Western democracies, he put high on his list the glorification of the state at the expense of the rights and dignity of the individual.

A plan to visit England was frustrated by his death in 1923. The course of five lectures, which he was to have delivered in London and Oxford during March of that year, were published posthumously under a title that puts his work in perspective: *Der Historismus und seine Überwindung* ("Overcoming Historical Relativism"), a more revealing title than that of the English edition (*Christian Thought: Its History and Application*). Three volumes of Troeltsch's collected works appeared toward the end of his life, a fourth being published after his death (*Gesammelte Schriften*, Tübingen, 1922–25, 4 vol.). They do not contain all his published writings, but those for which Troeltsch himself would have wished to be remembered.

BIBLIOGRAPHY. A brief autobiography of Troeltsch, "Meine Bücher," is included in vol. 4 of his collected works, *Gesammelte Schriften* (1922–25); biographical material may be found in WALTER KOEHLER, *Ernst Troeltsch* (1941). A full bibliography and a list of Troeltsch's works with translations are contained in B.A. REIST, *Toward a Theology of Involvement: The Thought of Ernst Troeltsch* (1966). R.S. SLEIGH, *The Sufficiency of Christianity* (1923), is still a useful book for the theologically interested reader. Troeltsch's social philosophy is well presented in W.F. KASCH, *Die Sozialphilosophie von Ernst Troeltsch* (1963).

(Ev.S.)

Tromp, Maarten and Cornelis

Maarten and Cornelis Tromp, father and son, both famous Dutch admirals, played prominent roles in the Dutch wars of the 17th century. Maarten Tromp's victory over the Spanish in the Battle of the Downs, in 1639, signalled the passing of Spain's power at sea.

(Left) Maarten Tromp, engraving by Cornelis Danckerts de Ry (1603–56). (Right) Cornelis Tromp, detail of an oil painting by Sir Peter Lely (1618–80) and Willem van de Velde. In the Nederlandsch Historisch Scheepvaart Museum, Amsterdam.
By courtesy of the Nederlandsch Historisch Scheepvaart Museum, Amsterdam

Maarten Tromp. Maarten was born on April 23, 1598, at Den Briel (Brielle), the son of Harpert Maartenszoon. At the age of nine, he sailed with his father, the captain of a small man-of-war. When his father changed to the merchant fleet, Maarten accompanied him, but in 1609 the ship was taken by an English pirate, his father was killed, and Maarten was forced to serve the pirate captain for two years. After his return to Holland, he rejoined the navy in 1617. He took part in a successful expedition against Algerian pirates and was made helmsman. In 1619 he left the navy to sail with a merchant fleet to the Mediterranean, but in 1621 he fell once more into the hands of pirates. Set free after a year, he became a lieutenant in the Dutch navy. In 1621 the Twelve Years' Truce between the Netherlands and Spain expired, and it became necessary to prepare the fleet for war. In 1624 Tromp received his first commission as a captain, and five years later he commanded the flagship of the new lieutenant admiral, Piet Heyn, who was killed on the first voyage in a fight with pirates from Ostend. After that Tromp operated successfully in the Flemish coastal waters, but his relations with Lieut. Adm. Philips van Dorp were strained, and this, combined with family circumstances, led him to resign from the navy in 1634. In 1636 he became a director of naval equipment at the Admiralty of the Maas. When van Dorp resigned, Tromp was appointed lieutenant admiral of Holland, at that time the highest post in the navy under the stadtholder, who was also the admiral general of the republic. Witte Corneliszn de With was nominated his vice admiral, which was to prove an unhappy combination. Nevertheless, de With and the vice admiral of Zeeland, Johan Evertsen, collaborated successfully with Tromp in February 1639, when he defeated a fleet of Dunkirk privateers; he then met a large Spanish armada that was transporting some 13,000 Spanish recruits to Flanders. Commanded by Adm. Antonio de Oquendo and several other experienced captains, the fleet consisted of 45 warships and 30 merchantmen hired as troopships. When Tromp spotted the armada off Beachy Head on September 15, 1639, he had only 13 vessels at his command; his other detachments were cruising in the Strait of Dover and off Dunkirk. De With arrived with five sail the next day, and the Dutch captains decided to give battle. After six hours of fighting, the armada—overcrowded with recruits who accounted for an extremely high number of casualties—withdrew to repair damages. The next day no action could take place for lack of wind, but the Dutch were reinforced by a Zeeland squadron, and, in the early morning of September 18, Tromp attacked the Spaniards in the Strait of Dover. In the afternoon Oquendo withdrew into the neutral roadstead of the Downs. Tromp, after taking in fresh supplies of gunpowder at Calais, soon followed him there, only separated by an English squadron under the command of Sir John Penington. Both fleets stayed on for weeks, and, while in Holland enthusiasm for Tromp's success led to a most unusual effort to strengthen the navy, the admiral showed himself a very tactful diplomatist in negotiating with the English. By October 10 the Dutch fleet was strong enough to challenge the Spaniards, and on October 21 Tromp attacked Oquendo, and Penington's efforts at protection were of little avail. In the Battle of the Downs, the armada was completely defeated, suffering severe losses both in ships and manpower. In 1640 Tromp was knighted by Louis XIII and in 1642 by Charles I when he visited Dover to escort Queen Henrietta Maria and Princess Mary to Holland.

Maarten's early career

Defeat of the Spanish

Tromp's main task during the next years was action against the Dunkirk pirates who continued to attack the Dutch merchant fleet. In 1646 Tromp helped the French capture Dunkirk, after which the Order of St. Michael was conferred upon him. After the Peace of Westphalia in 1648, which concluded the Thirty Years' War, the activities of the Dutch navy diminished until, in 1651, growing privateering between Scandinavia and Gibraltar made it necessary to reinforce the neglected fleet and to protect maritime trade. Relations with England became increasingly strained after the Navigation Act (1651), which was passed to restrict Dutch trade with British possessions, while much resentment was also caused by the English claim to sovereignty over the seas.

A skirmish with Adm. Robert Blake off Dover in May 1652 resulted in the First Dutch War, which marked a crisis in the rivalry between England and the Netherlands as carriers of world trade. Although Tromp was unable to stir the English admirals to action later in the year—for which he was censured by the Dutch authorities, who even kept him from his command for some months—he defeated Blake off Dunge Ness in December. But the English fleet was superior to the Dutch; Tromp was unable to continue his successes and lost the three-day battle between Portland and Calais (March 1653), as well as the Battle of Gabbard in June. Tromp was killed in the battle off Terheijde near Scheveningen (on August 10, 1653). He was buried with great pomp in the Oude

Outbreak of First Dutch War

Kerk (Old Church) at Delft. He combined great gifts as a sea commander with an amiable personality and an unusually considerate attitude toward his crews.

Cornelis Tromp. Cornelis Tromp, the second son of Maarten Tromp, was born on September 9, 1629. After serving as a lieutenant of his father's ship in 1645, he became a captain in 1649. He fought the North African pirates in the Mediterranean (1650) and, in the First Dutch War, the British. After taking part in the Battle of Leghorn (1653) against the English, he was made a rear admiral. He always showed a strong need for independent action and found pleasure in a fiery battle. In 1654, he fought the Algerians and, in 1656, sailed to the Baltic to take part in the First Northern War (1655–60) between Sweden and Poland. In 1663 he was appointed commander of the Dutch fleet in the Mediterranean. Some years of inactivity followed before he returned to the fleet as vice admiral (1665) during the Second Dutch War. In 1666 he was promoted to lieutenant admiral of the Admiralty of the Maas and made commander in chief of the Dutch fleet, but, when Adm. Michiel de Ruyter returned from the West Indies, the older and more experienced officer was given Tromp's commission, which caused understandable bitterness on Tromp's part. In 1666 he switched to the Admiralty of Amsterdam and soon came into conflict with de Ruyter. A more serious conflict arose in July 1666 after de Ruyter blamed his defeat by the English on the lack of assistance received from Tromp. This led to the withdrawal of Tromp's commission as lieutenant admiral, after which he left the navy. He then refused an invitation to enter French service. In 1673 Prince William III of Orange was able to reconcile de Ruyter with Tromp, who was a well-known sympathizer of the House of Orange. He was restored as lieutenant admiral of the Admiralty of Amsterdam and fought with de Ruyter in the battles of Schooneveld and Kijkduin in the same year. After the Treaty of Westminster (1674), between England and the Netherlands, he cruised the French coast and then, contrary to his instructions, sailed off to the Mediterranean on an expedition that was unsuccessful. He was censured by the admiralty. In 1676 Tromp became commander in chief of a combined Danish–Dutch fleet that operated against Sweden and stayed in Danish service until 1678. Afterwards he helped the Elector of Brandenburg to recover the island of Rügen from Sweden. He then returned to Holland and in 1691 received command of the fleet as lieutenant admiral general of the republic; but, being ill, he did not sail and died on May 29, 1691. He had been made a baronet by Charles II of England and a count by the King of Denmark.

Cornelis' rivalry with de Ruyter

Trotsky, Leon

Second only to Lenin, Leon Trotsky was the outstanding leader of the Russian Communist Revolution and, in many respects, the most colourful and controversial personality to emerge in its course. A gifted theorist and agitator, Trotsky was the principal leader of the October (November, new style) 1917 uprising and went on to serve the Soviet government as commissar of foreign affairs and commissar of war, before his ultimate political defeat and exile by Joseph Stalin.

Trotsky.
H. Roger-Viollet

Early life and education. Trotsky was born Lev Davidovich Bronstein in the village of Yanovka in the Ukraine on November 7 (October 26, old style), 1879. His father, David Bronstein, was an independent farmer of Russified Jewish background who had settled as a colonist in the steppe region. His mother, Anna, was middle class and educated. He had an older brother and sister, not counting two siblings who died in infancy.

At the age of eight, young Bronstein was sent to school in Odessa, where he spent the next eight years residing with the family of his mother's nephew, a liberal intellectual. He showed intellectual brilliance and a literary and linguistic gift. When he moved to Nikolayev in 1896 to complete his schooling, he was drawn into an underground Socialist circle and introduced to Marxism. After briefly attending the University of Odessa in 1897, he returned to Nikolayev to help organize the underground South Russian Workers' Union.

Revolutionary career. In January 1898, Bronstein was arrested for revolutionary activity and spent the next four and a half years in prison and in exile in Siberia (during which time he married his co-conspirator Aleksandra Sokòlovskaya and fathered two daughters). He escaped from Siberia in 1902 with a forged passport bearing the name Trotsky, which he adopted as his revolutionary pseudonym. His wife remained behind, and the separation became permanent.

Exile, imprisonment, and marriage

Following his escape, Trotsky made his way to London, where he joined the group of Russian Social-Democrats working with Vladimir Ulyanov (Lenin) on the revolutionary newspaper *Iskra* ("The Spark"). A remarkably articulate speaker and writer, Trotsky quickly assumed a leading role within the party.

At the Second Congress of the Russian Social-Democratic Workers' Party, held in Brussels and London in July 1903, Trotsky sided with the Menshevik faction—advocating a democratic approach to Socialism—against Lenin and the Bolsheviks, rejecting Lenin's dictatorial methods and organizational concepts aiming at immediate revolution. Shortly before this, in Paris, Trotsky had met and married Natalya Sedova, by whom he subsequently had two sons, Lev and Sergey (both of whom later used their mother's name, Sedov).

Upon the outbreak of revolutionary disturbances in 1905, Trotsky returned to Russia. He became a leading spokesman of the St. Petersburg Soviet (council) of Workers' Deputies when it organized a revolutionary strike movement and other measures of defiance against the Tsarist government. In the aftermath, Trotsky was arrested with the other leaders of the soviet, jailed, and brought to trial in 1906.

While in jail Trotsky wrote one of his major theoretical works, "Results and Prospects," setting forth his theory of permanent revolution. This was an effort to adjust Marxist theory to Russian conditions of a backward country in revolutionary ferment. A bourgeois revolution in Russia, Trotsky held, would lead to a continuous or permanent state of revolution during which the proletariat could take power in the urban centres. Even though Russia was a largely peasant country, this seizure of urban power would not prove temporary in Trotsky's view

because the revolution in Russia would create a permanent state of revolution internationally as well. The Russian Revolution would inspire proletarian revolution in the West and assure the establishment of Socialist governments that could support the revolutionaries in Russia.

In 1907, after a second exile to Siberia, Trotsky once again escaped abroad. He settled in Vienna and supported himself as a journalist, serving as a war correspondent in the Balkan Wars of 1912–13. He remained active in Russian Social-Democratic émigré circles as a celebrated but isolated figure on the left wing of the Menshevik faction. As such, he engaged in intermittent polemics with Lenin and the Bolsheviks over organizational and tactical questions.

At the outbreak of World War I, Trotsky joined the majority of Russian Social-Democrats who condemned the war and refused to support the war effort of the Tsarist regime. He moved to Switzerland and thence to Paris, where he helped edit an anti-war Russian journal. In 1915 he participated in the international conference of anti-war Socialists at Zimmerwald in Switzerland. Trotsky's anti-war agitation led to his expulsion from France in 1916. He went to Spain, whence he was ordered out again, and arrived in New York in January 1917. There he joined the Bolshevik theoretician Nikolay Bukharin in editing the Russian-language paper *Novy Mir* ("The New World").

Leadership in the Revolution of 1917. Trotsky hailed the outbreak of revolution in Russia in February (March, new style) as the opening of the permanent revolution he had predicted. Independently, he took a position similar to Lenin in calling for the overthrow of Prince Georgy Lvov's Provisional Government by the workers. Late in March, Trotsky and his family left the United States by ship for Russia but were detained by the British authorities when the vessel put in at Halifax, Nova Scotia. Released a month later at the behest of the Russian government, Trotsky reached Petrograd in mid-May and assumed the leadership of a left wing Menshevik faction, the Interdistrict Group, who were of one mind with the Bolsheviks in agitating for a new revolution.

Following the abortive July Days uprising, Trotsky was arrested in the crackdown on the Bolshevik leadership carried out by Aleksandr Kerensky's liberal government. In August, while still in jail, Trotsky was formally admitted to the Bolshevik Party at the party's Sixth Congress, along with the Interdistrict Group. He was also elected to membership on the Bolshevik Central Committee. Trotsky was released from prison in September, at the time of General Lavr Kornilov's abortive right wing coup against Kerensky, and shortly afterward he was elected chairman of the Petrograd Soviet of Workers' and Soldiers' Deputies when the Bolsheviks and their allies established a majority in it. Thenceforth, until the Bolshevik seizure of power, while Lenin was still in hiding, Trotsky was the principal leader of the Bolshevik Party in its preparations to take power.

Conversion to Bolshevism

In the debates among the Bolsheviks over whether to accede to Lenin's insistence on the violent seizure of power, Trotsky took a middle course. He agreed with Lenin's call for the overthrow of the Provisional Government but calculated that this could be done under the cloak of legitimacy provided by the forthcoming Second All-Russian Congress of Soviets, which the Bolsheviks expected to dominate. He threw himself into the work of winning control over the Petrograd garrison, particularly through the Military Revolutionary Committee of the Petrograd Soviet (which he inspired as chairman of the soviet, though he was not actually chairman of the committee). Trotsky's strategy was to mobilize enough force to protect the Congress of Soviets while it voted itself into power and to prevent a countercoup by the Kerensky government in the meantime.

When fighting was precipitated by an ineffectual government raid early on November 6 (October 24, old style), Trotsky took a leading role in directing countermeasures for the soviet, while reassuring the public that his Military Revolutionary Committee meant only to defend the Congress of Soviets. Governmental authority crumbled quickly, and Petrograd was largely in Bolshevik hands by the time Lenin reappeared from the underground in the early hours of November 7 (October 25, O.S.) to take direct charge of the Revolution and present the Congress of Soviets with an accomplished fact when it convened 24 hours later.

Subsequently, the Bolshevik leaders, including Trotsky, were loath to admit that they had been waiting for action by the congress, and Trotsky went so far as to suggest that his speeches to that effect were prevarications to deceive the opposition. Official Soviet histories under Stalin and since have leaned heavily on Trotsky's reluctance to attack the Provisional Government prior to the congress, even alleging this as evidence of treason to the Revolution.

On the afternoon of November 7 (October 25, O.S.) Trotsky made one of his most impassioned speeches to the Petrograd Soviet, to proclaim the overthrow of the Provisional Government and to introduce Lenin in public. Addressing the Congress of Soviets that evening, Trotsky was uncompromising in his defense of the power now violently won. The congress was swiftly led to proclaim the Bolsheviks' program and to install the new Soviet government headed by the Council of People's Commissars, with Trotsky as commissar of foreign affairs.

Military leader of the Revolution

Trotsky continued to function as the military leader of the Revolution when Kerensky vainly attempted to retake Petrograd with loyal troops. He organized and supervised the forces that broke Kerensky's efforts at the Battle of Pulkovo on November 13 (October 31, O.S.). Immediately afterwards, he joined Lenin in defeating proposals for a coalition government including Mensheviks and Socialist Revolutionaries.

Role in Soviet government. As foreign commissar, Trotsky's first charge was to implement the Bolsheviks' program of peace by calling for immediate armistice negotiations among all the warring powers. Germany and its allies responded, a cease-fire was agreed on, and in mid-December peace talks were begun at Brest-Litovsk, though Trotsky continued vainly to invite support from the Allied governments. Early in January 1918, Trotsky entered into the peace negotiations personally and shocked his adversaries by turning the talks into a propaganda forum. He then recessed the talks and returned to Petrograd to argue against acceptance of Germany's annexationist terms, even though Lenin had meanwhile decided to pay the German price for peace and thus buy time for the Soviet state. Between Lenin's position and Bukharin's outright call for revolutionary war, Trotsky proposed the formula "no war, no peace." When the Germans resumed their offensive in mid-February, the Bolshevik Central Committee was compelled to make a decision; Trotsky and his followers abstained from the vote, and Lenin's acceptance of the German terms was narrowly endorsed.

Following the conclusion of the Treaty of Brest-Litovsk, Trotsky resigned as foreign commissar and turned the office over to Georgy Chicherin. He was immediately made commissar of war, theretofore a committee responsibility. As war commissar, Trotsky faced the formidable task of building a new Red Army out of the shambles of the old Russian Army and preparing to defend the Communist government against the imminent threats of civil war and foreign intervention. Trotsky chose to concentrate on developing a small but disciplined and professionally competent force. His abandonment of the revolutionary ideal of democratization and guerrilla tactics prompted much criticism of his methods among other Communists. He was particularly criticized for recruiting former tsarist officers ("military specialists") and putting them to work under the supervision of Communist military commissars. Trotsky's military policies were resisted unsuccessfully by a coalition of ultraleft purists and rival party leaders, notably Stalin, with whom Trotsky had an acrimonious clash over the defense of the city of Tsaritsyn (later Stalingrad, now Volgograd). Trotsky's approach was, however, vindicated by the success of the

Red Army in turning back attacks by the anti-Communist White armies in 1918 and 1919, with Trotsky himself frequently in charge in the field.

With the triumph of the Communist forces and the end of the Russian Civil War in 1920, Trotsky, retaining his office as commissar of war, turned his attention to the economic reconstruction of Russia. He first proposed a relaxation of the stringent centralization of War Communism to allow market forces to operate. Rejected in this, he endeavoured to apply military discipline to the economy, using soldiers as labour armies rather than demobilizing them, and attempting to militarize the administration of the transportation system. Trotsky was one of the earliest Soviet thinkers to conceive of the coercive role of the state in accelerating the economic development of the country, a possibility neglected in Marxist theory but made the cornerstone of Soviet economic policy under Stalin later on.

Economic reconstruction

During the Civil War and War Communism phase of the Soviet regime, Trotsky was clearly established as the number-two man next to Lenin. He was one of the initial five members of the Politburo when that top Communist Party policy-making body was created in 1919. In sheer intellectual power and administrative effectiveness, he was Lenin's superior and did not hesitate to disagree with Lenin on numerous occasions, but he lacked facility in political manipulation to win party decisions against Lenin. Trotsky took a prominent part in the launching of the Comintern (Communist International) in 1919 and wrote its initial manifesto calling for the overthrow of capitalism throughout the world.

As a relative newcomer, moving in abruptly to the top level of leadership in the Bolshevik Party, Trotsky incurred the personal enmity of a number of long-standing Bolsheviks, particularly Grigory Zinoviev, who had figured as Lenin's second in command for several years prior to 1917. Trotsky and Zinoviev were adversaries on every party issue from 1917 to 1924. Trotsky's later struggle with Stalin was less personal, although the two clashed more than once during the Civil War period.

In the winter of 1920–21 widespread dissension broke out over the policies of War Communism, not only among the populace but among the Communist Party leadership as well. The point at issue in the protracted controversy was the future role of the trade unions. The utopian left wing wanted the unions to administer industry; Lenin and the cautious wing wanted the unions confined to supervising working conditions; Trotsky and his supporters tried to reconcile radicalism and pragmatism by visualizing administration through "governmentalized" unions representing the central state authority.

Kronstadt Rebellion

The crisis came to a head in March 1921, with agitation for democracy within the party on the one hand and armed defiance represented by the naval garrison at Kronstadt on the other. At this point Trotsky sided completely with Lenin, commanding the forces that suppressed the Kronstadt Rebellion and backing the suppression of open factional activity in the party. As did virtually the entire party, Trotsky accepted Lenin's retreat from ideal communism in favour of the New Economic Policy, including his conventional view of the trade unions. This degree of accord, however, did not prevent Trotsky from losing a substantial degree of political influence at the Tenth Party Congress in March 1921. The party Secretariat, up to this time controlled by followers of Trotsky, was restaffed and put in the hands of supporters of Stalin.

The struggle for the succession. When Lenin was stricken with his first cerebral hemorrhage in May 1922, the question of eventual succession to the leadership of Russia became urgent. Trotsky, owing to his record and his charismatic qualities, was the obvious candidate in the eyes of the party rank and file, but jealousy among his colleagues on the Politburo prompted them to combine against him. As an alternative, the Politburo supported the informal leadership of the troika composed of Zinoviev, Lev Kamenev, and Stalin, with Stalin, as general secretary of the Communist Party, rapidly obtaining control of the organizational levers.

In the winter of 1922–23 Lenin recovered partially and turned to Trotsky for assistance in correcting the errors of the troika, particularly in foreign trade policy, the handling of the national minorities, and reform of the bureaucracy. In December 1922, warning in his then-secret "Testament" of the danger of a split between Trotsky and Stalin, Lenin characterized Trotsky as a man of "exceptional abilities" but "too far-reaching self-confidence and a disposition to be too much attracted by the purely administrative side of affairs." Just before he was silenced by a final stroke in March 1923, Lenin invited Trotsky to open an attack on Stalin, but Trotsky chose to bide his time, possibly contemplating an alliance with Stalin against Zinoviev. Stalin then moved rapidly to consolidate his hold on the party organization and the Central Committee at the 12th Congress in April 1923. Trotsky had lost his most auspicious opportunity for establishing himself as Lenin's successor, partly, as he explained himself, out of a reluctance to assert himself while Lenin still lay dying.

Struggle against Stalin

By fall, alarmed by inroads of the secret police among party members and efforts to weaken his control of the war commissariat, Trotsky decided after all to strike out against the party leadership. In October he addressed a wide-ranging critique to the Central Committee, stressing especially the violation of democracy in the party and the failure to develop adequate economic planning. Reforms were promised, and Trotsky responded with an open letter, "The New Course," detailing the direction they should take. This, however, served only as the signal for a massive propaganda counterattack by the leadership against Trotsky and his supporters on grounds of factionalism and opportunism. At this critical moment Trotsky fell ill of an undiagnosed fever and could take no personal part in the struggle. Because of Stalin's organizational controls, the party leadership easily won, and the "New Course" controversy was terminated at the 13th Party Conference in January 1924 (the first substantially stage-managed party assembly) with the condemnation of the Trotskyist opposition as a petty bourgeois, Menshevik-like, illegal factional deviation. Lenin's death a week later only confirmed Trotsky's isolation. Convalescing on the Black Sea coast, Trotsky was deceived about the date of the funeral, failed to return to Moscow, and left the scene to Stalin.

Attacks on Trotsky did not cease. When the 13th Party Congress, in May 1924, repeated the denunciations of his violations of party discipline, Trotsky vainly professed his belief in the omnipotence of the party. The following fall he took a different tack in his essay *The Lessons of October 1917*, linking the opposition of Zinoviev and Kamenev to the October Revolution with the failure of the Soviet-inspired German Communist uprising in 1923. The party leadership replied with a wave of denunciation, counterposing Trotskyism to Leninism, denigrating Trotsky's role in the Revolution, and denouncing the theory of permanent revolution as a Menshevik heresy. This verbal abuse was followed in January 1925 with Trotsky's removal from the war commissariat.

Early in 1926, following the split between the Stalin–Bukharin leadership and Zinoviev–Kamenev group and the denunciation of the latter at the 14th Party Congress, Trotsky joined forces with his old adversaries Zinoviev and Kamenev to resume the political offensive. For a year and a half this "United Opposition" grasped at every opportunity to put its criticisms before the party membership, despite the increasingly severe curbs being placed on such discussion. Again they stressed the themes of party democracy and economic planning, condemned the leadership's concessions to bourgeois elements (especially the peasantry), and denounced Stalin's theory of "Socialism in one country" as a pretext for abandoning world revolution.

The response of the leadership to this campaign was a rising tide of official denunciation, supplemented by an anti-Semitic whispering campaign. In October 1926 Trotsky was ousted from the Politburo; just a year later he and Zinoviev were dropped from the Central Committee for printing their platform clandestinely. After an abor-

tive attempt at a demonstration on the tenth anniversary of the Revolution in November 1927, the two were expelled from the Communist Party. At the 15th Congress in December, the opposition was ritually condemned without a single voice represented in its favour, and the entire Trotskyist group was expelled from the party.

During this period of fruitless political struggle, Trotsky carried on an enormous intellectual activity. He produced books on a wide range of subjects from international politics to literature and the elevation of mass culture, as well as innumerable platforms, essays, and diatribes that were condemned to remain unpublished.

Exile and assassination. In January 1928, Trotsky and his principal followers were exiled to remote parts of the Soviet Union, Trotsky himself being assigned to Alma-Ata in Central Asia. There he kept up an active correspondence with his supporters, condemning Stalin's methods in initiating the new industrialization drive and endeavouring to keep his own men from making their peace with Stalin. In January 1929 Trotsky was banished from the territory of the U.S.S.R.

Trotsky was initially received by the government of Turkey and domiciled on the island of Prinkipo. He plunged into literary activity there and completed his autobiography and his history of the Russian Revolution, while simultaneously striving to organize and encourage the anti-Stalin factions that had been expelled from various Communist parties throughout the world. In 1933 Trotsky secured permission to move to France. After Hitler's victory in Germany, he gave up the hope of reforming the Communist International and called on his followers to establish their own revolutionary parties and form a Fourth International. This movement (whose American branch was the Socialist Workers' Party) proved to be little more than a shadow organization, although a small founding conference was officially held in France in 1938.

In 1935 Trotsky was compelled to move to Norway, and in 1936, under Soviet pressure, he was forced to seek asylum in Mexico, where he settled at Coyoacán, near Mexico City. He was represented as the principal conspirator, in absentia, in the treason trials of former Communist opposition leaders held in Moscow in 1936, 1937, and 1938. The evidence of treasonable plotting was, however, proven to be fictitious by an investigating commission chaired by the American philospher John Dewey.

Trotsky remained outspoken in his criticisms of the Stalin regime as a bureaucratic and "Bonapartist" perversion of the dictatorship of the proletariat. He came to the conclusion that the Russian Revolution had as early as 1923 entered the conservative phase of Thermidor (by analogy with the overthrow of the radical Jacobins in France in July 1794, in the month of Thermidor according to the Revolutionary calendar). This backsliding of the Revolution Trotsky explained with reference to his theory of permanent revolution: a Socialist regime under Russian conditions of backwardness, isolated by the failure of world revolution, was bound to degenerate. By 1937 he was calling for a new revolution in the U.S.S.R. to restore power to the workers.

Subsequent to Trotsky's political defeat in 1927, the official history of the Communist Party was rewritten to minimize and denigrate Trotsky's role in the Revolution and in the Soviet regime. After the Moscow Trials he was represented as having been a counterrevolutionary plotter ever since the Revolution. Following Premier Nikita Khrushchev's destalinization campaign in 1956, the treatment of Trotsky's role was moderated but not fundamentally re-examined. His widow was unsuccessful in petitioning for his rehabilitation by the Soviet authorities.

Trotsky was the object of two assassination attempts, presumably by Stalinist agents. The first, a machine gun attack on his house, failed. The second was successful when a Spanish Communist by the name of Ramon Mercader, who had won the confidence of the Trotsky household, fatally wounded Trotsky with an alpine axe on August 20, 1940. The Soviet government disclaimed any responsibility, and the murderer was sentenced to the maximum 20-year term under Mexican law.

Assessment. Trotsky was undoubtedly the most brilliant intellect brought to prominence by the Russian Revolution, outdistancing Lenin and other theoreticians such as Bukharin both in the range of his interests and in the imaginativeness of his perceptions. He was an indefatigable worker, a rousing public speaker, and a quick and decisive administrator. On the other hand, Trotsky was not successful as a leader of men, partly because he allowed his brilliance and arrogance to antagonize the lesser lights in the Communist movement, partly because of the intellectual's perception of subtleties that inhibited his decisiveness at such critical political moments as 1917 and 1923. Perhaps he fatally compromised himself when he became a Bolshevik in 1917, subordinating himself to Lenin's leaderhip and accepting the methods of dictatorship that he had previously condemned.

Had Trotsky won the struggle to succeed Lenin, the character of the Soviet regime would almost certainly have been substantially different, particularly in foreign policy, cultural policy, and the extent of terroristic repression. Trotsky's failure, however, seems almost inevitable considering his own qualities and the conditions of authoritarian rule by the Communist Party organization. Trotsky comes close to the archetype of the tragic hero, ultimately destroyed by the consequences of the steps he accepted in his pursuit of revolutionary greatness.

MAJOR WORKS

The Moscow edition of Trotsky's collected works, begun in 1924, was discontinued after 1927. English editions of individual writings include *Our Revolution: Essays on Working-class and International Revolution, 1904–1917* (1918); *Terrorizm i kommunizm* (1920; *The Defence of Terrorism: Terrorism and Communism*, 1921; new ed., 1935); *Mezhdu imperializmom i revolyutsiey: Osnovnye voprosy revolyutsii na chastom primere Gruzii* (1922; *Between Red and White: A Study of Some Fundamental Questions of Revolution, with Particular Reference to Georgia*, 1922); *Voprosy byta* (1923; *Problems of Life*, 1924); *Literatura i revolyutsiya* (1923; *Literature and Revolution*, 1925); *Uroki Oktyabrya* (1924; *The Lessons of October 1917*, 1925; new version, 1937); *O Lenine: Materialy dlya biografa* (1924; *Lenin*, 1925); *Kuda idet Angliya?* (1925; *Where Is Britain Going?*, 1926); *Ikh moral i nasha* (1925; *Their Morals and Ours*, 1939); *K sotsializmy ili k kapitalizmy?* (1926; *Towards Socialism or Capitalism?*, 1926); *The Real Situation in Russia* (1928); *Moya zhizn: Opyt avtobiografii* (1930; *My Life: An Attempt at an Autobiography*, 1930); *Permanentnaya revolyutsiya* (1930; *The Permanent Revolution*, 1931); *Istoriya russkoy revolyutsii*, 2 vol. (1931–33; *The History of the Russian Revolution*, 3 vol., 1932–33); *Problems of the Chinese Revolution* (1932); *What Next? Vital Questions for the German Proletariat* (1932); *Stalinskaya shkola falsifikatsii* (1932; *The Stalin School of Falsification*, 1937); *The Suppressed Testament of Lenin* (1935); *The Third International After Lenin* (1936); *The Revolution Betrayed: What Is the Soviet Union and Where Is It Going?* (1937); *Stalin: An Appraisal of the Man and His Influence* (1941); *Diary in Exile, 1935* (1958).

(R.V.D.)

Trucks and Buses

A bus is a road vehicle, usually driven by an internal-combustion engine; it is designed to carry a number of passengers, generally on a fixed route. In most cities buses have largely or entirely replaced electric streetcars, and they carry much intercity passenger traffic.

A truck, or lorry, is a motor vehicle designed to carry freight, or goods. Trucks are driven by gas, diesel, or gasoline engines, and they provide a fast and flexible transportation system for durable and perishable commodities of all kinds. In most countries they carry a substantial part of the long-distance cargoes and do most of the short-distance hauling.

In the early 1970s there were over 50,000,000 trucks and buses throughout the world, more than a fifth of all road vehicles. Annual world production of trucks and buses was about 7,000,000.

Buses. *Development.* In 1830 Sir Goldworthy Gurney of Great Britain designed a large stagecoach driven by a steam engine that may have been the first bus in operation. In 1895 an eight-passenger omnibus, driven by a four- to six-horsepower (hp) single-cylinder engine, was built in Germany. In 1903 the Austro-Daimler firm built an omnibus that had a four-cylinder, eight-horsepower engine with a four-speed transmission. In 1904 an experimental route in Germany from Wendeburg to Braunscherg was begun, using a Büssing-built vehicle. In 1905 buses in Berlin pulled trailers carrying passengers, a practice that continued until 1962.

Until the 1920s the technical history of the bus was that of the motor truck, since the early bus consisted of a bus body mounted on a truck chassis. The majority of present-day school buses are made in this way. In 1922 the first vehicle with a chassis specifically designed for bus service was made in the United States by Fageol Safety Coach Company of Oakland, California. Its frame was about one foot lower than a truck frame, and it also had an extra-long wheelbase, a wide tread, and an engine in front. In 1926 the Fageol organization developed the first integral-frame bus, with twin engines mounted amidships under the floor. The integral frame utilized the roof, floor, and sides of the bus as structural members.

First vehicle designed as bus

Other early bus manufacturers were Mack and Yellow Coach in the United States, both of which built gasoline-electric models. In these buses, a gasoline engine drove a direct-current generator, and the output of the generator provided electrical power for the driving motors on the rear wheels. This electrical system performed the functions of a transmission; *i.e.*, it multiplied driving torque and provided a means of connecting and disconnecting the engine from the drive wheels. In 1928 the first transcontinental bus service was initiated in the United States.

In 1931 the first rear engine in an integral-frame bus was introduced. Two-stroke-cycle diesel engines were first used in buses in 1938 and were still used by most city and intercity models in the 1970s.

Advantage of air suspension

In 1953 air suspension was first used in buses; in the 1960s most of the integral-frame models continued to employ this type of suspension; the others used conventional metal leaf springs. Air suspension, although first tried on automobiles and trucks, found more general acceptance on buses. It required an air compressor, and automobile manufacturers and consumers soon concluded that the improvement in riding comfort did not justify the expense of the equipment for passenger cars.

Air suspension consists of two or four air springs (heavy rubber bellows) per axle (Figure 1). The air springs are supplied with air from an air reservoir in which the pressure is maintained at about 100 pounds per square inch (7 kilograms per square centimetre). An advantage gained from this type of suspension is that as the load increases or decreases the level and height of the vehicle remain constant. This is accomplished by valves that are actuated by the vehicle height between the body and the axle; as the load is increased, the air pressure is increased in the air spring. The increased unit pressure multiplied by a nearly constant area gives a greater load capacity. As the load is removed, the air is released from the air spring, reducing the pressure and load capacity.

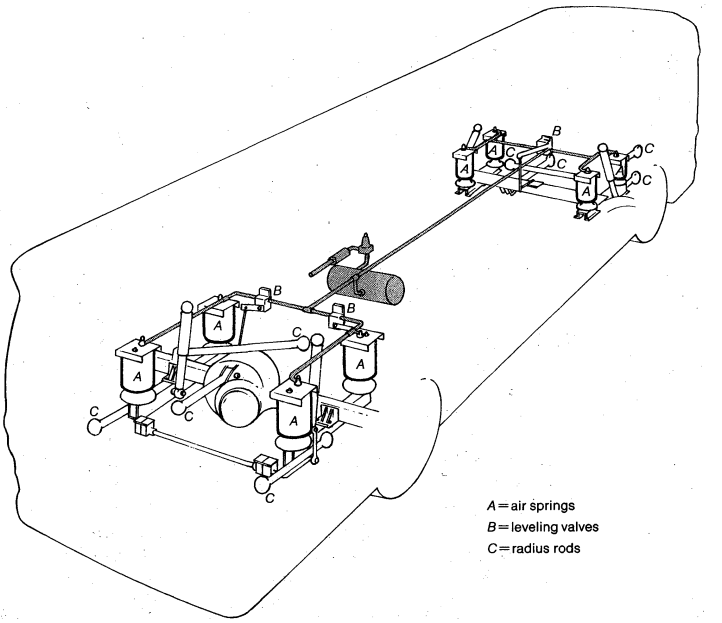

Figure 1: Air suspension for a modern bus or motor coach. The shaded area indicates the air lines.

Unlike the leaf spring but like the coil spring, the air spring is capable of withstanding only vertical forces. Consequently, braking and cornering forces must be absorbed by links or arms with one end attached to the axle and the other to the body by pin or ball joints.

Another interesting development in motor-bus transportation was the Scenicruiser introduced in the United States in 1954 for transcontinental use. It utilizes air suspension and has six wheels, two singles in the front for the steering axle and four doubles in the rear in a tandem arrangement (one axle directly behind the other with an interconnection to allow the equalization of the load). Thus, the weight of this vehicle, about 30,000 pounds (14,000 kilograms) empty, is supported by ten tires, two on the front axle and four on each of the rear axles. The frame is of the integral type and provides two levels. The first level carries the driver, ten passengers, and sanitary facilities; the upper level carries 33 passengers and has a windshield so that passengers can see forward. The Scenicruiser is powered by two four-cylinder two-stroke-cycle diesel engines of 133 horsepower each. Only a limited number of these vehicles were built because of cost.

Two-level design of Scenicruiser

Modern buses. In Europe, especially in England, the double-decker bus is used to minimize the street space occupied and to take advantage of the greater manoeuvrability of the shorter wheelbase without loss of passenger capacity. A typical bus of this type carries 26 passengers on the lower deck and 30 on the upper. In Germany, double-decker and 1½-decker buses are operated, as are trolley buses and articulated buses. An articulated bus is one in which a single-deck bus pulls a trailer, using a flexible joint. Consequently, unless it is turning a corner, the vehicle appears to be one continuous unit. In most of the world, however, the trend is toward one-unit single-deck vehicles, usually of large size. In Japan as late as 1963, 21-passenger buses were used in Tokyo and Kyōto, often mounted on a truck chassis. The improvement of roads and the building of expressways have triggered the rapid expansion of the automotive industry in Japan, which, in 1970, included eight bus manufacturers building buses ranging in size from small gasoline-driven units to large diesel-driven units.

There are four main types of buses: city or transit, suburban, intercity, and school. The city bus operates within the city limits and is characterized by low maximum speed, low-ride platform, provision for standing passengers, two entrances on the curb side, low-back seats, and no luggage space or racks. The suburban bus is designed for short intercity runs, with roof windows op-

Characteristics of the intercity bus

tional for sightseeing; back seats are high, some luggage space and luggage racks are provided, and there is a single, front entrance. The intercity type has a high-ride platform to provide maximum luggage space under the passengers, high-back seats, overhead luggage racks, individual reading lights, and a washroom. A typical intercity coach weighs about 26,000 pounds (12,000 kilograms), has a capacity of 47 passengers, a 285-horsepower two-stroke-cycle V-8 diesel engine, a four-speed manual transmission, and air brakes. School buses generally consist of a bus body mounted on a long-wheelbase truck chassis, but some integral-frame buses are now being manufactured.

Gas-turbine engines may be adopted for some types of buses, though in the early 1970s they were not in wide use. To provide wider, more comfortable bus seats, overall width has been increased on some new models.

Trucks. In 1896 Gottlieb Daimler of Germany built the first motor truck. It was equipped with a four-horsepower engine and a belt drive with two speeds forward and one in reverse. In 1898 the Winton Company of the United States produced a gasoline-powered delivery wagon with a single-cylinder six-horsepower engine.

In World War I motor trucks were widely used and in World War II largely replaced horse-drawn equipment on most fronts. A notable vehicle was the four-wheel-drive, quarter-ton-capacity, short-wheelbase jeep, capable of performing a variety of military tasks.

Types and definitions. Trucks can be classified as either straight or articulated. A straight truck is one in which all axles are attached to a single frame. An articulated vehicle is one that consists of two or more separate frames connected by suitable couplings. A truck tractor is a motor vehicle designed primarily for drawing truck-trailers and constructed to carry part of the weight and load of a semitrailer, which is a truck-trailer equipped with one or more axles, so constructed that the end and a substantial part of its own weight and that of its load rests upon a truck tractor. In contrast, a full trailer is so constructed that all of its own weight and that of its load rests upon its own wheels.

Use of fifth wheel for articulated units

A device called a fifth wheel is used to connect a truck tractor to a semitrailer and to permit articulation between the units. It generally includes a lower half, consisting of a trunnion (pivot assembly) plate and latching mechanism, mounted on the truck tractor for connection with a kingpin mounted on the semitrailer. A semitrailer may be converted to a full trailer by a trailer-converter dolly, an auxiliary axle assembly equipped with the lower half of a fifth wheel, a drawbar, and other special parts.

Axle assemblies of heavy trucks may be made up of two or more axles, any of which may be powered. Normally, they are so spaced that the distance between axle centres is not more than one and one-half times the overall diameter of the wheel and tire. If the axles are separated by a larger distance the assembly is called a spread tandem.

Shown in Figure 2 are several types of trucks and truck tractors in use, with a digit code to aid in identification of the vehicles. The first digit refers to the power unit and a second single digit refers to a full trailer. A digit with an S prefix refers to a semitrailer; for example, 2-S1 means a two-axle tractor and one-axle semitrailer; 3-2 means a three-axle truck with two-axle full trailer; 2-S1-2 means a two-axle tractor, one-axle semitrailer, and two-axle full trailer.

Frames. Truck and truck-tractor frames, except for the very small sizes, have remained separate from the cab and body. The frame is generally made of two channel sections of alloy steel with a standardized width of 34 inches (0.86 metre) overall. Semitrailers and tank trailers in many instances now employ the integral, or unitized, type of construction.

Suspensions. The most common form of front suspension is a drop-forged one-section front axle attached to the frame through leaf springs and shock absorbers. In 1960 individual front suspension was introduced.

The variations of rear suspensions for trucks and truck tractors are almost limitless. In the case of a truck with a single powered axle, the axle is generally attached to the frame by leaf springs. The axle is always full-floating; *i.e.*, all the weight is carried by the axle housing and none by the live or driving axle inside the housing. Thus, if a driving axle breaks, the load is still supported by the axle housing. The axle may be a single reduction type, meaning that it has one-gear reduction, or double reduction. A two-speed axle is one in which there is a gear change built into the axle. This makes it possible to have two speeds for each transmission speed. The tandem-drive axle has two powered axles. There may be two drive shafts, one to each axle. There is always a system of levers between the two axles to equalize the load. A powered axle may be either the Hotchkiss type, in which all of the driving and braking thrust is taken by the leaf springs, or the torque-arm type, in which the thrusts are taken by the rods. Because the vertical movement of the body is only one-half that of the wheels in a tandem axle, this axle is used successfully with solid rubber springs, reducing maintenance to a minimum.

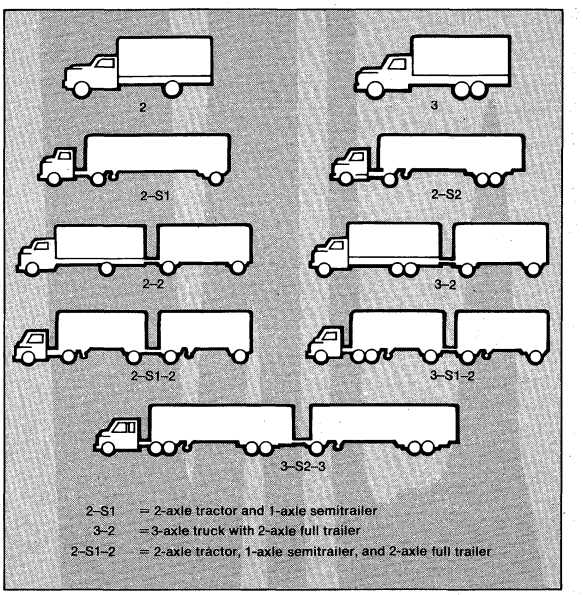

Figure 2: Truck types as designated by code based on axle arrangement.

Steering. Steering of trucks, with their relatively heavy loads, was a problem until power steering came into use in the early 1950s. Steering is always by the Ackermann system, which provides a kingpin for each front wheel. Maximum cramp angle of the front wheels is about 35 degrees. The minimum turning radius is dependent on the wheelbase. A few vehicles have been built with two steering axles in the front.

Ackermann steering system

Engines and fuels. Until the 1930s the gasoline engine was widely used for trucks, especially in the United States, but since World War II the diesel engine has become increasingly favoured for trucks used for long-distance hauls. In 1950 the Boeing Company of the U.S. installed the first gas turbine in a truck; in the 1960s there was renewed interest in this type of engine. In 1952 an engine using liquid-propane gas was introduced. While the diesel engine has the disadvantage of high initial cost, the propane-burning engine has the disadvantage of lower output for a given engine displacement.

Tires. Although pneumatic tires appeared on automobiles as early as 1904, large trucks were equipped with hard rubber tires until World War I. Cotton was replaced by rayon in the carcass of truck tires in the 1930s, with wire and nylon appearing a decade later. Recent developments include the use of a single wide tire to carry the same load as a dual wheel. Tire chains first became available in 1904, knobby snow tires by 1936, and snow tires with embedded wire coils about 1950. One of the latest and most effective versions of this tire has curved tread ribs. To reduce costs, many trucks use recapped tires, extending the life of the carcass about two and a half times. In 1955 tubeless tires became available in large truck sizes.

Transmissions. Although automatic transmissions for trucks have been available since the 1950s, they have not received popular acceptance for large units. For some diesels it is necessary to operate the engine within a relatively narrow speed range, typically 1,500 to 2,200 revolutions per minute. This requires a large number of forward speeds. One of the most recent diesel-powered units has 16, obtained by combining two transmissions, each with four forward speeds. The single-plate dry-disk clutch is commonly used to connect and disconnect the engine from the transmission.

Large number of forward speeds

Brakes. The first truck brakes were brake shoes operating directly on the wheels. From this simple beginning has evolved one of the most complex braking systems found on any type of vehicle. The first air brakes were introduced in 1918. Seven years later four-wheel brakes were introduced on trucks, and the internally-expanding type was introduced by 1930. In the late 1930s the vacuum booster, or hydraulic brake, was introduced. This was the power brake available on the automobiles in the mid-1950s.

Another means of brake application is electrical. A floating armature contracts a rotating disk on the wheel when electric current is applied, and through a cam arrangement applies the shoes to the drums. Vacuum brakes working off the vacuum in the intake manifold of the spark-ignition gasoline engine have been used to apply the brakes on car carriers. Air-over-hydraulic brakes are also used in some vehicles.

Air, air-over-hydraulic, vacuum, and electrical brakes are all adaptable to articulated vehicles. Of these methods of application, air, or full air, as it is sometimes called, is the most widely used. The engine-driven compressor supplies air at a nominal pressure, regulated by an air governor. Air pressure is indicated by a pressure gauge and a low-pressure warning device, either audible or visual. Air is stored in the reservoirs and supplied to the brake valves; a foot valve supplies air to all brake chambers on the vehicle, including those being towed. Another brake valve is hand controlled and applies the brakes on the towed vehicle only. Both the foot pedal and hand valve supply air to the same service line, which extends back to the towed vehicles. The second, or emergency, line carries full air pressure when the vehicle is in operation. If this line is broken, the emergency brakes are applied on all towed vehicles from air reservoirs located on the towed vehicles. After reaching the brake chamber from the brake valves, the air acts on a diaphragm connected to a push rod, which in turn actuates a cam that moves the shoes against the brake drum. In the early 1970s the cam was being replaced by a wedge.

Use of air brakes

In recent years much attention has been given to the problem of brake failures that have resulted from loss of air pressure. The emergency system mentioned previously can be utilized in case of a failure in the service line by the use of the tractor protection valve and control valve. The driver can flip the lever of the control valve and apply all brakes on the towed vehicles.

There is another form of safety system that in normal use is a parking brake but in the event of loss of air can be used as an emergency system. It is known as a DD3 actuator. The driver has the option of using the axle on which the DD3 actuators are mounted as a parking system or as an emergency braking system by operating a push-pull button. Once this system is actuated, a mechanical lock holds the brake on, even if all air pressure is lost.

Another emergency system is the spring brake system, in which springs are used to apply the brakes if the air has been lost. As long as normal air pressure is available, the spring brake actuator is inactive and the normal brake chambers apply the brakes. The driver can place the emergency system in action at his option by means of a push-pull valve.

Athough air-cooled, disk-type hand brakes on the drive shafts of heavy-duty trucks have been used for some time, it was not until recent years that experimental models for the wheels were available. In the early 1970s there was rather strong interest in antilocking brakes for articulated vehicles in order to reduce the possibility of jackknifing.

Truffaut, François

When his film *The 400 Blows* won the "best direction" prize at the 1959 Cannes Festival, François Truffaut established himself as a leader of the French cinema's *nouvelle vague* ("new wave")—a term for the simultaneous presentation of first feature films by a number of French directors—a tendency that profoundly influenced the rising generation of film makers around the world. The New Wave marked a reaction against the commercial production system: the well-constructed plot, the limitations of a merely craftsmanlike approach, and the French tradition of quality with its heavy reliance on literary sources. Its aesthetic theory required every detail of a film's style to reflect its director's sensibility as intimately as a novelist's prose style retraces the workings in depth of his mind—hence the phrase *le camera-stylo* ("camera-pen"). The emphasis lay on visual nuance, for, in keeping with a general denigration of the preconceived and the literary, the script was often treated less as a ground plan for a dramatic structure than as merely a theme for alfresco improvisation. Improvised scenes were filmed, deploying the visual flexibility of newly developed television equipment (*e.g.*, the hand-held camera) and techniques (*e.g.*, extensive postsynchronization of dialogue). The minimization of costs encouraged producers to gamble on unknown talents, and the simplicity of means gave the director close control over every aspect of the creative process, hence Truffaut's term *auteur,* or film author.

Truffaut was born in Paris on February 6, 1932, into a working-class home. His own troubled childhood provides the inspiration for *The 400 Blows,* a semi-autobiographical study of a working-class delinquent. It is the first of the Antoine Doinel trilogy, tracing its hero's evolution from an antisocial anguish to a happy and settled

Truffaut (right) directing Jean-Pierre Léaud in *Les Deux Anglaises et le Continent,* 1971.

domesticity. Outside his art, Truffaut is reticent about his private life, although it is known that he was sent to a reformatory before leaving school at 14 to work in a factory. But his interest in the cinema brought him to the attention of the critic André Bazin, doyen of the monthly avant-garde film magazine *Cahiers du Cinéma*, who incorporated him into the staff. For eight years Truffaut asserted himself as the most truculent critic of the contemporary French cinema, which he considered stale and conventional, and advocated a cinema that would allow the director to write dialogue, invent stories, and, in general, produce a film as an artistic whole in his own style. Thus, he was influential in the cinema world before he actually made a film. Like his leading character in *Stolen Kisses*, another film in the Doinel series, he deserted from his military service, being committed to various prisons until he was able to resume his journalistic career and, eventually, put his ideas into creative practice. Again like Doinel in *Domicile conjugale* (*Bed and Board*), he married and became the father of two daughters.

Film critic

His initial creative effort was a short slapstick comedy *Une Histoire d'eau* (1958), for which he felt unable to evolve a suitable conclusion and which he turned over to his unfailingly ingenious contemporary Jean-Luc Godard. His second short, *Les Mistons* (1958), depicting a gang of boys who thoughtlessly persecute two young lovers, met with sufficient appreciation to facilitate his first feature-length film, *The 400 Blows*. An evocation of the adolescent's pursuit of independence from a staid adult world of conformity and protocol, for which Truffaut evinced a romantic sympathy, the film proved to be one of the most popular New Wave films, especially in England and the United States. Two tenderly pessimistic studies in sexual tragedy followed, *Jules and Jim* (1961) and *Shoot the Piano Player* (1960), the latter adapted from the American thriller *Down There* by David Goodis, a genre for which Truffaut has evinced great admiration. After these three films he seems to have had a period of hestitation. His films since then, however, have all been intensely personal and are divided between two themes: studies in forlorn childhoods—*e.g.*, The Doinel trilogy and *The Wild Child* (1970), the chronicle of an 18th-century doctor who attempts to domesticate an uncivilized child; and sensitive melodramas sadly celebrating disastrous confrontations between shy heroes and boldly emancipated or possessive women. The first theme shows the influence of film maker Jean Vigo, in its uncompromising stance against authority of any kind, and of Jean Renoir, in its feeling for place and atmosphere and its mingling of the nostalgic with sudden outbursts of blatant humour, as well as of Truffaut's personal experience. The second owes much to the American *roman noir*, or "black novel," the diverse manifestations of which, from the morally disintegrated heroes of William Faulkner to the sadistic gangsters of Mickey Spillane, have fascinated French novelists from Sartre to the present. One senses a certain hero worship, also, in Truffaut's long, published conversations with the veteran American film maker Alfred Hitchcock, whose work he admires in complete defiance of his earlier theories. Of Truffaut's features only *Fahrenheit 451*, a film version of Ray Bradbury's science-fiction novel, falls outside these categories, though it relates to the American style and the poetic-melodramatic form. Through his production company, Les Films du Carrosse, Truffaut coproduced, among other films, Godard's first feature and Jean Cocteau's last.

New wave director

Truffaut's cinematic style

For Truffaut, now, the cinema must be, on the one hand, personal and, on the other, a splendid spectacle, like a circus. On the one hand, childhood's vulnerability; on the other, its joys. The style of his first three films, at once delicate, lyrical, and exceptionally fertile in cinematographic invention, has become, partly by choice, more prosaic and conventional. Controversy has centred on the extent to which his films involve a militant conservatism—whether, for example, Truffaut in *The Wild Child* deplores, documents, feels nostalgic for, or positively and without reservation, approves the narrow, strict rigidities with which its psychologist (played by Truffaut himself) sets about civilizing the abandoned, autistic child. It may be that Truffaut's inspiration is rooted in the nostalgias and despairs of his childhood, and as with success he has matured into adult and father, so his films have lost in lyricism, while maintaining their fidelity to life's prosaic side. But life's grayness and flatness are recorded with a sense of resignation and quiet achievement quite distinct from platitude or petulant nihilism.

MAJOR WORKS

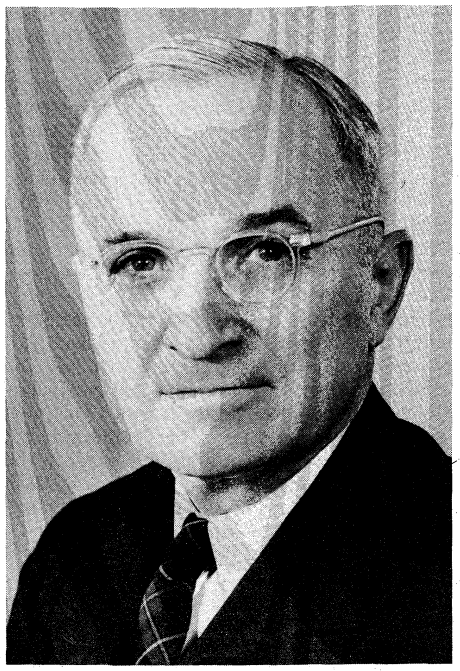
Les Mistons (1958, *The Mischief-Makers*); *Les Quatre Cents Coups* (1959, *The 400 Blows*); *Tirez sur de pianiste* (1960, *Shoot the Piano Player*); *Jules et Jim* (1961, *Jules and Jim*); *La Peau douce* (1964, *Silken Skin, The Soft Skin*); *Fahrenheit 451* (1966); *La Mariée était en noir* (1968, *The Bride Wore Black*); *Baisers volés* (1968, *Stolen Kisses*); *La Sirène du Mississippi* (1969, *The Mississippi Mermaid*); *L'Enfant sauvage* (1970, *The Wild Child*); *Domicile conjugale* (1970, *Bed and Board*).

BIBLIOGRAPHY. GRAHAM PETRIE, *The Cinema of François Truffaut* (1970); and C.G. CRISP, *François Truffaut* (1972), are two useful book-length studies. In addition to TRUFFAUT's *Hitchcock* (1967), the scripts of *Les Quatre Cents Coups* (1969) and *Jules et Jim* (1968) have been translated into English.

(R.Du.)

Truman, Harry S.

In a comparison of U.S. presidents, Harry S. Truman, the 33rd president of the United States (served 1945–53), must be judged one of the strongest. Yet during his term of office his reputation was that of a man far too small for his job. Compared unfavourably by Northern Democrats with his popular predecessor, Franklin D. Roosevelt, condemned by Southern Democrats for his liberal civil rights program, and at war with Republican isolationists and economic conservatives, Truman spent a turbulent period in office. But after his term the significance of his efforts slowly became evident, especially his foreign policy goal of containing Communist expansion and his largely unsuccessful programs of social and economic reforms to raise standards of living for workers and farmers and to broaden civil rights for minorities; his continual pursuit of these goals kept them viable for future action.



The keys to Harry Truman's outlook were a Midwestern agrarianism, a suspicion of big business, and an inordinate interest in history and battles. In personality he was characterized by a low boiling point, a loyalty to his friends, an inoffensive cockiness, and native shrewdness and wariness.

Early life

Truman was born in Lamar, Missouri, on May 8, 1884, the son of a mule trader and farmer. His paternal forebears were English and first came to America in 1666. Truman attended school in Independence, Missouri. He completed high school in 1901; but he could not go to college because of family financial reverses, nor could he attend West Point because of his vision. He became a bank clerk in Kansas City; then in 1906 he took over management of his maternal grandmother's farm at Grandview. He also served as local postmaster, town road overseer, and national guardsman. He became a partner in a lead mine in 1915 and in an oil-prospecting business a year later, but both failed.

Truman distinguished himself in heavy action as a captain in World War I, showing bravery and other qualities of leadership. On June 28, 1919, he married Elizabeth Bess Wallace, an Independence girl he had known since childhood. He became a partner in a Kansas City haberdashery store; and when the business failed, he entered politics with the help of Thomas Pendergast, a Democratic boss of Jackson County.

With support of Pendergast's machine and of World War I veterans, Truman won a seat as county judge in 1922. But despite excellent work, in 1924 (the same year his daughter Margaret was born) non-Pendergast Democrats combined with the Ku Klux Klan to defeat him. Truman then sold memberships in the Kansas City Automobile Club and attended night classes for two years at the Kansas City Law School. A state bank in Englewood in which he became a partner went into bankruptcy be-

Truman, 1945.

cause of the fraudulent activities of its former owner; but Truman enjoyed his first business success following his organization of the Community Savings & Loan Association in Independence.

With Tom Pendergast's backing, in 1926 he became presiding judge of the county court. As a two-term, eight-year county administrator, Truman's reputation for honesty and good management gained him Republican as well as Democratic support. Meanwhile, Pendergast was gaining dictatorial control over Jackson County; he achieved statewide power in the early 1930s, determining who would serve as Missouri's governor and as its members of the U.S. House of Representatives. That Truman was not in his inner circle was revealed in 1932 when Pendergast stifled his ambition to become governor and refused to name him to the Missouri delegation to the Democratic National Convention.

Reputation for honesty

In 1934 Truman's political career seemed ended because of the two-term tradition attached to his job. But the machine's gangsterism in the March municipal election, in which four persons were killed at the polls, had a direct bearing on his future. After three individuals rejected Pendergast's subsequent offer of support in the coming U.S. Senate primary contest, Truman, his fourth choice, quickly accepted. Truman was elected with the help of a suspicious machine vote in Jackson County.

Truman entered the U.S. Senate in 1935 under the cloud of being the puppet of a crooked boss. But his attention to duties and his friendly personality soon won over his colleagues. He was the author of the Civil Aeronautics Act of 1938, and his two-year committee investigation led to the Transportation Act of 1940. The outlook for Truman's re-election in 1940, however, was gloomy; the Pendergast machine lay in shambles, with Tom Pendergast in prison for having taken bribes. President Roosevelt offered Truman a face-saving place on the Interstate Commerce Commission, but he stubbornly ran for another term even though newspapers rated him a distant third in a three-man primary race. Yet because of the last-minute support of Robert E. Hannegan, a young St. Louis Democratic subboss, Truman won by a slender margin.

The nation's growing defense and then war production programs soon launched Truman into his major senatorial endeavour. His Special Committee Investigating National Defense exposed a long list of graft, waste, and product deficiencies and brought him public praise. At the same time, he used his expanding patronage power to reward Hannegan with a series of appointments. The advancement of Hannegan to chairman of the Democratic National Committee in January 1944 led to a successful effort to have Roosevelt replace Vice Pres. Henry A. Wallace with Truman on the victorious 1944 presidential ticket. Truman's vice presidency lasted only 82 days, during which time he met with Roosevelt only twice and had little knowledge of the administration's programs and plans. Roosevelt died on April 12, 1945. Truman was a month away from his 61st birthday when he took the presidential oath of office. Vital decisions had to be made at a relentless pace, despite his lack of tutelage. In swift order he made final arrangements for the San Francisco charter-writing meeting of the United Nations, helped arrange Germany's unconditional surrender on May 8, and went in July to his first and only summit meeting, at Potsdam, Germany, for inconclusive talks about a peace settlement. The Pacific war ended officially on September 2, after atomic bombs had been dropped on the Japanese cities of Hiroshima and Nagasaki following Truman's orders. His justification for the bombings was a report from advisers that 500,000 Americans would be lost in an invasion of Japan.

Succession to the presidency

Truman enjoyed a five-month honeymoon with Congress, which ended in September 1945 when he submitted his "Economic Bill of Rights," which included social reforms that he hoped would head off a return to economic depression. The developing vocal opposition, added to public weariness over meat shortages and inflation and the defection of Roosevelt admirers when Truman installed his own choices in his Cabinet, combined to give Republicans control of Congress in 1946. Two years later many Democratic leaders believed Truman could not win election and demanded that he retire. But the 1948 convention nominated him, with Sen. Alben W. Barkley as his running mate. All public opinion polls showed that the New York governor Thomas E. Dewey, the Republican nominee, would be an easy winner. Undaunted, Truman carried out a "give 'em hell" campaign, repeatedly denouncing the "Republican do-nothing 80th Congress." In November he upset a complacent Dewey by a 114-electoral-vote margin.

In his State of the Union message in 1949, Truman proposed the Fair Deal, a liberal 24-plank domestic program. But despite his efforts, only a single plank was enacted into law—a low-cost public housing measure. He fared much better in foreign affairs, however, where he considered the Soviet Union the principal roadblock to world peace. To restrict Soviet territorial advances and spreading spheres of influence, he developed a "containment" policy, thus setting the course of U.S. foreign policy for decades to come. Among his Cold War moves were the Truman Doctrine of economic and military aid to Greece and Turkey in 1947 to reduce Communist pressures on their governments; the four-year $17,000,000,000 Marshall Plan of 1948 for economic recovery in western Europe; and the North Atlantic Treaty Organization (NATO) pact of 1949, a collective security agreement with non-Communist European nations. When China came under Communist control in 1949, Truman's containment policies were extended to include that giant nation. He also established the Central Intelligence Agency (CIA) in 1947, initiated the Berlin airlift of 1948 to bring supplies into the former German capital when the Soviets blocked surface entrances, instituted the Point Four Program of 1949 to provide aid to underdeveloped countries, and decided in 1950 to construct the hydrogen bomb in order to maintain an arms lead over the Soviets, who had recently exploded an atomic bomb.

In June 1950 Communist North Korea crossed the 38th parallel boundary and attempted to seize South Korea. Truman sent U.S. forces to Korea under Gen. Douglas MacArthur with UN sanction. Once MacArthur had liberated the south, the administration ordered the capture of North Korea; but MacArthur's advance to the Yalu River boundary with Manchuria brought hundreds of thousands of Chinese Communist troops into the fighting. MacArthur's insistence on attacking China as well forced Truman to fire him.

Outbreak of the Korean War

The unpopularity of the continuing war and the uncovering of unsavoury and fraudulent activities by several federal officials made Truman's last two years in office appear chaotic. A further decline of confidence in the government was brought on by the charges of Sen. Joseph R. McCarthy of Wisconsin that the State Department and other agencies were Communist-controlled.

After Truman left office in January 1953 and returned to Independence, his popularity soared. And with the perspective of passing years the haze surrounding his presidency lifted. What remained was a man who had generally succeeded in his foreign policy and a president who, as Harry Truman himself once put it, had "done his damndest." He died on December 26, 1972, in Kansas City, Missouri, and was buried at the Truman Library grounds in Independence, Missouri.

BIBLIOGRAPHY. ALFRED STEINBERG, *The Man from Missouri* (1962), covers Truman's life and activities through his presidency. Other biographies are JONATHAN DANIELS, *The Man of Independence* (1950), which contains a good account of Truman's early career; and CABELL PHILLIPS, *The Truman Presidency* (1966), a complete study. WILLIAM HILLMAN, *Mr. President* (1952), has letters and excerpts from Truman's diaries. WILLIAM M. REDDIG, *Tom's Town, Kansas City and the Pendergast Legend* (1947), is the best work on the Pendergast machine. DONALD H. RIDDLE, *The Truman Committee* (1964), deals with the Senate period; TRISTRAM COFFIN, *Missouri Compromise* (1947), presents a picture of the early Truman presidency; TOM CONNALLY and ALFRED STEINBERG, *My Name Is Tom Connally* (1954), relates aspects of the unfolding Cold War. See also HARRY S. TRUMAN, *Memoirs*, 2 vol. (1955–56); *Public Papers of the Presidents: Harry S. Truman, 1945–53*, 8 vol. (1961–66), the best collection of source materials; and MARGARET TRUMAN, *Harry S. Truman* (1973), a candid, readable account that was written by his daughter.

Trusts, Law of

The trust is one of the most comprehensive institutions of modern law, being rivalled in scope and flexibility only by the limited company, or corporation. Although there are many different kinds of trusts, they all include the feature that a person who is called the trustee has vested in him property that he is bound by an equitable obligation to hold and, in many cases, to administer on behalf of other persons or institutions, who are termed beneficiaries, though the trustee himself may be one of them. There may be a trust of any property that is capable of being owned or transferred.

An increasing number of the world's legal systems now recognize, in a variety of forms, the institution of the trust; but for many centuries its development was one of the principal achievements of Anglo-American law.

HISTORICAL DEVELOPMENT

The "use" of medieval England

The predecessor of the modern trust was the medieval "use," the creation of which can be traced to the limitations and burdens imposed upon landowners of freehold land by the feudal common law in England. Until the 16th century there could not be a will of freeholds at common law, but the practice grew up of transferring the land to another, termed the feoffor to uses, who undertook to hold it for purposes declared by the feoffor (that is, the grantor). This transaction was employed not only as a legitimate method of providing for property management and for conveyancing, however, but also as a method of defrauding creditors, depriving feudal landlords of their dues, and permitting religious institutions to derive the benefit of land that they could not own directly. For about 150 years the carrying out of the use depended on the conscience of the person entrusted with the property, because there was no writ by which the common-law courts could enforce it. Toward the end of the 14th century, however, the chancellor who administered equity began to issue decrees for its enforcement, and the use changed from a merely honorary to an enforceable obligation.

The loss of feudal revenue to the feudal lords and, particularly, to the king as the ultimate overlord was the principal reason for the passing of the Statute of Uses (1535), which was intended to abolish the use. Through interpretations and court decisions, however, some types of use escaped the operation of the statute; and, in any event, the statute set in motion changes in the transfer of land. It came to pass that a greater variety of legal estates could be created than had previously been possible at law; and, although the statute destroyed the possibility of making a will to uses, the subsequent Statute of Wills (1540) for the first time permitted a legal will of freehold land. Furthermore, in the next 200 years all the main features of the modern trust were established by the decisions of the courts of equity.

The appearance of the modern trust

Although the modern trust is derived from the medieval use, there are important differences between the two institutions. The use was developed in respect to land. The trust is applicable to all forms of property and particularly to commercial securities of all kinds. Further, the great majority of uses were passive; that is, the feoffee was not expected to act in relation to the land but had to allow the beneficiary to administer it. The vast majority of modern trusts are active—the trustee administers the property—and in consequence the courts of equity have developed a body of equitable rules defining the administrative powers of the trustee. These relate to trustee investments—the power to sell, lease, or mortgage trust property; the powers of maintenance and advancement of beneficiaries; the power to appoint agents; and numerous other matters. During the last century many of these rules have been embodied in statutes in the United Kingdom, the United States, and the countries of the Commonwealth.

One of the most striking features of the law of trusts during the present century has been its progressive extension in some civil-law countries, such as Mexico and Cuba, as well as in all English-speaking countries that have adopted to some degree the common law.

THE CHARACTERISTICS OF TRUSTS

Elements involved in a trust. Certain features are always found in a trust.

Settlor. The settlor is so called because early trusts in England were created in marriage and other settlements. He is the person who owns property and goes through the acts necessary to create a trust of it.

Trust property. There can be no trust without identified property to which the trust is to attach, which is called the trust property or subject matter. It may consist, for example, of real property, stocks, bonds, mortgages, insurance policies, a bank account, or real estate.

Trustee. Although a trustee is not necessary in order that a trust be created (the court will supply one if none is named by the settlor), the trust cannot be carried out without some person in whom title to the trust property can be vested and who can perform the acts of trust administration. There may be two or more trustees. These are usually persons in whom the settlor has confidence (relatives, friends, or business associates) or corporations to whom the power to carry out trusts has been given by statute (banks and trust companies). A person who is named as trustee may decline or accept, as he chooses. After acceptance he may resign (usually by court permission, but in England, under statutory provisions, usually requiring consent of his co-trustees); he may be removed by the court if he has committed serious breaches of trust or if his continuance greatly endangers the welfare of the beneficiaries. In the United States, in most cases before a trustee can act, he must go through certain formalities called qualification—for example, filing a surety bond. Corporate trustees are generally excused by statute from giving a bond, but they are required to deposit a security fund with a public official to guarantee their responsibility.

The role of the trustee

In England, under the Public Trustee Act (1906), and in certain other jurisdictions, an official has been appointed to undertake the work of trustee. Fees are charged, but the settlors and beneficiaries are offered the advantage of a state guarantee against loss. The institution is useful in offering a trustee who can be appointed when there is no other suitable candidate.

Beneficiary. No private trust can exist without beneficiaries who are identifiable legal entities (natural persons or corporations) or a class of persons (such as children of the settlor). Although the beneficiaries must be described with certainty at the beginning of the trust, provision may be made for the addition of new beneficiaries as persons are born and other events happen; and so the group may shift in membership from time to time, as long as all are clearly identifiable at any particular time.

Trust instrument. The trust instrument is the document in which the settlor expresses his intent to have a trust and describes its provisions. It usually consists of a deed or a will.

The varieties of trust. *Express trusts.* An express trust arises as a result of the deliberate act of the creator of the trust. It is an equitable institution for which no particular form is generally required, so long as the intention to create a trust is plainly manifested. Particular statutes may nevertheless impose requirements for particular kinds of trust. Thus Section 53(1) of England's Law of Property Act (1925) provides that all declarations of trust of land or of any interest in land shall be "manifested and proved" by some writing signed by the declarer. It is not necessary that this writing should come into existence at the time when the trust is created. It is sufficient if it exists when steps are taken to enforce the trust. This statute relates primarily to trusts created inter vivos—that is, by a person during his lifetime. It is, however, a common practice for a testator to establish a trust by his will, usually for the benefit of his family. When this occurs, the creation of the trust must satisfy the requirements of the law of wills in the country where the testamentary disposition is made. In England, for example, the Wills Act (1837) requires all testamentary acts to be in writing, signed by the testator at the foot or end of the will, and attested by the signatures of two witnesses (neither of whom may receive a benefit under the will).

When the instrument establishing a trust sets out all the beneficial limitations that the settlor intends, or when it provides the machinery whereby these limitations can be determined (as, for example, when the settlor gives the trustees power to divide among a class of beneficiaries in such proportion as they should decide), the trust is said to be executed, and the court will construe its terms in accordance with the general rules applicable to documents of this kind. This situation means that if the settlor uses such technical terms as "heirs" or "next of kin," they will be given the meaning that the law of property attaches to these terms.

Executed, executory, and discretionary trusts

Contrasted with the executed trust is that which is executory. Executory trusts are created by more than one document. The first usually does no more than transfer property to trustees, indicating the general purposes for which they will hold it. At a later date a more elaborate trust instrument is prepared, setting out in detail the objects for which the trust is being created. An employer, for example, might transfer a block of shares to trustees for the purpose of establishing a pension fund for his employees; or the parents of two persons engaged to be married might transfer property to trustees for the benefit of the spouses and their issue. In the latter case, a trust instrument would normally come into existence only after the marriage was celebrated. In both cases the transfer of property would be sufficient to establish the trust, and the court, in construing it, would seek to give effect to the general intention of the settlor.

Modern trust instruments frequently create discretionary trusts. In these the trustees have complete discretion to apply trust funds within a specified class of persons—the shares that each member of the class takes being determined from time to time by the trustees. If the class is within a family, the discretion will enable the trustees to take into account the needs of the family at times after the trust has come into existence and also to accommodate the effects of changing taxation upon the shares taken by beneficiaries.

Implied trusts. A number of trusts come into existence as a consequence of the operation of equitable presumptions. They are, therefore, trusts implied by law. Thus, if A provides the purchase money for a house and the conveyance is taken in the name of B, then in the absence of any expressed intention, the law implies that B holds as a trustee for A (unless A is the father or husband of B, in which case there is a presumption that A wished to confer a benefit on B). One special variety of an implied trust is a resulting trust. This situation arises whenever there is a disposition of the whole interest in the property at law to trustees without a complete disposition of the beneficial interest in equity. If property is transferred to A, for example, on trust to pay the income to B for life, with no instruction about what is to happen on B's death, then on B's death A will hold the property on a resulting trust for the settlor. A similar presumption will operate when property is transferred to A with a direction to pay specified amounts of the income to various beneficiaries and, after these payments have been made, there is surplus income. This again will be held on trust for the settlor.

Constructive trusts. The term constructive trust is applied to a wide variety of relationships, the common element in which is the imposition by courts of equity of an obligation to hold property for the benefit of another, independently of the wishes of the person in whom the property is vested. Thus, for example, if a trustee (who is legally forbidden from making a profit from his trust unless expressly permitted to do so by the settlor) profits by misuse of trust property, the courts will direct that he hold that profit on a constructive trust for the beneficiary. In general, anyone who stands in a fiduciary relationship to another (such as a guardian, a solicitor, or other confidential agent) will become a constructive trustee of any property acquired by misuse of his position. In England a constructive trust is regarded as a special variety of trust—that is, a relationship between trustee and beneficiary. In the United States, a constructive trust is generally applicable to anyone who is found in possession of property that he is not entitled to retain, and the remedy is available to any person who is entitled to its recovery.

Remedies against the trustee profitting from the trust

Statutory trusts. Modern statutes have in some cases created trusts as a means of facilitating the holding or devolution of property. Thus, on the death of a person intestate, his personal representatives may hold his estate on a statutory trust for his issue and certain other classes of relatives. Or if there should be a conveyance of a legal estate to an infant jointly with one or more adults, the adults will serve as trustees for themselves and the infant (because the infant himself cannot hold a legal estate in land). Also, when there is a conveyance of land to a number of persons as joint tenants or tenants in common, four out of the total may act as trustees for all.

Public and private trusts. As the name suggests, public trusts are trusts that benefit the public or some general class within it, such as the members of a profession or the inhabitants of a locality. The most numerous and important trusts within this class are charitable trusts, but there are others that are not charitable, such as a trust for a golf club or a trade association.

Because charitable trusts are allowed to continue indefinitely and are granted many other privileges (such as freedom from taxation), it often becomes important to decide whether a trust purpose involves substantial social advantages and is therefore technically charitable or is a private trust. Certain purposes are admittedly charitable, as, for example, the advancement of education and scientific research, the prevention or cure of disease, the relief of poverty, and the support of religion. According to Lord Macnaughten (in the Pemsel case, 1891) there is another class of charitable gifts "for other purposes beneficial to the community." In this class may be cited gifts to furnish governmental services and to beautify towns and cities. Among borderline cases may be placed gifts for cemeteries and monuments, generally not charitable at common law but made so by many statutes, though not in England; the furnishing of recreation and amusement, not charitable in England until the enactment of the Recreational Charities Act, 1958, but approved in the

Charitable trusts

United States; and the protection and care of animals, charitable if for domestic animals in general but not if for particular animals or for wild animals that are hostile to man. Trusts to aid a political party are not charitable.

The social benefit involved in a charity must be substantial. Hence the aid of a business enterprise that has small incidental public advantages is not charitable. The views of the courts as to what is charity are controlling and not the opinion of the settlor. At one time in England religious trusts were not charitable unless for the benefit of the established church, but toleration acts have changed the law, and now the advancement of any religion not contrary to current morality is charitable. In the United States the support of any religion would probably be sustained as charitable.

THE FUNCTIONS OF TRUSTS

Family provision. One of the main objects of the development of the law of trusts has been to provide machinery whereby a settlor may make provision for the successive members of his family to the extent that the law will permit. This purpose is emphasized by the fact that trusts may be made either during life or by will to take effect on death and frequently involve strict settlement of land.

Trusts in marital settlements and in wills

One form of trust that is often executed by a living donor is the marriage settlement, either on his own marriage or on the marriage of a member of his family. By such a settlement, property is usually given to trustees for the benefit of the husband and wife during their joint lives; thereafter for the survivor for his or her life; and finally for division among their children or remote issue upon attainment of a specified age.

Trusts arising by will are exceedingly common and often take the form of a trust for sale. By such a trust, the trustees are directed to sell all the testator's assets to pay his debts and to invest the proceeds in income-bearing trustee securities for the beneficiaries. These will usually be the surviving spouse for the remainder of his or her life, and thereafter for the children or remoter issue of the testator in equal shares. In default of children, there may be other trusts for remoter relatives.

The dominating motive in establishing a family trust is to give financial security to one's close relatives. At various times, therefore, there have evolved a number of devices for their protection. These may be inserted by the settlor, but in some systems of law they are now recognized by statute. In general, for instance, an infant beneficiary under trust may not directly touch his interest because he lacks legal capacity. The trustees thus have discretionary powers to use his income for his maintenance, education, and benefit, irrespective of whether he has parents bound by law to support him. If, at any time, there is an excess of income after the infant has been maintained, this is used as capital and is invested.

All modern systems of law make special provision for the protection of persons of unsound mind; but most of them also make it possible for the property to be protected by means of a trust, in which the trustees enjoy wide discretionary powers to employ income and, if necessary, capital for the maintenance and benefit of such persons. The property of irresponsible persons may also be protected in a similar way. In England this is achieved through the establishment of a protective trust, by means of which the interest of the beneficiary vests in the trustees on a discretionary trust for his benefit. In the United States most jurisdictions permit the same end to be achieved by means of a spendthrift trust or spendthrift clause, which often confines the beneficiary to the enjoyment of the income of his property only as it falls due.

Protective and spendthrift trusts

The high incidence of modern taxation has given a new importance to the trust, as it has become the chief instrument of estate planning. Moreover, in England the Variation of Trusts Act (1958) has given beneficiaries and trustees the right to apply to the courts for the modification of trust dispositions; one reason for such an application is the desire to frame new limitations making taxation (possibly introduced after the settlement was made) less severe.

Social functions. A very wide variety of social and public purposes may be achieved by way of trusts. Social clubs, trade unions, and philanthropic organizations of all kinds commonly hold their property in this way, the trustees representing the institution so far as the outside world is concerned. Possibly the most important trusts within this class are the charitable trusts mentioned earlier. In these cases the beneficiaries are not identifiable persons because society as a whole is presumed to be the beneficiary of such a trust, and any human beings who are involved are merely conduits through whom the advantages flow to the state. Thus in the case of a trust to aid the poor, the impoverished individuals chosen yearly by the trustees to receive trust income are not the beneficiaries; rather society, which is benefitted by the relief of poverty, is considered the beneficiary.

Charity in the legal sense is a technical concept that has proved difficult to define with precision. The Statute of Charitable Uses (1601) enumerated a number of purposes considered charitable at that date, but even that was not exhaustive. In *Commissioners of Income Tax* v. *Pemsel*, decided by the British House of Lords in 1891, charitable trusts were classified as (1) trusts for the advancement of education, (2) trusts for the advancement of religion, (3) trusts for the relief of poverty, and (4) trusts for other purposes beneficial to the community, not falling under any of the other three heads. This decision has been generally followed, but it should be added that not all purposes beneficial to the community are charitable and that words such as philanthropic or benevolent are wider than charitable, and, accordingly, trusts established for such purposes may not stand up.

There are many trusts for social purposes that cannot take effect as charities, either because they do not benefit the public generally, or some public section of it, or because their trust deeds include both charitable and noncharitable objects. Such trusts must therefore conform to the law governing private trusts, and in particular the objects for which they exist must be certain.

Commercial functions. In modern times trusts have been used increasingly in a variety of ways in commercial life. A principal service of trust companies for business corporations, for example, is to act as trustees for their bond issues. As trustee under a corporate bond indenture, a trust company takes title to or a lien upon any property that may be put up as security, certifies the genuineness of each bond, observes whether or not the corporation continues to fulfill its obligations as set forth in the indenture, and takes action to protect the bondholders should the corporation default upon these obligations. Usually, it also manages whatever sinking fund the corporation provides for the redemption of the bonds and makes the interest and principal payments to the bondholders out of funds supplied by the corporation. In a comparable capacity, trust companies serve as trustees for equipment-trust certificates issued on behalf of railroad companies to acquire locomotives and cars.

Corporate trusts

Another important service of trust companies for business corporations is to act as trustees for their employee profit-sharing and pension plans. Depending upon the terms of these plans, the trust companies invest the funds in securities or use them to buy annuity contracts from life insurance companies.

Another complicated modern development has been the business-insurance trust, evolved for the purposes of minimizing taxation and at the same time ensuring the transmission of a business enterprise, or a major holding in such an enterprise, to one or more persons (possibly a relative or an associate) on death of the settlor.

TRUSTS IN CIVIL-LAW SYSTEMS

Neither Roman law nor modern legal systems directly or remotely derived from it have evolved the trust with its highly developed operation; that is, they have not determined the trustee's right to administer property distinct from the beneficiary's right to enjoy it. This situation is partly a carry over of the Roman concept of property, which did not readily lend itself to this conception of dual ownership; but it is also a reflection of the fact that

Roman law systems have developed fiduciary institutions for somewhat similar purposes in a different way.

In old Germanic law, the absence of the capacity to make a will was supplied by the practice of conveying property to an individual called a *Salmann*, who undertook to comply with the donor's instructions with regard to its disposition. Normally there would be a reservation of a life interest to the donor. By this transaction the *Salmann* became the legal owner of the property, subject to a fiduciary obligation to carry out the donor's instructions. (In this institution it is possible to discover the origin of the executor and the administrator in English law.) When the influence of Roman law was revived in Germany in the 19th century, however, the functions of the testamentary executor were limited, and there developed the concept of the *Treuhänd* as an institution not necessarily connected with the law of succession. By this institution property is once again transferred to the ownership of the *Treuhänder* for a declared purpose. If he seeks to act contrary to that purpose he will not succeed in transferring the property, and the settlor has a personal right against him for any loss. Some legal writers have argued that the *Treuhänd* is a conveyance of property subject to resolutive conditions. Thus if the *Treuhänder* commits a breach of trust, or the purposes for which the trust was created fail, the settlor can recover the property. So far as the beneficiary is concerned, his right is limited to seeking the performance of the *Treuhänder*'s obligation in his favour. Unlike the beneficiary under a trust, he has no right against the trust property itself.

The concept of *Treuhänd*

In Roman law systems, primary obligations on behalf of others were imposed by what was called a *fiducia*—a two-stage transaction in which (1) ownership of the property was conveyed to the fiduciary, and (2) the fiduciary agreed to use his right only for the attainment of the purpose for which the conveyance had been made, with a further undertaking to reconvey when the purpose had been fulfilled. In the later Roman law and in modern systems there has been extensive development of this fideicommissum, as it came to be called. It was originally a means of circumventing the rule that only Roman citizens could be established as heirs, but it became widely used to settle property on death. It differs from the trust on several counts: (1) Whereas the trustee's legal ownership and the beneficiary's equitable ownership are concurrent, the fideicommissary's ownership commences only when that of the fiduciary ends, and vice versa. (2) Thus the fideicommissum does not distinguish between legal and equitable estate, as does the trust. (3) The rights of the fideicommissary, once vested, are good against the whole world, and another fiduciary cannot destroy or burden it by alienation or charge—which is not always true under trusts. (4) The fideicommissum almost always arises by testamentary act, though in some Roman law systems, such as that of The Netherlands, there does seem a trend toward creating them inter vivos in marriage settlements.

The concept of fideicommissum

Another civil-law concept sometimes compared with the trust is the hypothec. This is a charge of one person over the property of another. Hypothecs exist for a wide variety of purposes, such as security for a debt, but they are also used to protect a person's rights over property in fiduciary or quasi-fiduciary situations. Thus in French civil law, a married woman has a hypothec over the property of a husband to protect her marital right of property; and a ward has a similar hypothec on the property of the guardian.

Charitable purposes in the civil law. Gifts for charitable purposes have been treated in the civil law in a way quite distinct from that of Anglo-American law. In the latter, the prospective benefactor may (1) give the property to an existing institution or foundation, relying on the terms of the latter's trust deed or character of incorporation to secure fulfillment of his wishes; or (2) he may transfer the property to trustees to apply it to the organization; or (3) he may find it necessary to establish a trust for a new institution, founded directly to carry out his instructions. In the civil law there is a close analogy to the first method; property may be transferred to an existing foundation that will become subject to a charge to carry out the donor's instructions. This was in fact the sole means of making gifts to charity in classical Roman law.

Other ways of making charitable gifts have been devised in systems derived from, or influenced by, Roman law. German law took advantage of the concept of the *Treuhänd*, making the church itself the *Treuhänder*. In more recent German law and in some other systems, the donor achieves his object frequently by creating a new foundation as an alternative to presenting an existing institution with a gift that may be subject to charge. Under modern German law there are provisions regulating the creation of a *Stiftung*, or charitable foundation, which has corporate personality. Every *Stiftung* must have a board of directors (*Vorstand*) through which it acts; but while the membership of the board may change, the *Stiftung* itself is unaffected. In Anglo-American law there has been development of a similar kind in the creation of a corporate trusteeship for some large charities.

The German *Stiftung*

The reception of the trust in civil-law countries. Some civil-law writers have raised objections to the idea of introducing the trust itself; basically, they feel that the civil law of property does not lend itself readily to the concept of dual ownership, which is fundamental to the trust, with its division of rights over the property between trustee and beneficiary. Laymen, too, seem particularly disturbed by the separation of the trustee's right to administer property from the beneficiary's right to enjoy it. From the point of view of the civil law, whoever has the beneficial enjoyment of property is its owner and has the right to freely dispose of it. Taking the right of property disposal away from an owner (as thus conceived) would appear to violate civil-law rules. These difficulties appear more plainly in French law than in many other civil-law systems, some of which have even given statutory definitions to the rights that are enjoyed specifically by trustee and beneficiary.

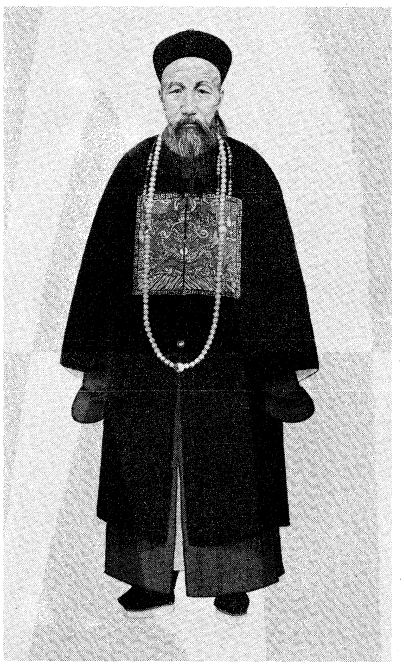
One striking feature of modern legal development has nevertheless been the reception of the trusts in numerous countries with a civil-law background. It has been introduced into Sri Lanka (formerly Ceylon) and South Africa, which have basically the Roman–Dutch system of law, and it has been adopted in the civil-law systems of Quebec, Liechtenstein, Panama, Puerto Rico, Mexico, and Venezuela. The reception has been influenced especially in Mexico by the works of the French writer P. Lepaulle, whose treatise *Traité théorique et practique des trusts*, published in 1932, did much to explain to lawyers trained in the civil law the nature of the institution and of the rights and duties that it gave.

BIBLIOGRAPHY. An account of the historical development of uses and trusts is contained in SIR W. HOLDSWORTH, *History of English Law*, vol. 4 and 6. The most complete accounts of the modern law of trusts in England, written primarily for practitioners, may be found in T. LEWIN, *Lewin on Trusts*, 16th ed. (1964); and SIR A. UNDERHILL, *Law Relating to Trusts and Trustees*, 12th ed. (1970). The two leading American treatises are: A.W. SCOTT, *The Law of Trusts*, 3rd ed. (1967); and G.G. BOGERT, *Handbook of the Law of Trusts*, 4th ed. (1963). D.W. WATERS, *The Constructive Trust* (1964), is a valuable comparison of English and American views of this institution.

The trust in Scotland is traced in T.B. SMITH, *The Trust in the Civil Law* (1962). The trust was introduced by statute into India and Ceylon (now Sri Lanka) during British rule; the *Indian Trust Act 1882* is discussed by AGGARWAL (2nd ed., 1954); and L.J.M. COORAY, *Reception in Ceylon of the English Trust* (1971), is a valuable discussion of the trust in Ceylon (now Sri Lanka), in comparison with the fideicommissum, which was derived from Roman-Dutch law. Similarly, in South Africa, where Roman-Dutch law is again the basic law, the English trust was introduced during British rule; it is acutely discussed by A.M. HONORE, *The South African Law of Trusts* (1966). The only modern work on the trust in New Zealand is that by P. NEVILL, *Concise Law of Trusts, Wills and Administration in New Zealand*, 2nd ed. (1957).

Many articles on the trust in civil-law countries are scattered through legal journals, but among major works, P.G. LEPAULLE, *Traité théorique et practique des trusts* . . . (1932), is essential first reading. Two Swiss discussions are: MAX BRUNNER, *Wesen und Bedeutung der englisch-amerikanischen Treu-*

händ (1931); and CLAUDE RAYMOND, *Le trust et le droit Suisse* (1954). Generally, for civil-law countries, two important works are: F. WEISER, *Trusts on the Continent of Europe* (1936); and K.W. RYAN, "The Law of Trusts," in *An Introduction to the Civil Law* (1962).



(G.W.K.)

Tseng Kuo-fan

The official most responsible for suppressing the Taiping Rebellion (1850–64), and hence, the saviour of the Ch'ing dynasty (1644–1911), Tseng Kuo-fan was a follower of Confucius, China's most famous teacher and philosopher, and actually applied the Master's principles.

Early career in civil service. Tseng Kuo-fan was born on November 26, 1811, in Hsiang-hsiang, in eastern Hunan Province, some 200 miles inland from China's south coast. His prosperous family was dominated by his grandfather, Tseng Yü-p'ing, a farmer with social ambitions. Tseng Kuo-fan passed the prefectural examination in 1833, one year after his father had succeeded at his 17th attempt. The next year, he passed the provincial examination and, after failing the metropolitan examination at the capital in 1835, finally passed in 1838.

Tseng Kuo-fan, portrait by an unknown artist. In the National Palace Museum, Taipei, Taiwan.

The *chin-shih* ("doctorate degree") led to appointment to the Hanlin Academy, a body of the most outstanding scholars in the country, which performed literary tasks for the court, and Tseng served continuously in the capital for over 13 years. He was introduced to the writings of such philosophers of the Sung dynasty as Ch'eng Hao, Ch'eng I, and Chu Hsi, and he always remained devoted to interpreting the Confucian Classics.

Confucian influences

Tseng's intellectual progress helped his political career. He was soon appointed junior vice president of the Board of Ceremonies, serving later as vice president of the Boards of Defense, Works, Justice, and Finance. Tseng was, nevertheless, bored with his routine life and wanted to help the people more substantially. In 1850, 1851, and early in 1852, he repeatedly submitted memorials criticizing the Emperor's personal behaviour, the government's financial policy, and Imperial treatment of an outspoken official.

Military exploits. In 1852, Tseng Kuo-fan's mother died, and, in accordance with prevailing custom, he asked permission to observe the three-year mourning period at home. This granted, he was soon called into service again when the Taiping rebels, who had taken up arms in 1850, had by 1852 reached the fertile Yangtze River Valley in south central China, seriously threatening the Ch'ing dynasty's survival. The rebellion, a great religious–political upheaval, eventually caused the loss of some 20,000,000 lives and was the greatest threat the Ch'ing dynasty had ever faced. Tseng joined the local defense forces in Hunan early in 1853, gradually shouldering more and more responsibility for the rebellion's suppression.

This was accomplished in 1864, owing largely to the intense conflicts among the Taiping leadership but also partly to Tseng's own leadership and perseverance. He had suffered two serious naval defeats in 1854, had been surrounded by enemy troops at Ch'i-men (some 130 miles west of the coast at Hang-chou) in 1861, and had frequently lacked adequate finance and staff, but, nonetheless, he fought on for 12 years.

Compromise with lobbying

During his campaign Tseng concluded that ethics alone were insufficient for politics and that leadership necessitated compromise with subordinates' vainglorious greed. Thus, on resuming military responsibilities in July 1858, having stayed at home for a mere one and one-half years —this time to mourn his father—he conscientiously answered letters, received petitioners, and magnanimously, though selectively, recommended subordinates for promotion. Consequently, he became very popular with his army, though still maintaining discipline.

Later administrative activity. Victory over the Taiping rebels in 1864 was the climax of his career. Thereafter, he was mainly an administrator, serving twice as governor general of Chiang-nan and Chiang-hsi (about 100 miles inland from the southeast coast) and once as governor of Chihli. Between May 1865 and October 1866 he again assumed military command in order to quell the Nien Rebellion that took place in northern China, but was compelled to resign after criticism by government censors.

Tseng never had an opportunity to work at the capital again after 1864, but his prestige, power, and open-mindedness enabled him to make important changes. Li Hung-chang, his protégé, gained tremendous power in the government, power that few other Chinese officials ever held and that, when passed on to the official Yüan Shih-k'ai, finally led to the collapse of the Ch'ing dynasty. (When the dynasty fell, Yüan Shih-k'ai served as president of the Republic of China.) With Tseng's support, Jung Hung, a graduate of Yale University in the United States, established an ironwork in Shanghai that later became the Chiang-nan Arsenal and is still a shipbuilding centre. It was upon Tseng's recommendation, too, that the government introduced student education overseas.

Tseng had four younger brothers, four sisters, two sons and five daughters. He treated them affectionately and frequently wrote them letters relating his experiences. Despite his contributions to the modernization of China, his views toward women were rather old-fashioned: family harmony was to be achieved by women's tolerance of masculine supremacy.

Tseng died in Nanking (some 100 miles upriver from the Yangtze's mouth on China's east coast) on March 12, 1872, and was given the posthumous title of Wen-Cheng, the highest title given to civil officials under the Ch'ing dynasty.

Since the 1920s, Tseng's role in history has caused controversy. Conservatives, such as the Kuomintang (KMT), or Nationalist Chinese, leaders, after 1928, hailed him as a symbol of Confucianism and a model of moral cultivation, while revolutionaries, including several founders of the Kuomintang and most of the Communist leaders, bitterly criticized him for nationalist reasons. He was essentially a Confucian without being dogmatically conservative in policy, and it was with the philosophy of the ancient reformer that his deepest loyalties lay.

Tsinghai

Tsinghai (Ching-hai in Pin-yin romanization), a province of northwestern China in the Tibetan Highlands, has an average elevation of 13,000 feet (4,000 metres). It is bounded on the north and east by Kansu, on the southeast by Szechwan, on the south and west by the Tibetan Autonomous Region, and on the west and north by the Sinkiang Uighur Autonomous Region. The province, a historic home of nomadic herdsmen, is noted for its horse breeding; recent geological surveys have given it new prominence as a source of both oil and coal.

The province derives its name from a large lake, the Ch'ing Hai (Blue Lake), which is conventionally known as Koko Nor, in the northeast. Tsinghai has an area of about 278,400 square miles (721,100 square kilometres), and its population in 1970 was 2,100,000. The capital is Hsi-ning (Sining), which is 120 miles west of Lan-chou, Kansu Province.

History. Tsinghai was a remote region of China, lying to the west of the historic provinces that made up China proper. Parts of it came under Chinese control in the 3rd century BC. For centuries it was sparsely occupied by nomadic herdsmen, chiefly Tibetans and Mongols, plus a few Chinese settlers on farms around the northeastern corner of Koko Nor. The Chinese population increased over the years, and Tsinghai was made a province of China in 1928.

Physical geography. Most (about 90 percent) of the province consists of mountains and high plateaus. In the north are the Ch'i-lien Shan-mo (Ch'i-lien Mountains), which form the divide between the interior and exterior drainage systems of China. Through the central part of the plateau extend the Pa-yen-k'a-la Shan (Gory Bayan-khara-ula; a spur of the Kunlun Mountains), which serve as the watershed of the headwaters of both the Yangtze and Huang (Yellow) rivers. In the southern part of the plateau, the Tsinghai–Tibetan boundary parallels the T'ang-ku-la Shan-mo. Between these high mountains are broad valleys, rolling hilly areas, and extensive flat tableland.

In the northwestern part of the plateau lies the Tsaidam Basin, an immense, low-lying area between the Pa-yen-k'a-la and the Ch'i-lien ranges, which is surrounded by high mountains. The basin proper is vast and flat, its lowest point about 8,700 feet above sea level. There are many fertile spots in the piedmont and lakeside areas of the basin. The southeastern part of the basin is a broad swamp formed by a number of rivers flowing from the snowcapped T'ang-ku-la Shan-mo.

Climate

The extensiveness and the complex terrain of the region result in great variations in climate, soil, and vegetation. On the whole, the climate is typically continental, being influenced by the region's remoteness from the sea and by the mountain ranges in the south and east that bar maritime winds. The average annual precipitation in most places is less than four inches, most of which occurs during the summer. Winter is dry, cold, and windy; summer is hot. Strong winds from the Mongolian Plateau blanket the region with a sea of sand, which presents a serious menace to local agriculture. Grass thrives on the vast plateau, however, and the region possesses some of China's best pasturelands for sheep, horses, and yaks. Antelope, wild horses, wolves, foxes, and bears occur, and exotic birds are found in many places.

Population. There are many national minorities in Tsinghai, including Tibetan, Han (Chinese), Mongol, and Hui (Chinese Muslims). The Tibetans comprise about 35 percent of the total population, the Han about 30 percent, the Hui about 20 percent, and the Mongols 10 percent, with various other nationalities comprising about 5 percent of the total.

The national minorities

The Tibetans speak Tibetan and the Mongols Mongolian; both follow Tibetan Buddhism (Lamaism). The Han are Chinese in language, culture, and religion. Hui (T'ung-kan) speak Chinese but are Muslims.

Although Tsinghai is the third-largest political unit in China, it is thinly populated, having about eight persons per square mile (2.9 persons per square kilometre).

Administration. The provincial capital is Hsi-ning. The province is subdivided for administrative and governmental purposes into six autonomous nationality areas (*tzu-chih-chou*) and one municipality (*shih*). The special status of the Tsaidam Basin was reflected administratively in late 1956 by the establishment of a separate Tsaidam Administrative District, with its headquarters at Ta-ch'ai-tan, a new settlement situated on the northern edge of a salt swamp and at the junction of east–west and north–south roads. In 1964 the Tsaidam district was reincorporated into the Hai-hsi Mongol-Tibetan-Kazakh Autonomous District.

Education. The educational system of the province consists of elementary schools, high schools, and temple schools. There are two types of elementary schools, comprehensive (for six years) and junior (for four years). For the whole province, there are about 60 comprehensive elementary schools and 600 junior elementary schools, for male students only. The number of students ranges from 35 to 65 for each school. There are five elementary schools for girls. Among the ethnic groups, the Hui have the highest percentage of attendance. There are eight high schools that have about 200 students each and one, Kunlun High School, that has more than 3,000 students. Temple education plays an important role in the province. Among the Tibetan Buddhists, a child who becomes a lama begins his studies at the age of ten and continues for more than ten years. A Muslim child's studies begin when he is six years old and continue for 15 years.

Economy. Economically, Tsinghai is divided into two parts by the Jihyneh Mountains. On the eastern side is the Huang Ho drainage, consisting of large tracts of farmland crisscrossed by irrigation canals and dotted with settlements. Spring wheat, barley, and Irish potatoes are the principal crops. On the western side is the plateau basin, where herds of cattle, yaks, horses, and sheep graze on vast stretches of grassland. Most of the Tibetan and Mongol minorities have long engaged in herding there. The output of sheep and yak wool is high and of good quality. Vast areas of land in the pastoral areas have been opened up for cultivation, introducing a mixed farming–livestock economy. The Kunlun and Ch'i-lien mountains are well forested, and in the farming areas there are peach, apricot, pear, apple, and walnut orchards. Among the timber products are spruce, birch, Chinese pine, and Chinese juniper.

Agricultural products and livestock

The development of the Tsaidam Basin oilfield began in the late 1950s, and a considerable quantity of crude oil is now produced there. The basin also has deposits of coal, iron ore, and other minerals, including potassium, which supplies a large fertilizer plant located in the basin. The big salt lakes offer large reserves of borax and especially of salt—so much that blocks of salt are used to pave roads, build bridges, and construct houses.

In older days, Tsinghai had only a few small and poorly equipped tanneries and match factories, all located in Hsi-ning. Today, a number of industrial enterprises have been established, most notably in woolen textiles and dairy products.

Transportation and communications. The opening of the Lan-chou–Hsi-ning section of the Lan-chou–Tsinghai railway in 1959 provided the province's first rail link with the rest of China. Truck transportation is important, and main highways lead from Hsi-ning to Lan-chou, Chang-yeh in Kansu, Tibet, Sinkiang, and Kan-te in Tsinghai. Several highways, including the Tsinghai–Tibet highway, intersect at the southern margin of the Tsaidam Basin at Ko-erh-mu (Golmo), making it a communications centre.

Cultural life. Urban cultural institutions such as museums, theatres, universities, and libraries are few. Life is largely rural, strongly influenced by the traditional culture of the several ethnic and nationality groups that make up the population. Among the Mongols and Tibetans, for example, one son from every family is supposed to enter a lamasery. This custom imposes a limitation on population growth. The chief monastery in Tsinghai is about 20 miles from Hsi-ning. It is a centre of Tibetan Buddhism (Lamaism), to which thousands of believers make pilgrimages from the Mongolia region, Tibet, Sinkiang, and Szechwan.

(C.-M.H.)

Tsiolkovsky, Konstantin Eduardovich

Konstantin Eduardovich Tsiolkovsky, Russian research scientist in aeronautics and astronautics, pioneered the development of rocket and space research. He was among the first to study the aerodynamics of airfoils with a wind tunnel and to work out the theoretical problems of rocket travel in space.

Tass—Sovfoto

Tsiolkovsky.

Tsiolkovsky was born on September 17, 1857, in Izhevskoye, Ryazan Province, into a family of modest means. His father, Eduard Ignatyevich Tsiolkovsky, a provincial forestry official, was a Polish noble by birth; and his mother, Mariya Ivanovna Yumasheva, was Russian and Tatar. The boy lost his hearing at age nine as a result of scarlet fever; four years later his mother died. These two events had an important bearing on his early life in that, being obliged to study at home, he became withdrawn and lonely, yet self-reliant. Books became his friends. He developed an interest in mathematics and physics, and, while still a teen-ager, began to speculate on space travel.

Two major influences

At 16 Tsiolkovsky went to Moscow, where he stayed for three years, studying chemistry, mathematics, astronomy, and mechanics, attending lectures with the aid of an ear trumpet, and expanding his grasp of the problems of flight. But the elder Tsiolkovsky understandably wanted his deaf son, notwithstanding his growing ability to deal with abstruse questions in physics, to achieve financial independence. After discovering that the youth was going hungry and overworking himself in Moscow, his father called him home to Vyatka in 1876.

The future scientist soon passed the teachers examination and was assigned to a school in Borovsk, about 100 kilometres from Moscow, where he began his teaching career, married Varvara Yevgrafovna Sokolovaya, and renewed his deep interest in science. Isolated from scientific centres, the deaf teacher made discoveries on his own. Thus, in Borovsk, he worked out equations on the kinetic theory of gases. He sent the manuscript of this work to the Russian Physico-Chemical Society in St. Petersburg, but was informed by the chemist Dmitry Ivanovich Mendeleyev that it already had been done a quarter century before. Undaunted and encouraged by Mendeleyev, he continued his research. Impressed by the intellectual independence of this young provincial school teacher, the Russian Physico-Chemical Society invited him to become a member.

In 1892 Tsiolkovsky was transferred to another teaching post in Kaluga, where he continued his research in astronautics and aeronautics. At that time he took up the problem that occupied almost all his life: the problem of constructing an all-metal dirigible with an adjustable envelope. In order to demonstrate the validity of his experiment, he built a wind tunnel, the first in Russia, incorporating into it features that would permit testing the aerodynamic merits of various aircraft designs. Since he did not receive any financial support from the Russian Physico-Chemical Society, he was obliged to dip into his family's household budget in order to build the tunnel; he investigated about 100 models of quite diverse designs.

Building a wind tunnel

Tsiolkovsky's experiments were subtle and extremely clever. He studied the effects of air friction and surface area on the speed of the air current over a streamlined body. The Academy of Sciences learned of his work and granted him modest financial aid of 470 rubles, with which he built a larger wind tunnel. Tsiolkovsky then compared the feasibility of dirigibles and airplanes, which led him to develop advanced aircraft designs.

While investigating aerodynamics, however, Tsiolkovsky began to devote more attention to space problems. In 1895 his book *Gryozy o zemle i nebe* (*Dreams of Earth and Sky*) was published, and in 1896 he published an article on communication with inhabitants of other planets. That same year he also began to write his largest and most serious work on astronautics, "Exploration of Cosmic Space by Means of Reaction Devices," which dealt with theoretical problems of using rocket engines in space, including heat transfer, a navigating mechanism, heating resulting from air friction, and maintenance of fuel supply.

Problems of space travel

The first 15 years of the 20th century undoubtedly were the saddest time of Tsiolkovsky's life. In 1902 his son Ignaty committed suicide. In 1908 a flood of the Oka River inundated his home and destroyed many of his accumulated scientific materials. In 1911, after participating in a revolutionary movement, his oldest daughter Lyubov Konstantinovna was arrested. The Academy of Sciences did not recognize the value of his aerodynamic experiments, and, in 1914, at the Aeronautics Congress in St. Petersburg, his models of an all-metal dirigible met with complete indifference. Depressed by these events, Tsiolkovsky turned to the problems of alleviating poverty; they occupied his attention until the revolution in 1917, when he was 60 years old.

In the final 18 years of his life, Tsiolkovsky continued his research, with the support of the Soviet state, on a wide variety of scientific problems. His contributions on stratospheric exploration and interplanetary flight were particularly noteworthy and played a significant role in contemporary astronautics. The German scientist Hermann Oberth wrote, "You have lighted the flame and we will not permit it to go out, but will try to accomplish the greatest dream of mankind." In 1919 Tsiolkovsky was elected to the Socialist Academy (later the Academy of Sciences of the U.S.S.R.). On November 9, 1921, the

council of the People's Commissars granted him a pension for life in recognition of his services in education and aviation. Before his death in Kaluga, after surgery for stomach cancer, on September 19, 1935, Tsiolkovsky bequeathed his entire lifework to the Soviet state.

(M.S.A.)

Tundra

The Finns called their treeless northern reaches the *tunturi*, but the concept of a vast frozen plain as a special ecological realm was developed by the Russians and called by them the tundra. Dotted by lakes and bogs and crossed by streams, the tundra supports a patchy mantle of low vegetation, mainly grasses, sedges, and dwarf shrubs. A meagre variety of animals inhabits the tundra, although in surprisingly large numbers. Characteristic rock fields (fell-fields) and windswept earthen mounds (hummocks) may be barren except for seemingly painted-on lichen growth and scant mossy crevices. Alternate freezing and thawing, the constant factor shaping the tundra, and the presence of a permanently frozen subsoil layer, the permafrost, are unique features that set the tundra apart from the polar vastness of ice and snow, on the one hand, and the evergreen forest belt, on the other. Essentially, there are two kinds of tundra: the Arctic tundra, lying north of the coniferous forest and encircling the North Pole, and the Alpine tundra, clothing the mountain slopes above the treeline in temperate regions. The Antarctic, virtually covered with ice, lacks a well-developed tundra, though lichens, mosses, and at least three species of flowering plants occur in more favourable habitats.

THE ENVIRONMENTAL SETTING

The global extent of tundras is considerable. The southern limit of Arctic tundra, an area roughly one-tenth of the earth's land surface, follows the northern edge of the coniferous forest belt (see map). In North America most of the tundra lies above 60° N, while in Eurasia most of it occurs north of 70° N, except in eastern Siberia where it extends to 60° N in Kamchatka. This bulge northward in Eurasia results from warmer summers over a large land mass.

Patterned ground

Patterned ground, a conspicuous feature of most tundras, results from differential movement of soil, stone, and rock on slopes and level land, plus a downward creep (solifluction) of the soil mantle. These phenomena result from freeze–thaw cycles, especially in spring and fall. Such features as rock rings, stripes, and polygons in alpine regions are usually 6 to 12 inches (15 to 30 centimetres) across. In the Arctic tundra, rock slabs may be found standing on end. Solifluction terraces and lobes are common in many Alpine tundras where there is adequate moisture for soil lubrication.

While permafrost is an ever-present feature of the Arctic and Antarctic, it is seldom encountered in Alpine tundra. The southern limit of continuous permafrost is within the northern forest belt of North America and Eurasia. Its southern boundary can be correlated with average annual air temperatures of 20° F (−7° C), south of which the permafrost exists in patches. Over much of the Arctic, permafrost extends to a depth of 300 to 1,500 feet (90 to 456 metres) to 2,000 feet (610 metres) in a few areas of Siberia. The summer thaw penetrates to a depth of 6 to 12 inches (15 to 30 centimetres) in the higher latitudes of the Arctic and from 1.5 to 10 feet (0.5 to 3 metres) in lower latitude sites with a complete plant cover and well-drained soils. Most biological activity is limited to this thawable area, in terms of root depth, burrowing of animals, and decomposition of organic matter (see PERMAFROST).

Tundra climates are variable and range from the severe polar deserts, with temperatures averaging 40° F (5° C) in midsummer and about −25° F (−32° C) in midwinter, to Alpine conditions of cool summers and moderate winters with temperatures seldom falling below 0° F (−18° C). Precipitation, measured as water, is less than 15 in. (38 cm) annually over most of the Arctic tundra; roughly two-thirds of it falls as summer rain, the remainder falling in expanded form as snow, from 25 in. (64 cm) to rarely more than 75 in. (191 cm).

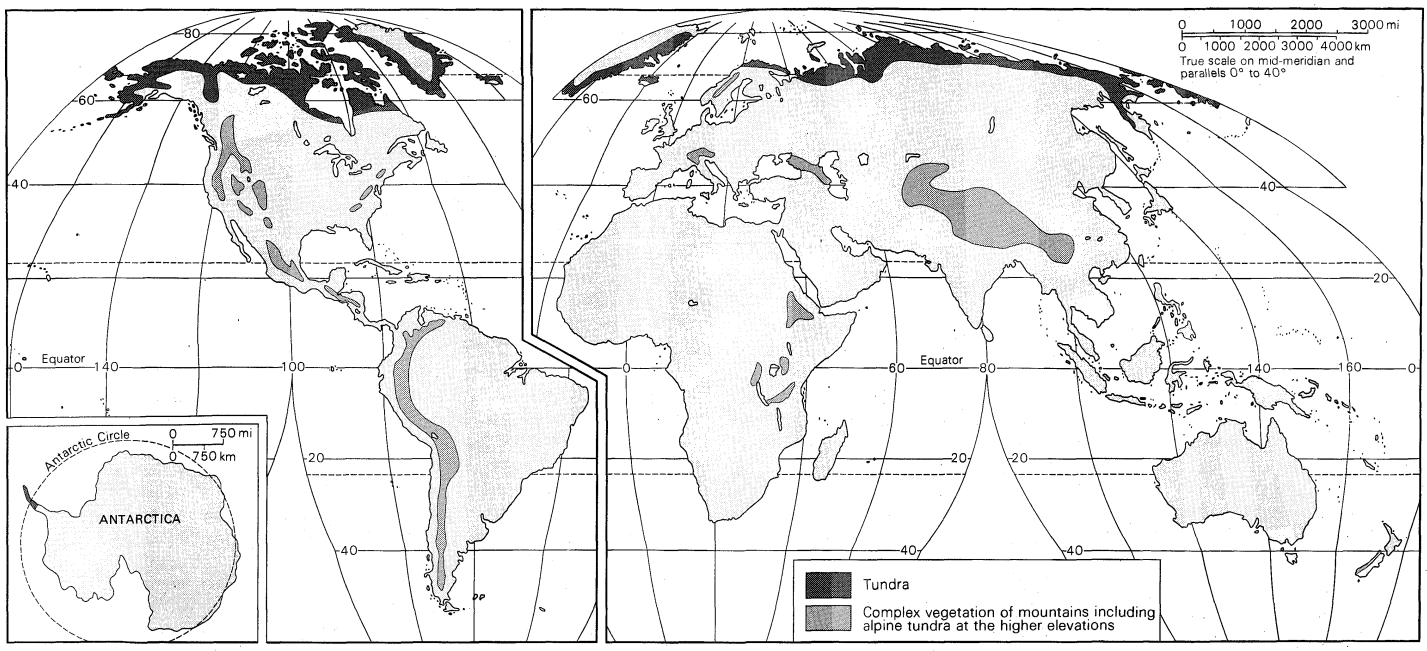
The Arctic tundra is more characterized by low summer temperatures than by low winter temperatures. The coastal tundra is cooler and foggier than inland tundra. Late summer and early fall are the cloudiest seasons because of the availability of groundwater for evaporation. With the first winter freeze, the clear skies return.

The presence of permafrost retards drainage, and low lands of the Arctic tundra become saturated and boggy during the summer thaw. Alpine tundra is generally drier, even though precipitation, especially as snow, is higher than in Arctic tundra. The lack of a continuous permafrost and the steep topography result in rapid drainage, except in certain Alpine meadows.

Although winds are not so strong in the Arctic as in Alpine tundras, their influence on snowdrift patterns and whiteouts (blowing snow) is an important climatic factor. Blizzard conditions may reduce visibility to 30 feet (about nine metres) and cause snow crystals to penetrate any tiny opening in clothing and buildings. Winds in the Alpine tundras are often quite strong; they may average five to ten miles per hour only two feet (60 centimetres) above ground level, and they quite frequently reach 75 to 125 miles per hour in high reaches of the Rockies and the Alps.

Important differences between Arctic and Alpine tundras include day length and carbon dioxide levels. Plants and animals of Alpine tundras are subjected to the same day–night regime as are other organisms at lower elevations in temperate regions. Numerous activities of these organisms are controlled by the length of the night. Over most of the Arctic, light prevails continuously for one to four months, and biological rhythms are induced by variables other than a daily dark period. Many tundra plants flower abundantly only when exposed to continuous or near continuous light. Insects' rhythms of feeding, flight, and swarming, normally controlled by light–dark cycles, respond rather to prevailing temperature or sunlight. Birds and large mammals appear to observe a "quiet period" in early morning, though not as pronounced as in animals in temperate region Alpine tundras. Carbon dioxide levels are lower in Alpine tundras because of thinner air at higher altitudes. Alpine plants are more efficient in utilizing these lower levels of carbon dioxide in photosynthesis than are their Arctic counterparts.

THE BIOTIC COMPONENT



In Arctic and Alpine tundras, the number of species of plants and animals is usually small compared with temperate regions, yet the number of individuals per species is often high. As a result, food and feeder relationships are simple and more subject to upset if a critical species decreases in numbers or is eliminated.

Plant life. In many Alpine tundras and over much of the Arctic tundra, the general appearance of the vegetation is that of a greenish-brown, low grassland. While plants do not remain in flower for more than a few days or weeks, the blossoms are generally large in relation to plant size and are rather colourful, especially in Alpine habitats.

Species variation

Change in species composition with time (succession), which leads to a more stable, or climax, community, is, as in deserts and other severe environments, often very slow. In many instances, vegetational changes are cyclic rather than directional, with the erosion of soil and plants by wind and needle ice being an important factor. Succession along lake and pond shores, river floodplains, animal burrows, etc. does occur with the replacement of one group of species by another group. In many cases, succession is mainly the shift in the relative numbers of a species rather than a total replacement.

Across the southerly Arctic tundra, with vast areas of low relief, boggy peat soils with an abundance of lakes

World distribution of tundra and mountain vegetation.
Adapted from *Biological Sciences Curriculum Study Green Version High School Biology*, 2nd ed.; Chicago: Rand McNally & Co., 1968

and meandering rivers prevail. These coastal plain areas are dominated by sedges and cotton grass, and mosses including *Sphagnum* are common. On slightly elevated sites, often only 6 to 24 in. (15 to 60 cm) above the wet peaty soils, low willows, grasses, and rushes occur. Taller willows, grasses, and plants in the sunflower and legume families are common on the sands and gravels of riverbanks.

On higher lands, foothills, and Arctic mountains, the vegetation is quite sparce.

Transitions from mountain forest to the shrub- and herb-dominated Alpine tundra at higher altitudes is very similar to the transition from coniferous forest belt to Arctic tundra. The Alpine transition, however, occurs over only a few hundred feet of vertical rise. Timberline trees are mostly spruce, fir, and pine, with very few deciduous tree species. Willow clumps less than 2 ft (60 cm) tall are common among the scattered clumps of stunted trees (*Krummholz*) and beyond, where snowdrifts are extensive. Willows are also common along streams, in the lee of rocks, and in basins or the lee side of ridges, where winter snow is deeper.

On gentle slopes where soil has developed, extensive meadows occur. On wind swept ridges, cushion plants dominate. On rocky slopes and peaks, plants are found in scattered patches where there is a bit of soil and some snow cover in winter.

In higher mountains, having much snow, ice, and exposed rock, lichens and mosses manage to grow on rocks. Vascular plants usually end at or just below the line of permanent snow.

In Alpine tundra, as in the Arctic tundra, the plant communities are influenced by soil drainage; snow cover and time of melt; and localized microclimates with their differences in temperature, wind, soil moisture, and nutrients.

Animal life. Organisms of the northern Alpine tundra probably evolved before those of the Arctic tundra in the Mongolo-Tibetan Plateau. Few Alpine animals contributed to the evolution of Arctic tundra species because of physical barriers and animal specialization. Alpine plants, however, and some animals migrated east and west via mountain ranges to Europe and North America. Lowland tundra animals appear to have evolved in Central Eurasia when tundra replaced the cold temperate steppe. These animals then migrated to Europe in mid-Pleistocene times (about 1,000,000 years ago) and to North America later.

Warm interglacial periods eliminated many tundra species and were probably detrimental to the reinvasion of truly Alpine animals. Thus the Alps, Rocky Mountains, and other ranges have a restricted Alpine fauna today, with the larger animals spending only the more favourable seasons above timberline, grazing in the lowlands in winter.

As a product of east–west migration routes from Central Asia, many of the common Arctic animals are circumpolar. These include polar bear, Arctic fox, Arctic wolf, Arctic hare, Arctic weasel, several species of lemming, ptarmigan, snowy owl, and also a number of species of waterfowl.

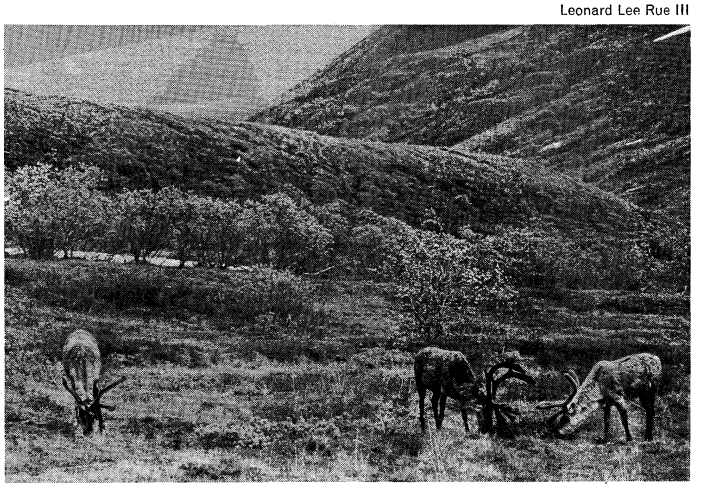
With plant growth and many aspects of animal activity confined to two to four months of the year, when temperatures are above freezing, evolution has favoured a rapid completion of life cycles. Tundra organisms are opportunistic. Many species of plants are perennials that flower within a few days after the snow begins to melt, and some produce ripe seed within four to six weeks. Very few species are annuals. Plants one to 3 in. (2.5 to 7.5 cm) tall typically flower first because they are in the warmer air layers near the soil surface. Some plants frozen while in flower when sudden storms hit continue to develop and produce seed upon thawing. Many plants set few seeds but depend mostly upon runners or underground stems for increasing their numbers. A few species produce bulblets that develop roots and shoots on the parent plant before they drop to the ground. The hairy flower stalks of cottongrass (*Eriophorum*), lousewort (*Pedicularis*), and willows (*Salix*) retain warm air, raising the temperature near the stalks 5° to 15° F (3° to 9° C); this ability is an important adaptation for flowering in areas where air temperatures may approach the freezing point.

During cloudy periods, in shade, and at night, flower temperature is very similar to that of the surrounding air, but in sunlight flowers may be to 4° to 18° F warmer than the air around them.

Although the number of species of Arctic insects is small compared with that of temperate regions, those that are present are quite successful. Arctic insects resist freezing winter temperatures. In some species a high glycerol content acts as an "antifreeze" to lower the temperature at which freezing occurs. Many tundra insects and spiders are dark in colour, as a result of which they absorb more sunlight and maintain higher body temperatures. Some of the tundra species of black flies and mosquitoes do not require a blood meal before depositing their eggs, in contrast to their temperate-region counterparts.

Most tundra birds are migratory, staying long enough to

nest and molt. An exception is the ptarmigan, which feeds upon willow buds and other exposed plant parts in winter and upon leaves, buds, and flowers in summer. Ptarmigan have heavily feathered feet, which provide some insulation against the winter snow and ice. Several migratory birds feed upon seeds and fruits until the emergence of insects and spiders in summer.



Small mammals of the tundra have high reproductive rates; most notable in this regard are the lemmings, which reach a population peak every three to five years in some regions. Lemmings remain active all winter, living under the snow where they feed upon roots of grasses and sedges; they may even reproduce under the thin yet insulative snow layer. When the lemming population increases, many plants are harvested and there is a large accumulation of feces. The manuring around animal burrows adds nitrogen and other nutrients, which stimulate plant growth.

With environmental extremes as pronounced as they are in the Arctic and with the number of species so limited, there are often considerable oscillations in animal populations. The populations of lemming predators, such as jaegers, snowy owls, and foxes, closely follow the rise and fall of lemming numbers. Snowy owls migrate to the coniferous forest belt during lemming "lows," and the number of foxes drops significantly. When lemming peaks are reached, vegetation becomes scarce and large number of lemmings move into less densely populated areas.

Characteristic large herbivores in the Arctic are caribou in North America, both domestic and wild reindeer in Eurasia, and musk oxen on Greenland and some of the Canadian Arctic islands. These animals are rather large, considering the severe environments in which they live. Such size confers an adaptive advantage: there is less surface area relative to volume and therefore less opportunity for heat to dissipate to the outside. Musk oxen are especially well equipped for surviving in cold climates because of their exceptionally thick coats. Caribou and reindeer are equipped with sharp hooves and antlers, which enable them to cut through snow for winter foraging on lichens and flowering plants.

Adaptive advantage of size

Leonard Lee Rue III

Caribou feeding on mosses, lichens, and dwarf trees common to the tundra.

Geese often denude areas of cotton grass, leaving behind mostly mosses and indirectly promoting deep thaws that may result in soil creep on slopes.

Important birds of prey are the jaegers, which are summer visitors, and the snowy owls, permanent residents, though the latter move southward into the forest in winters when food supply is scarce. The several species of jaegers and the owls feed upon small birds and insects, although lemmings are the most important item of their diet.

Polar bear are as much a part of the marine environment as they are of the tundra. In winter they spend much of their time hunting seal. Foxes and wolves often follow bear to feed on leftovers. In summer, foxes and wolves are found mostly on land, where they raise their young and feed on birds and small mammals.

Alpine tundras are similarly limited in the number of animal species and diversity. Accumulating evidence indicates that Alpine animal life in the Northern Hemisphere evolved in the Central Asian highlands and spread to Europe via mountain systems and to North America via the Bering Straits.

Many animals found in Alpine tundras are not especially adapted for year-round Alpine life and undergo vertical migrations, descending into the less severe forest environments in winter and returning to the heights in summer. Such mammals include the mountain sheep, ibex, chamois, several wildcats, and many birds. Mountain goats spend more time in winter at higher elevations than do ptarmigan.

In contrast with Arctic tundra mammals, some Alpine ones hibernate, such as marmots, ground squirrels, and zapodids. These animals consume large amounts of vegetation in summer and early fall before hibernation begins. Other small mammals, such as the pika and voles, cache hay in the fall for winter feeding, while rabbits and others forage as they can in winter. Foxes range over large areas of Alpine habitats in winter.

Many tundra animals sport white coats in winter, among them the foxes, wolves, ptarmigan, and polar bears. This camouflage helps both predator and prey: predators can steal up without detection and prey can hide easily in the snow.

BIOLOGICAL PRODUCTIVITY

The biological production of plants and animals is an important measure of natural ecological systems or ecosystems. A five-year international program (1967–72) dealing with an assessment of marine, freshwater, and terrestrial ecosystems is being conducted in more than 50 countries. As a part of the International Biological Program (IBP), tundra ecosystem studies are designed to determine the total production, rates of production, and the general functioning of these little-known systems. Major studies are underway in Alaska, Canada, England, Finland, Ireland, Norway, Sweden, and the U.S.S.R. While few data are available, there is enough to show some patterns.

In polar regions the greatest biological production occurs in marine waters rather than on land, with higher production occurring in the Antarctic than in the Arctic Ocean (see POLAR BIOMES).

Production studies of Arctic tundra lakes indicate that there are many species of algae and even aquatic mosses living in the higher latitudes of the Arctic. These support a limited number of small crustaceans, worms, and insect larvae, which in turn support the Arctic char, a fish related to salmon.

Plant production

Plant production in the tundra appears to range from three to ten grams of vegetable matter per square metre of area (g/m^2), in willow–dryas barrens of the higher latitudes of the Arctic to values of 100 to 250 g/m^2, in lower latitude sedge-dominated wet sites. The widespread cotton-grass–dwarf-shrub heath communities produce about 50 to 75 g/m^2 in new shoots per year. Values for temperate region grasslands and forests are about four to six times as great as the maximum rates for the Arctic tundra.

The accumulating data for Alpine tundras show 50 to 100 g/m^2 in windswept habitats, 100 to 200 g/m^2 in meadows, and values of 250 to 300 g/m^2 in dwarf-shrub heath communities. These values are higher than those in the Arctic because the growing season is often longer by several weeks.

These data do not tell the entire story, for the amount of plant material (standing crop) is often 10 to 25 times greater below ground than above ground, which indicates that the soil environment may be more favourable for growth than is the air.

In many tundras, the harvest by plant-eating animals is no more than 0.1 to 2.0 percent of the live plants per year. This means that most of the plants produced fall to decay and are decomposed by micro-organisms.

With Alpine and Arctic vegetation so sparse, it is no accident that man has harvested herbivorous animals, including caribou, reindeer, ducks, and geese, rather than harvesting native or cultivated plants as he does in other major vegetation types (forests, grasslands, deserts).

Tungsten Products and Production

Tungsten, in its various forms, is a widely used industrial material. It is particularly important as an alloying element in the production of high-speed steel and, as cemented tungsten carbide, in cutting tools and other applications requiring hardness. The pure metal retains its strength at high temperatures, and additions of tungsten to other metals may improve their high-temperature strength.

The word tungsten (derived from the Swedish words *tung*, "heavy," and *sten*, "stone") was first used in 1755 by Baron Axel Fredrick Cronstedt, who applied it to the mineral later known as scheelite because of its high density. Other researchers identified the ore as a compound of lime and a previously unknown substance and discovered the same mysterious substance, which they named "wolfram," in a mineral that contained iron and manganese. Today the metal is known as tungsten in British and American usage and as wolfram in European. The mineral is known as either wolfram or wolframite.

Tungsten was a rare metal until 1847 when industrial development was started under a British patent for the manufacture of sodium tungstate and tungstic acid. A later patent (1857) described the manufacture of iron-tungsten alloys, which were to form the basis of modern high-speed steels. Industrial development followed an exhibition of tungsten tool-steels by Bethlehem Steel Corporation at Paris in 1900.

Lamp filaments

The first application of unalloyed tungsten was as filaments in electric incandescent lamps, following the production of ductile filaments by a powder metallurgical process patented in 1909, a process that remains the basis of modern production methods.

Tungsten carbide in cast form was produced in Germany in 1914, but was too brittle to be useful. Not until 1927 did the Krupp laboratory in Essen discover that when tungsten carbide powder is mixed with a bonding, or cementing, material such as cobalt, the product is much less brittle and retains its hardness. Cemented carbide found an immediate application in metallurgy in dies and tools requiring great hardness.

MINING

Tungsten minerals are widely distributed. The commercially important ones are wolframite and scheelite. Wolframite is iron and manganese tungstate (Fe, Mn)WO_4, a mixed crystal of huebnerite, $MnWo_4$, and ferberite, $FeWO_4$. Scheelite is calcium tungstate, $CaWO_4$.

In 1970 it was estimated that the free world reserve was 253,000 tons (226,000 metric tons) of tungsten metal content. Reserves in China, North Korea, and the U.S.S.R. may be about four times as great.

Every tungsten deposit must be examined critically to determine the most suitable and economic method of concentration. The method chosen will depend upon the type of mineral, associated minerals, and the identity of the gangue (worthless material in which the mineral occurs).

Gravity methods of concentrating the relatively heavy tungsten minerals are used frequently, though most large-scale mills use a combination of flotation and gravity methods.

If calcite and apatite are the principal contaminants, acid leaching can be used to upgrade the concentrate. Low-grade concentrate is also converted to synthetic scheelite by chemical treatment. Roasting, magnetic separation, or electrostatic separation may also be used to improve the quality.

Molybdenum, tin, and bismuth may be present in the ore in sufficient quantities to warrant their recovery, a circumstance that can complicate the process.

The aim of most mills is to produce a concentrate containing a minimum of 60 percent tungsten trioxide, WO_3. A range of 60 to 70 percent is normal.

METAL RECOVERY

The first step in the recovery of tungsten from wolframite is to fuse it with sodium carbonate under oxidizing conditions or by digestion with a concentrated sodium hydroxide solution. Scheelite is usually decomposed by digestion with concentrated hydrochloric acid.

Wolframite reaction

The reaction between wolframite and sodium carbonate may be carried out in a gas-fired reverberatory furnace at 800° C with constant rabbling (stirring) or in a gas-fired rotary furnace at a slightly higher temperature sufficient to cause the charge to flow down the kiln. In the case of digestion with a sodium hydroxide solution, the reaction is best carried out in a steam-heated autoclave.

The resulting product is leached with water to produce sodium tungstate liquor, which can be treated with calcium chloride solution to produce insoluble calcium tungstate (synthetic scheelite).

Hydrochloric acid is added, while stirring, to a slurry of the calcium tungstate to produce insoluble tungstic acid (H_2WO_4) and soluble calcium chloride. The tungstic acid is recovered by filtering, washing, and drying.

The digestion of scheelite with concentrated hydrochloric acid yields a crude tungstic acid. After the calcium chloride is washed out, the dried acid contains 80 to 98 percent WO_3. Purification is achieved by dissolving the tungstic-acid sludge in concentrated ammonia solution, filtering and evaporating to produce ammonium paratungstate crystals, $5(NH_4)_2O \cdot 12WO_3 \cdot xH_2O$. Further purification is obtained by decomposing the crystals with hydrochloric acid and redissolving the precipitated tungstic acid in ammonia solution and crystallizing again as ammonium paratungstate.

Most tungsten powder is produced by hydrogen reduction of tungstic acid, tungstic oxide, or ammonium paratungstate.

Particle size. The particle size of the powder is important in determining the success of the subsequent operations and it is necessary to produce different types of powder for various applications. Tungsten powder for the production of massive metal (sheet, rod, and wire) has a wide range of particle size to produce maximum compaction, whereas the particle size of powder for conversion to carbide for hard metal production should be tightly controlled around the size specified, which size will vary from less than one micron to several microns, depending on the application. The reduction procedure must be carefully controlled to produce the required type of powder.

Reduction. The basic reduction process is to pass metal boats charged with tungstic acid or oxide through a heated tube with a counterflow of hydrogen. The acid or oxide is reduced to metal, and water vapour is removed in the flow of hydrogen. The temperature of reduction varies from 700° to 1,100° C; the higher the temperature, the coarser

the powder. For the finest powder it is necessary to use a shallow charge of oxide with a high flow of dry hydrogen and carry out reduction at a low temperature, preferably in two stages. For coarser metal with a wide range of particle size, deep charges are reduced at high temperatures.

Some tungsten powder is produced by carbon reduction of the oxide, but this powder is less pure than hydrogen-reduced metal and is used mainly for alloy production.

High-purity tungsten powder is produced by the hydrogen reduction of tungsten hexafluoride in a fluidized bed at 550° C.

THE METAL AND ITS ALLOYS

Powder metallurgy

Tungsten powder is converted to massive metal by a powder metallurgy process. The powder is pressed into a bar shape that is presintered in hydrogen to give it enough strength to be handled. The bar is then clamped vertically between electrical contacts in a hydrogen-filled chamber, and a current of several thousand amperes is passed directly through it. The temperature of the bar is raised to about 3,000° C and held at that temperature for about 30 minutes.

The sintered bar (93–95 percent of the density of solid tungsten) is too brittle to be worked at ordinary temperatures; it can, however, be forged and rolled at about 1,500° C.

Production of rod and wire is accomplished by swaging (passing the metal while hammering through a die). The first pass is made at 1,500° C and the temperature gradually lowered to about 1,200° C. As the metal is worked it becomes more dense and more ductile.

Plate and sheet are produced from sintered bar by forging at 1,500° C followed by rolling first at 1,400° C, and later down to 700° C as the ductility increases.

Small additions of nickel (about 1 percent) result in lower sintering temperatures, but the resulting product cannot be worked.

The difficulties in melting tungsten (melting point about 3,400° C) have been overcome with the development of melting by means of an electric arc or by electron-beam melting techniques, but the resulting product in both cases is an ingot with coarse columnar grains unsuitable for working.

Tungsten components have been made by other methods than powder metallurgy; *e.g.*, by centrifugally casting arc-melted tungsten, usually with a little added molybdenum; by building up shapes on formers by plasma-spraying tungsten powder; and by slip casting followed by sintering.

Depositing tungsten in vapour form from tungsten hexafluoride is used to produce coatings of tungsten.

Hot isostatic compaction is a recently developed means of consolidating tungsten powder. The tungsten powder is sealed in a metal container and heated in a high-pressure, inert gas. Full-density tungsten is produced at pressures of 10,000 to 20,000 pounds per square inch, at temperatures between 1,500° and 1,600° C.

Applications of tungsten metal. The applications are based on tungsten's high melting point, excellent high-temperature strength, and good heat and electrical conductivity. It is used for lamp filaments, electrical contacts, X-ray cathodes, heating elements, and equipment (including thermocouples) for high-temperature furnaces.

Aerospace applications. Aerospace applications have been investigated, but the good high-temperature mechanical properties of tungsten are marred by a lack of resistance to oxidation. Alloying has failed to overcome this fault. Protective coatings have achieved some improvement, but none is completely satisfactory in providing resistance to oxidation, abrasion, alternate heat and cold, and impact. Tungsten nozzles have been used in some types of rocket motors. The material is usually in the form of porous sintered tungsten infiltrated with silver.

Important alloys and their uses. Stellite is the name of an important series of alloys containing cobalt (30 to 56 percent), chromium (30 percent) and tungsten (10 to 20 percent), and small additions of carbon. These alloys combine excellent hot-hardness with good corrosion and oxidation resistance at high temperatures. The alloys can be used as solid tool bits or hard-facing rods for deposition as abrasion-resisting coatings on ferrous metals. Cast shapes are also used for surgical implants.

Additions of rhenium (35 atomic percent; that is, 35 percent of the atoms in the alloy are rhenium) greatly improve low-temperature ductility of tungsten. Aerospace and nuclear applications are considered possible, but the high cost of rhenium is a deterrent. Tungsten containing 26 percent rhenium is used in thermocouples for temperatures up to 3,000° C.

Heavy metal, an alloy of tungsten (93 percent), copper (2 percent), and nickel (5 percent), is used because of its high density for machine-balancing weights and for containers for radioactive substances.

Composites of "alloys" of tungsten and copper or silver, produced by infiltrating porous sintered tungsten with copper or silver, are used for electrical contacts for switch gear.

Small amounts of thoria (about 1 percent) are incorporated in tungsten to improve its high-temperature properties, particularly its resistance to sagging.

Cutting steels. An important use for tungsten is in making high-speed cutting steels that retain their hardness at high temperatures. These steels contain 6 to 20 percent tungsten with molybdenum, chromium, vanadium, or niobium. Tungsten can be added to steel in various forms, such as ferrotungsten (about 78 percent tungsten), melting base alloy (about 35 percent tungsten), scrap that is high in tungsten, and high-purity scheelite (natural or synthetic). Metal powder, pellets, and certain proprietary compositions are also used.

Most ferrotungsten is produced by carbon reduction of the concentrate in an electric furnace. A metallothermic process uses aluminum and silicon reducing agents.

Chemical compounds—preparation and uses. The most important compound is tungsten carbide (WC). It is used in the production of cemented carbides (hard metal) because of its great hardness, which it retains at high temperatures.

The carbide is prepared by heating an intimate mixture of tungsten powder with the required amount of carbon, in a nonoxidizing atmosphere, at about 1,400° to 1,500° C. The product is crushed and milled to a fine powder and intimately mixed with the requisite amount of fine cobalt powder by prolonged ball-milling.

The normal procedure is to press the mixed powder to the shape required. Usually a lubricant such as paraffin wax is incorporated in the powder to aid pressing and to reduce wear on the dies. The wax is removed by heat treatment before sintering at about 1,400° C. Originally, sintering was performed in a hydrogen atmosphere; but vacuum sintering, particularly when titanium and tantalum carbides are present, has largely replaced this technique. Large pieces of cemented carbide are produced by hot-pressing to shape in carbon dies.

The main use for cemented carbides is as cutting tools. The tool is brazed or mechanically fixed to a steel shank. Additions of titanium and tantalum carbides improve the cutting qualities. The application of a thin deposit of titanium carbide on the surface of the cemented carbide tools has, it is claimed, produced a very large increase in the cutting life.

The cobalt content of cemented carbides usually varies between 6 and 15 percent, the strength increasing and the hardness decreasing as the cobalt increases.

Other important applications for cemented carbides include drawing dies, rock drills, wear-resisting parts for machinery, automobile tire studs for use on icy roads, and deposits on other metals to reduce wear.

When tungsten is melted in a carbon crucible with an addition of carbon, the alloy WC–W_2C is produced. It may be cast—*e.g.*, in the form of sleeves—and used as sand-blast nozzles, or crushed and incorporated in hard-facing welding rods.

Economic importance. The Table gives the world production of tungsten ore and concentrates.

(G.L.M.)

Tunicata

The Tunicata, a subphylum of the Chordata, are a diverse group of about 2,100 species of marine organisms that includes forms that are sessile (*i.e.*, fixed to the sea floor or to some other surface) and pelagic (*i.e.*, drifting in the open sea). Tunicates are distinguished by the presence of a soft outer protective covering—the test, or tunic—and by the occurrence in the larvae (and in the adults of one group) of a notochord, or stiffening rod, which supports a muscular tail. The presence of a notochord is of evolutionary significance; it is possible that the tunicate larva represents the ancestral type of chordate organism.

General features. *Economic importance.* Tunicates are of economic importance because they grow on submerged man-made structures and in some cases—as on ships' hulls—affect their performance. Some species yield substances useful in the treatment of leukemia and other diseases. Pelagic forms are important as successful herbivores (*i.e.*, plant-eating animals), thus forming a link in ecological food chains.

Size range and distribution. Larvacea, the smallest tunicates, are often scarcely visible unless parts of the body are pigmented. Ascidiacea vary in length from a few millimetres to about 30 centimetres (about one foot). The Thaliaceae are usually organized into colonies, some of which may attain a length of four metres.

Tunicates are almost universally distributed throughout the seas of the world, from the intertidal zones down to the deepest regions (abyss). Pelagic forms occur in the vast expanse of open ocean. The sessile ascidians, or sea squirts, are often found on the sea bottom, along or near the shores of all oceans; they also grow on seaweeds, on or under rocks, in submerged sand flats, on coral reefs, on submarine cables, on ship bottoms, on wharf piles, and on the shells of lobsters and mollusks. They abound from polar regions to the tropics. Some species are cosmopolitan; others are distributed only locally.

Appearance. Externally tunicates are enclosed by the test, except for two apertures, or siphons. A water current for feeding and respiration is drawn in through a so-called branchial siphon; after filtration the water is discharged through an atrial siphon. Sessile forms, the Ascidiacea, have the two apertures close together near the anterior, or front, end and are attached posteriorly to the sea floor or to the surface of an object.

Natural history. *Solitary and colonial forms.* Ascidians may be solitary or live in colonies. In colonial forms the individuals, called zooids, may be separate or fused so that they share a common atrial siphon. Each zooid, however, has its own branchial siphon; this arrangement occurs in one pelagic group, Pyrosomida, which forms thimble-shaped colonies. Zooids are arranged around the body wall in such a way that the branchial siphons open to the exterior and the atrial siphons open internally. The common effluent from the atrial siphons is discharged through the open end of the "thimble" to propel the organism forward. In Salpida and Doliolida (both pelagic groups), the zooids have apertures at opposite ends of the body; the discharge of water from the atrial siphon propels the organism forward. Both groups may, nevertheless, form complicated colonies in the course of their life cycle. The pelagic Larvacea bear a superficial resemblance to the ascidian larva and probably represent a neotenic development (*i.e.*, the organism achieves sexual maturity even though otherwise not fully developed).

Separate or fused zooids in colonies

Reproduction and life cycle. Tunicates are usually dioecious—*i.e.*, male and female reproductive systems usually occur in different individuals. In most forms, fertilization and embryonic development take place in the surrounding water; in a few species, however, embryos are retained in the atrial cavity during development. Embryonic development is rapid and may be completed in nine hours, producing a tadpole-like larva about one millimetre (0.04 inch) long. Two-thirds of each larva consists of a muscular tail supported by a notochord and containing a hollow dorsal (*i.e.*, along the back) nerve cord. In the anterior trunk region the branchial sac and the alimentary canal are forming. A dorsal sensory vesicle, or organ, is sensitive to light and gravity, and the larva has three anterior adhesive papillae, or fingerlike projections.

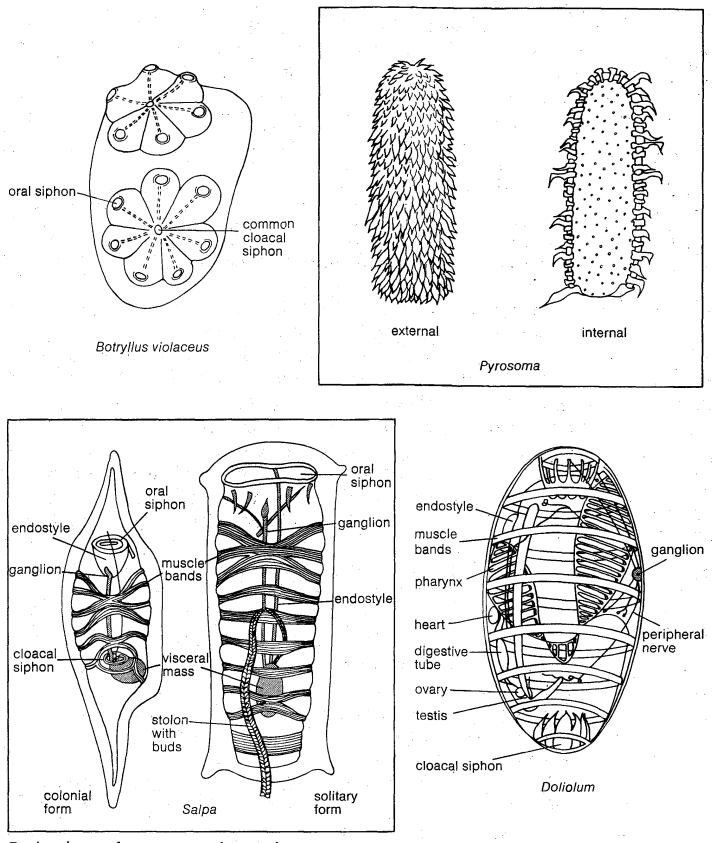
Ascidian larvae are free-swimming for a period of six hours to several days, after which they settle on a surface, attaching themselves to it with the papillae. Immediately after attachment the tissues of the tail are resorbed into the trunk and form food reserves, which are utilized dur-

ing metamorphosis into an adult ascidian; metamorphosis takes from 42 hours to several days. In pelagic tunicates, metamorphosis occurs without attachment.

Budding and other types of asexual reproduction

In colonial forms, budding (*i.e.*, the development of a new individual from an outgrowth of the parent that usually breaks off) or some other type of asexual reproduction occurs. Four types of budding occur in Ascidiacea. Stolons, or rootlike processes, may grow out from the posterior end of the ascidian zooid, giving rise to new buds; the resulting zooids may either separate (as in Clavelinidae) or remain in functional continuity with one another (Perophoridae). In the family Didemnidae, two small buds appear on the esophagus; one bud grows into a new thorax (branchial sac), the other into a new abdomen; the new thorax subsequently attaches to the old abdomen, and the new abdomen attaches to the old thorax to form two new zooids. In Polyclinidae and related families, the thorax and abdomen are resorbed into a postabdomen, which subsequently develops into several buds, each of which grows into a new zooid. In Botryllidae new buds arise from outgrowths of the body wall.

Ventral stolonic (rootlike) outgrowths are the characteristic type of bud formation in pelagic tunicates, but complicated life cycles occur in both Doliolida and Salpida. In Doliolida the solitary form is a gonozooid, a sexually reproducing organism. The larva gives rise to an oozoid, or asexually reproducing form. Buds formed by the stolon migrate to a dorsal outgrowth of the oozoid, where they are arranged in several series, some as feeding zooids, some as supporting zooids onto which the young gonozooid bud attaches and grows. When fully grown, the gonozooid breaks free to complete the life cycle. In Salpida the oozoid forms chains of zooids from the ventral stolon. Each zooid in a chain is a sexually reproducing gonozooid; the entire chain lives a colonial existence.



In temperate latitudes, tunicates usually spawn in spring and summer and may produce several generations each year. Many colonial forms regress in the autumn, overwintering as dormant buds. In the tropics, reproduction goes on throughout the year. Growth is rapid: in solitary forms sexually mature adults may develop in two months; in colonial forms the process is even faster.

Ecological adaptations. The fact that larval tunicates do not feed necessitates that the larval period be brief and that metamorphosis be rapid. Adult pelagic forms utilize phytoplankton, or microscopic plants, as their primary source of food. Larvacea feed exclusively on nannoplankton (*i.e.*, plankton smaller than 0.04 millimetre [0.002 inch] in diameter). The sessile ascidians utilize a variety of suspended materials. Differences in the branchial structure of tunicates are probably functional adaptations to the type of material ingested. Most ascidian species live on hard surfaces such as rock faces and piers; a few species, however, have adapted to living in sand and mud. Ascidians apparently are poor competitors; in sessile communities they often appear to die off as more successful forms such as sponges displace them. The lifespan of colonial forms is often short and in some instances may not exceed six months. Solitary forms usually live 18 to 24 months.

Habitat and life-span of the ascidians

Form and function. *Structural features.* The structure of tunicates is best studied in the ascidian zooid. The branchial siphon is anterior, and the atrial siphon is dorsal. The test surrounding the animal is a living structure supplied with blood vessels. The true body wall, or mantle, is in direct contact with the inner surface of the test and is supplied with muscles for opening and closing the siphons and for contracting the whole body. The branchial siphon leads into a large sac, or pharynx, which occupies much of the interior of the animal; a space, the atrial cavity, remains between the pharnyx and the mantle and connects with the exterior through the atrial siphon. The walls of the branchial sac, the main food-collecting structure, are pierced by many apertures, or stigmata, giving it the appearance of a fragile latticework.

Cilia (*i.e.*, tiny hairlike structures) around the margins of the stigmata drive water from the branchial sac into the atrial cavity and provide the main water current through the animal. Mucus secreted from a groove, the endostyle, on the ventral side of the branchial sac is transferred by cilia across the inner side of the sac trapping food from the water. The food-laden mucus is rolled into a cord on the dorsal side of the sac and carried backward to the esophagus along a fold, the dorsal lamina. Tentacles surrounding the base of the branchial siphon prevent large particles from entering the sac and ensure that only finely divided, suspended particles are utilized as food. The esophagus leads posteriorly to the alimentary canal, which loops so that the anus opens into the atrial cavity just below the atrial siphon. This arrangement ensures that waste material is carried away in the outgoing stream of water. Posterior to the intestine lies the heart, which supplies blood vessels to the test, alimentary canal, branchial sac, and to the mantle. The gonads lie in the loop of the intestine, and the gonoducts, or tubes that carry sperm or eggs to the outside, open posteriorly to the anus.

Body plans of representative tunicates.

From P.A. Meglitsch, *Invertebrate Zoology*, copyright © 1967 by Oxford University Press, Inc.; reprinted by permission

In primitive ascidians (*e.g.*, *Ciona*) the alimentary canal, heart, and gonads are enclosed by two membranous sacs, the epicardia, which grow backward from the branchial sac. Epicardia probably correspond to coelomic sacs (the body cavities of higher forms). In more highly evolved ascidians the epicardia lose their connection with the pharynx and take on new functions. In some they become storage sacs for insoluble body wastes; in others they become involved in the growth of new tissue during asexual reproduction.

Variations in the ascidian visceral system

Within ascidians the above organization may be modified in two ways. In one evolutionary line the viscera descend behind the thorax to form a distinct abdomen; in some species a further extension forms a postabdomen in which the gonads descend posterior to the alimentary canal. In the second line of development, the viscera fold forward and lie beside the branchial sac between it and the mantle.

Physiology and biochemistry. Tunicates exhibit a number of interesting physiological and biochemical features. The direction of blood flow is reversible. The heart normally beats between 50 and 100 times in one direction

before stopping and then resuming its beat in the opposite direction. This activity is controlled by so-called pacemakers at either end of the heart, but the functional significance of such reversal is obscure. The nature of the pacemakers is also uncertain, but it is generally believed that they are myogenic (centred in the heart muscle itself) and not neurogenic (*i.e.*, nervously controlled).

The blood contains a number of different cell types, the most important of which are amoebocytes, macrophages, morula cells, and nephrocytes. Amoebocytes and macrophages are concerned with routine metabolic processes; *e.g.*, gas exchange, nutrition. Morula cells are usually pigmented and contain vanadium or iron compounds that in some way have to do with the secretion and deposition of material for the test; the precise role of these cells is not yet fully understood. Some authorities believe that morula cells deposit carbohydrate (*e.g.*, sugars, starches); others have suggested that the carbohydrate is secreted by the epidermis, or outer cell layer, and that morula cells contribute protein to the test. Such differences of opinion may result from differences in the chemical composition of the test and the manner of its formation in the different species studied.

Digestion is extracellular; *i.e.*, it takes place within the alimentary canal, and most digestive enzymes (biological catalysts) are secreted in the stomach. Absorption takes place in the intestine. The pyloric gland is made up of a system of fine tubules ramifying over the walls of the intestine and opening by a duct into the pylorus, or that region of the gut between stomach and intestine. The function of the pyloric gland has not yet been established with certainty.

The nervous system consists of a small ganglion that is situated in the mantle wall between the two siphons and associated with a plexus, or nerve network, which branches throughout the mantle wall and siphonal muscles.

Theories of neural-gland function

Closely associated with the nerve ganglion is the neural gland, which opens immediately anterior to the dorsal wall of the branchial sac. Its proximity to the nerve ganglion has led to the suggestion that it may have a regulatory function comparable with that of the pituitary gland in higher chordates. It has also been suggested that the neural gland may have a sensory function in testing incoming water or in detecting the presence of eggs or sperm of other members of the species and initiating spawning. It is possible that the neural gland has several functions; it remains one of the most enigmatic structures in ascidian biology.

Classification. *Distinguishing taxonomic features.* Within the class Ascidiacea, the position of the gonad and the structure of the branchial sac are considered the most important taxonomic characters. In Thaliacea, the organization of the colony, the nature of the transverse muscles, and the form of the branchial sac are of significance. In Larvacea, the form of the endostyle (ventral groove), spiracles (respiratory holes), and tail are diagnostic characters.

Annotated classification.

SUBPHYLUM TUNICATA

Larval forms with many chordate features absent in adult. In the adult the pharynx is perforated with ciliated apertures for filter feeding and respiration; the circulatory system is open, with tubular heart; dioecious (sexes separate), with well-differentiated gonads and ducts; found worldwide in seas; about 2,100 species described.

Class Ascidiacea (sea squirts)

Sessile (fixed to sea floor); outlet siphon located dorsally; branchial region (pharynx) with transverse rows of ciliated apertures or stigmata; larvae free-swimming; solitary or colonial forms.

Order Enterogona

Body divided into thorax and abdomen or undivided; impaired gonad lies within loop of intestine.

Suborder Aplousobranchiata. Branchial sac simple without internal longitudinal bars or vessels; intestinal loop always posterior to branchial sac.

Suborder Phlebobranchiata. Branchial sac has internal anteroposteriorly directed tubular vessels.

Order Pleurogona

Body never divided into thorax and abdomen; gonads in lateral body wall.

Suborder Stolidobranchiata (Ptychobranchiata). With internal anteroposteriorly directed vessels; wall of pharynx folded to increase surface area.

Class Thaliacea

Wholly pelagic (open-sea dwelling) forms with alternating cycles of sexual and asexual reproduction; asexual buds form from a ventral vessel.

Order Pyrosomida

Colonies of hollow floating tubes open at one end only, individuals being imbedded in the wall of the tube; intake siphons extend from the outer surface; outflow siphons open into the hollow interior of the colony.

Order Doliolida

Primary individuals reproduce by budding; budded individuals become sexually mature; recognizable, but temporary, tadpole stage.

Order Salpida

Primary individuals reproduce by budding; buds form a long chain; eggs attached to parent; no tadpole stage.

Class Larvacea

Minute forms with trunk and tail resembling ascidian larva; anterior epidermis secretes complex structure around animal that acts as food-collecting device.

Critical appraisal. The Tunicata have left no fossil record; their origin and affinities with groups other than chordates are obscure. The view that they represent a degenerate offshoot of the Chordata is no longer accepted. It is now believed that the tailed larva with a notochord was evolved by the ascidians either to improve the orientation of the larva at the time of attachment or in response to production of the test and consequent loss of cilia for locomotion. The ancestral form was probably similar to *Ciona*, with the gut loop lying immediately posterior to a simple branchial sac and with open epicardia. Some authorities believe that this was a solitary form and that asexual reproduction arose independently at different times during the evolution of the group. Other authorities believe that asexual reproduction was an ancestral character and that all forms of budding have a common origin. These viewpoints have not yet been resolved, but it is agreed by most authorities that further evolution of the ascidians resulted, on the one hand, in descent of the viscera and simplification of the branchial sac to form the Aplousobranchiata and, on the other hand, in a turning forward of the viscera and internal folding of the branchial sac to form the Stolidobranchiata. The Thaliacea have in common their asexual mode of reproduction from a ventral stolon as well as their pelagic habit. The Pyrosomida probably arose from a sessile ascidian stock. The organization of the branchial sac suggests that this occurred very early in tunicate evolution. Doliolida and Salpida are considered to have evolved successively from the Pyrosomida. The origin of the Larvacea is still uncertain, but they may represent the neotenic larva of either an ascidian or a doliolid.

Tuning and Temperament, Musical

Musical sound largely depends on the organization of pitch, the high or low quality of sound; and the determination of acceptable pitch plays a large part in both the theory and practice of music. The adjustment of one sound source—such as a voice, a string, or a column of air enclosed in a wind instrument—to produce a desired pitch in relation to a given pitch is called tuning. Two concepts fundamental to the theory of tuning are those of frequency ratio and of consonance and dissonance. A given musical pitch is determined by the frequency of vibration of the sound wave that produces it, as a′ = 440 cycles per second. An interval, or distance between two pitches, can thus be mathematically described as the ratio of the frequency of the first pitch to the frequency of the second. Various frequency ratios can be reduced to the same basic relationship; for example, 440:220 and 30:15 and 750:375 can all be reduced to the ratio 2:1.

Consonance and dissonance

When two tones are sounded together the subjective reaction may be anything from one of perfect consonance (concord, harmony, repose) to one of extreme dissonance (harshness, clashing, tension). Dissonance is produced by beats (interference between pulsations of sound waves), and it is found that maximum dissonance occurs when the rate of beats between the two tones is about 33 per second. Consonance results from the absence of beats, which occurs only when the ratio between the frequencies of the two tones is numerically simple. When the two tones are tuned to the same pitch, they are said to be in unison (ratio 1:1) and their consonance is absolute. Next in order of consonance comes the octave (2:1), the interval between c and c′ (encompassing eight notes of the piano keyboard); another highly consonant interval is the fifth (3:2, as from c to g). When a unison, octave, or fifth is slightly mistuned, the resulting combination is markedly dissonant and is judged "out of tune." The slight mistunings that occur in systems of tempered tuning are necessary for reasons that will be discussed later in this article.

The problems of tuning. So long as music consists of melody without harmony, consonance plays little part in the determination of successive pitches in a scale. Many primitive scales are sung, not played, and are variable in the exact pitches of their notes. When instruments are made, it is often necessary to determine precise pitches. The tendency is either to make the steps in the scale sound equal in size or to place them in simple arithmetic relationship to one another. The fundamental unit is the octave, which has the unique property that its two notes are felt in some indefinable way to be the same, though in pitch level they are recognizably different. For this reason, high and low voices naturally sing the same tune an octave apart. In nearly all musical cultures the octave is subdivided into a number of steps, each a simple fraction of an octave. In the diatonic, or seven-note scale, for example, which is the basis of Western music and is represented by the white notes on the piano keyboard, there are five steps of one-sixth of an octave and two of one-twelfth. In contrast to these uncomplicated fractions, the frequency ratios of these intervals are actually the irrational numbers: $\sqrt[6]{2}$:1 and $\sqrt[12]{2}$:1. As has been noted, consonance is related to simple frequency ratios such as 2:1. Consequently, the arithmetic subdivision of the octave can never produce perfectly consonant intervals. This unavoidable fact underlies many of the problems in the history of tuning. Insignificant when notes are heard melodically, it becomes highly important when notes of different pitch are heard simultaneously. The complex development of harmony has been the most striking peculiarity of Western music, and it has brought with it a host of tuning problems.

Conflict of scale and consonance

Apart from the octave, which presents no problem, there are really only three distinct intervals in the diatonic scale the consonance of which is important. These are the fifth (3:2), the major third (5:4, as C–E), and the major sixth (5:3, as C–A). The other three consonant intervals are the fourth (4:3), the minor sixth (8:5, one-twelfth of an octave smaller than a major sixth, as D–B), and the minor third (6:5, as D–F). The intervals of this second group are not truly distinct, for they can be derived from the first three by inversion—*i.e.*, by transposing the lower note of the interval up an octave. Thus, inverting the fifth c–g yields the fourth g–c′. Inverting the major third c–e yields the minor sixth e–c′, and inverting the major sixth c–a yields the minor third a–c′. Because of the phenomenon of inversion, if the fifths in a scale are in tune, the fourths also will be in tune. For each of these six intervals the tuning expressed by the above simple frequency ratios sounds "right"; if modified slightly in either direction it sounds seriously out of tune. The same cannot be said of other intervals of the diatonic scale. The major and minor seventh (as c–b and d–c′) and the diminished fifth (as b–f′), with their inversions, sound dissonant in any case; they have no one tuning that is clearly more acceptable than another. Hence the harmonic merits of any tuning system depend on the way fifths, major thirds, and major sixths are tuned. In the diatonic scale (indefinitely extended through several octaves) there are six perfect fifths (F–C, C–G, G–D, D–A, A–E, E–B), three major thirds (F–A, C–E, G–B), and four major sixths (F–D, C–A, G–E, D–B). It is impossible to tune the seven notes of the scale so that each of these 13 intervals is maximally consonant. This is the second inescapable obstacle to perfection in the tuning of the diatonic scale.

Inversion of intervals

Classic tuning systems. Of the two ancient Greek systems that were chiefly used in the Middle Ages, one, Pythagorean tuning, makes all the fifths perfectly consonant. As a result, all the major thirds and major sixths are sharp (too wide) by 22 cents (a cent is 1/1200 of an octave) or by the ratio of 81:80. This amount is called a comma of Didymus, and it makes intervals severely dissonant when their notes are sounded simultaneously. Within the gamut, the pitch range in use during the Middle Ages, a major third or sixth mistuned by a comma beats between 6 and 32 times a second. Melodically, the Pythagorean system is satisfactory. (Table 1 compares whole tone and semitone sizes in the four main tuning systems.) Pythagorean tuning makes all five whole tones (the larger steps in the diatonic scale) equal at 9:8 (204 cents), and the two semitones (the smaller steps) equal at 256:243 (90 cents). The semitones are considerably less than half the whole tones in size, but this is not particularly objectionable in a melody.

The Pythagorean system

Ptolemaic tuning, often misleadingly named just intonation, sacrifices one of the fifths (D–A), which is altered to 40:27 from the simpler ratio 3:2, making it flat (too narrow) by a comma. The advantage of this system is that all the major thirds are true, or "in tune," as are all the major sixths except F–D, which is tuned to the ratio 27:16, as in the Pythagorean tuning (instead of to 5:3). The triad D–F–A is quite unusable, although the other triads used are perfectly in tune. (A triad is a chord built of two thirds.) For melody the system has the drawback of employing two different sizes of whole tones: C–D, F–G, and A–B are major tones (9:8 or 204 cents), and D–E and G–A are minor tones (10:9 or 182 cents). The difference is noticeable without being great enough to suggest that they are two purposely distinct intervals. To sing the first phrase of "Three Blind Mice" with the middle note perceptibly too high can hardly have seemed satisfactory at any period.

Just intonation

Although just intonation occupied the attention of many theorists, its disadvantages are so great that it is doubtful whether the system was ever strictly applied to harmonized music. Some kind of temperament may have been practiced empirically long before it was described in writing. The addition over several centuries of the five chromatic notes (the black notes of the piano), giving the full chromatic scale, certainly does nothing to improve either the Pythagorean or the Ptolemaic tuning (see Table 2, which shows the deviation of the four main tuning systems from the ideal tuning of the principal intervals). To either system the use of the chromatic notes adds more true fifths but also more untrue thirds and sixths. The advantages of just intonation over Pythagorean tuning are experienced only in chords made up of white notes.

Table 1: Melodic Comparison of the Four Principal Tuning Systems*

	diatonic scale				chromatic scale

semitones

*The sizes of successive steps in the diatonic and chromatic scales are shown for each of the four systems, in cents. Black notes of the chromatic scale are indicated by bold lines.

With the development of harmony and the increased use of chromatic notes, both tuning systems became increasingly unsatisfactory.

Temperament. The first mention of temperament is found in 1496 in the treatise *Practica musica* by the Italian theorist Franchino Gafori, who stated that organists flatten fifths by a small, indefinite amount. This practice tends to spread out the mistuning of the fifth D–A over several fifths, so that all are tolerable although none is perfect. This principle was systematized as mean-tone temperament, first described in 1523. Under this scheme, all the major thirds of the scale are made perfect (*i.e.*, are tuned in the simple ratio 5:4); it results in an imperfection in the tuning of fifths that is spread out evenly over the entire cycle. Specifically, the interval of two octaves and a major third is tuned perfectly and divided into four fifths (C–G–d–a–e′), each of which has the ratio $\sqrt[4]{5}$:1 (compared to 3:2 for a perfectly tuned fifth). The fifths are flat by a quarter of a comma, which is much less dissonant than a comma: it gives a beat rate of 0.9 to 4 per second for fifths that fall within the compass of the medieval gamut. All major sixths are sharp by the same amount. Melodically, the scale resulting from mean-tone temperament is superior to the Ptolemaic (just intonation) scale, for all the whole tones are equal in size, being exactly half a true major third, or 193 cents. This is the source of the system's name: the mean, or average, whole tone. The semitones of the diatonic scale are relatively large, at 117 cents.

Mean-tone temperament

Mean-tone temperament, specifically designed for keyboard instruments, was an acceptable compromise so long as the black notes used in a composition did not extend beyond E♭ and G♯. As soon as D♯ was needed as well as E♭, the system collapsed. The keyboard provided only one key for E♭ and D♯. This key was tuned as E♭ and with no reference to the G♯ below it. The enharmonic fifth G♯–E♭ (in which E♭ is treated as equal to D♯) is nearly two commas out of tune in the mean-tone system. Worse even than the mistuned fifth of just intonation, it was often given the name "the wolf." Organs were occasionally built with split black keys so that E♭ and D♯ could be differently tuned and also A♭ and G♯. This expedient slightly extended the range of usable harmonies, but a more drastic remedy was soon needed. By spreading out the mistuning of the "wolf" fifth among its neighbours, in the same way that their predecessors had spread out the mistuning of the fifth D–A, musicians of the 17th century moved imperceptibly away from mean-tone temperament, in which the fifths are tuned unequally, toward the system of equal temperament, in which all fifths are equally flat.

Equal-tempered tuning

In equal temperament, all intervals are made up of semitone units, each of which is set exactly at a 12th of an octave, or 100 cents. A fifth is built of seven semitones; in relation to a pure fifth, it is 2 cents flat. A major third is four semitones and is 14 cents sharp; a major sixth is nine semitones and is 16 cents sharp. Because in equal temperament the intervals are identical in all parts of the chromatic scale, the system is the only one that can accommodate the expanded range of harmonies of 19th- and 20th-century music. Melodically, it fulfills the ideal of equal steps. The price for these great advantages is the total disappearance of perfectly tuned intervals, save only the octave. For the piano and the harpsichord this is scarcely a drawback: the characteristic tone of these instruments is, in any case, rich in dissonant components. Indeed, it has been found that piano tuners systematically set octaves and even unison strings out of tune. But on the organ, with its purer and more sustained tone, the disadvantages of equal temperament are considered by many to outweigh its blessings. In England such musicians as the organist and composer Samuel Sebastian Wesley continued to oppose it even as late as the mid-19th century.

On fretted instruments, such as lutes, guitars and viols, the frets extend across the fingerboard, producing at any one point divisions of equal lengths on strings of different pitch. Unless equal temperament is used, the positioning of the frets results in mistuned octaves and unisons when the same note is played on different strings. For this reason equal temperament was applied at least as early as the 16th century in the construction of fretted instruments.

It has often been stated that singers and players on instruments of undetermined tuning, such as violins and trombones, naturally use just intonation when performing together. Experimental evidence does not support this theory. In such circumstances musicians tend either to play in equal temperament, or, if anything, to distort intervals away from perfect consonance. Most probably this is the result of generations of conditioning. Moreover, it has been found that few musicians can distinguish melodically between just intonation and equal temperament and that those who can do so prefer the latter.

Other tuning systems. An enormous number of systems of tuning have been proposed and experimented with at different times, many involving subdivision of the octave into other than 12 equal units. None of them has passed into general use.

Table 2: Harmonic Comparison of the Four Principal Tuning Systems*

	diatonic scale						added black notes					enharmonic intervals			
Perfect fifths	F-C	C-G	G-D	D-A	A-E	E-B	E♭-B♭	B♭-F	B-F♯	F♯-C♯	C♯-G♯	G♯-E♭

Major sixths	F-D	C-A	G-E	D-B			E♭-C	B♭-G	A-F♯	E-C♯	B-G♯	F♯-E♭	C♯-B♭	G♯-F	
Pythagorean tuning	+22	+22	+22	+22			+22	+22	+22	+22	+22	−2	−2	−2	
"just intonation"	+22	0	0	0			+22	+22	+22	+22	+22	+20	+20	+20	
mean-tone temperament	+6	+6	+6	+6			+6	+6	+6	+6	+6	+49	+49	+49	
equal temperament	+16	+16	+16	+16			+16	+16	+16	+16	+16	+16	+16	+16	

*The tuning of each of the three basic intervals is analyzed for each system. Deviations from the "true" intervals are given in cents. 100 cents = 1 equal-tempered semitone. The sizes of the "true" intervals are as follows: perfect fifth, 702 cents; major third, 386 cents; major sixth, 884 cents.

Tuning and musical history. It is seldom realized what an important effect tuning practices have had on the development of harmony and tonality. From the 10th to the 13th centuries thirds and sixths—now considered consonant—were treated as dissonances simply because, according to then-current tuning methods, they *were* dissonances. In Pythagorean tuning, only the bare fifth and octave could provide a tolerable point of repose in music accompanied by the organ. Although just intonation permitted some harmony based on triads, the use of sharpened leading notes (the last note of the scale, leading upward into the first), which by the 16th century had caused the older system of modes to disintegrate, was made acceptable only by the use of some kind of temperament. At a later date it was the existence of lutes tuned in equal temperament that made possible the more extreme experiments in chromaticism of composers such as Luca Marenzio (1553–99) and Carlo Gesualdo (*c.* 1560–1613). The formation of a unified orchestra was probably delayed by the simultaneous practice of two incompatible tuning systems—mean-tone for keyboard instruments, equal temperament for lutes and viols. The decline of viols and their replacement by the violin family may have been hastened by the inability of viols to play with the organ. The modern orchestra began with the Vingt-quatre Violons du Roi (Twenty-four Violins of the King) of Louis XIV, and most later Baroque music is based on a keyboard instrument with from one to 30 members of the violin family, playing in mean-tone temperament. The cycle of six related keys, established in the operas of Alessandro Scarlatti (1660–1725) and the sonatas of Arcangelo Corelli (1653–1713) and followed closely in most of the music of J.S. Bach (1685–1750) and George Frideric Handel (1685–1759), is probably a direct outcome of mean-tone temperament. Within the limits of mean-tone temperament, the six keys exhaust the chromatic compass available. On the other hand, "wolf" chords may have been deliberately introduced by Domenico Scarlatti (1685–1757), François Couperin (1668–1733), and other composers to give an added piquancy to certain harpsichord passages. Many harpsichord players, including Bach, would retune a few notes of their instruments to prepare to play a piece in a new key, shifting the "wolf" fifth to part of the scale where it would do no harm. But in organ works such temporary retuning was hardly possible. Bach's organ tuning must have been as close to equal temperament as modern instruments are, although it is known that he was opposed to a strictly mathematical equality of intervals. By his title *Well-Tempered Clavier* he probably meant a kind of modified mean-tone temperament.

Enharmonic modulation

Enharmonic modulation, in which one note (say B♭) is treated as identical to another (say A♯) that actually has the same pitch only in equal temperament, was an exceptional device in Baroque music. But as orchestras became free of keyboard instruments and as keyboard instruments increasingly adopted equal temperament, it became a normal stock-in-trade, allowing the use of a series of key changes in one direction that eventually returns to the original key. Thus, it is not unusual for Mozart to complete the cycle of 12 keys in the course of a movement. Equal temperament permitted 19th-century composers to use the 12 notes of the chromatic scale with the utmost freedom. It also fixed those 12 notes so immutably in the Western musical consciousness that the revolutionary developments of 20th-century music, far from undermining them, have tended to perpetuate them.

ELLIS, *On the Sensations of Tone*, 1875), still the classic treatment of the subject, with useful additional observations by the translator; J. MURRAY BARBOUR, *Tuning and Temperament: A Historical Survey* (1951), a comprehensive study of the theoretical aspects of the subject, with a good bibliography; LLEWELYN S. LLOYD and HUGH BOYLE, *Intervals, Scales and Temperaments* (1963), designed for the musician; PAUL C. GREENE, "Violin Intonation," *Journal of the Acoustical Society of America*, 9:43–44 (1937), disposes of the theory that violinists naturally play in just intonation; ROGER E. KIRK, "Tuning Preferences for Piano Unison Groups," *ibid.*, 31:1644–48 (1959), shows that musicians prefer groups of unison strings on the piano to be mistuned; D.W. MARTIN and W.D. WARD, "Subjective Evaluation of Musical Scale Temperament in Pianos," *ibid.*, 33:582–585 (1961), shows that musicians do not prefer just intonation to equal temperament; FRITZ A. KUTTNER and J. MURRAY BARBOUR, *The Theory of Classical Greek Music; Meantone Temperament in Theory and Practice;* and *The Theory and Practice of Just Intonation*, Musurgia Records, Theory Series A, No. 1–3, an opportunity to hear the three major tuning systems that preceded equal temperament, both in scales and chords and in actual music.

(N.T.)

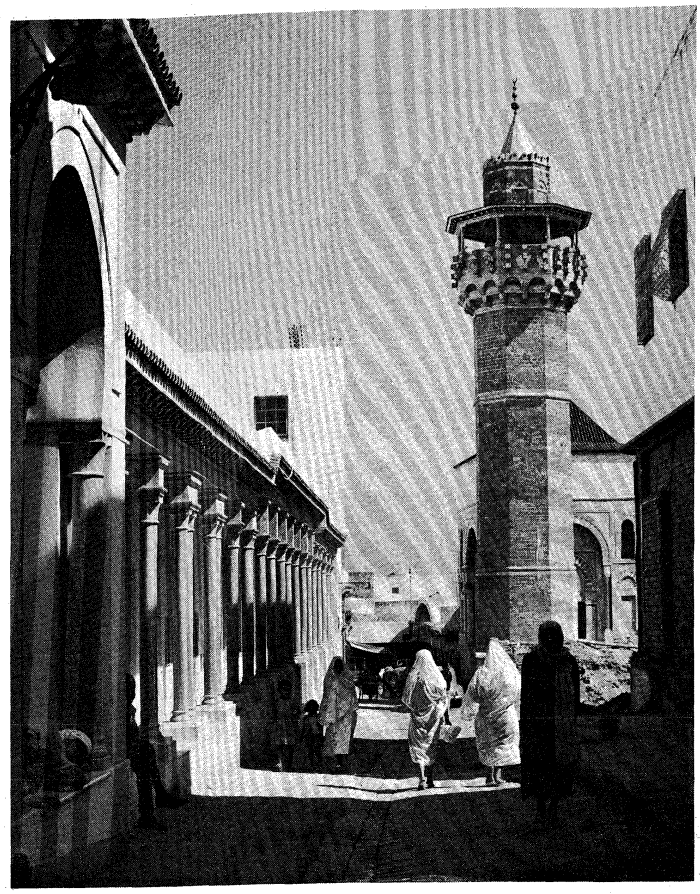
Tunis

Tunis (Arabic: Tūnus or Tūnis), the capital and largest city of the Republic of Tunisia and of the *wilāyat* (governorate) of Tunis, is one of the oldest of Mediterranean cities. It is situated to the southwest of the Gulf of Tunis, six miles inland from its ancient outport of Ḥalq al-Wādī (La Goulette). Located near the site of ancient Carthage, now a suburb of the city, it occupies a key position on the Barbary Coast of North Africa, between the western and eastern basins of the Mediterranean Sea. Its mixture of medieval and modern architecture, its exotic covered markets, and other historic and scenic sights have long appealed to visitors, and tourism, in fact, is Tunis' fastest growing industry. A steady and increasing influx of population from rural areas presents it with long-term employment, housing, and other urban problems. The *wilāyat* of Tunis has an area of 803 square miles (2,080 square kilometres).

History. Nothing certain is known about the origins of the city of Tunis, which is mentioned in Greek and Latin texts under the name Tynes, or Tunes. It was undoubtedly founded by the Libyans, the earliest occupants of the area, and it was probably these Libyans who, in about 800 BC, surrendered the site of Carthage to a colony of

Phoenicians from Tyre. Tunis soon gravitated into the orbit of Carthage, sharing its fortunes—and misfortunes. In 146 BC, during the Third Punic War, between Carthage and Rome, Tunis, like Carthage, was destroyed. But it arose from its ruins and even flourished under the rule of the Roman emperor Augustus, although there is not much record of it during Roman, Vandal, and Byzantine times.

When Carthage was destroyed a second time by the Arab conqueror Ḥassān ibn an-Nuʿmān in 698, Tunis was no more than a poor, small town. Ḥassān established an arsenal at Tunis, bringing in a thousand Coptic families from Egypt; among them were specialists in shipbuilding.



Rebuilding of the city by the Arabs

The new city was at first the seat of a governor; from the time of the reign of the Aghlabids (800–909), however, it shared with al-Qayrawān the role of capital city. Its oldest and most venerated monument, the mosque of az-Zaytūnah, had been built around 734 and remained until 1958 the seat of the country's oldest university. The local Banū Khurāsān dynasty (1059–1159) did a great deal to expand and beautify the city. The suburbs of Bāb as-Suwayqah on the north and Bāb al-Jazīrah on the south date from this period. The Almohad caliphs of Morocco, however, reduced Tunis to the role of a provincial seat (1160–1236). Under the Ḥafṣid dynasty (1236–1574), however, it regained its position as the capital, which it has held since. It was the Ḥafṣids who organized the specialized covered markets (suqs) so that each trade had its own separate quarter. In around 1300 the old city assumed its definitive form which it still retains.

Tunis has endured many trials in its history. King Louis IX (*q.v.*) of France (St. Louis), on the Eighth Crusade in 1270, besieged it and met his death from plague beneath its walls. In the middle of the 14th century, the Marīnids of Morocco took it twice. In 1534 it was the turn of the famous Barbary corsair Barbarossa (Khayr ad-Dīn) to capture it, though he had to surrender it almost at once to Charles V, Holy Roman emperor (1535). The city then passed into the hands of the Turks (1539). It was retaken by the Spaniards, who held it from 1573 to 1574 but who were obliged to yield it to the Ottoman Empire, under whose rule it remained until the French protectorate (1881–1956). It was occupied by the Germans in 1942 and liberated by British forces and Allied troops in 1943. It became the national capital of Tunisia when independence was achieved in 1956.

The contemporary city. *City plan.* Tunis occupies a slightly elevated isthmus separating two salt lakes—the Buḥayrat Tūnis (Lake of Tunis) on the east and the marshy Subkhat as-Sījūmī on the southwest. The old city, al-Madīnah (227 acres), together with the suburbs of Bāb as-Suwayqah and Bāb al-Jazīrah (428 acres) comprise the ancient nucleus of Tunis. This old city, lying on the side of hills sloping down from the old fort (Qaṣabah), on a high point in the west, is oval in shape and is encircled by boulevards that have replaced the ancient walls. Of the old gates, only Bāb Manārah and Bāb al-Baḥr (Gate of the Sea) still stand. The old city's colourful az-Zaytūnah Street leads to Bāb al-Baḥr, from which the Avenue de France and its extension the Avenue Habib Bourguiba, the capital's largest (nearly 200 feet wide) artery sweeps into the modern, European-style city. The modern city began to develop on the flat, low-lying land between the old city and the Lake of Tunis to the east especially after 1830, when the European presence and interest became more manifest with the occupation of Algiers.

Transportation. A canal connecting the port of Ḥalq al-Wādī (La Goulette) with the shallow Lake of Tunis was cut in 1893. The new harbour complex of Tunis–Ḥalq al-Wādī, inaugurated in 1967, greatly increased the capacity of the port to handle both passengers and merchandise. Al-ʿUwaynah International Airport is a few miles northeast of the city; the increase in air traffic in the 1960s and 1970s necessitated the creation of a second airport (at Tunis–Carthage) equipped with runways for large jet aircraft. The city is the eastern terminus of the railroad from Morocco and has rail and road links with the interior and with coastal towns.

A street in a section of al-Madīnah, the old city of Tunis.

Population

Demography. The population of Tunis, 186,000 at the time of the 1926 census, stood at 685,000 by the time of the 1966 census; of that number, 352,000 were males. The population of the *wilāyat* of Tunis, including the city, was 790,000. It is estimated that by the early 1970s the population of the *wilāyat* had reached 1,127,000 inhabitants, 950,000 of whom were in the city of Tunis. Of this population, 52 percent are under 20 years of age, and many are unable to find employment. To relieve that situation, emigration was being organized and encouraged. In addition to a high birth rate, an exodus from the rural areas that the authorities have been unable to stem has brought about the fast rise in the city's population. A quarter of the entire population of Tunisia is concentrated in an area of only 89 square miles. This trend appears to be intensifying, and it is estimated that by 1980 Greater Tunis will contain 1,500,000 inhabitants.

Housing and architectural features. Out of a total of approximately 144,000 dwellings in the *wilāyat* of Tunis, 63,000 were individual houses, 26,000 apartments, 33,000 collective houses (rented lodgings, with rooms grouped around an interior courtyard), and 18,000 shacks (*gourbis*); the remainder consisted of tents or other temporary shelters. Of these dwellings, about 70,000 had running water, 90,000 had electricity, and 40,000 were supplied with gas.

Appearance of the city

The buildings give the city the appearance of being low and white. The cathedral, the municipal theatre and handicrafts centre, the banks, and the principal hotels and cafes are on the Avenue Habib Bourguiba. In 1971 the sky-blue silhouette of the 21-story Africa Hotel rose up, towering over the avenue. In general, the buildings of the modern city are never more than six or seven stories tall, while the tortuous alleys of the old medieval city thread among one-story cubes of ancient, windowless houses. To move from one section of Tunis to another is seemingly to travel back several centuries in time. There is a sharp contrast between the hovels of Mellassine, located amid the muddy marshes of Sabkhat as-Sījūmī, and the gleam-

ing villas of the new residential quarters on higher ground, some of which overlook the Gulf of Tunis. Great efforts have been made to create healthful working-class quarters at a moderate price, but there is resistance to change.

Economic life. Agriculture remains the chief source of wealth, olives and cereals being the principal crops grown in the surrounding farmlands. Manufactures include foodstuffs, olive oil, textiles, carpets, and cement and metal building structures; there are also chemical (superphosphate), metallurgical, machine, and electrical industries and railways workshops. There are two thermoelectric plants, at Ḥalq al-Wādī, and a lead smelter, at Maqrīn. Tourism is of particular economic importance; tourist accommodations, which could house about 3,500 at a time in 1966, had increased to over 5,000 by 1970.

Industrial activity and tourism

Government. The *wilāyat* (governorate) of Tunis is composed of nine administrative units, called delegations, and 22 communes. It has at its head a governor, appointed by the government, who presides over the municipal council of the city of Tunis. There are 30 councillors who are elected to the municipality for three-year terms by direct universal suffrage and who are eligible for re-election.

Public health and education. Within the *wilāyat* there were, early in the present decade, ten hospitals, two auxiliary hospitals, 25 local dispensaries, and 21 rural dispensaries.

The city's water is supplied from an artificial lake and various wells, springs, and subterranean sources from as far away as 60 miles to the south in the catchment of the Wādī al-Kabīr-Milyān. It is carried by pipeline to a reservoir in the Bāb al-Jazīrah quarter.

In the late 1960s there were about 110,000 pupils in the primary schools, of whom 50,000 were girls. The University of Tunis (founded in 1960) had a student body of 11,000 in the early 1970s.

Cultural life and entertainment. Tunis has two cultural centres, as well as a theatre that is used by international theatre groups. The summer festival—the Festival of Carthage, held in July—has achieved a certain renown. Among the city's attractions are its thermal baths, dating from the time of Rome's Antonine emperors (who ruled in the 2nd century), the heights of Sīdī-Bū Saʿīd, and the exoticism of its markets (suqs); in addition, several parks and green areas have been established. Nearby, southeast of the city along the valley of the Wādī Milyān, are magnificent remains of the aqueduct (originally Roman) from Jabal Zaghwān to Carthage.

Thermal baths and exotic markets

Projects intended to improve the already difficult traffic situation, to save the character of al-Madīnah, and to modernize the city are envisaged. The most important of these is perhaps the project to transform the 7,000 acres of the Lake of Tunis, now a source of pollution, into a vacation spot.

BIBLIOGRAPHY. On the history of Tunis, see CHARLES R. DESSORT, *Histoire de la ville de Tunis* (1924), now somewhat out of date; and HENRI SALADIN, *Tunis et Kairouan* (1908), which should be used with caution. For the contemporary situation, the following are suggested: J.B. DARDEL and C. KLIBI, "Un Faubourg clandestin de Tunis: le Djebel Lahmar," *Cahiers de Tunisie (CT)* 3:211–224 (1955); P. SEBAG, "Le Bidonville de Borgel," *CT*, 6:267–309 (1958); *L'évolution d'un ghetto nord-africain: la hara de Tunis* (1959); "Le Faubourg de Sîdî Fathallâh," *CT*, 8:75–136 (1960); and *et al., Un Faubourg de Tunis: Saida Manoubia* (1960).

Tunisia

The Republic of Tunisia (in Arabic al-Jumhūrīyah at-Tūnisīyah) is a small country with an area of 63,378 square miles (164,150 square kilometres) and an estimated population of 5,194,000 in 1971. It occupies a central position of primary strategic importance in the Mediterranean, where its situation has kept it open to virtually every historic influence in the region. It is bounded by Algeria to the west and southwest, Libya to the southeast, and the Mediterranean Sea to the east and north. The capital is Tunis.

With its 750 miles of coastline, Tunisia has often been compared to the hull of a ship, solidly moored on the continent but also freely washed by the waves; in consequence, its destiny, as its leaders never tire of repeating, is at once Mediterranean and Maghribian (the Maghrib, or the "Arab West," consists of the northwest African countries of Morocco, Algeria, Tunisia, and Libya). As North Africa constitutes a single geographic entity, the lines separating Tunisia from Libya and from Algeria do not assume the form of any natural barrier but, rather, have been shaped by the vicissitudes of human history. As a result, there have been many attempts, so far unproductive, to restore natural frontiers; Maghrib Arab unity is one of the political goals of every North African country.

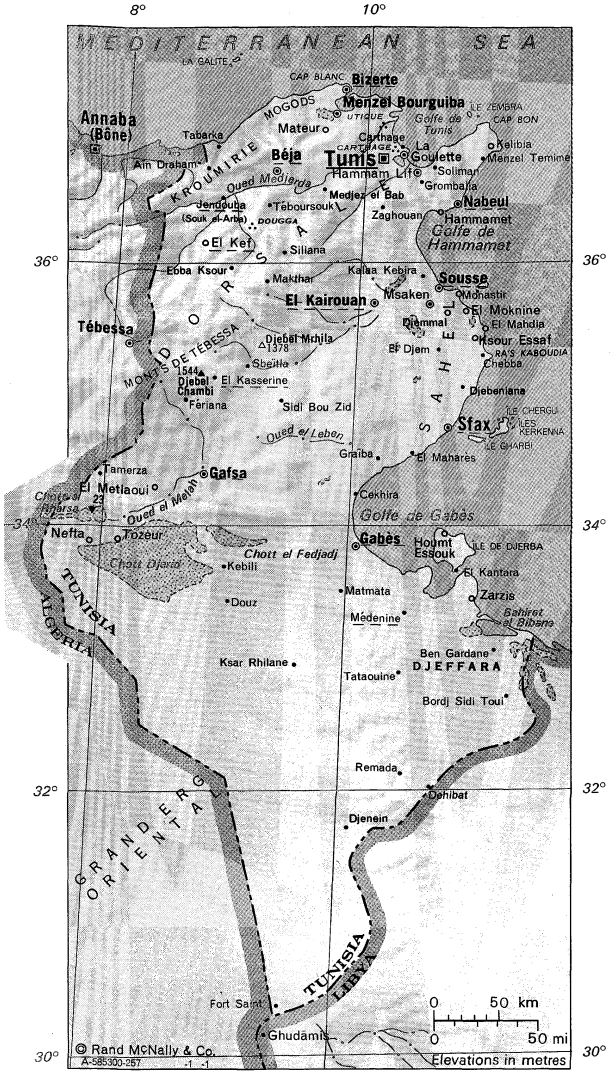
Tunisia's strategic situation

Unlike its immediate neighbours, who are potentially rich, Tunisia has somewhat meagre resources at its disposal. In addition, its usable territory is limited and its domestic market restricted, and the problem of promoting economic development is particularly difficult. Thus, after the stagnation that opened the way to the trials and changes of the colonial era, Tunisia is entering the modern world with determination, sometimes with imagination, but without decisive economic advantages. For associated physical features, see ATLAS MOUNTAINS; and SAHARA (DESERT); see also the city article TUNIS; for historical aspects, see NORTH AFRICA, HISTORY OF.

THE LANDSCAPE

Relief and drainage. Tunisia is characterized by its moderate relief. The Tunisian Dorsale, a southwest to northeast mountain range that is an extension of both the Atlas Saharien (Saharan Atlas) of Algeria and of the Haut Atlas of Morocco, tapers off in the direction of the Gulf of Tunis in the northeast, on which stands Tunis. The highest peak, Kāf ash-Shaʿnabī (Mt. Chambi), located near the centre of the Algerian border, rises to 5,066 feet (1,544 metres), while Jabal Zaghwān (Mt. Zaghouan), about 30 miles southwest of Tunis, reaches only 4,249 feet (1,295 metres). Between the limestone peaks of the central Tunisian Dorsale and the sandstone chains of the Kroumirie mountains in the northwest, which reach altitudes of 3,000 feet, and of the Mogods, which run along the deeply indented coastline to the north, lies the valley of the Majardah (Medjerda), which is formed by a series of ancient lake basins covered with alluvium. This valley was once the granary of ancient Rome and remains the richest grain-producing region of Tunisia.

The Majardah and its tributaries form the principal river system; the river crosses the northern part of the country, flowing northeastward to empty into the Gulf of Tunis.



To the south of the Tunisian Dorsale lies a region of high steppes (treeless plains), with altitudes ranging from about 600 to 1,500 feet, crossed by north–south secondary ranges. Further south begins a low–steppe zone, then a series of *shaṭṭ* (salty lake) depressions. Large plains border the eastern coasts, while the extreme south consists of desert.

Climate, vegetation, and animal life. Tunisia is situated in the hot temperate zone between the 37th and the 30th parallels. It has a Mediterranean climate characterized by mild, rainy winters and hot, dry summers. Prevailing winds are from the west most of the year, producing unsettled weather. In summer the prevailing wind is from the northeast, but Saharan influences also appear that give rise to the sirocco, a hot, blasting wind from the south that can have a seriously drying effect on vegetation.

Temperatures are affected by the sea, being less extreme at Sūsah (Sousse) on the coast, for example, than at al-Qayrawān inland. Temperatures at Sūsah over a 50-year period (1901–50) varied from an average daily low of 44° F (less than 7° C) for the month of January to an average daily high of 89° F (32° C) for the month of August. Comparable temperatures at al-Qayrawān were 40° F (4° C) in January and 99° F (37° C) in August.

Temperature and rainfall

The amount of rainfall is irregular. In 1968, 51 inches were recorded at al-Fayjah in northwest Tunisia, as opposed to four inches at Maṭmāṭah. Generally, from the middle of autumn to the middle of spring, northern Tu-

TUNISIA

nisia receives more than 16 inches of rainfall, and the steppe region receives from six to 16 inches. Amounts also vary considerably from one year to another; for example, 36 inches fell at Makthar in north central Tunisia in 1963–64, in contrast to 16 inches in 1966–67. Harvests vary as a result, being poor in dry years.

The vegetation and animal life of the country are affected by these climatic conditions. From north to south, the Kroumirie forest of cork oaks, with its fern undergrowth sheltering wild boars, gives way to steppes covered with esparto grass and populated with small game, and finally to the desert, where hunting is forbidden so as to preserve the remaining gazelles. Scorpions are found in all regions; among dangerous snakes are the horned viper and the cobra. Desert locusts sometimes damage crops in the southern part of the country.

Traditional regions. Tunisia is divided into four natural and demographic regions: the north, which is relatively fertile and well watered; the semi-arid central region; the Sāḥil in the east central coastal region, which is pre-eminently olive-growing country; and the south, where, except in the oases, all vegetation disappears. In the central and southern regions, there are still tribes that have preserved a certain cohesion through following a quasi-nomadic way of life. Ethnic mixtures in these regions are rare. In the north, on the other hand, particularly along the coasts, the population is quite mixed, the life of the cultivator is more complex, the villages are more crowded, and the cities are larger. In the early 1970s the cities were continuing to expand at the expense of the countryside. In 1970, the estimated urban population numbered about 2,200,000 out of a total of 5,100,000.

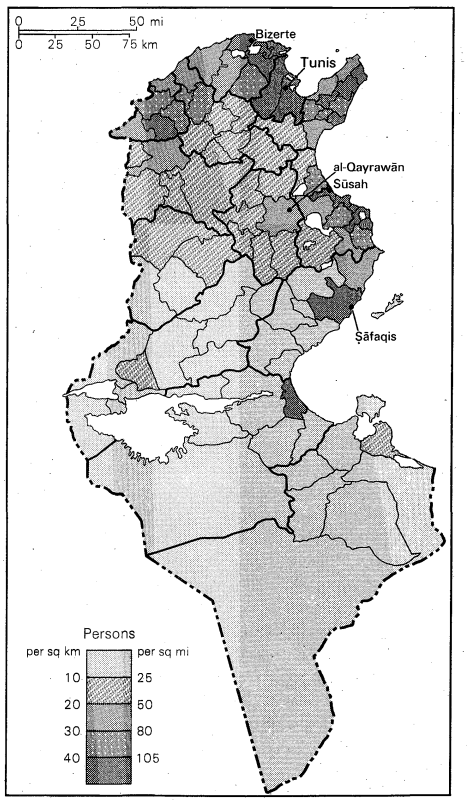
Apart from Tunis (population about 944,000 in 1969), the largest towns (1966 population) are Ṣafāqis (Sfax), with 100,000 inhabitants; Sūsah (Sousse), with 75,000; Bizerte (Banzart), with 65,000; and al-Qayrawān (Kairouan), with 45,000.



THE PEOPLE

Groups historically associated with the contemporary country. The population of Tunisia is essentially Arab Berber. Throughout the centuries Tunisia has, however,

received various waves of immigration; these have included Phoenicians, black Africans, Jews, Romans, Vandals, and Arabs, as well as Muslim refugees from Sicily, who settled in as-Sāḥil (Sahel) after their homeland was captured by the Norman kings in 1091. The most important immigration, however, was that of the Spanish Moors, which began after the fall of Seville, in Spain, in 1248 and turned into a veritable exodus in the early 17th century; 200,000 Spanish Muslims thus settled in the area of Tunis, in the Majardah Valley, and on Cape Bon in the north, bringing with them urban traditions and more advanced agricultural and irrigation techniques. Finally, from the 16th to the 19th centuries, the Turks brought in their wake different elements of Asiatic or European origin. This great ethnic diversity is still seen in the variety of Tunisian family names.

Languages

The cultural Arabization of the country can be considered to have been essentially completed by the end of the 12th century. Today less than 1 percent of the population, in the south, still speaks the Berber language. French, introduced during the protectorate (1881 to 1956), paradoxically came into wider use after independence because of the spread of education. Although Arabic is the official language of the country, French continues to play a dominant role in the press, education, and government, and Tunisia, significantly, was among the countries that in the 1950s and 1960s worked to organize the French Community.

Population density of Tunisia.

The last indigenous Christian communities in Tunisia, which were still sizable in the 12th century, disappeared as long ago as the end of the 14th century. Only the Jewish community has survived, but its membership, which in the early 1970s numbered approximately 85,000, was constantly decreasing as a result of emigration. Non-Muslim foreigners, who numbered about 250,000 in 1956, in the early 1970s scarcely exceeded 40,000.

Demography. Tunisia has a high birth rate. Despite the authorization or tolerance of all contraceptive methods, the present population growth rate is 2.5 percent. Forty-six percent of the population is less than 15 years of age. This high rate of growth has led to a policy of emigration; 130,000 Tunisians work abroad, 80,000 of them in France, 30,000 in Libya, and 10,000 in Germany. The Tunisian population is very unevenly distributed. There are 180 inhabitants per square mile in the north and in as-Sāḥil (Sahel) compared with 25 on the steppes.

Tunisia, Area and Population

Despite the efforts at family planning, in the early 1970s the rate of population growth was not expected to drop in the near future, a fact that posed serious economic problems.

THE ECONOMY

Tunisia is a country with a low national income. Its gross national product per inhabitant increased from $147 U.S. a year in 1957 to $230 in 1969, as compared with more than $4,200 for the United States and $1,210 for the Soviet Union. Its annual growth rate for the period 1960 to 1971 was 3.7 percent overall and 1.5 percent per inhabitant. For 1970, the overall rate seemed to be between 6 and 7 percent. The rate of investment was between 10 and 15 percent. Tunisia is classed among the "developing" countries, its standard of living is about equal to that of Algeria but higher than that of Morocco.

Resources and resource exploitation. The Tunisian economy is characterized by the predominance of the agricultural over the manufacturing sector. In the early 1970s, about 60 percent of the population was engaged in agriculture, producing 19 percent of the national income. Yields are low and crops are, in addition, endangered by changes in the weather. The manufacturing sector, despite major efforts toward investment and acquisition of equipment in the 1960s, remained insufficiently developed. Another factor of imbalance arises from the difference in conditions between the north and the Sāḥil, on the one hand, which are more fertile and more economically developed, and the central and southern regions, on the other, which have fewer natural advantages.

Natural resources

Natural resources of the soil and subsoil are relatively meagre. The lumber industry is essentially confined to the exploitation of oak and cork from the Kroumirie forest in the north. The esparto grass of the plains is used for the manufacture of quality paper. The principal mineral resource is phosphate. By the late 1960s, however, Tunisian phosphate production was encountering difficulties, largely because of United States and Moroccan competition, a circumstance that led to a fall in production.

Other mineral resources are iron, lead, zinc, and mercury. Petroleum, discovered in the extreme south in 1964 at the al-Borma field, by the early 1970s was beginning to play an important role in the Tunisian economy. Of the 4,150,000 tons extracted in 1970, 1,150,000 tons were sent to the Bizerte refinery, in operation since 1963, and 2,860,000 tons were for export. The constantly increasing petroleum revenues rose from 8,500,000 dinars (0.52 dinars = $1 U.S.; 1.25 dinars = £1 sterling in Dec. 1971) in 1969 to 15,000,000 dinars in 1970, when production exceeded 4,100,000 tons. Oil discoveries made in 1971 in

the Ṣafāqis (Sfax) area will make it possible to double production, and other encouraging indications have been noted in the Gulf of Gabes (Qābis) on the east coast.

Tunisia's agriculture, which in the early 1970s accounted for 22 percent of its exports, remains its principal source of income. The low yields are primarily due to the division of the property into excessively small plots and the predominance of obsolete farming methods. The uncertainty of the rainfall often jeopardizes harvests; grain production is generally inadequate, and Tunisia has had to resort to imports. In addition to cereal grains, the principal products are citrus fruits, olive oil, and dates. Wine is also important, but output is decreasing. In order to improve agricultural production, dams and wells are being used to expand the irrigated area, but water resources nevertheless remain limited. The fishing industry is, however, fully developed. Sheep, goats, and cattle are raised to a limited extent.

The industrialization of Tunisia has encountered two major difficulties. Raw material and power supplies are inadequate, and the domestic market is limited. Notable and sometimes costly projects, such as the Manzil Bū Ruqaybah (Menzel-Bourguiba) iron-smelting complex, located near Bizerte, however, have been successfully established since independence was achieved in 1956. Existing industries produce foodstuffs, textiles, clothing, construction materials, household articles, and fertilizers. In the early 1970s efforts were being made to develop the south economically; for example, the Industries Chimiques Maghrébines (Maghreb Chemical Industries) complex, which produces phosphoric acid, was opened at Qābis in 1971. Tourism, however, remains Tunisia's leading industry. The number of tourists rose from 200,000 in 1966 to 400,000 in 1970. (M.Ta.)

Trade, finance, and management of the economy. Tunisian overseas trade still reflects the importance of primary production. About three-fifths of the exports by value are foodstuffs and raw mineral products, including petroleum. About a third of all trade is with France, with which Tunisia reached an agreement on trade and tariffs following the abolition of a customs union in 1959. The balance of payments is frequently adverse, and in some years this has obliged the government to limit imports. In the late 1960s an increasing proportion of Tunisia's trade was being channelled to the countries of the European Economic Community, to which it had applied for associate membership in 1967 with a measure of success. At that time Kuwait, the United States, and West Germany were advancing generous capital aid loans.

The strength of the dinar and of the economy was helped in the late 1960s by international confidence in the political stability of Tunisia. The Banque Centrale de Tunisie performs the functions of an issuing bank. (W.C.B.)

Economic doctrine

Tunisian economic doctrine consists of a flexible and undogmatic form of Socialism based on the existence of three sectors—private, cooperative, and parastate (comprising chiefly gas, electricity, and railway services). The attempt at collectivization, which was carried out in the 1960s through the forced spread of the cooperative system, finally resulted in failure, particularly in the agricultural sector, and was abandoned in 1969. There are three large professional organizations. The Union Générale des Travailleurs Tunisiens (General Union of Tunisian Workers; U.G.T.T.) is the principal trade union, and there are also associations grouping employers and farmers respectively.

Transportation and communications. The network of roads (about 10,000 miles) and of railways (about 1,420 miles) is sufficiently dense so that all metropolitan areas of any importance are linked with the interior regions. Tunisia is connected by both road and rail with Algeria and Morocco but only by road with Tripoli (Ṭarābulus), Libya, and with Cairo, since the railway ends at Qābis. Train service, however, is slow and uncomfortable, and except for the main routes, the roads are quite narrow.

The principal ports are Tunis-Ḥalq al-Wādī (La Goulette), which is the outpost of Tunis, Ṣafāqis (Sfax), Bizerte (Banzart), and Sūsah (Sousse), as well as the port of Qābis, which was opened in 1970 and accommodates 50,000-ton ships. An oil pipeline runs from Edjeleh, Algeria, to the port of aṣ-Ṣukhayrah on the Gulf of Gabes.

Despite the creation of the Munastīr and Jarbah airports, which handle domestic or tourist (charter) flights, international air traffic is directed almost exclusively through al-ʿUwaynah airport near Tunis. Telecommunications have benefitted from an extensive modernization effort.

Tunisia is connected to Libya by microwave and to Algiers and Rabat by cable. In addition, the Qulaybīyah–Sicily and Bizerte–Marseilles cables give Tunisia access to the European automatic network. In 1971 there were over 76,000 telephone subscribers, of whom almost half were in Tunis.

ADMINISTRATION AND SOCIAL CONDITIONS

The structure of government. The Tunisian constitution, currently under revision, was promulgated in 1959; it defines Tunisia as a republic whose religion is Islām and whose official language is Arabic. Legislative power is exercised by the National Assembly, which consists of 90 delegates elected for five-year terms by universal suffrage. Executive power is in the hands of the president of the republic, who is both head of state and of government. He must be a Muslim and is elected for a five-year term by universal suffrage at the same time as the deputies; he is elegible for three consecutive terms.

The country is administered by the Cabinet, headed, since 1969, by a prime minister. The most important ministry is not that of defense, since the role and size of the armed forces has been somewhat reduced but rather that of national education, which in 1970 received almost one-quarter of the national budget. The 12 Cabinet ministers are responsible to the president rather than to the Assembly. Since 1957 the president has been Habib Bourguiba (*q.v.*).

Judicial power is exercised by judges whose independence is constitutionally guaranteed.

The Tunisian national army has a strength of about 24,000 men. The navy possesses two escort vessels and six patrol boats. There is a small air force.

The constitution guarantees "freedom of opinion, expression, press, publication, assembly, and association" ("under the conditions defined by law"), as well as the right to form trade unions. Tunisia in reality is governed under a one-party system, that of the Destour Socialist Party, generally called the Neo-Destour, to distinguish it from an older Destour Party founded in 1920 (*Destour* meaning "constitution"), which holds all the seats in the National Assembly. All Tunisians, including women, who are at least 20 years of age can vote. There is always a massive turnout for elections, with from 90 to 99.5 percent of the registered voters participating.

Local administration

The country is divided into 13 administrative areas called *gouvernorats* (*wilāyāt* in Arabic), which are headed by governors (*wālī*). Each *gouvernorat* is designated by the name of its chief town and is in turn subdivided into units called *délégations* (*muʿtamadīyāt*), whose number varies according to the *gouvernorat*'s size. *Muʿtamadīyāt* are administered by a *muʿtamad* and are in turn divided into varying numbers of districts called *cheikhats* (*mashyakhāt*).

Social conditions. *Education.* Education is free to all students, and scholarships in schools and universities are offered largely on the basis of merit and need. The number of students—and consequently the number of schools and teachers—has steadily increased since independence, at a rate that in the early 1970s was generally considered to be too high in relation to the rate of economic growth. Between the time of independence (1956) and the early 1970s, the number of students in primary schools rose from about 225,000 (of whom about 75,000 were girls) to more than 935,000 (of whom 370,000 were girls); in the secondary schools, from 30,000 to 195,000; and in higher education, from 2,000 to 10,000.

This growth has been accompanied by a certain drop in

educational standards; it has also posed problems of financing and of finding enough job opportunities for qualified people. A board of education was thus formed in 1971 to revise Tunisia's educational policy. A new tendency at this time was to place more emphasis on technical and agricultural training. Along with education, great efforts were being made in the early 1970s to improve housing, sanitation, and medical care. Significant results were being obtained, but these efforts were limited by problems of financing.

Social welfare. The living standards of the population in general are quite low. An improvement, recorded in 1971, brought the daily earnings of agricultural workers, who are at the bottom of the scale, up to 0.6 of a dinar. The monthly wage of a labourer is about 25 dinars, and that of a lower ranking government worker, about 35 dinars. Salaries are markedly higher in the private sector, varying from between 50 dinars for office workers to 250 dinars for managers. Rents range from a few dinars a month for a hovel, to 100 dinars for a comfortable house, rising to 200 dinars and more for luxurious lodgings. The advantages available to the less privileged consist, in addition to the distribution of milk to newborn babies and of school lunches, of free medical care for the destitute and of the extension of the social security system (providing medical benefits and hospitalization, etc.) to virtually all wage earners.

Cultural life. Tunisia is an Arab-speaking Muslim country that was deeply imbued with French culture during the 75 years of the protectorate, which ended in 1956. As in Algeria, but to a lesser extent, there was an attempt to establish a Tunisian literature written in French, but the trend apparently never took root. Although Tunisians generally use French in all scientific disciplines, they remain genuinely attached to Arabic in the literary sphere —in poetry, the novel, and the short story. Several literary reviews, the most important of which is *al-Fikr* ("Thought"), open their pages to youthful talents and stimulate literary output. Modern Tunisian literature, the subject of great debate on radio, television, and in the various government-sponsored Maisons de la Culture (Houses of Culture), has made remarkable progress, but it has not yet produced works of sufficient power to rival foreign and especially French literature, which is still preferred by the young. Tunisian literature continues to receive governmental encouragement, however, and an association of Tunisian writers was founded in 1971.

The state of the arts

Although the Tunisian cinema is still in its infancy, having to its credit no more than a few successful short films, Tunisian painting can already lay claim to a certain tradition. Some of the artists enjoy a genuine local celebrity and have also exhibited abroad. The music conservatory, while devoting attention to developing national traditions, emphasizes the classical European heritage.

A major effort is in progress to diffuse and decentralize cultural benefits, although means are necessarily limited. Maisons de la Culture are being established in the chief towns, and travelling libraries bring films and books to the most remote corners. Television, which naturally plays an important role, likewise covers the entire country; its programs are in Arabic and French, and provide information and education as well as entertainment. Finally, mention may be made of the various scientific journals, connected with various research institutes and schools.

Prospects for the future. Geography has determined Tunisia's fate by making it a hyphen, thus giving it a calling always to seek a balance between different forces. The land of St. Augustine and of Ibn Khaldūn, a haven for the Arab Muslim tradition and at the same time a gateway to the West, Tunisia constitutes a melting pot for a multitude of cultural traditions.

The major problem now confronting Tunisia is that of economic development. Although Tunisia has benefitted from extensive foreign aid and has itself made considerable developmental investment, the laboriously launched enterprises frequently show deficits. Tunisia, moreover, is obliged to import not only industrial equipment and products but also large quantities of foodstuffs, particularly cereal grains and meat, and its balance of trade constantly shows a deficit. The balance of payments, however, showed a surplus in the early 1970s, thanks to tourist revenues, to money sent by Tunisians working abroad to their families, and to influxes of capital in the form of investments or loans.

The current trend is toward granting priority to agriculture, improving crop yields, organizing emigration of workers, encouraging enterprises that require little capital and large amounts of labour, and reducing population pressure by making family planning more effective. Finally, it is hoped that wealth from new petroleum discoveries may help to finance Tunisia's future development.

Tunnelling and Underground Excavation

A tunnel is an essentially horizontal underground passageway produced by excavation or occasionally by nature's action in dissolving a soluble rock, such as limestone. A vertical opening is usually called a shaft. Tunnels have many uses: for mining ores, for transportation—including road vehicles, trains, subways, and canals—and for conducting water and sewage. Underground chambers, often associated with a complex of connecting tunnels and shafts, increasingly are being used for such things as underground hydroelectric-power plants, ore-processing plants, pumping stations, vehicle parking, storage of oil and water, water-treatment plants, warehouses, and light manufacturing; also command centres and other special military needs.

True tunnels and chambers are excavated from the inside—with the overlying material left in place—and then lined as necessary to support the adjacent ground. A hillside tunnel entrance is called a portal; tunnels may also be started from the bottom of a vertical shaft or from the end of a horizontal tunnel driven principally for construction access and called an adit. So-called cut-and-cover tunnels (more correctly called conduits) are built by excavating from the surface, constructing the structure, and then covering with backfill. Tunnels underwater are now commonly built by the use of an immersed tube: long, prefabricated tube sections are floated to the site,

sunk in a prepared trench, and covered with backfill. For all underground work, difficulties increase with the size of the opening and are greatly dependent upon weaknesses of the natural ground and the extent of the water inflow.

This article is divided into the following sections:

I. History
  Ancient tunnels
  From the Middle Ages to the present
    Canal and railroad tunnels
    Subaqueous tunnels
    Machine-mined tunnels
II. Tunnelling techniques
  Basic tunnelling system
    Geological investigation

    Improvement of surface environment
    Scope of the tunnelling market
  Potential applications
  Improved technology

I. History

ANCIENT TUNNELS

It is probable that the first tunnelling was done by prehistoric men seeking to enlarge their caves. All major ancient civilizations developed tunnelling methods. In Babylonia, tunnels were used extensively for irrigation; and a brick-lined pedestrian passage some 3,000 feet (900 metres) long was built around 2180 to 2160 BC under the Euphrates River, to connect the royal palace with the temple. Construction was accomplished by diverting the river during the dry season. The Egyptians developed techniques for cutting soft rocks with copper saws and hollow reed drills, both surrounded by an abrasive, a technique probably used first for quarrying stone blocks and later in excavating temple rooms inside rock cliffs. Abu Simbel Temple on the Nile, for instance, was built in sandstone about 1250 BC for Ramses II (in the 1960s it was cut apart and moved to higher ground for preservation before flooding from the Aswān High Dam). Even more elaborate temples were later excavated within solid rock in Ethiopia and India.

The Greeks and Romans both made extensive use of tunnels: to reclaim marshes by drainage and for water aqueducts, such as the 6th-century-BC Greek water tunnel on the isle of Samos driven some 3,400 feet (one kilometre) through limestone with a cross section about six feet (two metres) square. Perhaps the largest tunnel in ancient times was a 4,800-foot-long, 25-foot-wide, 30-foot-high (1,500 × 8 × 9 metres) road tunnel (the Pausilippo) between Naples and Pozzuoli, executed in 36 BC. By that time surveying methods (commonly by string line and plumb bobs) had been introduced, and tunnels were advanced from a succession of closely spaced shafts to provide ventilation. To save the need for a lining, most ancient tunnels were located in reasonably strong rock, which was broken off (spalled) by so-called fire quenching, a method involving heating the rock with fire and suddenly cooling it by dousing with water. Ventilation methods were primitive, often limited to waving a canvas at the mouth of the shaft, and most tunnels claimed the lives of hundreds or even thousands of the slaves used as workers. In AD 41, the Romans used some 30,000 men for ten years to push a 3.5 mile (six-kilometre) tunnel to drain Lake Fucinus. They worked from shafts 120 feet (37 metres) apart and up to 400 feet (120 metres) deep. Far more attention was paid to ventilation and safety measures when workers were freemen, as shown by archaeological diggings at Hallstatt, Austria, where salt-mine tunnels have been worked since 2500 BC.

Largest ancient tunnel

FROM THE MIDDLE AGES TO THE PRESENT

Canal and railroad tunnels. Because the limited tunnelling in the Middle Ages was principally for mining and military engineering, the next major advance was to meet Europe's growing transportation needs in the 17th century. The first of many major canal tunnels was the Canal du Midi (also known as Languedoc) tunnel in France, built in 1666–81 by Pierre Riquet as part of the first canal linking the Atlantic and the Mediterranean. With a length of 515 feet and a cross section of 22 by 27 feet (157 × 7 × 8 metres), it involved what was probably the first major use of explosives in public-works tunnelling, gunpowder placed in holes drilled by hand-held iron drills. A notable canal tunnel in England was the Bridgewater Canal Tunnel, built in 1761 by James Brindley to carry coal to Manchester from the Worsley mine. Many more canal tunnels were dug in Europe and North America in the 18th and early 19th centuries. Though the canals fell into disuse with the introduction of railroads around 1830, the new form of transport produced a huge increase in tunnelling, which continued for nearly 100 years as railroads expanded over the world. Much pioneer railroad tunnelling developed in England. A 3.5-mile (six-kilometre) tunnel (the Woodhead) of the Manchester–Sheffield Railroad (1839–45) was driven from five shafts up to 600 feet (180 metres) deep. In the United States, the first railroad tunnel was a 701-foot (214-metre) construction on the Allegheny Portage Railroad. Built in 1831–33, it was a combination of canal and railroad systems, carrying canal barges over a summit. Though plans for a transport link from Boston to the Hudson River had first called for a canal tunnel to pass under the Berkshire Mountains, by 1855, when the Hoosac Tunnel was started, railroads had already established their worth, and the plans were changed to a double-track railroad bore 24 by 22 feet and 4.5 miles long (7 × 7 metres by seven kilometres). Initial estimates contemplated completion in three years; 21 were actually required, partly because the rock proved too hard for either hand drilling or a primitive power saw. When the state of Massachusetts finally took over the project, it completed it in 1876 at five times the originally estimated cost. Despite frustrations, the Hoosac Tunnel contributed notable advances in tunnelling, including one of the first uses of dynamite, the first use of electric firing of explosives, and the introduction of power drills, initially steam and later air, from which there ultimately developed a compressed-air industry.

First use of explosives

Simultaneously, more spectacular railroad tunnels were being started through the Alps. The first of these, the Mont Cenis Tunnel (also known as Fréjus), required 14 years (1857–71) to complete its 8.5-mile (14-kilometre) length. Its engineer, Germain Sommeiller, introduced many pioneering techniques, including rail-mounted drill carriages, hydraulic ram air compressors, and construction camps for workmen complete with dormitories, family housing, schools, hospitals, a recreation building, and repair shops. Sommeiller also designed an air drill that eventually made it possible to move the tunnel ahead at

Tunnels in the Alps

the rate of 15 feet (4.5 metres) per day and was used in several later European tunnels until replaced by more durable drills developed in the United States by Simon Ingersoll and others on the Hoosac Tunnel. As this long tunnel was driven from two headings separated by 7.5 miles (12 kilometres) of mountainous terrain, surveying techniques had to be refined. Ventilation became a major problem, which was solved by the use of forced air from water-powered fans and a horizontal diaphragm at mid-height, forming an exhaust duct at top of the tunnel. Mont Cenis was soon followed by other notable Alpine railroad tunnels: nine-mile (14-kilometre) St. Gotthard (1872–82), which introduced compressed-air locomotives and suffered major problems with water inflow, weak rock, and bankrupt contractors; the 12-mile (19-kilometre) Simplon (1898–1906); and the nine-mile (14-kilometre) Lötschberg (1906–11), on a northern continuation of the Simplon railroad line.

Nearly 7,000 feet (2,100 metres) below the mountain crest, Simplon encountered major problems from highly stressed rock flying off the walls in rock bursts; high pressure in weak schists and gypsum, requiring ten-foot- (three-metre-) thick masonry lining to resist swelling tendencies in local areas; and from high-temperature water (130° F [54° C]), which was partly treated by spraying from cold springs. Driving Simplon as two parallel tunnels with frequent crosscut connections considerably aided ventilation and drainage.

Lötschberg disaster and its effect

Lötschberg was the site of a major disaster in 1908. When one heading was passing under the Kander River Valley, a sudden inflow of water, gravel, and broken rock filled the tunnel for a length of 4,300 feet (1,300 metres), burying the entire crew of 25 men. Though a geologic panel had predicted that the tunnel here would be in solid bedrock far below the bottom of the valley fill, subsequent investigation showed that bedrock lay at a depth of 940 feet (290 metres), so that at 590 feet (180 metres) the tunnel tapped the Kander River, allowing it and soil of the valley fill to pour into the tunnel, creating a huge depression, or sink, at the surface. After this lesson in the need for improved geological investigation, the tunnel was rerouted about one mile (1.6 kilometres) upstream, where it successfully crossed the Kander Valley in sound rock.

Most long-distance rock tunnels have encountered problems with water inflows. One of the most notorious was the first Japanese Tanna Tunnel, driven through the Takiji Peak in the 1920s. The engineers and crews had to cope with a long succession of extremely large inflows, the first of which killed 16 men and buried 17 others, who were rescued after seven days of tunnelling through the debris. Three years later another major inflow drowned several workers. In the end, Japanese engineers hit on the expedient of digging a parallel drainage tunnel the entire length of the main tunnel. In addition, they resorted to compressed-air tunnelling with shield and air lock (see below), a technique almost unheard of in mountain tunnelling.

Subaqueous tunnels. Tunnelling under rivers was considered impossible until the protective shield was developed in England by Marc Brunel, a French émigré engineer. The first use of the shield, by Brunel and his son Isambard, was in 1825 on the Wapping–Rotherhithe Tunnel through clay under the Thames River. The tunnel was of horseshoe section 22¼ × 37½ feet (7 × 12 metres) and brick lined. After several floodings from hitting sand pockets and a seven-year shutdown for refinancing and building a second shield, the Brunels succeeded in completing the world's first true subaqueous tunnel in 1841, essentially nine years' work for a 1,200-foot- (370-metre-) long tunnel. In 1869 by reducing to a small size (eight feet [2.4 metres]) and by changing to a circular shield plus a lining of cast-iron segments, Peter W. Barlow and his field engineer, James Henry Greathead, were able to complete a second Thames tunnel in only one year as a pedestrian walkway from Tower Hill. In 1874, Greathead made the subaqueous technique really practical by refinements and mechanization of the Brunel–Barlow shield and by adding of compressed air pressure inside the tunnel to hold back the outside water pressure. Compressed air alone was used to hold back the water in 1880 in a first attempt to tunnel under New York's Hudson River; major difficulties and the loss of 20 lives forced abandonment after only 1,600 feet (480 metres) had been excavated. The first major application of the shield-plus-compressed-air technique occurred in 1886 on the London subway with an 11-foot (3.3-metre) bore, where it accomplished the unheard-of record of seven miles (11 kilometres) of tunnelling without a single fatality. So thoroughly did Greathead develop his procedure that it was used successfully for the next 75 years with no significant change. A modern Greathead shield illustrates his original developments as pictured in Figure 1: miners working under a hood in individual small pockets that can be quickly closed against inflow; shield propelled forward by jacks; permanent lining segments erected under protection of the shield tail; and the whole tunnel pressurized to resist water inflow.

Greathead technique

Once subaqueous tunnelling became practical, many railroad and subway crossings were constructed with the Greathead shield, and the technique later proved adaptable for the much larger tunnels required for automobiles. A new problem, noxious gases from internal-combustion engines, was successfully solved by Clifford Holland for the world's first vehicular tunnel, completed in 1927 under the Hudson River and now bearing his name. Holland and his chief engineer, Ole Singstad, solved the ventilation problem with huge-capacity fans in ventilating buildings at each end, forcing air through a supply duct below the roadway, with an exhaust duct above the ceiling. Such ventilation provisions significantly increased the tunnel size, requiring about a 30-foot (nine-metre) diameter for a two-lane vehicular tunnel.

Many similar vehicular tunnels were built by shield-and-compressed-air methods—including Lincoln and Queens tunnels in New York City, Sumner and Callahan

in Boston, and Mersey in Liverpool. Since 1950 however, most subaqueous tunnelers preferred the immersed-tube method, in which long tube sections are prefabricated, towed to the site, sunk in a previously dredged trench, connected to sections already in place, and then covered with backfill. This basic procedure was first used in its present form on the Detroit River Railroad Tunnel between Detroit and Windsor, Ontario (1906–10). A prime advantage is the avoidance of high costs and the risks of operating a shield under high air pressure, since work inside the sunken tube is at atmospheric pressure (free air).

Machine-mined tunnels. Sporadic attempts to realize the tunnel engineer's dream of a mechanical rotary excavator culminated in 1954 at Oahe Dam on the Missouri River near Pierre, South Dakota. With ground conditions being favourable (a readily cuttable clay–shale), success resulted from a team effort: Jerome O. Ackerman as chief engineer, F.K. Mittry as initial contractor, and James S. Robbins as builder of the first machine—the "Mittry Mole." Later contracts developed three other Oahe-type moles, so that all of the various tunnels here were machine-mined—totaling eight miles (13 kilometres) of 25- to 30-foot (eight- to nine-metre) diameter. These were the first of the modern moles that since 1960 have been rapidly adopted for many of the world's tunnels as a means of increasing speeds from the previous range of 25 to 50 feet (eight to 15 metres) per day to a range of several hundred feet per day. The Oahe mole was partly inspired by work on a pilot tunnel in chalk started under the English Channel for which an air-powered rotary cutting arm, the Beaumont borer, had been invented. A 1947 coal-mining version followed, and in 1949 a coal saw was used to cut a circumferential slot in chalk for 33-foot- (ten-metre-) diameter tunnels at Fort Randall Dam, South Dakota. In 1962 a comparable breakthrough for the more difficult excavation of vertical shafts was achieved in the U.S. development of the mechanical raise borer, profiting from earlier trials in Germany.

II. Tunnelling techniques

BASIC TUNNELLING SYSTEM

Four categories of tunnels

Tunnels are generally grouped in four broad categories, depending on the material through which they pass: soft ground, consisting of soil and very weak rock; hard rock; soft rock, such as shale, chalk, and friable sandstone; and subaqueous. While these four broad types of ground condition require very different methods of excavation and ground support, nevertheless, nearly all tunnelling operations involve certain basic procedures: investigation, excavation and materials transport, ground support, and environmental control. Similarly, tunnels for mining and for civil-engineering projects share the basic procedures but differ greatly in the design approach toward permanence, due to their differing purposes. Many mining tunnels have been planned only for minimum-cost temporary use during ore extraction, although the growing desire of surface owners for legal protection against subsequent tunnel collapse may cause this to change. By contrast, most civil-engineering or public-works tunnels involve continued human occupancy plus full protection of adjacent owners and are much more conservatively designed for permanent safety. In all tunnels, geological conditions play the dominant role in governing the acceptability of construction methods and the practicality of different designs. Indeed, tunnelling history is filled with instances in which a sudden encounter with unanticipated conditions caused long stoppages for changes in construction methods, in design, or in both, with resulting great increases in cost and time. At the Awali Tunnel in Lebanon in 1960, for example, a huge flow of water and sand filled over two miles (three kilometres) of the bore and more than doubled construction time to eight years for its ten-mile (16-kilometre) length.

Geological investigation. Thorough geological analysis is essential in order to assess the relative risks of different locations and to reduce the uncertainties of ground and water conditions at the location chosen. In addition to soil and rock types, key factors include the initial defects controlling behaviour of the rock mass; size of rock block between joints; weak beds and zones, including faults, shear zones, and altered areas weakened by weathering or thermal action; groundwater, including flow pattern and pressure; plus several special hazards, such as heat, gas, and earthquake risk. For mountain regions the large cost and long time required for deep borings generally limit their number; but much can be learned from thorough aerial and surface surveys, plus well-logging and geophysical techniques developed in the oil industry. Often the problem is approached with flexibility toward changes in design and in construction methods and with continuous exploration ahead of the tunnel face, done in older tunnels by mining a pilot bore ahead and now by drilling. Japanese engineers have pioneered methods for prelocating troublesome rock and water conditions.

Geologic problems in rock chambers

For large rock chambers and also particularly large tunnels, the problems increase so rapidly with increasing opening size that adverse geology can make the project impractical or at least tremendously costly. Hence, the concentrated opening areas of these projects are invariably investigated during the design stage by a series of small exploratory tunnels called drifts, which also provide for in-place field tests to investigate engineering properties of the rock mass and can often be located so their later enlargement affords access for construction.

Since shallow tunnels are more often in soft ground, borings become more practical. Hence, most subways involve borings at intervals of 100–500 feet (30–150 metres) to observe the water table and to obtain undisturbed samples for testing strength, permeability, and other engineering properties of the soil. Portals of rock tunnels are often in soil or in rock weakened by weathering. Being shallow, they are readily investigated by borings, but, unfortunately, portal problems have frequently been treated lightly. Often they are only marginally explored or the design is left to the contractor, with the result that a high percentage of tunnels, especially in the United States, have experienced portal failures. Failure to locate buried valleys has also caused a number of costly surprises. The five-mile (eight-kilometre) Oso Tunnel in New Mexico offers one example. There, in 1967, a mole had begun to progress well in hard shale, until 1,000 feet (300 metres) from the portal it hit a buried valley filled with water bearing sand and gravel, which buried the mole. After six months' delay for hand mining, the mole was repaired and soon set new world records for advance rate—averaging 240 feet (70 metres) per day with a maximum of 420 feet (130 metres) per day.

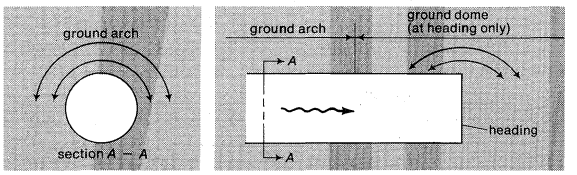
Excavation and materials handling. Excavation of the ground within the tunnel bore may be either semicontinuous, as by hand-held power tools or mining machine, or cyclic, as by drilling and blasting methods for harder rock. Here each cycle involves drilling, loading explosive, blasting, ventilating fumes, and excavation of the blasted rock (called mucking). Commonly, the mucker is a type of front-end loader that moves the broken rock onto a belt conveyor that dumps it into a hauling system of cars or trucks. As all operations are concentrated at the heading, congestion is chronic, and much ingenuity has gone into designing equipment able to work in a small space. Since progress depends on the rate of heading advance, it is often facilitated by mining several headings simultaneously, as opening up intermediate headings from shafts or from adits driven to provide extra points of access for longer tunnels.

Removing waste material

For smaller diameters and longer tunnels, a narrow-gauge railroad is commonly employed to take out the muck and bring in men and construction material. For larger size bores of short to moderate length, trucks are generally preferred. For underground use these require diesel engines with scrubbers to eliminate dangerous gases from the exhaust. While existing truck and rail systems are adequate for tunnels progressing in the range of 40–60 feet (12–18 metres) per day, their capacity is inadequate to keep up with fast-moving moles progressing at the rate of several hundred feet per day. Hence, consider-

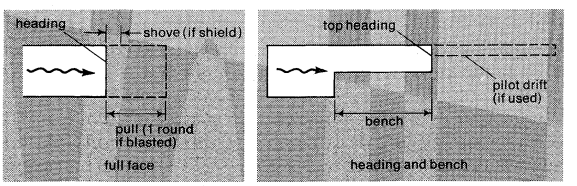
able attention is being devoted to developing high-capacity transport systems—continuous-belt conveyors, pipelines, and innovative rail systems (high-capacity cars on high-speed trains). Muck disposal and its transport on the surface can also be a problem in congested urban areas. One solution successfully applied in Japan is to convey it by pipeline to sites where it can be used for reclamation by landfill.

For survey control, high-accuracy transit-level work (from base lines established by mountain-top triangulation) has generally been adequate; long tunnels from opposite sides of the mountain commonly meet with an error of one foot (30 centimetres) or less. Further improvements are likely from the recent introduction of the laser, the pencil-size light beam of which supplies a reference line readily interpreted by workmen. Most moles in the United States now use a laser beam to guide steering; and some machines are experimenting with electronic steering automated by the laser beam.



Ground support. The dominant factor in all phases of the tunnelling system is the extent of support needed to hold the surrounding ground safely. Engineers must consider the type of support, its strength, and how soon it must be installed after excavation. The key factor in timing support installation is so-called stand-up time; *i.e.*, how long the ground will safely stand by itself at the heading, thus providing a period for installing supports. In soft ground, stand-up time can vary from seconds in such soils as loose sand up to hours in such ground as cohesive clay and even drops to zero in flowing ground below the water table, where inward seepage moves loose sand into the tunnel. Stand-up time in rock may vary from minutes in ravelling ground (closely fractured rock where pieces gradually loosen and fall) up to days in moderately jointed rock (joint spacing in feet) and may even be measured in centuries in nearly intact rock, where the rock-block size (between joints) equals or exceeds size of the tunnel opening, thus requiring no support. While a miner generally prefers rock to soft ground, local occurrences of major defects within the rock can effectively produce a soft-ground situation and thus generally require radical changes to a soft-ground type of support in order to pass through such areas.

Stand-up time



Under most conditions, tunnelling causes a transfer of the ground load by arching to sides of the opening, termed the ground-arch effect (Figure 2, top). At the heading the effect is three-dimensional, locally creating a ground dome in which the load is arched not only to the sides but also forward and back. If permanence of the ground arch is completely assured, stand-up time is infinite, and no support is required. Ground-arch strength usually deteriorates with time, however, increasing the load on the support. Thus, the total load is shared between support and ground arch in proportion to their relative stiffness by a physical mechanism termed structure–medium interaction. The support load increases greatly when the inherent ground strength is much reduced by allowing excessive yield to loosen the rock mass. Because this may occur when installation of support is delayed too long, or because it may result from blast damage, good practice is based on the need to preserve the strength of the ground arch as the strongest load-carrying member of the system, by prompt installation of proper support and by preventing blast damage and movement from water inflow that has a tendency to loosen the ground.

Because stand-up time drops rapidly as size of the opening increases, the full-face method of advance (see Figure 2, centre), in which the entire diameter of the tunnel is excavated at one time, it is most suitable for strong ground or for smaller tunnels. The effect of weak ground can be offset by decreasing the size of opening initially mined and supported, as in the top heading and bench method of advance. For the extreme case of very soft ground, this approach results in the multiple-drift method of advance (Figure 3), in which the individual drifts

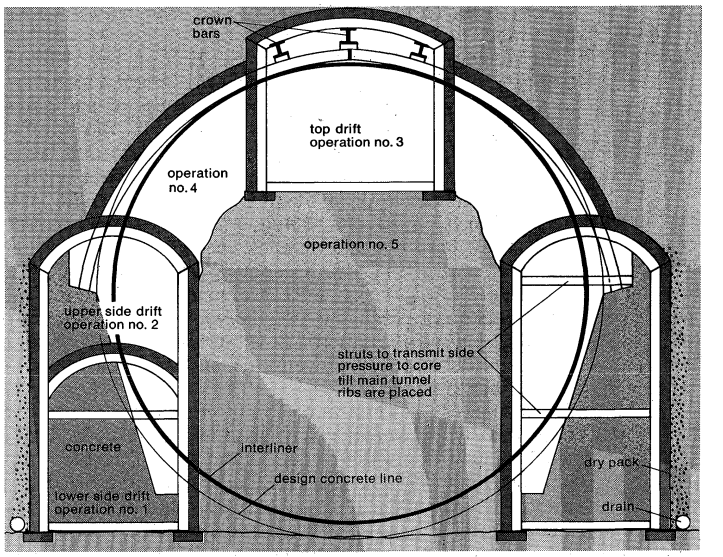

Figure 3: Multiple-drift method of excavation.

are reduced to a small size that is safe for excavation and portions of the support are placed in each drift and progressively connected as the drifts are expanded. The central core is left unexcavated until sides and crown are safely supported, thus providing a convenient central buttress for bracing the temporary support in each individual drift. While this obviously slow multidrift method is an old technique for very weak ground, such conditions still force its adoption as a last resort in some modern tunnels. In 1971, for example, on the Straight Creek interstate highway tunnel in Colorado, a very complex pattern of multiple drifts was found necessary to advance this large horseshoe-shaped tunnel 42 by 45 feet (13 by 14 metres) high through a weak shear zone over 1,000 feet (300 metres) wide, after unsuccessful trials with full-face operation of a shield.

In early tunnels, timber was used for the initial or temporary support, followed by a permanent lining of brick or stone masonry. Since steel became available, it has been widely used as the first temporary stage or primary support. For protection against corrosion, it is nearly always encased in concrete as a second stage or final lining. Steel-rib support with timber blocking outside has been widely employed in rock tunnels. The horseshoe shape is common for all but weakest rocks, since the flat bottom facilitates hauling. By contrast, the

stronger and more structurally efficient circular shape is generally required to support the greater loads from soft ground. Figure 2, bottom compares these two shapes and indicates a number of terms identifying various parts of the cross section and adjacent members for a steel-rib type of support. Here a wall plate is generally used only with a top heading method, where it serves to support arch ribs both in the top heading and also where the bench is being excavated by spanning over this length until posts can be inserted beneath. Newer types of supports are discussed below with more modern tunnel procedures, in which the trend is away from two stages of support toward a single support system, part installed early and gradually strengthened in increments for conversion to the final complete support system.

Environmental control. In all but the shortest tunnels, control of the environment is essential to provide safe working conditions. Ventilation is vital, both to provide fresh air and to remove explosive gases such as methane and noxious gases, including blast fumes. While the problem is reduced by using diesel engines with exhaust scrubbers and by selecting only low-fume explosives for underground use, long tunnels involve a major ventilating plant that employs a forced draft through lightweight pipes up to three feet (90 centimetres) in diameter and with booster fans at intervals. In smaller tunnels, the fans are frequently reversible, exhausting fumes immediately after blasting, then reversing to supply fresh air to the heading where the work is now concentrated.

High-level noise generated at the heading by drilling equipment and throughout the tunnel by high-velocity air in the vent lines frequently requires the use of ear plugs with sign language for communication. In the future, equipment operators may work in sealed cabs, but communication is an unsolved problem. Electronic equipment in tunnels is prohibited, since stray currents may activate blasting circuits. Thunderstorms may also produce stray currents and require special precautions.

Control of dust and heat

Dust is controlled by water sprays, wet drilling, and the use of respirator masks. Since prolonged exposure to dust from rocks containing a high percentage of silica may cause a respiratory ailment known as silicosis, severe conditions require special precautions, such as a vacuum-exhaust hood for each drill.

While excess heat is more common in deep tunnels, it occasionally occurs in fairly shallow tunnels. In 1953, workers in the 6.4-mile (10.3-kilometre) Telecote Tunnel near Santa Barbara, California, were transported immersed in water-filled mine cars through the hot area (117° F [47° C]). In 1970 a complete refrigeration plant was required to progress through a huge inflow of hot water at 150° F (66° C) in the seven-mile (11-kilometre) Graton Tunnel, driven under the Andes to drain a copper mine in Peru.

MODERN SOFT-GROUND TUNNELLING

Settlement damage and lost ground. Soft-ground tunnels most commonly are used for urban services (subways, sewers, and other utilities) for which the need for quick access by passengers or maintenance staff favours a shallow depth. In many cities this means that the tunnels are above bedrock, making tunnelling easier but requiring continuous support. The tunnel structure in such cases is generally designed to support the entire load of the ground above it, in part because the ground arch in soil deteriorates with time and in part as an allowance for load changes resulting from future construction of buildings or tunnels. Soft-ground tunnels are typically circular in shape because of this shape's inherently greater strength and ability to readjust to future load changes. In locations within street rights-of-way, the dominant concern in urban tunnelling is the need to avoid intolerable settlement damage to adjoining buildings. While this is rarely a problem in the case of modern skyscrapers, which usually have foundations extending to rock and deep basements often extending below the tunnel, it can be a decisive consideration in the presence of moderate-height buildings, whose foundations are usually shallow.

Urban tunnels

In this case the tunnel engineer must choose between underpinning or employing a tunnelling method that is sufficiently foolproof that it will prevent settlement damage.

Surface settlement results from lost ground; *i.e.*, ground that moves into the tunnel in excess of the tunnel's actual volume. All soft-ground tunnelling methods result in a certain amount of lost ground. Some is inevitable, such as the slow lateral squeeze of plastic clay that occurs ahead of the tunnel face as new stresses from doming at the heading cause the clay to move toward the face before the tunnel even reaches its location. Most lost ground, however, results from improper construction methods and careless workmanship. Hence the following emphasizes reasonably conservative tunnelling methods, which offer the best chance for holding lost ground to an acceptable level of approximately 1 percent.

Hand-mined tunnels. The ancient practice of hand mining is still economical for some conditions (shorter and smaller tunnels) and may illustrate particular techniques better than its mechanized counterpart. Examples are forepoling and breasting techniques as developed for the hazardous case of running (unstable) ground. Figure 4 shows the essentials of the process: heading advanced under a roof of forepole planks that are driven ahead at the crown (and at the sides in severe cases) plus continuous planking or breasting at the heading. With careful work the method permits advance with very little lost ground. The top breastboard may be removed, a small advance excavated, this breastboard is replaced, and progress continued by working down one board at a time. While solid wall forepoling is nearly a lost art, an adaptation is termed spiling where the forepoles are intermittent with gaps between. Crown spiling is still resorted to for passing bad ground where spiles may consist of rails driven ahead, or even steel bars set in holes drilled into crushed rock.

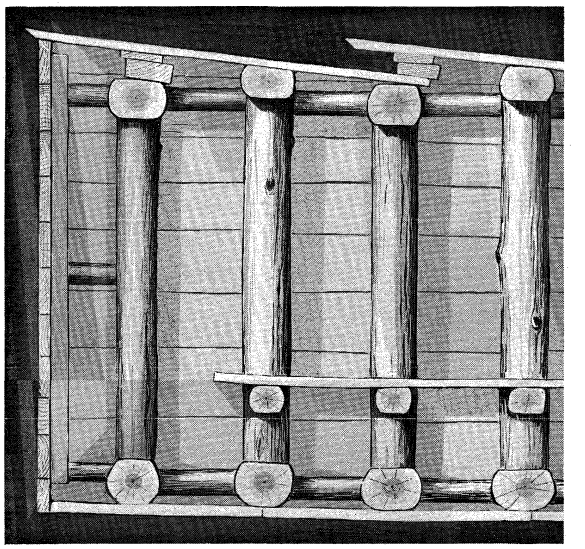

Figure 4: Heading advance by forepoling.

In ground providing a reasonable stand-up time, a modern support system uses steel liner-plate sections placed against the soil and bolted into a solid sheeted complete circle and, in larger tunnels, strengthened inside by circular steel ribs. Individual liner plates are light in weight and are easily erected by hand. By employing small drifts (horizontal passageways), braced to a central core, liner-plate technique has been successful in larger tunnels—Figure 5 shows 1940 practice on the 20-foot (six-metre) tunnels of the Chicago subway. The top heading is carried ahead, preceded slightly by a "monkey drift" in which the wall plate is set and serves as a footing for the arch ribs, also to span over as the wall plate is underpinned by erecting posts in small notches at each side of the lower bench. As the ribs and liner plate provide only a light support, they are stiffened by installation of a

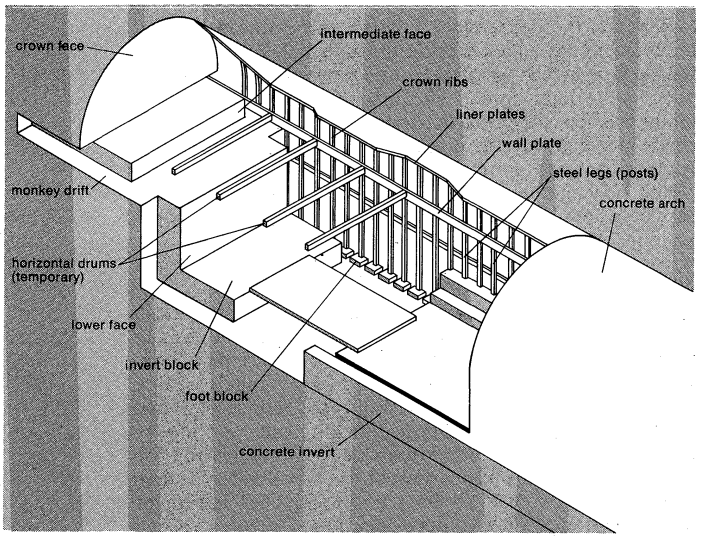

Figure 5: Soft-ground support by ribs and liner plates.

concrete lining about one day behind the mining. While liner-plate tunnels are more economical than shield tunnels, the risks of lost ground are somewhat greater and require not only very careful workmanship but also thorough soil-mechanics investigation in advance, pioneered in Chicago by Karl V. Terzaghi (founder of modern soil mechanics).

Shield tunnels. The risk of lost ground can also be reduced by using a shield with individual pockets from which men can mine ahead; these can quickly be closed to stop a run-in (Figure 1). In extremely soft ground the shield may be simply shoved ahead with all its pockets closed, completely displacing the soil ahead of it; or it may be shoved with some of the pockets open, through which the soft soil extrudes like a sausage, cut into chunks for removal by a belt conveyor. The first of these methods was used on the Lincoln Tunnel in Hudson River silt.

Internal support in shields

Support erected inside the tail of the shield consists of large segments, so heavy that they require a power erector arm for positioning while being bolted together. Because of its high resistance to corrosion, cast iron has been the most commonly used material for segments, thus eliminating the need for a secondary lining of concrete. Today, lighter segments are employed. In 1968, for example, the San Francisco subway used welded steel-plate segments, protected outside by a bituminous coating and galvanized inside. British engineers have developed precast concrete segments that are proving popular in Europe.

An inherent problem with the shield method is the existence of a two- to five-inch (five- to 13-centimetre) ring-shaped void left outside the segments as the result of the thickness of the skin plate and the clearance needed for segment erection. Movement of soil into this void could result in up to 5 percent lost ground, an amount intolerable in urban work. Lost ground is held to reasonable levels by promptly blowing small sized gravel into the void, then injecting cement grout (sand–cement–water mixture) into voids of the gravel.

Water control. A soft-ground tunnel below the water table involves a constant risk of a run-in; *i.e.*, soil and water flowing into the tunnel, which often results in complete loss of the heading. One solution is to lower the water table below the tunnel bottom before construction begins. This can be accomplished by pumping from deep wells ahead and from well points within the tunnel. While this benefits the tunnelling, dropping the water table increases the loading on deeper soil layers. If these are relatively compressible, the result can be a major settlement of adjacent buildings on shallow foundations, an extreme example being a 15- to 20-foot (five- to six-metre) subsidence in Mexico City due to overpumping.

Dropping the water table

When soil conditions make it undesirable to drop the water table, compressed air inside the tunnel may offset the outside water pressure. In larger tunnels, air pressure is generally set to balance the water pressure in the lower part of the tunnel, with the result that it then exceeds the smaller water pressure at the crown (upper part). Since air tends to escape through the upper part of the tunnel, constant inspection and repair of leaks with straw and mud are required. Otherwise, a blowout could occur, depressurizing the tunnel and possibly losing the heading as soil enters. Compressed air greatly increases operating costs, partly because a large compressor plant is needed with standby equipment to insure against loss of pressure and partly because of the slow movement of men and muck trains through the air locks. The dominant factor, however, is the huge reduction in productive time and lengthy decompression time required for men working under air to prevent the crippling disease known as the bends (or caisson disease), also encountered by divers. Regulations stiffen as pressure increases up to usual maximum of 45 pounds per square inch (three atmospheres) where daily time is limited to one hour working and six hours for decompression. This plus higher hazard pay, makes tunnelling under high air pressure very costly. In consequence, many tunnelling operations attempt to lower the operating air pressure, either by partially dropping the water table or, especially in Europe, by strengthening the ground through the injection of solidifying chemical grouts. French and British grouting-specialist companies have developed a number of highly engineered chemical grouts, and these are achieving considerable success in advance cementing of weak soil, thus considerably reducing tunnelling difficulties.

Tunnel blowout

Soft-ground moles. Since their first success in 1954, moles (mining machines) have been rapidly adopted worldwide. Close copies of the Oahe moles were used for similar large-diameter tunnels in clay shale at Gardiner Dam in Canada and at Mangla Dam in Pakistan during the mid-1960s, and subsequent moles have succeeded at many other locations involving soft rocks. Of the several hundred moles built, most have been designed for the more easily excavated soil tunnel and are now beginning to divide into four broad types (all are similar in that they excavate the earth with drag teeth and discharge the muck onto a belt conveyor, and most operate inside a shield).

Four types of moles

The open-face-wheel type is probably the most common. In Figure 6 a scale model is used to illustrate the operation of the wheel within a shield and the lining of precast concrete segments that are conveyed forward for

By courtesy of Calweld, Division of Smith International Incorporated, Santa Fe Springs, California

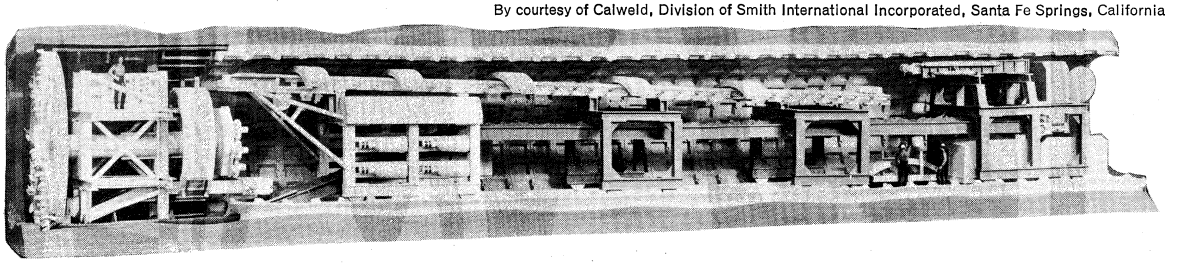

Figure 6: Scale model of a tunnelling system (20 feet, two inches in diameter) for excavation in firm ground. The mechanism includes a wheel-type boring machine, electrohydraulic trailing power unit, 360° revolving drum-type segmented lining erector, segmented lining handling conveyor, and muck-removal conveyor.

erection within the tail of the shield. In the wheel in Figure 6 the cutter arm rotates in one direction; in a variant model it oscillates back and forth in a windshield-wiper action that is most suitable in wet, sticky ground. While suitable for firm ground, the open-face mole has sometimes been buried by running or loose ground.

The closed-faced-wheel partly offsets this problem, since it can be kept pressed against the face while taking in muck through slots. Since the cutters are changed from the face, changing must be done in firm ground. This kind of mole performed well on the 1968 San Francisco subway in soft to medium clay with some sand layers, averaging 30 feet (nine metres) per day. In this project, mole operation made it cheaper and safer to drive two single-track tunnels than one large double-track tunnel. When adjacent buildings had deep foundations, a partial lowering of the water table permitted operations under low pressure, which succeeded in limiting surface settlement to about one inch (25 millimetres). In areas of shallow building foundations, dewatering was not permitted; air pressure was doubled to 28 pounds per square inch (2 atmospheres), and settlements were slightly smaller.

A third type, still in the pioneering stage, is the pressure-on-face mole. Here, only the face and the tunnel proper operates in free air—thus avoiding the high costs of labour under pressure. In 1969 a first major attempt used air pressure on the face of a mole operating in sands and silts for the Paris Metro. A 1970 attempt in volcanic clays of Mexico City utilized a clay–water mixture as a pressurized slurry (liquid mixture); the technique was novel in that the slurry muck was removed by pipeline, a procedure simultaneously also used in Japan with a 23-foot- (seven-metre-) diameter pressure-on-face mole. The concept is being further developed in England, where an experimental mole of this type was constructed in 1971.

The digger-shield type of machine is essentially a hydraulic-powered digger arm excavating ahead of a shield, whose protection can be extended forward by hydraulically operated poling plates, acting as retractable spiles. In 1967–70 in the 26-foot- (eight-metre) diameter Saugus–Castaic Tunnel near Los Angeles, a mole of this type produced daily progress in clayey sandstone averaging 113 feet (34 metres) per day and 202 feet (62 metres) maximum, completing five miles (eight kilometres) of tunnel one-half year ahead of schedule. In 1968 an independently developed device of similar design also worked well in compacted silt for a 12-foot- (four-metre-) diameter sewer tunnel in Seattle.

Pipe jacking. For small tunnels in a five- to eight-foot (1.5- to 2.5-metre) size range, small moles of the open-face-wheel type have been effectively combined with an older technique known as pipe jacking, in which a final lining of precast concrete pipe is jacked forward in sections. Figure 7 illustrates the system as used in 1969 on two miles (three kilometres) of sewer in Chicago clay with jacking runs up to 1,400 feet (430 metres) between shafts. A laser-aligned wheel mole cut a bore slightly larger than the lining pipe. Friction was reduced by bentonite lubricant added outside through holes drilled from the surface, which were later used for grouting any voids outside the pipe lining. The original pipe-jacking technique was developed particularly for crossing under railroads and highways as a means of avoiding traffic interruption from the alternate of construction in open trench.

With Chicago experience showing a potential for progress of a few hundred feet per day, the technique is becoming attractive for small tunnels.

MODERN ROCK TUNNELLING

Nature of the rock mass. It is important to distinguish between the high strength of a block of solid or intact rock and the much lower strength of the rock mass consisting of strong rock blocks separated by much weaker joints and other rock defects. While the nature of intact rock is significant in quarrying, drilling, and cutting by moles, tunnelling and other areas of rock engineering are concerned with the properties of the rock mass. These properties are controlled by the spacing and nature of the defects, including joints (generally fractures caused by tension and sometimes filled with weaker material), faults (shear fractures frequently filled with claylike material called gouge), shear zones (crushed from shear displacement), altered zones (in which heat or chemical action have largely destroyed original bond cementing the rock crystals), bedding planes, and weak seams (in shale, often altered to clay). Since these geological details (or hazards) usually can only be generalized in advance predictions, rock-tunnelling methods require flexibility for handling conditions as they are encountered. Any of these defects can convert the rock to the more hazardous soft-ground case.

Geostress

Also important is the geostress; *i.e.*, the state of stress existing *in situ* prior to tunnelling. Though conditions are fairly simple in soil, geostress in rock has a wide range because it is influenced by the stresses remaining from past geological events: mountain building, crustal movements, or load subsequently removed (melting of glacial ice or erosion of former sediment cover). Evaluation of the geostress effects and the rock mass properties are primary objectives of the relatively new field of rock mechanics and are dealt with below with underground chambers since their significance increases with opening size. Therefore, this section emphasizes the usual rock tunnel, in the size range of 15 to 25 feet (five to eight metres).

Conventional blasting. Blasting is carried on in a cycle of drill, load, blast, ventilate fumes, and remove muck. Since only one of these five operations can be conducted at a time in the confined space at the heading, concentrated efforts to improve each have resulted in raising the rate of advance to a range of 40–60 feet (12–18 metres) per day, or probably near the limit for such a cyclic system. Drilling, which consumes a major part of the time cycle, has been intensely mechanized in the United States. High-speed drills with renewable bits of hard tungsten carbide are positioned by power-operated jib booms located at each platform level of the drilling jumbo (a mounted platform for carrying drills). Truck-mounted jumbos are used in larger tunnels. When rail-mounted, the drilling jumbo is arranged to straddle the mucker so that drilling can resume during the last phase of the mucking operation.

By experimenting with various drill-hole patterns and the sequence of firing explosives in the holes, Swedish engineers have been able to blast a nearly clean cylinder in each cycle, while minimizing use of explosives.

Reducing explosive-loading time

Dynamite, the usual explosive, is fired by electric blasting caps, energized from a separate firing circuit with locked switches. Cartridges are generally loaded individually and seated with a wooden tamping rod; Swedish efforts to expedite loading often employ a pneumatic cartridge loader. American efforts toward reduced loading time have tended to replace dynamite with a free-running blasting agent, such as a mixture of ammonium nitrate and fuel oil (called AN-FO), which in granular form (prills) can be blown into the drill hole by com-

pressed air. While AN-FO-type agents are cheaper, their lower power increases the quantity required, and their fumes usually increase ventilating requirements. For wet holes, the prills must be changed to a slurry requiring special processing and pumping equipment (see EXPLOSIVES).

Rock support. Most common loading on the support of a tunnel in hard rock is due to the weight of loosened rock below the ground arch, where designers rely particularly on experience with Alpine tunnels as evaluated by two Austrians, Karl V. Terzaghi, the founder of soil mechanics, and Josef Stini, a pioneer in engineering geology. The support load is greatly increased by factors weakening the rock mass, particularly blasting damage. Furthermore, if a delay in placing support allows the zone of rock loosening to propagate upward (*i.e.*, rock falls from the tunnel roof), the rock-mass strength is reduced, and the ground arch is raised. Obviously, the loosened rock load can be greatly altered by a change in joint inclination (orientation of rock fractures) or by the presence of one or more of the rock defects previously mentioned. Less frequent but more severe is the case of high geostress, which in hard, brittle rock may result in dangerous rock bursts (explosive spalling off from the tunnel side) or, in a more plastic rock mass, may exhibit a slow squeezing into the tunnel. In extreme cases, squeezing ground has been handled by allowing the rock to yield while keeping the process under control, then remining and resetting initial support several times, plus deferring concrete lining until the ground arch becomes stabilized.

Steel rib sets

For many years steel rib sets were the usual first-stage support for rock tunnels, with close spacing of the wood blocking against the rock being important to reduce bending stress in the rib. Advantages are increased flexibility in changing rib spacing plus the ability to handle squeezing ground by resetting the ribs after remining. A disadvantage is that in many cases the system yields excessively, thus inviting weakening of the rock mass. Finally, the rib system serves only as a first-stage or temporary support, requiring a second-stage encasement in a concrete lining for corrosion protection.

Concrete lining. Concrete linings serve to aid fluid flow by providing a smooth surface and insure against rock fragment falling on vehicles using the tunnel. While shallow tunnels are often lined by dropping concrete down holes drilled from the surface, the greater depth of most rock tunnels requires concreting entirely within the tunnel. Operations in such congested space involve special equipment, including agitator cars for transport, pumps or compressed-air devices for placing the concrete, and telescoping arch forms that can be collapsed to move forward inside forms remaining in place. The invert is generally concreted first, followed by the arch where forms must be left in place from 14 to 18 hours for the concrete to gain necessary strength. Voids at the crown are minimized by keeping the discharge pipe buried in fresh concrete. The final operation consists of contact grouting, in which a sand–cement grout is injected to fill any voids and to establish full contact between lining and ground. The method usually produces progress in the range of 40 to 120 feet (12 to 36 metres) per day. In the 1960s there was a trend toward an advancing-slope method of continuous concreting, as originally devised for embedding the steel cylinder of a hydropower penstock. In this procedure, several hundred feet of forms are initially set, then collapsed in short sections and moved forward after the concrete has gained necessary strength, thus keeping ahead of the continuously advancing slope of fresh concrete. As a 1968 example, Libby Dam's Flathead Tunnel in Montana attained a concreting rate of 300 feet (90 metres) per day by using the advancing slope method.

Rock bolts. Rock bolts are used to reinforce jointed rock much as reinforcing bars supply tensile resistance in reinforced concrete. After early trials around 1920, they were developed in the 1940s for strengthening laminated roof strata in mines (see MINING AND QUARRYING). For public works their use has increased rapidly since 1955, as confidence has developed from two independent pioneering applications, both in the early 1950s. One was the successful change from steel rib sets to cheaper rock bolts on major portions of the 85 miles (135 kilometres) of tunnels forming New York City's Delaware River Aqueduct. The other was the success of such bolts as the sole rock support in large underground powerhouse chambers of Australia's Snowy Mountain Project. Since about 1960, rock bolts have had major success in providing the sole support for large tunnels and rock chambers with spans up to 100 feet (30 metres). Bolts are commonly sized from 0.75 to 1.5 inches (19–38 millimetres) and function to create a compression across rock fissures, both to prevent the joints opening and to create resistance to sliding along the joints. For this they are placed promptly after blasting, anchored at the end, tensioned, and then grouted to resist corrosion and to prevent anchor creep.

Pioneering uses of rock bolts

Rock tendons

Rock tendons (prestressed cables or bundled rods, providing higher capacity than rock bolts) up to 250 feet (75 metres) long and prestressed to several hundred tons each have succeeded in stabilizing many sliding rock masses in rock chambers, dam abutments, and high rock slopes. A noted example is their use in reinforcing the abutments of Vaiont Dam in Italy. In 1963 this project experienced disaster when a giant landslide filled the reservoir causing a huge wave to overtop the dam, with large loss of life. Remarkably, the 875-foot- (270-metre-) high arch dam survived this huge overloading; the rock tendons are believed to have supplied a major strengthening.

Shotcrete. Shotcrete is small-aggregate concrete conveyed through a hose and shot from an air gun onto a backup surface on which it is built up in thin layers. Though sand mixes had been so applied for many years, new equipment in the late 1940s made it possible to improve the product by including coarse aggregate up to one inch (25 millimetres); strengths of 6,000 to 10,000 pounds per square inch (400 to 700 kilograms per square centimetre) became common. Following initial success as rock-tunnel support in 1951–55 on the Maggia Hydro Project in Switzerland, the technique was further developed in Austria and Sweden. The remarkable ability of a thin shotcrete layer (one to three inches [25 to 75 millimetres]) to bond to and knit fissured rock into a strong arch and to stop ravelling of loose pieces soon led to shotcrete largely superseding steel rib support in many European rock tunnels. By 1962 the practice had spread to South America. From this experience plus limited trial at the Hecla Mine in Idaho, the first major use of coarse-aggregate shotcrete for tunnel support in North America, developed in 1967 on the Vancouver Railroad Tunnel, with its 20- by 29-foot- (six- by nine-metre-) high cross section and two-mile (three-kilometre) length. Here an initial two- to four-inch (five- to ten-centimetre) coat proved so successful in stabilizing hard, blocky shale and in preventing ravelling in friable (crumbly) conglomerate and sandstone that the shotcrete was thickened to six inches (15 centimetres) in the arch and four inches (ten centimetres) on the walls to form the permanent support, saving about 75 percent of the cost of the original steel ribs and concrete lining.

Applying shotcrete

A key to shotcreting's success is its prompt application before loosening starts to reduce the strength of the rock mass. In Swedish practice this is accomplished by applying immediately after blasting and, while mucking is in progress, utilizing the "Swedish robot" shown in Figure 8,

From *Civil Engineering* (January 1970), *A.S.C.E.*

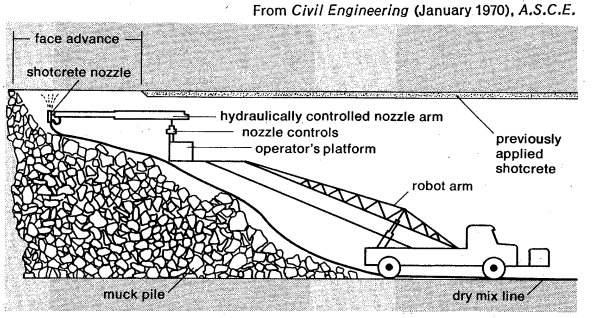

Figure 8: "Swedish robot" used for shotcreting.

which allows the operator to remain under the protection of the previously supported roof. On the Vancouver tunnel, shotcrete was applied from a platform extending forward from the jumbo while the mucking machine operated below. By taking advantage of several unique properties of shotcrete (flexibility, high bending strength, and ability to increase thickness by successive layers), Swedish practice has developed shotcreting into a single-support system that is strengthened progressively as needed for conversion into the final support.

Preserving rock strength. In rock tunnels, the requirements for support can be significantly decreased to the extent that the construction method can preserve the inherent strength of the rock mass. The opinion has been often expressed that a high percentage of support in United States rock tunnels (perhaps over half) has been needed to stabilize rock damaged by blasting rather than because of an inherently low strength of the rock. As a remedy, two techniques are currently available. First is the Swedish development of sound-wall blasting (to preserve rock strength), treated below under rock chambers, since its importance increases with size of the opening.

Rock moles

The second is the American development of rock moles that cut a smooth surface in the tunnel (Figure 9), thus minimizing rock damage and support needs—here limited to rock bolts connected by steel straps for this sandstone tunnel. In stronger rocks (as the 1970 Chicago sewers in dolomite) mole excavation not only largely eliminated need for support but also produced a surface of adequate smoothness for sewer flow, which permitted

a major saving by omitting the concrete lining. Since their initial success in clay shale, the use of rock moles has expanded rapidly and has achieved significant success in medium-strength rock such as sandstone, siltstone, limestone, dolomite, rhyolite, and schist. The advance rate has ranged up to 300 to 400 feet (90 to 120 metres) per day and has often outpaced other operations in the tunnelling system. While experimental moles have succeeded in cutting hard rock such as granite and quartzite, such devices are not yet economical, because cutter life is short, and frequent cutter replacement is costly. In the early 1970s, this seemed likely to change, however, as mole manufacturers sought to extend the range of application. Improvement in cutters and progress in reducing the time lost from equipment breakages were producing consistent improvements.

American moles have developed two types of cutters: disk cutters that wedge out the rock between initial grooves cut by the hard-faced rolling disks and roller-bit cutters using bits initially developed for fast drilling of oil wells. As later entrants in the field, European manufacturers have generally tried a different approach—milling-type cutters that mill or plane away part of the rock, then shear off undercut areas. Attention is also focussing on broadening the moles' capabilities to function as the primary machine of the whole tunnelling system. Thus, future moles are expected to not only cut rock but also explore ahead for dangerous ground; handle and treat bad ground; provide a capability for prompt erection of support, rock bolting, or shotcreting; change cutters from the rear in loose ground; and produce rock fragments of a size appropriate to capability of the muck removal system. As these problems are solved, the continuous tunnelling system by mole is expected largely to replace the cyclic drilling and blasting system.

Continuous-tunnelling system

Water inflows. Exploring ahead of the path of a tunnel is particularly necessary for location of possible high water inflows and permitting their pretreatment by drainage or grouting. When high-pressure flows occur unexpectedly, they result in long stoppages. When huge flows are encountered, one approach is to drive parallel tunnels, advancing them alternately so that one relieves pressure in front of the other. This was done in 1898 in work on the Simplon Tunnel, and in 1969 on the Graton Tunnel in Peru where flow reached 60,000 gallons (230,000 litres) per minute. Another technique is to depressurize ahead by drain holes (or small drainage drifts on each side), an extreme example being the 1968 Japanese handling of extraordinarily difficult water and rock conditions on the Rokko Railroad Tunnel, using approximately three-quarters of a mile (1,200 metres) of drainage drifts and five miles (eight kilometres) of drain holes in a 0.25-mile (400-metre) length of the main tunnel.

Heavy ground. The miner's term for very weak or high geostress ground that causes repeated failures and replacement of support is heavy ground. Ingenuity, patience, and large increases of time and funds are invariably required to deal with it. Special techniques have generally been evolved on the job, as indicated by a few of the numerous examples. On the 7.2-mile (11.6-kilometre) Mont Blanc Vehicular Tunnel of 32-foot (ten-metre) size under the Alps in 1959–63, a pilot bore ahead helped greatly to reduce rock bursts by relieving the high geostress. The five-mile (eight-kilometre), 14-foot (four-metre) El Colegio Penstock Tunnel in Colombia was completed in 1965 in bituminous shale, requiring the replacement and resetting of over 2,000 rib sets, which buckled as the invert (bottom supports) and sides gradually squeezed in up to three feet (90 centimetres), and by deferring concreting until the ground arch stabilized.

While the ground arch eventually stabilized in these and numerous similar examples, knowledge is inadequate to establish the point between desirable deformation (to mobilize ground strength) and excessive deformation (which reduces its strength), and improvement is most likely to come from carefully planned and observed field-test sections at prototype scale, but these have been so costly that very few have actually been executed, notably the 1940 test sections in clay on the Chicago subway and the 1950 Garrison Dam test tunnel in the clay–shale of North Dakota. Such prototype field testing has resulted however, in substantial savings in eventual tunnel cost. For harder rock, reliable results are even more fragmentary; but test sections were scheduled to start in 1971 on four United States rock tunnels.

Desirable and excessive deformation

Unlined tunnels. Numerous modest-size conventionally blasted tunnels have been left unlined if human occupancy was to be rare and the rock was generally good. Initially, only weak zones are lined, and marginal areas are left for later maintenance. Most common is the case of a water tunnel that is built oversized to offset the
