To describe all the variations of theatrical production is hardly feasible, but it is possible to indicate some of the major historical and contemporary kinds of production. One kind may be differentiated according to what is produced (the nature of the production). Another kind may be classed according to whom and why a work is addressed (occasion and purpose); still another in terms of how a work is produced (the system of production); a fourth in terms of who dominates production (the guiding artist); and, lastly, in terms of distinguishing marks of the production (the style).

KINDS ACCORDING TO THEIR NATURE

Nondramatic. Nondramatic productions include diverse oral and musical presentations, circus and vaudeville acts, and various types of pageantry.

The circus

As a form of presentation, circus is diverse, containing within its compass quite different orders of performance. These might be divided as to whether they are feats of daring, illusion, or drama. Acrobatics such as wire walking, flying the trapeze, or riding bareback excite wonder because of their difficulty and the dexterity they require. Presentation is rooted in a death-defying impulse. Lion taming, too, is a feat of daring and dexterity —though here the audience is mainly conscious of the audacity exhibited rather than the skill displayed. Feats of illusion involve conjuring of one sort or another. Whether the performer causes a woman to disappear or a body to levitate, skill in devising the act and carrying it off creates the illusion that the audience is seeing something happen that it knows is impossible. Dramatic feats usually involve only the clowns. In one sense this type of presentation properly belongs to the dramatic theatre. For convenience it is included here as a form of mime. It is allied to feats of illusion, as when a dozen clowns stream out of a tiny automobile. Generally, however, the clown engages in a highly refined and circumscribed dramatic activity (perhaps mimicking other nondramatic

performers) of a ludicrous, often grotesque, and quite improbable nature (see CIRCUS).

Pageantry is an entirely different kind of production. It can be either nondramatic or dramatic. In either case it is communal in purpose and organization. Nondramatic pageantry includes civic processions (such as the Festival of Roses parade in Pasadena, California), as well as static displays (the gymnastic demonstrations common in eastern Europe and China). The appeal of nondramatic pageantry lies in visual spectacle, particularly spectacle that overwhelms the individual. The performer presents himself as a member of the collective, and, even where one person might be in focus, such as the Queen of the Roses, he or she is passive and wins attention merely as the apex of a broad pyramid of performers. In certain religious pageants the focal figure is not a living person at all but the icon or statue of a god or saint. By extension, one form of pageantry eliminates the living participants altogether. A *son et lumière* display, which emphasizes the visual grandeur of an architectural marvel or a natural wonder, is a form of pageantry halfway between visual art and theatre.

Nondramatic pageantry

Dramatic pageantry has much in common with the nondramatic kind: there is communal involvement, stress on visual display, processional or static masses, and so on. It has, further, a fictional character. Either individual segments of the pageant illustrate a historical or hypothetical incident, or the pageant as a whole has a motif that may be historical or—more commonly in the past—mythic or allegorical. Performers in the U.S. re-enacting the dumping of tea into Boston Harbor exemplify historical pageantry; in England the assault on the Castle of Beauty by Knights of the Mount of Love, a pageant celebrating the marriage of Prince Arthur to Catherine of Aragon in 1501, exemplifies the allegorical type common at Renaissance courts. Pageantry of both the dramatic and nondramatic sort played and continues to play a significant role in the legitimization of political actions and the assertion of social prestige (see PAGEANT AND PARADE).

Dramatic. Central to dramatic production, of course, is the acted play involving, as described above, the performer-character in a fictional event. Dramatic production of this kind is divisible according to genre (including comedy, tragedy, farce), style (romantic, classical), or structure (architectonic unity of action, harmonic multiplicity of actions). There are, in addition, special examples of dramatic production distinguished by their alliance either to music or to dance.

Opera and musical comedy

Opera and musical comedy combine drama and music in varying degrees of dominance. Opera in particular straddles the border between these two arts, and much aesthetic discussion of this mode has concentrated on the relative importance of the enactment of the fiction or the elaboration of the music. The musical development of opera predominated in the 17th and 18th centuries, whereas emphasis since Richard Wager in the late 19th century has been increasingly on dramatic features. Operetta and musical comedy, the latter a peculiarly North American genre, are more closely allied to the theatre than to opera (see OPERA; POPULAR THEATRE).

Dramatic production stressing bodily or kinetic communication falls under the headings of dance and mime. Dance is the more clearly distinct art, though it shares so many features with the theatre that it is hard to say where one art ends and the other begins. Dance was a significant and essential element in the growth of Western drama; it was also a source and remains a feature of the Oriental. Traditional Chinese theatre, in fact, is a dance–song presentation of a fictional act, and the work of the U.S. choreographer and performer Martha Graham is properly dance-drama. When the fictional basis is slight or nonexistent and the movement of figures through space takes place within a relatively abstract framework, dance separates most evidently from drama. Thus, in ballet, the pas de deux often uses the drama as a point of departure for the kinetic exploration of space. Mime, on the other hand, remains closely connected to drama, being merely a highly specialized form of enactment. Relying on movement without words, it enjoyed an immense vogue in imperial Rome, contributed to the style of commedia dell'arte, and has undergone a modest revival at the hands of such French performers as Jean-Louis Barrault and Marcel Marceau (see BALLET; MODERN DANCE).

Folk productions. Mention should be made of productions that combine dramatic and nondramatic characteristics and also of those verging on what might be termed folk production. The prime example of the combined form is the vaudeville or variety show. It may be offered in a regular theatre, a nightclub, or even a circus. It brings together pieces that contrast with one another in style and tone. In a single performance, the audience might witness feats of daring and illusion, dramatic sketches, musical offerings, and dancing. Its theatrical appeal lies not only in the individual acts but also in the way they are climactically arranged.

The vaudeville or variety show

Folk production describes those communal events that, while social in character, include an element of presentation. Essentially, members of a community will offer a traditional piece as part of a larger festivity. Masked or costumed merrymakers may gather at or join a party, mix with the crowd or guests, give their piece, celebrate, and move on. The Feast of Fools, the *Purim-shpil*, and maypole dances exemplify this type of minimally produced theatrical play.

KINDS ACCORDING TO OCCASION AND PURPOSE

The principal types of theatrical occasion may conveniently be divided, as previously noted, between those that exist independently of any theatrical celebration and that are thus dependent upon communal production and those speculative presentations that create their own occasions and upon which commercial production thrives. Communal production is the responsibility of the social organism. It usually has civic, religious, educational, or cultural purposes or a combination of these. Commercial production principally has a recreational purpose, although it may also include any of the purposes of communal production. In the main, communal production is engaged in presenting a single performance to coincide with some extratheatrical event: a religious observance, a political ceremony, a military celebration. Commercial production requires continuing performance, frequency of presentation determined not by the nature of the occasion but by the size of the potential audience. The idea of a theatre season, an extended period of playing and producing, is a product of the commercial theatre.

Religious and civic. Among communal productions are those that are offered at a religious occasion. Though there are diverse theories about the origin of drama, most historians recognize that drama emerged from religious ritual, probably in order to heighten or celebrate significant stages of life, such as the maturation of the male or the change of a season. At what precise point the ritual act of religion gave way to the theatrical act of drama is uncertain, but formal drama is first met in ancient Greece.

Certainly, religious festivals gave rise to dramatic expression by re-enacting the passion and trials of the god or man-god on whom the religion centred. In Christian Europe, biblical plays became attached to particular festivities, the most notable being that of Corpus Christi. In the same way, the story of the assassination of Ḥusayn ibn ʿAlī, the Islāmic leader of the Shīʿite faction, was enacted at the Persian festival of Taʿziya. As in ancient Greece, these festivals would extend over many days during which all other communal activity ceased so that everyone could either participate in the play or join the audience.

Civic occasions are not usually so all-embracing. Under the term "civic occasions" fall those periodic celebrations connected with the life of a community, such as the Lord Mayor's pageant in London, or special celebrations determined by events, such as a military triumph in ancient Rome or a royal entry in 16th-century Brussels. Behind these productions lay the need and desire for social and political prestige. The occasion for seeing a production was also an occasion for seeing the general or the prince in all his splendour. In fact, the presentation

was conceived as a frame for the ruler and the virtues he ostensibly exemplified.

Educational. Initially, educational aims were subsumed under religious aims. But with the growth of educational institutions came theatrical performances given by students. A play might be enacted to enhance appreciation of its literary qualities, to celebrate a graduation, or to commemorate a national holiday. At first these productions were communal in character and occasional in presentation. Then, for brief periods in Elizabethan and Jacobean England, school and choral masters endeavoured to turn this communal activity into a commercial operation by utilizing boys as professional actors. During the 20th century, however, educationally based drama has concentrated upon younger students. While often having a recreational result in practice, in intent theatre for children has had an openly avowed educational purpose. The purpose might be to communicate a body of literature to the youngster, to inculcate a moral attitude, or to stimulate aesthetic and cultural appreciation. Sometimes this type of theatre has involved children as performers, sometimes adults. Although promoters of children's productions may be commercial managers, in general, sustained educational theatre has required communal support. Some countries, such as the Soviet Union, subsidize highly respected theatres for children and youth. The artists accept it as their principal responsibility to develop and prepare presentations for children of different age levels. The U.S. uses indirect means, such as educational grants from government sources, which partially subsidize productions for children.

Student productions

Theatre for specific and limited occasions is no longer widespread, however, as it once was. The performance of the Passion Play still occurs every ten years at Oberammergau in Germany, and the honouring of the Virgin Mary takes place annually at Elche in Spain, but such examples of communal production are rare. In their place continuous presentation, first pioneered by commercial operation, has now been adapted to renewed communal purposes. Where festivals appear, as they do with increasing frequency in the 20th century, they appear as cultural activities organized to make a body of dramatic literature, such as Shakespeare's works, available to the public. By enabling the audience to see a number of plays in a few days, they often succeed in immersing an audience in an atmosphere that counteracts the distractions of modern urban living.

Decline of communal productions

KINDS ACCORDING TO SYSTEM OF PRODUCTION

Theatrical production may be further differentiated according to the system of planning, rehearsing, and performing a play. Any system varies with the social and artistic conditions, but on the whole three kinds of operation seem to recur in the history of production. There is the single-performance system related to a community or institution. There is the repertory system of a more or less permanent professional company offering a variety of plays. And, finally, there is the commercial system of single productions kept in a continuous run of performances over as long a period as is profitable. These systems, while overlapping in methods and objectives, are distinct enough to warrant individual examination.

Single performance. Single or limited performance of a presentation, as part of institutional or communal life, is fairly common on a number of levels. The Greek city-state (polis), the medieval town, the Japanese temple, the school, and the club are but a few of the groups that give or have given such dramatic performances. Often the mode of production merely imitates the prevailing theatre of the time. There have, however, been times when the single-performance mode was itself the prevailing system. Both the Greek city-state and the medieval town organized their productions in a strikingly similar way, with the municipality exercising control. For the Athenians, municipal officials supervised the selection of the plays to be produced at the festivals, appointed a *choregus* who financed each play, arranged for the dithyrambic choruses of citizens, and organized the procession and presentations during the festival.

Similarly, medieval town officers—really the assembled chief artisans of the local craftsmen's guilds—undertook to assign to each guild the play it was to perform and designated the stations or sites for the performances. Whether the town as a whole or merely the individual guild was responsible for securing the text of a play is uncertain, but there was overall agreement on what portions of the biblical story would be enacted by the guilds.

There was, however, one difference between the Greek and medieval production systems. Until at least the 4th century BC, the Athenians presented new plays every year, whereas the medieval townspeople would re-enact the same plays or variations of them. Yet in both systems, many aspects of production (the theatre space used, the pool of actors, the store of costumes, for instance) were the same from year to year so that, single performance notwithstanding, each individual offering relied upon an established tradition.

The court masque

This was less true of the court masque (an allegorical dramatic performance featuring music and especially dancing) in Renaissance times, which was also presented only once. Although each production belonged to a tradition of courtly entertainment, masques of the 16th and 17th centuries became increasingly lavish and novel. A court official was responsible for the overall piece and so has something in common with the later theatre manager or entrepreneur. It was he who recommended a dramatic poet to provide the text, hired the actors, made arrangements for stage scenery to be provided and painted, and approved the results before offering them to the sovereign. The most fundamental distinction between this kind of production and earlier institutional types is that the masque was devised for the delectation of the monarch, and therefore his taste and will dictated what was done and how much was expended.

Permanent companies. The development of a production system depending on a permanent company introduced a new element into theatre, that of professional virtuosity. The emergence of professional theatre companies was a feature of the Renaissance and the growth of townships. Various courts had maintained performers throughout the medieval period, but these were usually musicians or single performers. With the emergence of the town, the theatre company began to appear throughout Italy, France, Germany, England, and Spain, usually consisting of between five and 12 actors who devoted their lives to the perfection of their craft.

The repertory troupe. Initially, the company was obliged to tour, since neither court nor city could employ full-time professionals. As a result, the actors became accustomed to performing in all kinds of physical spaces: in halls, on outdoor platforms, in chapels, on village greens. To compensate for rudimentary scenic spectacle, the actors used a rich array of costumes—some traditional garments for recurrent characters or situations, some deliberately opulent for their own sake. At all times the actors kept a number of plays fresh in mind so that, if they played an extended engagement in one place, they could offer their plays in repertory—that is, a new play at each performance, repeating plays on request or as business warranted. When a troupe finally settled in one city, it continued this mode of presentation, and thus a true repertory system was born.

Within this very broad system two stylistic differences may be observed. Some permanent troupes performed pieces in which the actors portrayed stock figures. Each actor had his or her speciality. Italian commedia dell'arte and Japanese kabuki both utilized such types. Molière, though far less rigid in portraying stock types, led a company each of whose members specialized in one kind of characterization. English and Spanish troupes, however, used actors who were much more flexible and who enacted generic types in the many stories that were dramatized. Otherwise, the companies had a great deal in common. Actors bought plays from writers, hired any supporting personnel they needed, and took the profits. Usually, they worked on a share system, dividing the proceeds among themselves. Sometimes one person might be the acknowledged head of the troupe; sometimes a

true partnership existed. In either case the operation was fundamentally the same.

Commercial management. The repertory troupe continued but eventually came to be managed by an individual. Initially, the manager was also an actor, and the actor-manager was in his heyday from the late 18th up to the beginning of the 20th century. With his appearance the production system changed. Instead of one's partner or fellow townsman at the head of the troupe, there was an employer. His concern was less with the continued living to be earned by the actor and more with the profit he could extract from the public. Gradually, out of this change emerged the stock company and the single-show association. The stock company was an acting troupe usually managed and organized for a limited period—called a season—to give a number of plays. Sometimes the manager would take the leading roles and engage others to support him. If he were not an actor himself, he would hire all the performers. The major shift in mode of production came when the stock companies stopped presenting plays in repertory—that is, a variety of plays given in alternation—and extended the run of a single play. This happened when city populations grew large enough to keep one play running for an indefinite time. At the end of the 17th century, a London play that had run eight performances was deemed a success. A generation later, however, the production of John Gay's *Beggar's Opera* in 1728 made theatrical history by running for 62 performances. By the mid-20th century, successful productions might run for five, six, and even seven years. One play, *The Mousetrap* by Agatha Christie, opened in 1952 and was still running in the early 1970s.

Stock companies and single-show systems

With the extended run there was little need to maintain a company of actors, even for a season. Instead, single-show contracts were negotiated. A manager or an actor would select a play that he thought might achieve an extended run, raise the necessary financial backing, hire actors, stage managers, scenic artists, a host of associates, and a theatre. Since a play was to be repeated indefinitely, it was feasible to invest a judicious amount of money in the accoutrements. Out of this system developed the need for someone who could coordinate the efforts of all the people involved and plan the final, overall effect. At first, the manager or actor-manager undertook this task. Later, individuals specializing in this work appeared.

With the stock company and especially with the single-show association grew the need for all the ancillary facilities of business and advertisement. Advertising, either by way of personal appearance, such as a parade through town before a performance, or by means of printed notices in newspapers and flyers, became extremely important in generating a sufficient audience for a show. Increasingly, in the late 19th and early 20th centuries, star actors became specially known for a single role or a small repertoire: Sarah Bernhardt for Marguérite Gautier in *Le Dame aux camélias*, Joseph Jefferson for Rip Van Winkle, Tommaso Salvini for Othello, James O'Neill (father of Eugene O'Neill) for the Count of Monte Cristo.

Modern repertory companies. During the rise of the stock company and single-show system, there continued to exist highly refined examples of the repertory ensemble. The Comédie Française, originally an amalgamation of two Parisian troupes, has endured from 1680 to the present. In opera the repertory system remains fundamentally unchanged. Toward the end of the 19th century, however, an idealization of the acting ensemble and the repertory system it supported became widespread throughout Europe. New theatres, devoted to naturalistic staging, were successfully established, and these, in time, became national theatres supported by the state. Most famous of these repertory theatres is the Moscow Art Theatre; others include the Abbey Theatre of Dublin, the Royal Shakespeare Company of Great Britain, and the Théâtre National Populaire of France. Meanwhile, traditional theatres such as the kabuki and Nō theatres of Japan have been declared national treasures. All of these theatres, because of government subsidy, maintain large staffs of actors, directors, designers, and other artists and craftsmen. Production is continuous. New plays or, more often, revivals of old plays enter the repertoire while former productions are dropped. The works of major national authors receive constant performance, thus establishing the main lines of tradition for the company. Often these repertory troupes conduct schools for training young people who might then enter the company. One of the chief aesthetic problems facing such companies is how to strike a balance between old and new. Theatre is, after all, a living art. By continuous repetition a production can atrophy. Yet it is the responsibility of these national theatres to offer their dramatic heritage to the people. Most theatres resolve this dilemma by bringing old productions up-to-date and by sponsoring studios and experimental activities where novel approaches may be tested. Where a dominant historical style has survived, as in the case of many Oriental dance and drama companies, maintenance of tradition rather than its adaptation to changing circumstances becomes the main objective.

Theatres with state subsidies

Fringe productions. These regular, established modes of production are supplemented by a host of fringe productions. They are variously called experimental, underground, and off-Broadway plays. In general, they involve a mixture of professional, would-be professional, and amateur actors. Often their objectives are programmatic: they espouse a style, an author, a political viewpoint, or an aesthetic ideal. Depending on civic or labour regulations, they usually endeavour to assemble productions cheaply. Presentations are offered in lofts, chapels, and other kinds of makeshift spaces, as well as in small theatres. Their production mode can be either single show or repertory.

Experimental, underground, and off-Broadway productions

In addition, there is another kind of theatre that represents a distinct break with the past. Certain groups, such as the Living Theatre or the Polish Laboratory Theatre in Wrocław led by Jerzy Grotowski, adopt a communal way of life. They regard mere professional association as an inadequate basis either for personal existence or artistic creation. Instead, the actors live cooperatively, share a common point of view about life, and seek to reflect that view in their theatrical productions. This shared life is superficially reminiscent of the touring troupe, but the endeavour to achieve a company ethos is closer to the religious motive of an earlier day.

KINDS ACCORDING TO THE CONTROLLING ARTIST

The fourth kind of production can be distinguished according to the dominance of the constituent artist. As a collective art, theatre strives to achieve the ideal of a well-balanced presentation in which all the participating workers have their just place. In practice, however, one or another of the contributing artists or producers has dominated the production system.

Actor domination. Perhaps the supreme example of the actor-dominated production can be found in the commedia dell'arte tradition. Not only did the actor have financial and administrative control over production, but the very quality of performance was woven almost wholly out of the actor's art. At first, in the 16th century, the commedia troupe consisted of travelling actors; by the 17th century many of them had found permanent residence at the courts of Italy and elsewhere in Europe. Each actor had his special role (Arlecchino, Pantalone, Brighella, the *innamorato* or lover among others) with its attendant set speeches and traditional business. The young would learn the tradition appropriate to a role and, if talented, embroider upon that tradition. Thus prepared, the actors would improvise a presentation on the thread of a story selected by the troupe leader. Scenarios of commedia dell'arte plays did exist, but they were only pale shadows of the production itself, which only came to life in performance.

Other actor-dominated theatres include the Elizabethan theatre, Chinese opera, and kabuki. In these instances, however, the complete blending of administrative control and artistic pre-eminence characteristic of the commedia did not go so far. The Elizabethan professional company, for example, had a production system based upon actor control of the repertory, but the artistic character of the

work was determined by the plays presented. However fine the actor's art, it was the dramatist's contribution that lent distinction to that theatre.

Dramatist and director domination. Rarely has the dramatist dominated a production system, unless, as occurred with Molière, he was also an actor. During certain periods the work of the dramatist, whatever his own responsibility, did determine the creative process in production. In ancient Greece the selection of a play was the first step in production. In the 19th and 20th centuries the acquisition of a script was also the preliminary step in establishing the single-show association. Only occasionally, as in the court theatre at Weimar, of which Johann Wolfgang von Goethe took charge during the late 18th century, did the dramatist as a dramatist take responsibility for establishing and conducting a theatrical enterprise.

In imperial Rome, the *dominus gregis* (manager of the festivals at which theatrical performances were given) controlled the lives and probably the art of the Roman comedians. During the 18th century the theatrical actor-manager came into prominence. But it was in the 19th century, with the rise of the stage director, that artistic, and in large measure, administrative control passed into the hands of a nonperformer. With the ideal of an artistically unified production there emerged one man to realize that unity—the director.

The stage director was responsible for modulating the acting, correlating the animate and inanimate aspects of production, and creating a single effect that inevitably became the expression of his own genius. At the turn of the 19th century, Edward Gordon Craig, illegitimate son of the British actress Ellen Terry, carried the ideal of unity even farther by recommending the merger of director and scenic designer and advocating the reduction of actors to automata completely responsive to the director-designer's vision. In this he was building upon the ideas of Adolphe Appia, a late-19th-century Swiss stage designer who saw in Richard Wagner's aspirations for music-drama the highest realization of the theatre's possibilities.

The designer's rise to special importance had begun during the Renaissance. In the first half of the 17th century, Inigo Jones was the driving force in creating the elaborate productions of the English court masque, while the machines of Nicola Sabbatini and the designs of Giacomo Torelli played significant roles in Italy and France.

The puppet show

A special form of theatrical technique, in which the manager, designer, and director are one, is the puppet show. The puppet is a general term that encompasses any inanimate figure manipulated by a human being. The figure may be a hand-operated puppet, either reduced or approaching life size, three-dimensional in form; a two-dimensional shadow puppet; or a string operated puppet called a marionette. They all share the common aesthetic whereby their movement in a highly restricted space creates the illusion of lifelikeness. In some cultures, such as the Javanese and the Turkish, the puppet show has been a major theatrical form. In Japan the *bunraku* doll theatre has competed successfully with the living actor of the kabuki theatre. In fact, many plays of the prominent writer Chikamatsu Monzaemon were originally for the puppet theatre (see PUPPETRY).

KINDS ACCORDING TO STYLE

A final method of categorizing production is according to style. This term is fraught with danger, for in theatre it has too often suggested actors' and directors' mannerisms rather than deeply ingrained characteristics of their work. Nevertheless, it is necessary to refer to style in order to distinguish the salient form of a particular theatre. Style, then, is the distinctive way in which the materials of a production (actor, script, space, time) are fused to project an impression upon the audience.

While the very word style suggests uniqueness, it is possible to speak about categories of style. For one thing a style of production may be composed of mixed modes of presentation or a single mode. Among styles of mixed modes are those that combine various media. Opera combines drama and music; the court masque combines drama, music, dance, and changing scenery. Greek tragedy combines spoken words, choral chant, and dance. Other types of presentation mix tonalities (comedy and tragedy), agents (living stagehands and performing dolls in *bunraku*), or masked and unmasked performers (commedia dell'arte). All of these mixed modes contribute to a distinctive style of performance, just as the single modes of Neoclassical tragedy, 19th-century Realism, and the dancers of Bali in Indonesia achieve their recognizable styles.

At one time it was customary to describe historical productions in terms of a supposed mode of performing behaviour. Thus, ancient Greek tragedy was considered austere, English Restoration performance mannered, Romantic acting bombastic. More thorough study of the various periods, however, has rendered such easy generalizations suspect. Scholars now realize that all productions share certain common objectives. They all convey in some measure a sense of reality for the particular audience addressed, although the sense of reality for one age may not be the same for another. They all combine elements of that reality (the familiar) with elements of the wondrous (the *mirabilia*). They all arouse interest in some features of the presentation as presentation (the sensuousness of the poetry, the cleverness of the business, the pleasure of the song), and—at the same time—in the revelation of the representation, that is, the fictional life that is being enacted on the stage. Style is thus determined not by the presence of one or another of these features but by the way the acting and script create a unique configuration out of these elements. Greek tragic style, for instance, is a result of the alternation of song and scene within an amphitheatre that has the effect of both distancing and yet involving the spectator. It is further delimited by the peculiar feature of the scenes in which highly impassioned moments of suffering, argumentation, and challenge are contained within an extremely strict rhetorical form, thereby producing the impact of an explosion. This dialectic of strict form and fierce passion is further heightened by the stately appearance of the masked actor, as well as by the alternation of "cool" ode and "hot" episode. But these elements are only the preconditions for Greek tragic style; the style itself can only be experienced in the theatre as a series of striking contrasts. The same holds true for all other theatrical styles.

Greek tragic style

IV. Theatrical production as a coherent art

Theatrical production can now be seen not as an amalgam of separate arts but as a coherent art manifesting itself in divergent ways. Central to all production is the performer–audience relationship, cemented together by the activity the player projects and to which the spectator adjusts. Out of a distinctive treatment of that activity and the social context in which it is presented comes each of the expressions of the theatre: drama, opera, acrobatics, and so on. Drama thus is not the sum of acting plus script plus scenery but the exploitation of one aspect of performing—the mimetic, or representational—in terms of performing space and time. But, since the other aspects of performance, such as dexterity, daring, and illusion, are all inherent in the performing act and coexist with each other and with the mimetic, they are also part of drama. Hence, any single aesthetic form, such as drama or opera, that may appear to be an autonomous art is but the cultivation of one facet of a multifaceted art. That is why one form may grow out of another, as opera did out of drama, or may crystallize in one manner for a time, only to disintegrate and reunite with other expressions of theatre, as drama seems to be doing with acrobatics and music in the 20th century. Seen in this context, theatrical production is pre-eminently the art in which human beings test their imaginative and physical capabilities by presenting themselves to each other in dazzling, yet recognizable, shapes.

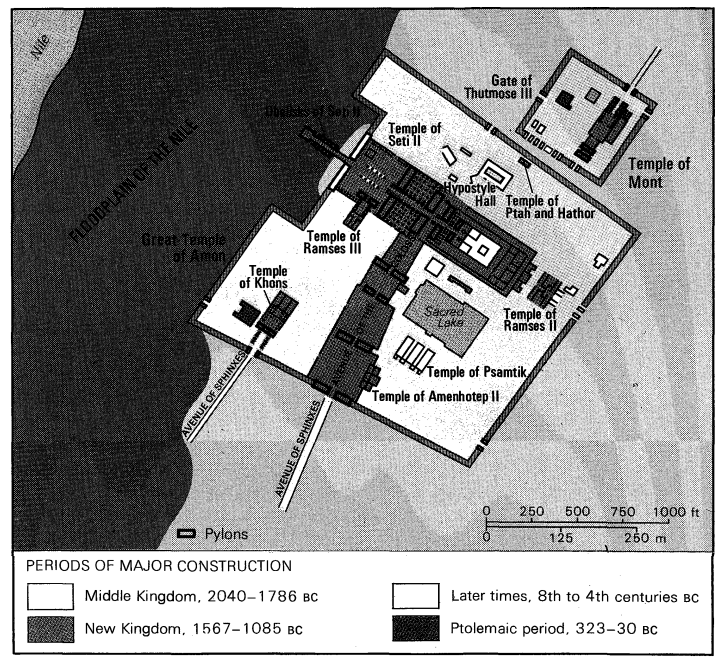
Thebes (Egypt)

Thebes, one of the famed cities of antiquity, the capital of the ancient Egyptian empire at its heyday, lay on either side of the Nile at approximately latitude 26° N; the modern town of Luxor, which occupies part of the site, is 419 miles south of Cairo. Ancient Thebes was about six miles square; the main part of the city was on the east bank; on the west bank was "the city of the dead"—the kings' mortuary temples, and the houses of those priests, soldiers, craftsmen, and labourers who were devoted to their service.

HISTORY

The ancient name of Thebes, Wase or Wo'se, was derived from the sacred *was* sceptre. The nome or province of Wase, the fourth of Upper Egypt, is known to have existed from the 4th dynasty onward. The earliest monuments that have survived at Thebes itself date from the 11th dynasty (2133–1991 BC), when the local nomarchs (governors) united Egypt under their rule. From this time Thebes became the royal capital and was called Nowe or Nuwe, "the city [of Amon]," after its chief god. The Greek name Thebes (Thebai) was derived from Ta-ope, the ancient Egyptian name for Luxor.

Age of prosperity



During the 12th dynasty (1991–1786 BC), the royal residence was moved to al-Fayyūm, but the kings of Egypt honoured Amon, their family god, and built temples at Thebes. The Hyksos invaders had little or no control over the area, and it was the kings of Thebes who finally drove them out of Egypt (*c.* 1560). Then began the era of greatest prosperity for Thebes. The 18th-dynasty pharaohs rebuilt it and made it their capital, embellishing its temples with the spoils of Asia and the tribute of Nubia. During the 15th century BC great palaces rose on either bank of the river, brightly painted and surrounded with gardens: noblemen had their estates round about, and in the crowded streets foreign traders and mercenaries mingled with the citizens. The pharaohs of the New Kingdom vied with each other in building great temples on the east bank and even larger mortuary temples on the west. The height of Theban prosperity was reached about 1400 BC in the reign of Amenhotep III, much of whose vast wealth from foreign tribute was poured into the temples of Amon. For a brief period in the reign of his son Akhenaton, Thebes fell on evil times; the city was abandoned by the court and the worship of Amon proscribed. With its restoration by Tutankhamen, however, Thebes soon regained its revenues and prestige and retained both through the reigns of Seti I and Ramses II, who still resided for part of every year in Thebes. The city continued to be richly endowed; according to ancient sources, Ramses III donated 86,486 slaves and vast estates to Amon's temples.

Decline

Under the later Ramessids Thebes began to decline; the government fell, it seems, into grave economic difficulties. In the reign of Ramses IX, about 1121 BC, a series of investigations into the plundering of royal tombs in the necropolis of western Thebes uncovered proof of corruption in high places, following an accusation made by the mayor of the east bank against his colleague on the west. The plundered royal mummies were moved from place to place and at last deposited by the priests of Amon in the tomb of Amenhotep II and in a tomb-shaft in Dayr al-Baḥrī. (The finding of these two hiding places was one of the great events of modern archaeological discovery.) Such maladministration in Thebes led to unrest and there were strikes among the necropolis workers. Control of local affairs tended to come more and more into the hands of the high priests of Amon, leading to a situation in which, after the death of the last Ramses, the government of Egypt was shared between the pharaoh in Tanis and the high pontiff at Thebes. Intermarriage and adoption strengthened the ties between them, daughters of the Tanite kings being installed as "God's Wife of Amon" at Thebes, where they wielded greater power.

The Napatan (Nubian) pharaohs made Thebes their capital. Its fame among the early Greeks was such that Homer speaks of the wealth of "hundred-gated Thebes." In 661 BC, however, it was sacked by Ashurbanipal's Assyrians, and although rebuilt by the Saites it never fully recovered. In Strabo's time (*c.* 63 BC–*c.* AD 21) the city had dwindled to a mere village visited by tourists who came to see the ancient temples.

Temple of Karnak.

ARCHAEOLOGY

Luxor and Karnak. *The temples of Karnak.* Karnak, on the east bank of the Nile, is a village that has given its name to the most northerly part of Thebes, the quarter in which the great temples of Amon, Mut, and Khons were situated. Its ancient name was Ipet-isut, or Eptesowe, "Chosen of Places." The ruins of Karnak cover a considerable area and are still impressive, though nothing remains of the houses, palaces, and gardens that must have surrounded the temple precinct in ancient times. The temples are enclosed within three walls. The most northerly is that of the temple of Mont, the war god, of which little now remains but the foundations. The southern temple, which has a horseshoe-shaped sacred lake, was devoted to the goddess Mut, wife of Amon; this also is much ruined. It was built largely by Amenhotep III, whose architect was commemorated by statues in the temple.

Temple of Amon-Re

Between these two precincts lay the largest of all Egyptian temples, and one of the largest in the world, the great metropolitan temple of the state god, Amon-Re. It is in fact not one temple but a complex of temples, added to and altered at many periods, and lacking, in consequence, a coherent plan. It has been called a great historical document in stone. In it are reflected the fluctuating fortunes of the Egyptian Empire. There are no fewer than ten pylons, separated by courts and halls, and nowadays numbered for convenience from west to east, Number 1 being the latest. The seventh and eighth pylons were erected by Thutmose III and Queen Hatshepsut; the ninth and tenth,

(Left) The Colossi of Memnon, now about 65 ft high, are virtually the only remains of Amenhotep III's great mortuary temple in western Thebes. (Centre) Capitals and lintels of the massive hypostyle hall, temple of Amon-Re, Karnak. (Right) The mortuary temple of Queen Hatshepsut at Dayr al-Baḥrī, western Thebes.

of Horemheb's reign, formed a series of processional gateways at right angles to the main axis, linking the temple with that of Mut to the south, and further, by way of the avenue of sphinxes, with the temple of Luxor two miles away.

The history of the temple must be briefly sketched. The original Middle Kingdom temple has left no trace save a small jubilee shrine of Sesostris (Senusret) I, now reconstructed from fragments found inside the third pylon. At the beginning of the 18th dynasty, Thutmose I enclosed the 12th-dynasty temple and fronted it with two pylons, the fifth and fourth, with a pillared hall of gilded cedarwood between. Hatshepsut pierced the roof with two tall obelisks, one of which still stands. In the reign of Thutmose III the temple was greatly enlarged; not only did he add to the existing structures, and add a pylon and pillared courts containing halls in which he inscribed the annals of his campaigns, but he also built to the east of the Middle Kingdom area a transverse temple in the form of a jubilee pavilion. On the walls of one of the rear rooms of this temple is carved a kind of pictorial catalogue of the strange animals and plants he had brought home from Asia in the 25th year of his reign. He was probably also the builder of the wall that runs round the temple from the fourth pylon eastward, and of the sacred lake to the south of it, on which the bark of Amon floated. Small additions were made by his successors, and Amenhotep III added a pylon (Number 3) to the west and greatly embellished the temple.

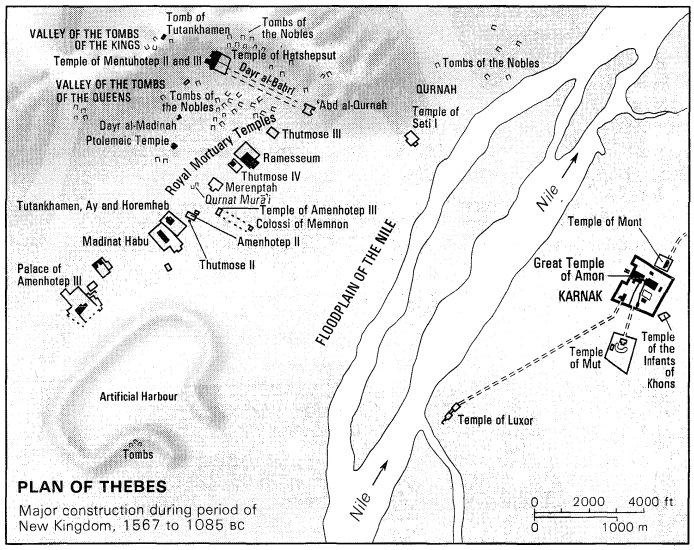
Hypostyle hall

The most striking feature of the temple of Karnak is the hypostyle (pillared) hall that occupies the space between the third pylon and the second, built by Ramses I. The area of this vast hall, one of the wonders of antiquity, is 5,800 square yards. It was decorated by Seti I and Ramses II, to whom much of the construction must be due, though it may have been planned and begun earlier. Fourteen enormous columns, 78 feet high, raised the roofing slabs of the central nave above the level of the rest so that light and air could enter through a clerestory. Seven lateral aisles on either side brought the number of pillars to 140. Historical reliefs on the outer walls show the victories of Seti in Palestine and Ramses II defeating the Hittites at the Battle of Kadesh.

Ramses III built a small temple to Amon outside the Ramesside pylon and at right angles to it, confronting a triple shrine erected by Seti II. The Bubastite kings of the 22nd dynasty, in adding a vast court to the front of the temple, incorporated both these small temples. The Bubastite Gate at the southeast corner of this court commemorates the victories won by Sheshonk I, the biblical Shishak, in Palestine in the reign of Rehoboam. The Napatan pharaoh Taharqa planned a tall colonnade, of which one pillar still stands, and perhaps began the giant first pylon, 370 feet wide and 143 feet high, which was continued by King Nectanebos (Nekhtnebef) in the 4th century BC but never completed. Beyond it, an avenue of sphinxes dating from Ramses II's reign leads to the quayside.

Within the enclosure of the great temple of Amon-Re are included a number of other small shrines and temples. A temple to Ptah and Hathor, in the north side of the enclosure, was built by Hatshepsut and Thutmose III and added to by the Ptolemies, who also embellished the great temple by the addition of granite shrines and gateways. To the south, Ramses III dedicated a temple to Khons, the moon god, which merits attention. A small late temple to Opet, the hippopotamus goddess, adjoins it.

Karnak presents a continual problem to the architects who seek to preserve it, for the foundations are inadequate and moisture from the Nile's annual flood has disintegrated the sandstone at the base of walls and columns. The work of repairing and strengthening goes on continuously, and in carrying out this work new discoveries are constantly being made. In one of the pylons, thousands of fragments were found from a temple built at Thebes by Akhenaton to his god Aton; this temple was destroyed when the cult of Amon was restored.



The temple of Luxor. The southern part of Thebes grew up around the other great temple of Amon, Ope or Ipet, "the Harim [of Amon]." The modern name, in Arabic al-Uqṣur, means "the palaces" or perhaps, after the Roman *castra* (remains of which have been found in the neighbourhood), "the forts." Here, close to the Nile and parallel with the bank of the river, King Amenhotep III built his beautiful temple dedicated to Amon-Re, king of the gods, his consort Mut, and their son Khons.

A small pavilion is all that is left of earlier work, though there was probably a temple here earlier in the 18th dynasty if not before. It was completed by Tutankhamen and Horemheb and added to by Ramses II; smaller additions were made in Ptolemaic times. The hypostyle hall was at one time converted into a Christian church, and the remains of another Coptic church can be seen to the west of it.

The original part of the temple consisted of a large peristyle court and a complex of halls and chambers beyond; on the east side of the central hall was the birth room, a chapel whose walls were decorated with scenes of the mystical marriage of Queen Mutemuia, Amenhotep's mother, with the god of Amon and of the birth of the royal child with the assistance of goddesses. One of the halls contains a granite shrine of Alexander the Great.

The great court is surrounded on three sides by a double row of graceful papyrus-cluster columns, their capitals imitating the umbels of the papyrus plant in bud. An entrance flanked by the towers of a pylon was planned for the north end, but this design was altered, and, instead, the most striking feature of the temple, a majestic colonnade of 14 pillars, 52 feet high, was added. This colonnade, which also has papyrus-umbel capitals, may have been intended for the central nave of a hypostyle hall similar to that at Karnak, but the side aisles were not built; instead, enclosing walls were built down either side. Ramses II added an outer court, decorated with colossal statues of himself between the pillars of a double colonnade, and a lofty pylon on which he depicted festival scenes and episodes from his wars in Syria. In front of the pylon were colossal images of the pharaoh and a pair of obelisks, one of which still stands; the other was removed in 1831 and re-erected in the Place de la Concorde in Paris.

In the forecourt of the temple is the mosque of Shaykh Yūsuf al-Ḥaggāg, the local Muslim saint. His feast is celebrated with a boat procession resembling an ancient rite, the "Beautiful Festival of Ope," during which, on the 19th day of the second month, Amon was said to come from Karnak on his state barge to visit his other temple at Luxor, escorted by the people of Thebes in holiday attire. Reliefs on the walls of the great colonnade depict preparations for the procession of sacred barks during the festival.

Ancient Thebes, east and west banks.

Western Thebes. Across the Nile from Luxor and Karnak, on the western bank, was another Thebes, the abode of the dead. The Egyptians called the whole region the Western City, or Kheftet-her-nebes, "She who is opposite to her lord." In Greco-Roman and Coptic times it was called Djeme. The presiding deity was a goddess, Mert-Seger, "the Lover of Silence," who was thought to live on the peak that dominates the range of cliffs in which the tombs are hollowed. After death, both pharaohs and commoners were ferried across the river to be buried in the necropolis of the west. The earliest cemeteries are in the most northerly part of the area; nomarchs of the early 11th-dynasty built pyramid-tombs on the desert edge north of the present village of Qurnah, where the cliffs approach most nearly to the river. Their successors, the Mentuhoteps who ruled the whole country, had larger tombs farther to the south. The largest, that of Mentuhotep II, was built at the head of the Valley of Asasif, at a spot known as Dayr al-Baḥrī, "the northern monastery." Here, dwarfed by a semicircle of towering cliffs, a combined pyramid tomb and funerary temple were erected on three ascending terraces.

The kings of the New Kingdom, fearing for the safety of their rich burials, adopted a new plan, that of building only their mortuary temples in the low desert within view of the valley, and concealing their tombs in a lonely valley (Bībān al-Mulūk, "the Valley of the Tombs of the Kings") in the western hills behind Dayr al-Baḥrī. Here, in tombs sunk deep into the heart of the mountain, the pharaohs of the 18th, 19th, and 20th dynasties from Thutmose I onward were interred, and also one or two queens and officials of high rank. The plan of the tombs varies considerably but consists essentially of a series of descending corridors interrupted by deep shafts to baffle robbers and by pillared chambers or vestibules; at the farther end is the burial chamber with a stone sarcophagus in which the royal mummy was laid, and store chambers around which furniture and equipment were stacked for the king's use in the next world. The walls were in many cases covered with sculptured and painted scenes depicting the dead king in the presence of deities, especially the gods of the underworld, and with illustrated magical texts similar to those found in funerary papyri, designed to help him on his journey through the nether regions. There were a number of these texts; they represent differing but not necessarily conflicting views of the afterlife in which the king had to undergo trials and surmount perils. In the *Book of That Which Is in the Underworld*, for instance, he travels in the boat of the sun god through 12 caverns that represent the 12 hours of the night. In the *Book of Gates* giant serpents guard the portals through which the sun has to pass, and strange jinns and demons help or hinder the boat on its way. Astronomical figures often decorated the ceilings of the burial chambers, and the sky-goddess Nut herself is sometimes painted across the firmament of stars.

Valley of the tombs of the kings

There are some 60 tombs in the valley, almost all of which were robbed in antiquity, many of them during the lifetime of the successors or of near descendants of the owners. In the time of Strabo, Greek travellers were able to visit 40. Only the little tomb of Tutankhamen on the floor of the valley, protected by a pile of rock chippings thrown down from a later Ramesside tomb, escaped pillage. The wonderful treasures exhumed from Tutankhamen's tomb, now in the Tutankhamen galleries of the Cairo museum, vividly indicate how rich the burial of a great pharaoh of the empire's heyday must have been. The longest tomb is Number 20, that of Queen Hatshepsut, whose burial chamber is nearly 700 feet from the entrance and descends 320 feet into the rock.

In the 19th and 20th dynasties, queens and a few favoured royal princes were buried in another valley today known as Bībān al-Ḥarīm, "the Valley of the Tombs of the Queens." It is situated at the southern end of the Theban necropolis, about 1½ miles west of the temple of Madīnat Habu. Here over 70 tombs have been found, very few of them inscribed and decorated. The earliest may be that of Sitre, wife of Ramses I. The most notable are those of Nefertari (Number 66), the favourite queen of Ramses II; of Prince Khaemwese (Number 44) and Prince Amonhirkhopshef (Number 55); and of a Ramesside queen called Titi (Number 52).

Tombs of officials

The limestone foothills that lie parallel to the river and about three miles away from it are honeycombed for a distance of over two miles with the tombs and tomb-chapels of high officials, mainly of the 18th, 19th, and 20th dynasties. The usual plan of these tombs included a forecourt, a transverse chamber, a long, corridor-like room, and, at the end, a chapel containing statues of the deceased and his family, in the floor of which a shaft or passage ran down to the burial chamber. After the funeral the shaft was filled in but the chapel and anterooms were kept open and visited by the family of the tomb owner. Near the villages of Dira 'Abū al-Nega' al-Asasif, al-Khūkhah Shaykh 'Abd al-Qurnah, Dayr al-Madīnah, and Qurnat Mura'i, several hundred tomb-chapels are still open to view. The walls are decorated with mural paintings, many of them wonderfully fresh and full of vivid interest, depicting the daily occupations of the ancient Egyptians. The dead are shown, in the outer rooms of these tombs, inspecting the workmen on their estates or in their hours of leisure hunting birds in the marshes or game in the desert, listening to music, or playing checkers

with their wives. In the infinite variety of these homely scenes, the whole cycle of the farmer's year, from plowing to harvest, is depicted—sculptors, metalworkers, weavers, and brickmakers ply their trades; and butchers, brewers, and cooks prepare food for the dead man's table. The treasurer goes on his rounds of inspection and the vizier receives foreign envoys to pharaoh's court. The gay patterns on the roofs derive from those in houses of the period. In the inner chapels fewer secular scenes are found. The funeral ritual is usually depicted: the cortège crossing the Nile, the ceremony of "Opening the Mouth" by the tomb door, the funerary feast; while in the innermost chamber there are representations of the deceased man and his wife in the company of Osiris and other gods undergoing the ordeal of judgment known as the "weighing of the heart" or being given nourishment by the goddess in the sacred sycamore. In the tombs of the late New Kingdom, purely religious scenes predominate.

The royal mortuary temples. In the New Kingdom, when the pharaohs hid their tombs in the secret valley, ostentation had to be concentrated in their mortuary temples, which rivalled each other in size and magnificence. Although they were designed for the performance of rites connected with the mortuary cult of the builder, they were all dedicated to Amon, the supreme god of Thebes, and had the character and essential form of a New Kingdom temple. They were built in western Thebes on the edge of the valley, in a sequence generally corresponding to a topographical arrangment from north to south. Only traces of most of the earlier ones remain. The most important will be mentioned here.

Temple of Hatshepsut

1. The temple of Hatshepsut at Dayr al-Baḥrī, which is the earliest large 18th-dynasty structure to survive and one of the most impressive. Here in the bay of cliffs, next to the pyramid-temple of Mentuhotep II mentioned above, the queen's architect Senenmut in about 1490 BC designed a series of colonnades and courts on three levels. The approach from the valley led through an avenue of sphinxes, and in the forecourt was a garden planted with trees and vines. On either side of the sloping ramp leading to the next level, against the terrace face, was a gallery whose roof was supported on a double row of columns; a similar gallery ran along the westward side of the court on the next level, with side chapels dedicated to Anubis and Hathor. The top terrace contained what may have been a hall of columns, with further chapels on either side and a sanctuary dug into the cliff behind. Many of the reliefs in the colonnades and chapels are of great beauty and considerable interest: one depicts the transport of two obelisks by barge from Aswān to Karnak, another the divine marriage of Queen Ahmes with the god Amon and the resultant miraculous birth of Hatshepsut herself, and a third the maritime trading expedition sent by the queen to Punt, the land of incense beyond the Red Sea.

Temple of Amenhotep III

2. The mortuary temple of Amenhotep III, which must have been the largest and most splendid of all the Theban temples. It was, however, almost completely demolished by later pharaohs and all that is left today are a few foundations, a huge *stela* 30 feet high, and the two great statues known as the Colossi of Memnon, which once flanked the gateway in front of the temple pylon but now sit like lonely sentinels in the middle of cultivated fields. The statues represent Amenhotep III; with their crowns they were nearly 70 feet high and each was hewn from a single block of stone. The northern one was the "singing Memnon" celebrated in classical times because on certain days, shortly after sunrise, it emitted a curious high note; numerous Roman tourists including the emperor Hadrian and his wife Sabina came to Thebes in order to hear this marvel, but in the reign of Septimius Severus the statue was patched with masonry and never "sang" again.

Temple of Seti I

3. The temple of Seti I at Qurnah, which survives only in part, the forecourt and pylon having disappeared. It was dedicated in part to the funerary cult of Ramses I, the father of Seti, and was completed by Seti's son, Ramses the Great, who figures largely in the reliefs. The walls are decorated with scenes of purely religious content in which the pharaohs make offerings to various gods or are favoured by them.

Temple of Ramses II

4. The Ramesseum, or mortuary temple of Ramses II (Ramses the Great), which, though much ruined, retains some of its ancient grandeur. The wide outer pylon is decorated with vigorous scenes of the king's wars against the Hittites in Syria, and the inner pylon with episodes from the Battle of Kadesh and scenes from the festival of the harvest god, Min. Tall figures of the king in the guise of Osiris decorate the pillars of the inner court. In the first court stood a seated colossus of Ramses II; only fragments of it are left, but enough to show that it was of enormous size. It must have been over 60 feet high and weighed about 1,000 tons. The hypostyle hall beyond the second court resembles that of the temple of Karnak; beyond were further pillared halls and a sanctuary that has now disappeared. Around the temple, within the high brick enclosure wall, are very extensive remains of vaulted buildings that must have been magazines, stables, workshops, and houses belonging to the temple staff. Diodorus Siculus describes the Ramesseum under the name of "the Tomb of Ozymandias" (i, 47–49).

Temple of Ramses III

5. The temple of Ramses III at Madīnat Habu. This is the latest and most southerly of the great New Kingdom mortuary temples. The general plan was modelled on that of the Ramesseum: a wide front pylon, an outer and an inner peristyle court separated by a second pylon, a large pillared hall and two smaller vestibules, and the sanctuary surrounded by smaller rooms. The hypostyle hall is partly ruined, the pillars having been dismantled to the level of the first or second drums, but the temple is otherwise well preserved. Scenes carved on the walls of the inner halls are of the usual ritual character, showing the king performing acts of worship before the gods, but in the first court there are also scenes of battle in which the king in his chariot mows down the Libyans, attacks an Amorite city, and leads Libyans, Asians, and sea raiders as prisoners before Amon and Mut. On the external wall of the temple a great sea battle between Egyptians and the Peleset (Philistines), Sherden and Shekelesh and other "peoples of the sea," is depicted with much lively detail. Another outstanding relief is that on the outer face of the great pylon, which shows the pharaoh hunting wild cattle in a reedy, marshy landscape. Adjoining the temple are the remains of a palace. The high gate in the eastern side of the perimeter wall of the temple area is battlemented like a fortress. Within the precinct are other smaller temples: one dates from the reign of Thutmose III and Hatshepsut but was altered and added to in various reigns and during the Ptolemaic and Roman periods; another is the small mortuary temple of a Saite queen. There are a sacred lake, a well, and remains, as in the Ramesseum, of houses and vaulted magazines built of mud brick.

The palace of Amenhotep III. South of the temple of Madīnat Habu lie the ruins of what must have been one of the finest buildings in western Thebes: the palace of King Amenhotep III and Queen Tiy at Malkata. It is in fact four palaces, one of which was occupied by the "great royal wife," for whom her husband constructed a huge lake on which she could sail in her barge. This lake has been identified with a great excavated basin, still traceable by a line of mounds to the southeast of Malkata; recent evidence, however, has thrown doubt on this: it may rather have been a harbour for shipping connected with the Nile.

In ancient Egypt there were other great cities, but none which has left so great a legacy to posterity. The great temples of Thebes with their historical scenes and inscriptions, the tombs with their wealth of illustration of daily life and religious belief, and the countless antiquities which now fill the museums and private collections of the world, are all aspects of that legacy. Few other sites have contributed more to our knowledge of early man than that of ancient Thebes.

BIBLIOGRAPHY. There are many good general descriptions of the antiquities of Thebes, among them G. LEGRAIN, *Les Temples de Karnak* (1929); and J. CAPART, *Thèbes, la gloire d'un grand passé* (1925; Eng. trans., *Thebes: The Glory of a Great Past*, 1926); the most recent, embodying research carried out since World War II, is C.F. NIMS' lavishly illustrated *Thebes of the Pharaohs* (1965). K. BAEDEKER,

Ägypten (1902; Eng. trans., *Egypt*, 8th ed., 1929), gives convenient plans and description of the monuments. Among the many archaeological publications special mention should be made of W.M.F. PETRIE, *Six Temples at Thebes* (1897); H.E. WINLOCK, *Excavations at Deir el Bahri, 1911–1931* (1942); E.H. NAVILLE, *The Temple of Deir el Bahari*, 7 vol. (1894–1908) and *The XIth Dynasty Temple at Deir el-Bahari*, 3 vol. (1907–13); and H.H. NELSON *et al.*, *Medinet Habu*, 12 vol. (1930-57). Extensive references may be found in the detailed and invaluable volumes of B. PORTER and R.B.L. MOSS, *A Topographical Bibliography of Ancient Egyptian Hieroglyphic Texts, Reliefs, and Paintings*, vol. 1, pt. 1, *Private Tombs*, rev. ed. (1960); pt. 2, *Royal Tombs and Smaller Cemeteries*, rev. ed. (1964); vol. 2, *Theban Temples* (1929). For the cult of Amun at Thebes, G. LEFEBVRE, *Histoire des grands prêtres d'Amon de Karnak jusqu'à la XXI^e dynastie* (1929); and the more recent work of E. OTTO, *Egyptian Art and the Cults of Osiris and Amon* (1968), should be consulted (further bibliography in the latter work). For the history of Thebes, see the revised first volumes of the *Cambridge Ancient History*, 3rd ed. (1970–71), esp. the chapters by WILLIAM C. HAYES (vol. 1, ch. 20, and vol. 2, ch. 9).

(M.S.D.)

Theism

Theism is the view that all limited or finite things are dependent in some way on one supreme or ultimate reality of which one may also speak in personal terms.

Theism's view of God can be clarified by contrasting it with that of deism, of pantheism, and of mysticism. Deism closely resembles theism; but for the deist, God is not involved in the world in the same personal way. He has made it, so to speak, or set the laws of it—and to that extent he sustains it in being. But subject to this final and somewhat remote control, God, as the deist sees him, allows the world to continue in its own way. This view simplifies some problems, especially those that arise from the scientific account of the world: one does not have to allow for any factor that cannot be handled and understood in the ordinary way. God is in the shadows or beyond; and, though men may still in some way centre their lives upon him, this calls for no radical adjustment at the human or finite level. The deist proceeds, for most purposes at least, as if there were no God—or only an absent one; and this approach is especially true of man's understanding of the world. This is why deism appealed so much to thinkers in the time of the first triumphs of modern science. They could indeed allow for God, but they had "no need of that hypothesis" in science or in their normal account of things. Religion, being wholly superadded, was significant only in a manner that involved little else in the world or in the way man lives. The theist, on the other hand, questions this view and seeks in various ways (as noted below) to bring man's relation to God into closer involvement with the way he understands himself and the world around him.

Theism, pantheism, and mysticism

Theism also sharply contrasts with pantheism, which identifies God with all that there is; and with various forms of monism, which regards all finite things as parts, modes, limitations, or appearances of some one ultimate Being, which is all that there is. Some types of absolute Idealism, a philosophy of all-pervading Mind, while regarding every finite thing as comprising some limitation of the one whole of Being, seek also to retain the theistic element in their view of the world; and they do this normally—as in the works of A.E. Taylor, Andrew Pringle-Pattison, or G.F. Stout—by stressing the role of unifying finite centres, such as self-conscious human beings, in the way the universe as a whole functions. But there is no recognition here of the finality of what is technically known as "the distinctness of persons." The theist, by contrast, considers the world to be quite distinct from its Author or Creator, human life being thus in no sense strictly the life of God, while also making room for a peculiarly intimate involvement of God in the world and in human life.

Mysticism in practice comes close to theism; but mystical thought, and much of its practice, has often involved a repudiation of the proper reality of finite things and sometimes (as in a recent work by W.T. Stace, *Mysticism and Philosophy*) tends to dismiss all of the finite manifold or multiplicity of things as some wholly unreal phantasm that has no place in the one undiversified Being, which alone is real. Theism is very far removed from ideas of this kind.

THEISM IN WESTERN THOUGHT

God encountered as person. The idea that the world, as man understands it in a finite way, is dependent on some reality altogether beyond his comprehension, perfect and self-sustained but also peculiarly involved in the world and its events, is presented with exceptional sharpness and discernment in the Old Testament, whence it became a formative influence in Hebrew history and subsequently in Christianity and Islām. Behind the creation stories; behind the patriarchal narratives, like that of Jacob at Bethel (Gen. 28) or wrestling with his strange visitor at Penuel (Gen. 32); and behind the high moments of prophecy, like Isaiah's famous vision in the Temple (Isa. 6), and of moving religious experience in the Psalms, in the Book of Job, and (with remarkable explicitness) in some well-known passages, like the story of Moses at the burning bush (Ex. 3)—behind all of these there lies a sense of some mysterious, all-encompassing reality by which man is also in some way addressed and which he may also venture to address in turn. Moses wished to see God, to have some explicit sign that could convince the people and establish his own authority; but he was shown, instead, that this is just what he could not have: all that he could be assured of was that God is real and is bound to be—"I am who I am," he was told. On the other hand, in the throes of this humbling and staggering experience, Moses began to learn also what was expected of him and how his people should live and be led. The God who was so strange and elusive was somehow found to be a God who "talked" to him and with whom people could "walk." The same seemingly bewildering claim of remoteness, almost to the point of unreality, linked with a compelling explicitness and closeness, is also found in other cultures, as illustrated below. This claim presents the reflective thinker with the twofold problem of theism, viz., how, in the first place, a reality as remote and mysterious as the God of theism—the "wholly other," in the famous words of the German theologian Rudolf Otto—can be known at all; and, second, how, if it can be known, it can be spoken of in precise and intimate ways and encountered as a person.

Old Testament theophanies

The existence of God. There have been many attempts to establish the existence of one supreme and ultimate Being—whom in religion one speaks of as God—and some of these have been given very precise forms in the course of time.

The influence of Plato and Aristotle. The pattern for many of these was laid down in ancient Greece by Plato. He taught about God mostly in mythical terms, stressing the goodness of God (as in *The Republic* and *Timaeus*) and his care for man (as in the *Phaedo*); but in the *Phaedrus*, and much more explicitly in the *Laws*, he presented a more rigorous argument, based on the fact that things change and are in motion. Not all change comes from outside; some of it is spontaneous and must be due to "soul" and ultimately to a supreme or perfect soul. Whether God so conceived quite gives the traditional theist all that he wants, however, is not certain. For God, in Plato, fashions the world on the pattern of immutable Forms and, above all, on "the Good," which is "beyond being and knowledge"; *i.e.*, it is transcendent and beyond the grasp of thought. But Plato's combination of the notion of the transcendent, which is also supremely good, and the argument from change provided the model for much of the course that subsequent philosophical arguments were to take. Aristotle made the argument from motion more precise, but he coupled it with a doubtful astronomical view and a less theistic notion of God, who, as the unmoved mover, is the ultimate source of all other movement, not by expressly communicating it but by being a supreme object of aspiration, all appetite and activity being in fact directed to some good. Aristotle thus set

the pattern for the more deistic view of God, whereas the theist, taken in the strict sense, turns more for his start and inspiration to Plato.

The causal argument. The argument for the existence of God inferred from motion was given a more familiar form in the first of the five ways of St. Thomas Aquinas, five major proofs of God that also owed much to the emphasis on the complete transcendence of God in the teaching of Plotinus, the leading Neoplatonist of the 3rd century AD, and his followers. (The word that Plotinus used for the ultimate but mysterious dependence of all things on God is emanation; but this characterization was not understood by him, as it has been by some later thinkers, as questioning the genuine independent existence of finite things.) In the first way, Aquinas put forward the view that all movement implies, in the last analysis, an unmoved mover; and though this argument, as he understood it, presupposes certain views about movement and physical change that may not be accepted today, it does make the main point that finite processes call for some ground or condition other than themselves.

The five ways of Aquinas

This becomes more explicit in the second way, which proceeds from the principle that everything must have an "efficient cause"—*i.e.*, a cause that actively produces and accounts for it—to the notion of a first cause required to avoid an infinite regress, or tracing of causes endlessly backward. As normally found, the idea of efficient causality, in respect to change and process, has many difficulties; and some would prefer to speak instead of regular or necessary sequence. But a more serious objection stresses the apparent inconsistency of thinkers who invoke a general principle of causality and then exempt the alleged first cause. As the child is apt to put it, "Who then made God?" To this a defender of St. Thomas, or at least of the present approach to the idea of God, would reply that the first cause is not supposed to be itself a member of any ordinary causal sequence but altogether beyond it, an infinite reality not itself a part of the natural or temporal order at all. This point, in fact, is what the third way, starting from the contingency of the world, brings out more explicitly. Nothing explains itself, and all other explanations fall short of showing in any exhaustive way why anything is as it is, or why there is anything at all. But it is also hard to suppose that things just happen to be. Nothing could come out of just nothing, and so the course of events as men find and explain them points to some reality that is not itself to be understood or explained in the normal way at all: it is Explanation with a capital *E*, as it were, that is seen to be necessitated by all that there is—of whose nature, however, nothing may be directly discerned beyond the inevitability of its being as the ultimate or unconditioned ground of all else and in this way transcendent or utterly mysterious in itself.

This way of thinking of the being and necessity of God has been impressively presented in the mid-20th century by notable thinkers like Austin Farrer, E.L. Mascall, and H.P. Owen and also by the present writer (see below *Bibliography*). Generally known as the cosmological approach to the idea of God, it has much in common with the insistence on the transcendence of God in recent theology.

The ontological argument. Scholars have often converged upon the same theme in what appears to be a very different line of argument, namely the ontological one, with which are associated especially the names of St. Anselm, first of the Scholastic philosophers (in the 11th century), and René Descartes, first major modern philosopher (in the mid-17th century). Proponents of this argument try to show that the very idea of God implies his existence. God is the greatest or most perfect being. If the attribute of existence, however, is not included in man's concept of God, he can then think of something more perfect, viz., that which has existence as well. Critics, such as Gaunilo—a monk of Marmoutier—in Anselm's day and Immanuel Kant—one of the major architects of modern philosophy—many centuries later, have fastened on the weakness that existence is not a predicate or attribute in the same way, at least, as colour or shape; but there have been highly ingenious attempts by influential religious thinkers of today to restate the argument in an acceptable form. (See especially the writings of Charles Hartshorne and Norman Malcolm.) Others find in the argument an oblique and needlessly elaborate way of eliciting the feeling that there must be some reality that exists by the very necessity of its own nature and to which everything else directs man's thought.

The arguments of Anselm and Descartes

The reference to value and design. Attempts to arrive at the idea of God in somewhat more comprehensible terms are reflected in the references to value and design in the fourth and fifth ways of St. Thomas; this approach, however, has been given a more explicit presentation and critical discussion in the works of David Hume, a mid-18th-century Scottish Skeptic, and in Kant. The main idea of the teleological argument, as it is called, is that of the worth and purpose, or apparent design, to be found in the world. This purposiveness is taken to imply a supreme Designer. It has been questioned, however (by Kant, for example), whether this argument can really get started without presupposing some feature of the causal argument. The presence of seemingly purposeless features of the world and of much that is positively bad, like wickedness and suffering, while always embarrassing for a theistic view, presents peculiar difficulties here. For the arguer is now throwing hostages to fortune in the shape of a special assessment of the way things actually happen, which goes far beyond the mere requirement of some ultimate ground, whatever the world appears to be like. The arguments from worth and design have, however, one considerable advantage, viz., that they provide a fairly straightforward way of learning about the nature of God and of ascribing a certain aim and character to him from one's understanding of the phenomena that he is required to explain. The supreme Designer or Architect is known from his works, especially perhaps as reflected in the lives of men; and this approach opens up one way of speaking of God, not just as mysterious power behind the world but as some reality whom man may come to know in a personal way from the way the world goes and from his understanding of what it means.

Many thinkers in the late 19th and early 20th centuries sought to establish man's knowledge of God in the way suggested through his understanding of himself and the world, and of these the most notable and valuable still today are the British theists James Ward, a psychologist, and F.R. Tennant, a philosophical theologian. But the work of thinkers like Pierre Teilhard de Chardin, a Jesuit paleoanthropologist, and the spate of discussion that he has provoked are also relevant here; and such work, in turn, owes much—directly or otherwise—to the work of evolutionary thinkers like Samuel Alexander and Henri Bergson and of modern scientists like Julian Huxley.

The views of Ward, Tennant, and Teilhard

The problem of particular knowledge of God. If the central theme of traditional theism, viz., that the finite world depends in some way on one transcendent and infinite Being, can be sustained, then a crucial problem presents itself at once: the question of how a being whose essence can never be known to man—who, as infinite, is bound to be beyond the grasp of reason and to remain wholly mysterious—how such a being can be said to be known at all, much less known and experienced in the close and intimate personal ways that the theist makes equally central to his claim. Part of the answer is that the theist does not claim to fathom the ultimate mystery of God or to know him as he is in himself. All that is claimed on this score is that man sees the inevitability of there being God in the contingent and limited character of everything else; and though this line of thought could not be adopted for any finite existence—since one could not normally affirm in any sensible way the existence of anything without specifying in some measure, however slight, what it is like—one can, nonetheless, regard the case of God as unique and not subject to the conditions of finite intelligibility. In these ways, an insight or intuition into the being of God may be claimed without a commitment to anything about his nature beyond the sort of completeness or perfection required to account for there being limited finite things. This insight is much in line with the "deliverances of religious

consciousness" in which it is claimed that God is "hidden," is "past finding out," that his ways are not man's ways, that he is eternal, uncreated, and so on. But the theist still has a major problem on his hands, for he also makes a central issue of the claim that God can be known—"met" and "encountered" in some way—indeed, that some very bold affirmations about God and his dealings with men may be made.

Theism and natural theology. Theists have tried to deal with this problem in various ways. One of these ways is their use of the doctrine of analogy, which owes a great deal to the teaching of St. Thomas Aquinas. Various types of analogy are distinguished in the traditional doctrine; but the central claim is that certain predicates, such as "love," "faithfulness," or "justice," may be affirmed of God in whatever way may reflect his involvement as the author of the limited realities, such as man, of which such predicates may be affirmed in the normal, straightforward way. The difficulty with this procedure is that, whatever it yields, the content of faith is still very thin and remote, far from the warm fellowship of personal relations. Most of the traditional sponsors of the doctrine admit this and contend, therefore, that the findings of their "natural theology," as it is called, must be supplemented by that of revelation or of divine disclosure. Theism, in fact, is hardly conceivable without some doctrine of revelation. But even if the theologian says that God takes the initiative in communicating himself to man, the epistemological problem remains of how men's essentially finite minds can apprehend anything pertaining to infinite or eternal Being.

Revelation and authority

Theism and religious experience. At this point, recourse is sometimes had to authority, the authority of a sacred book, an institution, or a system of doctrines, or one of divinely implanted images. But there must at least be some initial justification of an authority, to say nothing of an evaluation of rival claims. A more attractive solution, then, especially for those who stress the personal involvement of God in men's lives, is one posed in terms of religious experience. Such experience is usually given prominence in theistic contexts. It is sometimes understood in terms of paranormal phenomena, like hearing voices or seeing visions, which have no natural origin, or like being in some peculiar psychical state. Some of the faithful believe that God literally speaks to them (or spoke in times past to prophets) in this way. A more subtle view holds that men have reason to regard certain experiences as their clue to what they should say of God in his relation to them. The question then arises of how these experiences should be recognized; and various answers are given, such as that which stresses the formative influence (within such experiences) of the initial insight into the being of God and the patterning of the experiences, in themselves and in wider ramifications, as a result. Much use is made in this context of the analogy with men's knowledge of one another. Men do not know one another's minds, it is alleged, as they know their own but only as mediated through bodily states and behaviour. So a man may come to know God, who in his essence is impenetrable to him, from the impact that he makes within experiences and events that one would otherwise understand and handle just as one does other finite occurrences. In the molding and perpetuating of such experiences, prominence is given to imagination and to the place of figurative terms and symbolism. These forms have therefore a place of special importance in theistic types of religion, the personal encounter being extended and deepened through art and literature, song, dance, myth, and ritual. This fact, in turn, presents problems for thought and practice, since the art forms and ritual must not be allowed to take wing on their own and thereby be loosed from the discipline and direction of the proper dynamic of religious life.

Theism and religious language. Preoccupation with the forms in which religious life expresses itself has led some theistic writers to lean heavily on the contribution made to religious understanding today by studies of religious language. In some cases this concern has carried with it, as generally in much linguistic philosophy of today, a skeptical or agnostic view of the transcendent factor in religion. It is hard to see, however, how attenuations of this kind could be strictly regarded as forms of theism; though clearly, within their more restricted scope, they can retain many of the other characteristics of theism, such as the stress on personal involvement and response. This tendency is very marked in some recent studies of religion, in which the inspiration and form of theism are retained without the substance—though how long and how properly are moot points. There are others who, while retaining the transcendent reference of theism, look for the solution of the central problem less in the substance of religious awareness and in varieties of experience than in the modes of articulation and religious language. Controversy centres, to a great degree, on which of these approaches is the most fruitful.

The question of transcendence in theism

In the work of some theists today, the preoccupation with language is also combined with the existentialist stress on personal involvement and commitment. A good example of this approach is found in the work of I.T. Ramsey, the bishop of Durham, who, in spite of his insistence on disclosure situations, in which something peculiarly significant becomes alive to man, seems to concede more than a theist should to the skeptical strain in recent studies of religious language.

The nature of God in modern thought. Modern thought has thrown new light on issues, both old and new, regarding the nature of God.

Theism and incarnation. The core of human personality has often been thought to be man's moral existence, and, accordingly, theists have often taken this fact to be the main clue to the way they are to think of divine perfection and to the recognition of a peculiar divine involvement in the world. Prominence is thus accorded to the high ethical teaching and character of saints and prophets, who have a special role to play in transmitting the divine message. In some religions this tendency culminates in doctrines of incarnation, of God manifesting himself expressly in refined or perfected human form. This trend is peculiarly marked in the Christian religion, in which the claim is usually made that a unique and "once for all" incarnation of God has occurred in Christ. Incarnational claims seem certainly to take their place easily in some main forms of theism. The vindication of such claims, however—especially today—relies much on consideration of the personal factor in religion generally.

For these and related reasons, the theist today may find himself calling to his aid certain other disciplines that centre upon men as persons, such as psychology and anthropology. Not all of the forms and findings of these studies favour the theist, and he should take special note of their challenge when they seem hostile, for they may touch him at his tenderest spot. He may, on the other hand, find in such studies, and certain general literature that borders on kindred themes, substantial help in reconstructing his case in the full context of contemporary thought and culture.

Humanism and transcendence. It is indeed from certain modern studies of man and his environment that some of the most disturbing challenges to the theist have come. For it has been argued that the very idea of God, as well as the more specific forms that it takes, emanate from man's emotional needs for succour and comfort. It is in fact man himself, it is said, who has created God in his own image, and the attempt is made to substantiate this view from accounts of the proclivity of men, especially in early times, to personify natural objects—rivers, trees, mountains, and so forth—and, in due course, to confer peculiar properties upon them, leading in time to the notion of some superbeing in whom these powers and properties are concentrated. The classical statement of this position appeared before the development of anthropology and the modern systematic study of religions, viz., in David Hume's essay "The Natural History of Religion" (1757). This short but splendidly lucid and challenging work set the pattern for the more scientific and empirical studies of religion that began to take shape in the 19th century in pioneer work by E.B. Tylor, a British ethnologist and anthropologist, in his *Primitive*

Role of the sciences of religion

Culture (1871), and by Sir James Frazer, an ethnographer and historian of religion, in his *Golden Bough* (1890–1915). But a corrective to this approach was soon provided by other scholars equally renowned, who started from the historical and empirical evidence available to them at the time. Andrew Lang, a Scottish litterateur, drew attention to the phenomenon among very early peoples, of the High God, a Supreme Being who created himself and the earth and dwelt at one time on earth. John H. King, in *The Supernatural: Its Origin, Nature and Evolution* (1892), stressed the importance of the element of mystery in all religions, and another pioneer of religious anthropology, R.R. Marett, showed how extensively the savage ascribes the mysteries of life and power to a supernatural source. Lucien Lévy-Bruhl, a French sociologist, noted the pervasiveness of prelogical factors in primitive mentality, and Rudolf Otto, the most famous name in this context, found evidence in early forms of religion of a response to "the wholly other," the *mysterium tremendum et fascinans.*

The idea of a finite God. Concern with the problem of evil—*i.e.*, with reconciling the existence of evil with that of a good God—becomes acute for thinkers who rest their case mainly on what they find in the world around them; and this has led many to retreat to the notion of a finite God, according to which the world may be under the direction of a superior being who is nonetheless limited in power, though not in goodness. This is a serious alternative to the idea of a supreme and unlimited source of all reality as found in the usual forms of theism. Indeed, it is a moot point whether the idea of a finite God should be classified as a form of theism. It does come close to traditional theism, however, in its insistence on the unity and absolute benevolence of God. There are clearly advantages in the notion of God as a limited being, especially where evil is concerned; for though one could still insist that God intends nothing that is not wholly good, he can now account for extensive suffering and other ills on the basis of the limits to God's power. He is doing his utmost, the finitist holds, but there are things—refractory materials or explicitly evil powers—that he has not yet subdued, though hopefully he will eventually do so. There is also induced in this way a sense of urgency in man's own obligation to cooperate with God—to be a "fellow worker." God will clearly need his help though he himself is in the vanguard of the battle against evil. Thus, those who incline to the idea of a finite God usually have been activist in thought and practice.

There are also grave difficulties to be met. For if a thinker has recourse to the idea of God simply to account for what is otherwise bewildering in the finite course of things, he may find no warrant for the inference involved and indeed may find himself desperately clinging to what is sometimes called "the God of the gaps" (*i.e.*, of the gaps in man's explanations). If, on the other hand, he starts from the inherently incomplete character of finite explanation as such, or from the contingency of finite things, nothing short of an infinite or absolute God will meet the case. In addition, the usual attitude of religious people, or of what is sometimes known as "the religious consciousness," is that of a profound assurance and serenity that presupposes that God is "all in all" and beyond any possibility of being thwarted. It is also questionable whether the attitude of worship is appropriate for a limited being, however superior he may be to man.

The views of James, Perry, and the process philosophers

Among the outstanding advocates of the idea of a finite God were, at the turn of the 20th century, the U.S. Pragmatist William James and some of his disciples, notably Ralph Barton Perry. Thus, it is not surprising that a closely similar notion arising in the mid-20th century finds its main inspiration and support in the United States, viz., in the work of process philosophers, such as Charles Hartshorne and Schubert Ogden, who have developed some of the leading ideas of A.N. Whitehead, an eminent metaphysician. In their view, God is himself in process of fulfillment in some kind of identification with the world, which at the same time leaves him distinct in some sense from the universe, which he permeates and unifies. There are grave and admitted paradoxes in this view; and, in spite of the remarkable ingenuity of its advocates and their logical nimbleness, it is not clear that the paradoxes can be sustained nor that the difficulties that are shared with the simpler notion of a finite God can be overcome. Much in recent religious thought centres on this issue.

Theism in Islām. The Muslim faith owes much to the Semitic outlook from which the Old Testament and Christianity arose. It centres on a transcendent personal deity; but, in its regard for the holiness and majesty of God, it rejects incarnational doctrines as a form of blasphemy. There is, however, a paradoxical side to one form of Islām: while insisting that God is all in all, it sometimes tends to represent all of man's own actions as the action of God within him and thus has some tendency to identify man with God. This tendency, most marked in the mysticism of the Ṣūfīs, seems, as respects its monism, to veer away from theism but seems, as respects the sense of devotion and personal excitation that it inspires, to be in line with the more explicit forms of theism. In its main form, Islām, with its quite exceptional sense of the transcendence of God, is one of the most distinctively theistic religions, though at odds with the incarnational factor in Christian theism.

THEISM IN EASTERN THOUGHT

The trend toward the testing of theistic thought in the crucible of the special disciplines was continued not only in further anthropological studies (see *The Worship of the Sky-God,* by E.O. James) but also in extensive scholarly studies and translations of the sacred books of the great religions of the East.

Hindu theism. It was noted, for example, that the Vedic hymns that appear in the earliest Hindu scriptures contain significant intimations of a sense of "the wonder of existence," "the outpourings," as Savepalli Radhakrishnan, the former philosopher-president of India, has expressed it, "of poetic minds who were struck by the immensity of the universe and the inexhaustible mystery of life." Note was taken also of early manifestations of henotheism, a view that exalts several deities to the first place. The theme of some one supreme reality, the first principle, or the supreme self becomes more explicit in the *Upaniṣads,* ancient Hindu scriptures, while retaining a sense of its ineffableness. One hears of "the way of silence" and of the ultimate absorption of all into the one supreme reality, the "one who breathes breathless." This one is variously conceived in its relation to finite things; and although the transcendent reference is rarely absent, there is not the same recognition of the distinctness of finite beings that there is in Western theism or of the eternal self being involved in the world in a personal way. The *Upaniṣads* have, in fact, a variety of themes and emphases, tending generally toward a monistic and mystical philosophy; but on occasion the theistic element is very marked, as in the *Kaṭha* and the *Śvetāśvatara* books of the *Upaniṣads.* The absolutist and the theistic views are not always felt to be exclusive. This climate of thought has set the course for much of subsequent Hinduism, in which, along with the persistence of the monistic strain, the theistic note is sounded much more distinctly, especially in the doctrine and practice of *bhakti*—devotion to a personal God who bestows grace. In the famous *Bhagavadgītā* (probably 3rd or 4th century BC), a classic of religious literature, and in the teaching of the Brahmin Rāmānuja (11th century), considered the founder of the Viśiṣṭādvaita (qualified nondualism) school, the flowering of the more theistic side of Hinduism is found. In the Śaiva-siddhānta theology of South Indian Śaivism (a major cult of Hinduism), there is a firm insistence that the soul, in being united with God, is not annihilated or negated but only fused into the likeness of God, who, in turn, is always in loving pursuit of the soul. This doctrine makes the system "perhaps the highest form of theism that India was ever to develop" (R.C. Zaehner). In the closing words of the *Bhagavadgītā* is an insistence on a love of God for man and of man for God that represents a decisive turning point in the history of Hinduism:

Theism in the *Upaniṣads*

Think on me, worship me, sacrifice to me, pay me homage,

> so shalt thou come to me, I promise thee truly, for I love thee well. Give up all things of *dharma*, turn to me only as thy refuge. I will deliver thee from all evil. Have no care.

This theology has been well reflected in the 20th century in the devotionalism of Gandhi and in the writings of Sri Aurobindo, a philosopher and Yoga devotee, which reflect an indwelling of the divine within the world and a summons to high moral endeavour on the part of man that comes close to theism without explicitly accepting it.

Buddhism and theism. The same diversity of strains is found in Buddhism. Though Buddhism was at one time regarded as an atheistic religion leading to total elimination of self in a state of Nirvāṇa, a close examination of the evidence—in the Pāli *Tipiṭaka*, for example, the canon of the Theravāda school of Buddhism—leads to a revision in favour of the view that the seeming negativism of early Buddhist scriptures and the rejection of metaphysics reflect chiefly the caution arising from a profound recognition of the characterless elusiveness of the transcendent. And although the Buddhist doctrine of compassion and its rigorous intellectual and moral discipline may lack something of the warmth of a close personal commitment, the Buddhist adoration of the Buddha and of the *bodhisattvas* (those on their way to Enlightenment) afforded much scope to the religious responses that find their full expression in overt theism. This trend became more marked in the more popular forms of Buddhism and in the mythologies that centre upon the idea of the *bodhisattvas*.

Theism in other religions. In the same way, the seeming agnosticism of Confucian religion is qualified by its teaching about a power from beyond the world working for justice within it, a "Heaven-ordained relationship" that provides the basis of ethics and induces a deep consciousness of individuality. This trend became intensified in the conflations that resulted from the extension of Buddhism into China.

Theism in Confucianism, Sikhism, and Jainism

In the doctrines of Sikhism, a religion of the eastern Punjab that combines certain Muslim and Hindu elements, stress is laid upon personal awareness of God as a central and unifying factor in religion. In doctrine though not always in practice, however, the Sikhs reject every notion of an avatar, or incarnation. The religion of the Jains is nontheistic in theory, but the great figures of its tradition come to function as gods in popular religion. For a period in ancient Persia, there was established in the teaching of Zoroaster (Zarathushtra) a form of ethical monotheism in which the god Ahura Mazdā is the creator of the physical and moral world—though limited, for a time at least, by an opposing principle of evil (Ahriman).

The clue to the theistic element in the religions of primitive peoples may well be found in an observation by H.H. Farmer, a British philosophical theologian:

> We may surmise that at moments of living prayer and worship there is in primitive man a turning to *a* god as if he were in fact the one and only God, though without any expressly formulated denial of the existence of others; for the time being, the god worshipped fills the whole sphere of the divine.

BIBLIOGRAPHY. The classic recent statement of God's transcendence is A.M. FARRER, *Finite and Infinite*, 2nd ed. (1959), a difficult but essential book; C.A. CAMPBELL, *On Selfhood and Godhood* (1957), is an exceptionally lucid presentation that allows for the distinctness of finite beings; see also further statements in WILLIAM TEMPLE, *Nature, Man and God* (1934); H.H. FARMER, *God and Men* (1947); and H.D. LEWIS, *Philosophy of Religion* (1965). A. SETH PRINGLE-PATTISON presents the more traditional Idealist view in *The Idea of God in the Light of Recent Philosophy* (1920). An Idealism stressing the immediate awareness of other minds and of God is found in W.E. HOCKING, *The Meaning of God in Human Experience* (1912); a presentation similarly starting from Empiricism and science that culminates in a "Cosmic Teleology" is that of F.R. TENNANT, *Philosophical Theology*, 2 vol. (1928–30). E.S. BRIGHTMAN, *The Problem of God* (1930), treats God as a limited being (finitism).

Mysticism and theism: An excellent account of many types of mysticism is provided in DAVID KNOWLES, *The English Mystical Tradition* (1961). A comprehensive account (including Eastern mysticism), with profound reflections on mysticism's relation to theistic claims, is in R.C. ZAEHNER, *Mysticism, Sacred and Profane* (1957).

Theism and Idealism: Typical statements are A.E. TAYLOR, *The Faith of a Moralist*, 2 vol. (1930, reprinted 1968); G.F. STOUT, *God and Nature* (1952); A.C. EWING, *Idealism* (1934, reprinted 1950); JOSIAH ROYCE, *The World and the Individual*, 2 vol. (1900, reprinted 1959); and BRAND BLANSHARD, *Reason and Goodness* (1960). For difficulties Idealism poses for theism, see H.D. LEWIS, *The Elusive Mind*, ch. 14 (1969).

Arguments for God's existence: An excellent account appears in F.C. COPLESTON, *History of Philosophy*, vol. 2, ch. 34 (1950). For what lies behind the arguments (and their importance for God's transcendence), E.L. MASCALL, *He Who Is*, ch. 4–6 (1945), is unrivalled. See also the readings in ALVIN PLANTINGA, *The Ontological Argument* (1965); and *God and Other Minds* (1967); and in JOHN HICK, *The Many-Faced Argument* (1967). For its current revival, see CHARLES HARTSHORNE, *The Logic of Perfection* (1962); and NORMAN MALCOM, "Anselm's Ontological Arguments," *The Philosophical Review*, 69:41–62 (1960). For substantial articles on the traditional arguments, see *Religious Studies*, vol. 4, no. 2 (1969). The best recent account of the cosmological argument and transcendence is given by I.M. CROMBIE, "The Possibility of Theological Statements," in BASIL MITCHELL (ed.), *Faith and Logic* (1957). For the arguments from design and value, see H.P. OWEN, *The Moral Argument for Christian Theism* (1965); his exhaustive defense in *The Christian Knowledge of God* (1969); and ILLTYD TRETHOWAN, *Absolute Value* (1969).

Idea of a finite God: WILLIAM JAMES, *Pragmatism and the Will of God*, ch. 8 (1917), is the classical statement. See also R.B. PERRY, *Realms of Values* (1954, reprinted 1968); and the celebrated advocate of this view, E.S. BRIGHTMAN, *The Problem of God* (1930). For criticism, see C.A. CAMPBELL, *Scepticism and Construction*, ch. 8 (1931).

Process theology: Process theology stems from A.N. WHITEHEAD, *Process and Reality* (1929, reprinted 1969). Its most notable exponents are CHARLES HARTSHORNE in *The Logic of Perfection* (1962); and SCHUBERT OGDEN in *The Reality of God* (1966).

Religious experience: The pioneer work is WILLIAM JAMES, *The Varieties of Religious Experience* (1902, reprinted 1961). H.H. FARMER, *Revelation and Religion* (1954), maps out various religious attitudes and considers them in relation to a typical theistic view. Questions about the vindication of religious experience are discussed in *Our Experience of God* by H.D. LEWIS (1959 and 1969).

Religious language: The theistic position in linguistic religious philosophy is best represented in I.T. RAMSEY, *Religious Language* (1957). See also the masterly work by W.K. MUNDLE in *A Critique of Linguistic Philosophy* (1970).

World religions: See R.C. ZAEHNER, *At Sundry Times* (1958) and *Hinduism*, 2nd ed. (1966); R.L. SLATER, *World Religions and World Community* (1963); HANS JOACHIM SHOEPS, *Wesen und Geschichte* (1961; Eng. trans., *The Religions of Mankind*, 1968); and E.G. Themistocles

Themistocles, the creator of Athenian sea power and chief saviour of Greece from subjection to the Persian Empire in the invasion of 480 BC, is often unfavourably viewed by early writers. Admittedly a master strategist, he is often depicted as a slick politician, bent on enriching himself even in the crisis of the great war. The reason for this bias is perhaps that he was a strong democrat, hated by the Athenian upper classes; and their views, passed on to their friend the historian Herodotus and to Plato, himself an aristocrat, colour the whole tradition. Herodotus introduces him only at the onset of the crisis as "newly come to the front" (which is wrong) and drops him from his story at the end of 480. Only the historian Thucydides does him justice and calls the darkest charges against him "alleged."

Themistocles was born, at latest, about 524 BC. His father Neocles came of the aristocratic Lycomid family and was not poor; but his mother was a concubine, non-Athenian, possibly non-Greek. He thus owed his citizenship to the legislation of Cleisthenes, which, in 508, had made citizens of all free men of Athens. This no doubt contributed to his democratic sympathies. In 493 he was elected archon, the chief judicial and civilian executive

officer in Athens; this is the first recorded event of his life. As archon, he sponsored the first public works destined to make the defensible rocky bays of Piraeus, five miles from Athens, into harbours, replacing the nearer but unprotected beaches of Phaleron. He must also have been concerned in the trial of Miltiades, the great colonial Athenian prince, who arrived in flight from the Chersonese (Gallipoli) and was prosecuted by aristocratic rivals for having ruled as a monarch. Themistocles himself took a cool view of Miltiades' autocratic character; but his judgment was not at fault if he helped to save the strategist and tactician who, in 490, beat off the first Persian attack on Athens at Marathon.

After Marathon, most Athenians thought that the danger was past, but not so Themistocles. He also saw that Marathon—a victory for Athens' spearmen, middle class men who could afford the costly bronze panoply—could not be repeated if the enemy, strong in archers and cavalry, came again in much greater force. The only hope was to exploit the invader's supply difficulties, which would be great if Persia's naval allies, including the formidable Phoenicians, could be beaten at sea. But for this strategy Greece needed far more warships—the newly developed, specialized triremes—than it then had. Themistocles urged that the Athenian fleet, then 70 strong, be doubled or trebled; but he was opposed. The opposition was not without political overtones; for triremes would have to be paid for by those who had money, whereas armour, once one had it, cost nothing to maintain; and also, a strong navy would give political weight to the men who rowed the galleys, the poorer voters, as compared with the armoured-infantry middle class.

Advocacy of a large navy

The 480s were a period of intense political struggle. Miltiades died in disgrace (489), and from 487 to 483 other leaders were successively ostracized. Though never himself defeated, Themistocles must have been attacked repeatedly; he was the man accused by his enemies of being a danger to the established order. Nonetheless, in 483 he won his greatest triumph. The state-owned silver mines near Sunium were the site of a rich strike; and he persuaded the assembly, instead of "declaring a dividend," to devote the whole surplus to increasing the navy. Thus when Xerxes I, the Persian king, marched in 480, Athens had 200 triremes, though many of the rowers were still untrained.

Themistocles further succeeded in selling his naval strategy to the Peloponnesians, headed by Sparta, who could raise another 150 triremes. The combined fleet was to fight not on their own doorstep, as Greeks preferred to do, but as far forward as possible, exploiting the geographical situation. Serving under a Spartan admiral (since Corinth and Aegina would not serve under an Athenian), Themistocles conducted the main fleet to the straits north of Euboea. Here their presence forced the enemy to approach en masse down a coast with few beaches; and a typical north Aegean storm there inflicted losses that probably, in the end, proved decisive. But the Greeks were still outnumbered. In the Battle of Artemisium, fighting in a defensive half-moon formation, they suffered as well as inflicted heavy losses, and they knew that they must retire even before they heard that their small holding force on land had been destroyed at Thermopylae.

Battle of Salamis

One hope remained. Themistocles had persuaded the Athenians to evacuate women and children to the Peloponnese and, in the last resort, to retire to Salamis. If the Persians attacked that island citadel, a battle in the narrow sound might yet give a chance to the Greeks, with their armoured marines and heavier ships, against the better sailing ships commanded by the Persians. Persuading the Peloponnesians to join the Athenian fleet, Themistocles then lured Xerxes by a false message, suggesting that he himself was ready to change sides, into ordering an all-out attack. The Greeks enveloped the head of the Phoenician column as it emerged from the narrowest part of the strait and destroyed it; and though most of the other Asian contingents in the rear escaped, Xerxes had lost for good the command of the sea.

Sparta honoured Themistocles with a great ovation; but Athens, led during the crisis by the Areopagus, or council of nobles, gave the chief commands in 479 to the recalled exiles, Aristides and Xanthippus; and Themistocles' post-war history was a sad one. He outwitted the Spartans when they attempted to prevent Athens from rebuilding its defensive walls, but he failed to induce the people either to transfer their capital to Piraeus or, at that time, to reduce the powers of the Areopagus. The people, after their tremendous war effort, were in a mood of reaction. Though praised (not by name) in Aeschylus' *Persians* (472), Themistocles was at last ostracized. He lived at Argos for some years, during which democracy made headway in some parts of the Peloponnese. Then Sparta accused him of complicity in alleged intrigues with Persia. He escaped, and, until his death in about 460, served as governor of some Asian Greek cities still subject to the son of Xerxes.

BIBLIOGRAPHY. The histories by HERODOTUS and THUCYDIDES are primary. The *Life* by PLUTARCH is based on sources of various quality and must be used critically. Full discussions and a bibliography may be found in PETER GREEN, *The Year of Salamis, 480–479 B.C.* (1970), who uses and often disagrees with A.R. BURN, *Persia and the Greeks* (1962).

Theodoric the Great

As the Ostrogothic king of Italy from 493 to 526, Theodoric the Great was one of the most remarkable rulers of early medieval Europe. He conquered Italy, in which the control by the Roman Empire had disintegrated late in the 5th century, and ruled it peacefully for 33 years. His wish to impose racial harmony in his kingdom was the dominating feature of his rule and makes him uniquely great among the Germanic rulers who supplanted Roman administration in the West.

Theodoric was born about 454/455, the son of the Ostrogothic chieftain, Theodemir, and as a boy lived as a hostage in Constantinople, then the capital of the Eastern Roman Empire. Although he thus had some of the advantages of a Roman upbringing, he was said to have remained illiterate. This is undoubtedly an exaggeration: what is meant is that he never attained the skill in calligraphy that was expected of a ruler in the 5th and 6th centuries. At the time of his birth the Ostrogoths had recently escaped from the empire of the Huns, who had fiercely oppressed them, uprooting them from their homes in the Ukraine, transferring them to Pannonia, and taking away

Alinari

their grain. For more than 30 years after Theodoric's birth, the chief aim of the Ostrogoths was to find new land upon which they could settle and live in peace. In northern Pannonia they fought endlessly against other Germanic peoples, acted for and against the emperors at Constantinople, and sometimes received and sometimes were refused financial subsidies from the imperial government. On the death of his father in 471, Theodoric became his successor and soon led his people to new homes in Lower Moesia (in what is now Bulgaria), where they entered into relations, usually hostile, with another group of Ostrogoths led by Theodoric Strabo. Conditions in the Balkan provinces at this time were chaotic. Theodoric guided his people through the confusion with considerable skill but was unable to settle them safely and permanently on the land. The emperor Zeno gave him the title of patrician and the office of master of the soldiers and even appointed him as consul in 484; but in vain efforts to achieve his aims Theodoric frequently ravaged the imperial provinces and actually threatened Constantinople itself. In 488 Zeno ordered him to make his way to Italy, overthrow its barbarian ruler Odoacer, and govern the peninsula in the Emperor's name. With his people, who may have numbered 100,000 persons, Theodoric arrived in Italy in late August 489. In the following year he defeated Odoacer in three pitched battles and won control of nearly all Italy, but he could not take Ravenna, where Odoacer held out for more than three years. This war caused untold damage to city and country alike in northern Italy.

The circumstances of Odoacer's death illustrate the crueller side of Theodoric's character, a side he normally concealed. When the Ostrogoths had failed to take Ravenna, the two leaders agreed to govern Italy jointly, and Odoacer admitted Theodoric into the impregnable city on March 5, 493. In the palace of Lauretum ten days later, two Goths, pretending to be suppliants, suddenly seized Odoacer by the hands, and Theodoric cut him down with a sword. Theodoric went on to murder the dead man's wife and son and to massacre his followers remorselessly throughout northern Italy.

Theodoric's strengths and limitations

Whether Theodoric governed Italy as an independent king or as an official of the Roman emperor at Constantinople has been much debated. The truth appears to be that in theory he recognized the overlordship of the Eastern emperor; in practice, however, he was king both of the Romans and of the barbarians in Italy. In his official documents, he is simply "king" without qualification; he never defined of whom or of what he was the king. But there were some limits to his powers. He could not appoint legitimate consuls without confirmation by the emperor; he could issue edicts but not laws, though in practice there was little difference between the two; he could not confer Roman citizenship upon a Goth or appoint a Goth to a Roman civilian office or to the Senate; and his people could not legally intermarry with Romans. Early in his reign Theodoric put aside the skins or furs that Germanic rulers usually wore and surrounded his throne with something of Byzantine pomp. Unlike Odoacer, he dressed himself in the purple of the emperors.

Theodoric maintained peace in Italy throughout his 33-year reign. The Goths were settled in northern and central Italy, while Sicily and southern Italy as far north as Naples were free of them; but some of them lived in such overseas Ostrogothic dominions as Dalmatia and Pannonia. The Goths were divided from the Romans by language, for Gothic in the middle of the 6th century was both a spoken and a written language, used both for secular and for ecclesiastical matters. And they were further divided from the Romans by religion because they were Arian Christians, not Catholics, and they accepted the doctrines of the 4th-century heretical Gothic bishop Ulfilas.

Early in the 6th century Theodoric published his *Edict,* a collection of 154 rules and regulations. With one or two exceptions, these were not new laws but brief restatements in simple language of Roman laws that were already in existence. The *Edict* was a handbook issued for the convenience of judges, and it covered the cases that in the King's opinion were likely to come most frequently before the courts. The rules of the *Edict* applied to Goths as well as to Romans: in other words, the Goths were to be subject to Roman law, though not to Roman judges, and no provision was made for the recognition of their own national customs and usages. This was a discrepancy in Theodoric's policy of keeping Goths and Romans separate and of preventing fusion of the two nationalities.

Goths alone served in the army, and Romans were forbidden to carry arms. The Goths lived on the income of the estates on which they had been planted and also received an annual donative from the King. The warriors apparently went each year to Ravenna or wherever the King happened to be to receive the money from his own hand. On these occasions Theodoric would review the deeds of his troops, praising the brave and reprimanding the cowardly. Gothic soldiers on active service also received rations, either in kind or in the equivalent cash. Thus, the Ostrogoths of Theodoric's reign lived a very different life from that of their forebears, who had starved under the rule of the Huns; entering the Roman Empire and taking over one of its provinces had been profitable for them. The Romans of the kingdom continued to be governed by the old Roman civil service, which continued to exist more or less unchanged.

Preservation of racial harmony

The great aim of Theodoric's administration was to preserve harmony between Goths and Romans. He was never guilty of religious persecution. In his letters of appointment and elsewhere, he stressed above all else that the Goths must not oppress the Roman population, must not plunder their goods or ravage their fields, and must try to live amicably with them. He made endless high-minded appeals to the warriors to behave decently. He even stooped to point out that "it is in your interests that the Romans should be undisturbed, for while they enrich our Treasury they multiply your donatives." In fact, the animosity of the Gothic rank and file against the Romans was made clear over and over again, and no plea that might have held it in check was left unused by the King. He never missed an opportunity to propagate the idea of *civilitas* ("civilized life" or "civilization"), a concept that includes the maintenance of peace and order, racial harmony, and the outlawing of oppression and violence. "We do not love anything that is uncivilized," says one of his documents, "we hate wicked pride and its authors. Our Piety execrates men of violence. In a law suit let justice prevail, not the strong arm."

The end of Theodoric's reign was disgraced by the murder of the Roman scholar Boethius, which the King later regretted. Theodoric died on August 30, 526, and was buried in a remarkable tomb that still exists in Ravenna. He was succeeded by Athalaric, the son of his daughter Amalasuntha.

BIBLIOGRAPHY. No good biography of Theodoric has been published in English in recent years, and we must still rely

on THOMAS HODGKIN, *Italy and Her Invaders*, vol. 3–4 (1885), which, however, is excellent. See also WILHELM ENSSLIN, *Theoderich der Grosse* (1947), a sound, reliable work.

Theodosius I the Great

The Roman emperor Theodosius I (called the Great in Christian tradition) successfully maintained the unity of the disintegrating empire during his lifetime and greatly strengthened Christianity as the official religion of the state.

Giraudon

Theodosius I, detail from an embossed and engraved silver disk, late 4th century. In the Real Academia de la Historia, Madrid.

Background and youth. Theodosius was born January 11, 347 (possibly 346), near Cauca in the province of Gallaecia in northwestern Spain. His father was to become the general Flavius Theodosius; his mother's name is unknown. His grandparents, like his parents, were probably already Christians. Theodosius, who grew up in Spain, did not receive an extensive education but was intellectually open-minded and acquired a special interest in the study of history.

While on his father's staff, he participated in his campaigns against the Picts and Scots in Britain in 368–369, against the Alemanni in Gaul in 370, and against the Sarmatians in the Balkans in 372–373. As a military commander in Moesia, a Roman province on the lower Danube, he defeated the Sarmatians in 374. When his father was sentenced to death and executed as a result of political intrigues by enemies at court, Theodosius withdrew to his Spanish estates. At the end of 376, he married Aelia Flacilla, also a Spaniard. His first son, the future emperor Arcadius, was born in 377, and his daughter Pulcheria in 378. Immediately after the catastrophic defeat of the emperor Valens, who perished at the hands of the Visigoths and other barbarians on August 9, 378, near Adrianople, the emperor Gratian unexpectedly summoned Theodosius to his court. When Theodosius had once again proved his military ability by a victory over the Sarmatians, Gratian proclaimed him coemperor on January 19, 379. His dominion was to be the eastern part of the empire, including the provinces of Dacia (present-day Romania) and Macedonia, which had been especially infiltrated by barbarians in the preceding few years.

First years as emperor. In 379 and 380 Theodosius resided chiefly in Thessalonica. He sought first to rebuild the army, the discipline of which was considerably impaired, and to consolidate Rome's position on the Balkan peninsula. Military unpreparedness could not be overcome by conscription alone, which applied only to certain classes. Theodosius therefore directed that large numbers of Teutons, who had been barred from military service, be accepted by the army. By 379, however, when foreigners had already intermingled extensively with the rest of the army, both among the troops and in all ranks of the officer corps, Theodosius did no more than many of his predecessors to encourage this process. In contrast to the West, in Theodosius' provinces both Romans and Teutons were among the leading generals.

Recognizing that the barbarians, who had invaded the provinces as early as 375, could no longer be expelled by force and that he could count on Gratian for only limited assistance, Theodosius sought new possibilities for coexistence. This resulted in the friendly reception of the Visigoth Athanaric in 381 and the conclusion of a treaty of alliance, or *foedus*, with the main body of the Visigoths in the fall of 382. The Goths, who pledged themselves to lending military assistance, were assigned territory for settlement between the lower Danube and the Balkan mountains. Under this novel arrangement, an entire people was settled on imperial soil while retaining its autonomy. Theodosius may have hoped that the Goths would become integrated, as had a group of Goths who in *c.* 350 had settled near Nicopolis in Moesia; their leader, Bishop Ulfilas, undertook missionary work among the parties to the *foedus* of 382.

Treaty of alliance with the Visigoths

Some historians have regarded Theodosius as biassed in favour of the Goths. He has even been accused of having contributed decisively, through the treaty of 382, to the downfall of Rome. Yet, it should be noted that the policy of that treaty, which was undertaken in the justified expectation of raising Roman military strength and recultivating tracts of wasteland, by no means became customary. Instead, the Emperor took strict measures against further invasions by Teutonic bands and did not permit any doubts to arise as to Roman claims of superiority over the barbarians.

Theodosius' situation was complicated by the sharp antagonism that arose around 379 between disciples of the Nicene Creed (according to which Jesus Christ is of the same substance as God the Father) and several other Christian groups in his part of the empire. Theodosius himself, the first emperor who did not assume the title of *pontifex maximus* (supreme guardian of the old Roman cults), believed in the Nicene Creed, despite his Baptism only after a serious illness in the fall of 380. Out of political as well as religious motives, he energetically undertook to bring about unity of faith within the empire. His position was improved by the fact that during 379 the followers of the Nicene Creed gained ground, whereupon Theodosius on February 28, 380, without consulting the ecclesiastical authorities, issued an edict prescribing a creed that was to be binding on all subjects. Only persons who believed in the consubstantiality of God the Father, Son, and Holy Spirit were henceforth to be considered Catholic Christians, a designation that here appears for the first time in a document.

First designation of Catholic Christians

There is no doubt that the principle of religious intolerance was proclaimed in this edict. When assessing the edict, however—which should not be viewed simply as an isolated measure—it must be remembered that to the Christians Theodosius was emperor by the grace of God. While thus committed to defend the true faith, he by no means carried out his stated intention by force. The creed, prescribed in 380, was again defined at the beginning of 381 and ecclesiastically sanctioned, as it were, by a church council summoned to Constantinople by Theodosius in the summer of 381. That gathering is considered the second ecumenical council. The Symbolum Nicaeno-Constantinopolitanum (*i.e.*, the Niceno-Constantinopolitan Creed [or Symbol]), which is still used by most Christians, along with the ranking by the council fathers of the bishop of Constantinople directly after the bishop of Rome, can thus be traced back to Theodosius. Henceforth, the emperor's authority in matters of faith was to be recognized by the bishops of the East. There is no ground, however, for speaking of a rigidly organized imperial church controlled by the emperor.

The period when Theodosius stayed mainly in Constantinople, dating from the end of 380 to 387, is that to which most of his measures to improve the capital may be attributed. The plan for the Forum Tauri, the largest public square known in antiquity, designed after the model of Trajan's Forum in Rome, is outstanding. It is unclear, however, to what extent the Emperor encouraged the flowering of art and literature in his time.

The middle years. In 383, Maximus, a Spaniard who had been proclaimed emperor by the troops in Britain, asserted himself as ruler in the Western provinces (*praefectura Galliarum*). Suspicions that Theodosius was in collusion with the usurper and thus implicated in the death of Emperor Gratian in August 383 are unfounded. Theodosius, who had to acknowledge the sovereignty of Gratian's stepbrother Valentinian II, born in 371 and the nominal ruler in Italy since the end of 375, could not interfere with Maximus, for he lacked both sufficient military strength and secure borders. Yet, when Maximus invaded Italy in 387 and Valentinian was forced to flee to Thessalonica, Theodosius soon decided upon countermeasures. His decision was perhaps hastened through the influence of Valentinian's mother, whose daughter Galla he had married at the end of 387, having been a widower since 386. Theodosius' position by that time had become stronger. Long-standing negotiations with the Persians over the division of power in Armenia had resulted in a treaty that was to become the basis for a long period of peace on the eastern border. Having ordered one army division from Egypt to Africa and sent Valentinian with a fleet to Italy, Theodosius set out in the spring of 388 with the main body of troops to move against Maximus' army, which had invaded Pannonia in the Balkans. By July the enemy was defeated. When Maximus surrendered at the end of August he was branded as a usurper, but his followers were generally treated with leniency.

War against Maximus

In the same year, Theodosius again relinquished the West to his coemperor Valentinian but secured his own influence by placing the Frankish general Arbogast, a man he trusted, at Valentinian's side as principal adviser. By remaining in Italy until the spring of 391, where he resided mostly in Milan, Theodosius emphasized his claim to supreme authority throughout the empire. In 389 he visited Rome, where, accompanied by his four-year-old son Honorius, he made a triumphant entry. In Milan, Theodosius found in Bishop Ambrose an ecclesiastic who was intent upon cooperating effectively with the Emperor and even upon forming a friendship with him, although Ambrose pointed out to Theodosius the limits of the power of temporal rulers more clearly than had others. A conflict had already arisen between them in 388 over Theodosius' punishment of orthodox fanatics who had set fire to a synagogue and to the shrine of a sect. As a devout Christian, Theodosius finally acceded to the Bishop's wishes in the matter but took pains to make him understand that he was not willing to grant the Bishop greater influence in affairs of government.

A new conflict arose in 390 when, following the murder of one of his generals in Thessalonica, Theodosius issued an order for brutal retaliation. It was rescinded too late, so that a horrible massacre resulted among the population there. Ambrose had the Emperor's action condemned in a church council and bade him do public penance. After a prolonged hesitation, Theodosius complied with the order and was readmitted to communion at Christmas 390. His penance should not be construed as a victory of the church over the Emperor but only as a demonstration of the power of atonement over the penitent sinner. The claims that arose in future centuries that the church had been placed above the temporal power derived not from Theodosius' act of penance but only from the myth generated by it. Although Theodosius had gained an important ally in Ambrose, he continued intent on preserving the emperor's authority in the face of Ambrose and other bishops. While maintaining an entirely friendly attitude toward the church, Theodosius still took care in his legislation to see that the material interests of the state were sacrificed only to a very limited extent to church or clergy. In addition, Theodosius decided to enforce more strongly against the pagans the religious policy he had pursued since 379. In February 391 he prohibited sacrifices and the visiting of temples. Up to that time, he had basically tolerated the pagans and had entrusted adherents of the old cults with the highest offices.

Significance of Theodosius' penance

Quarrels between his second wife Galla and his son Arcadius, as well as his own view of the eastern capital as the centre of the empire, prompted Theodosius to move his residence back to Constantinople, where he arrived in November 391.

Victory over pagan usurpers. A new crisis arose for Theodosius three months after Valentinian's death on May 15, 392. Arbogast treacherously proclaimed as emperor of the West a former rhetoric teacher, Eugenius, who had close connections with the pagan aristocracy of the Senate. Theodosius, who did not yet dare to risk a civil war, delayed reception of a legation requesting recognition of Arbogast's puppet. On November 8, 392, he made his edicts of 391 more stringent by completely prohibiting the worship of the pagan gods. He left no further doubts as to his position when he elevated his son Honorius to Augustus in January 393 and thereby demonstrated that he would no longer tolerate any emperor other than himself and his sons. Because he still refrained from military action, his enemies occupied Italy in the spring of 393. Led by Nicomachus Flavianus, the forces striving to preserve the pagan cults gathered around Eugenius.

The now inevitable struggle for power was thus at the same time a struggle that would decide whether pagan religions would once again be tolerated within the empire alongside Christianity. Theodosius did not set out from Constantinople until May 394. As in 388, he made his way toward the Danube and then the Sava with his powerful army. His force consisted largely of barbarians and their allies, one of whose heads was Stilicho, a man of Vandal origin who had been married since 384 to the Emperor's niece Serena. Theodosius' sons Arcadius and Honorius stayed behind in the capital. Arcadius, who had been given the right to promulgate laws independently, was supposed to direct the government in the East.

War against Eugenius

Theodosius first met the enemy at the Frigidus River on the eastern border of Italy. Although Theodosius' advance guard, composed almost entirely of Visigoths, suffered heavy losses during an attempted breakthrough on September 5, 394, the Emperor ventured to attack the following day and was victorious. Later Christian tradition, emphasizing Theodosius' piety and trust in God, essentially interpreted the victory as a divine judgment: the god of the Christians had triumphed over the old Roman gods. After the deaths of Eugenius, Arbogast, and Nicomachus Flavianus, Theodosius showed himself lenient and strove to achieve the settlement between opposing forces necessary to strengthen imperial unity.

Probably as a result of the exertion of the campaign, Theodosius fell ill. He went to Milan, where he summoned Honorius in order to present him formally as Augustus of the West. Because Theodosius had appeared to recover, his death on January 17, 395, was generally unexpected. On his deathbed he had entrusted Stilicho, promoted to generalissimo after the victory at the Frigidus, with the care of his two sons. From Ambrose's funeral oration, filled with praise of the Christian ruler, it is evident that contemporaries had no doubt as to the continuing unity of the empire, for the question of succession seemed to have been settled in the best possible way. Yet, all too soon it was to become apparent that Theodosius had not chosen his advisers with sufficient care and that the men who were guiding the sickly Arcadius were unwilling to cooperate with Stilicho, who remained loyal to the dynasty. After his death, Theodosius' body was borne in state to Constantinople and interred in the mausoleum erected by Constantius II.

ENSSLIN, *Die Religionspolitik des Kaisers Theodosius d. Gr.* (1953), is fundamental for Theodosius' religious policy; it can be supplemented by N.Q. KING, *The Emperor Theodosius and the Establishment of Christianity* (1961). The Emperor's Gothic policy, especially in the light of contemporary sources, is discussed by M. PAVAN in *La politica Gotica di Teodosio nella pubblicistica del suo tempo* (1964). Useful information may also be found in J.B. BURY, *History of the Later Roman Empire*, new ed., vol. 1 (1923); and A.H.M. JONES, *The Later Roman Empire, 284–602*, 2 vol. (1964).

(A.Lip.)

Theology

Theology, meaning literally the study of God, is a discipline of religious thought that is restricted in its narrower sense, because of origination and format, to Christianity, but in its broader sense, because of its themes, to other religions. The themes of theology are God, man, the world, salvation, and eschatology (or the study of last times).

Nature of theology. The concept of theology that is applicable as a science in all religions and that is therefore neutral is difficult to distill and determine. The problem lies in the fact that theology as a concept had its origins in the tradition of the Greeks but that it obtained its content and method only within Christianity. Thus, theology, because of its peculiarly Christian profile, is not readily transferable in its narrow sense to any other religion. In its broader thematic concerns, theology as a subject matter is germane to other religions.

The terminological problem

The Greek philosopher Plato (*c.* 428–348/347 BC), with whom the concept emerges for the first time, associated with the term theology a polemical intention—as did his pupil Aristotle. For Plato theology described the mythical, which he allowed may have a temporary pedagogical significance that is beneficial to the state but is to be cleansed from all offensive and abstruse elements with the help of political legislation. This identification of theology and mythology also remained customary in the later Greek thought. In distinction to philosophers, "theologians" (as, for example, the poets of myth—*e.g.*, the 8th-century-BC Greeks Hesiod and Homer—or the cultic servants of the oracle at Delphi [Greece] and the rhetors of the Roman cult of emperor worship) testified to and proclaimed that which they viewed as divine. Theology thus became significant as the means of proclaiming the gods, of confessing to them, and of teaching and "preaching" this confession. In this practice of "theology" by the Greeks lies the prefiguration of what later would be known as theology in the history of Christianity. In spite of all the contradictions and nuances that were to emerge in the understanding of this concept in various Christian confessions and schools of thought, a formal criterion remains constant: theology is the attempt of adherents of a faith to represent their statements of belief consistently, to explicate them out of the basis (or fundamentals) of their faith, and to assign to such statements their specific place within the context of all other worldly relations (*e.g.*, nature and history) and spiritual processes (*e.g.*, reason and logic).

Limitations

Here, then, the above indicated difficulty becomes apparent. In the first place, theology is a spiritual or religious attempt of "believers" to explicate their faith. In this sense it is not neutral and is not attempted from the perspective of removed observation—in distinction to a general history of religions. The implication derived from the religious approach is that it does not provide a formal and indifferent scheme devoid of presuppositions within which all religions could be subsumed. In the second place, theology is influenced by its origins in the Greek and Christian traditions, with the implication that the transmutation of this concept to other religions is endangered by the very circumstances of origination. If one attempts, nevertheless, such a transmutation—and if one then speaks of a theology of primitive religions and of a theology of Buddhism—one must be aware of the fact that the concept "theology," which is uncustomary and also inadequate in those spheres, is applicable only to a very limited extent and in a very modified form. This is because some Eastern religions have atheistic qualities and provide no access to the *theos* ("god") of theology. If one nonetheless speaks of theology in religions other than Christianity or Greek religion, he implies—in formal analogy to what has been observed above—the way in which representatives of other religions understand themselves.

Relationship of theology to the history of religions and philosophy. *Relationship to the history of religions.* If theology explicates the way in which the believer understands his faith—or, if faith is not a dominating quality, the way in which a religion's practitioners understand their religion—this implies that it claims to be normative, even if the claim does not, as in Hinduism and Buddhism, culminate in the pretention to be absolutely authoritative. The normative element in these religions arises simply out of the authority of a divine teacher, or a revelation (*e.g.*, a vision or auditory revelation), or of any other kind of spiritual encounter over against which one feels committed. The newly evolving discipline of the history of religions, which encompasses also religious psychology, religious sociology, and religious phenomenology as well as philosophy of religion, has emancipated itself from the normative aspect in favour of a purely empirical analysis. This empirical aspect, which corresponds to the modern conception of science, can be applied only if it functions on the basis of objectifiable (empirically verifiable) entities. Revelation of the kind of event that would have to be characterized as transcendent, however, can never be understood as such an objectifiable entity. Only those forms of religious life that are positive and arise out of experience can be objectified. Wherever such forms are given, the religious man is taken as the source of the religious phenomena that is to be interpreted. Understood in this manner, the history of religions represents a necessary step in the process of secularization. Nevertheless, it cannot be said that theology and the history of religions only contradict one another. The "theologies"—for want of a better term—of the various religions are concerned with religious phenomena, and the adherents of the religions of the more advanced cultures are themselves constrained—especially at a time of increasing cultural interdependency—to take cognizance of and to interpret theologically the fact that besides their own religion there are many others. In this regard, then, there are not only analytical but also theological statements concerning religious phenomena, particularly in regard to the manner in which such statements are encountered in specific primitive or high religions. Thus, the objects of the history of religions and those of theology cannot be clearly separated. They are merely approached with different categories and criteria. If the history of religions does not surrender its neutrality, since such a surrender would thereby reduce the discipline to anthropology in an ideological sense (*e.g.*, religion understood as mere projection of the psyche or of societal conditions), theology will recognize the history of religions as a science providing valuable material and as one of the sciences in the universe of sciences.

Contributions of the history of religions to theology

Relationship to philosophy. The relationship of theology to philosophy is much more difficult to determine, because it is much more complicated. The problems can here only be mentioned. If one does not adhere to the narrow concept of philosophy that reduces it positivistically to logic or epistemology (theory of knowledge) but rather understands philosophy as the discipline that attempts to explicate the totality of being, the difference between this latter interpretation of philosophy in relation to theology becomes apparent. If theology is responsible to an authority that initiates its thinking, speaking, and witnessing—*e.g.*, a document containing revealed truth, as well as the spiritual testimony related to it—philosophy bases its arguments on the ground of timeless evidence, an evidence with which autonomous reason understands itself to be confronted. Since, on the other hand, theology also uses reason and systematically develops its tenets—however much its critical reflections are based on religious convictions—there are many common areas that have partly complementary significance but that partly also lead to polemical tensions.

The significance of theology. *The religious significance of theology.* Just as in the case of religions themselves, so also their theological reflections are not limited to a special religious sphere, separated from common life. Whoever speaks of God and the gods speaks at the same time of man and of the meaning of existence. He makes therewith statements about the world, its conditions of being created, its estrangement from the purpose of creation (*e.g.*, sin), and its determined goal (eschatology or view of the last times). Out of these state-

The scope of theological reflections

ments result normative directives for life in the world, not only for the purpose of gaining access to salvation but also for concrete ethical behaviour in the context of the I-Thou (or person to person) relationship, of the clan, of the nation, and of society. In ancient times, all aspects of life (*e.g.*, relationship between the sexes, hygiene, work, and other aspects) were determined religiously and permeated by cultic forms and practices. In this regard, every religion contains the totality of being that its "theology" intends to express—if one also includes certain rudiments of reflection in primitive religion in the concept "theology."

In primitive religions the tribe represents the pivot around which all world relations turn. The primeval (or mythical) time to which the tribe traces its own origins is also the time of salvation and fulfillment. Therefore, primitive religions primarily concern themselves with the ancestral cult. Involved in tribal concerns in the realm of religious thought are conceptions of *mana* (spiritual power, or force); *i.e.*, the teaching that tribal heads, medical men, and sorcerers are subjects of special charisma (spiritual power or influence) and more potent powers of life. In Eastern religions, as in Western religions, this understanding is infinitely refined, developed, and theologically reflected. In regard to the relationship of man to the world, many Eastern religions (especially Hinduism) have a definite skeptically tinged negative view of all reality, which is especially pronounced in contrast to the Christian doctrine of creation. Though this doctrine points to a "happy event" in Christianity, the call to life and reality is understood in Eastern thought in the opposite manner:

Man and the world

> To be man implies being cut off from all true reality. Creation should have never happened, and its faults should be eliminated as soon as possible . . . The illusion that I am is a calamity. Not death is to be explained, but rather birth. (Stephen Neill).

The cultural importance of theology. Since theology does not remain restricted to transcendent statements and to an esoteric and sacred realm, and since it rather encompasses all worldly dimensions (cosmology, anthropology, historiology, and other areas), it has always had important significance for cultural evolution and general intellectual life. Western historians hardly need to be reminded of the fact that the Old Testament prophetic theology of history (*e.g.*, the 8th-century-BC Hebrew prophets Amos and Isaiah) has decisively influenced the origins of the concept "history" and, indeeed, has made this concept possible in the first place. On Old Testament theology of history is based the understanding of history as a linear process, as directed to a goal (*i.e.*, the Kingdom of God) and qualified by the characteristic of singularity. This view of history contrasts with a cyclical understanding of successive events; *i.e.*, the view that history repeats itself. The fact that university and school were originally initiated by the church (as is still very often the case in mission fields) is based on the fact that theology has thematized in its various subjects the various dimensions of life (nature, history, ethics, and other disciplinary areas). Also, much of modern philosophy has emerged out of theological themes and categories—in such modern thinkers as the existential philosophers Martin Heidegger and Jean-Paul Sartre and even in the Communist thinker Karl Marx remnants of this fact are still observable. Modern philosophy has, by and large, only gradually emancipated itself from this theological origin, but this emancipation also took place in a manner that retained the dialectical relationship of theology and philosophy. That theological questions in the modern age of secularism are less openly posed than in the time of the Middle Ages does not reduce their lasting significance. They always re-emerge, often in disguised form, such as in the quest for the meaning of life and existence or in the nihilistic resignation over against that quest; furthermore, they re-emerge in the quest for the dignity of human existence, for the inviolability of life, the determination of human rights, and many other such questions. A theologian such as the German-American thinker Paul Tillich (1886–1965) has investigated specifically the secular realm in view of the relevance of these latent theological questions that are posed by modern man in his relationship to a constantly changing world.

The emergence of theological questions in a secular age

Theological themes. The themes discussed by theology are of universal dimensions. They encompass the doctrine of God, of man, and of the world. Even when no "doctrine of God" exists in the strict sense of the term, as in the case of what are sometimes called "atheistic" religions (*e.g.*, certain areas of Hinduism and Buddhism), man and the world are understood in the context of finality and therefore have religious aspects. The inclusion of the world in theological discussion also implies that behaviour in the world—that is, ethics—is included in theology; in some areas (*e.g.*, Confucianism) it gains a dominating position. Ethical conceptions—derived from theological concepts in the broad meaning of theology—are developed in contradictory forms: they can lead to ascetic world denial but also to a definite world affirmation. The first form is realized in Buddhism and Hinduism, the second in Confucianism. In Christianity both forms are represented. The theological theme of the relation of man and the world has been described by the 17th-century French scientist and thinker Blaise Pascal as the doctrine of the "dignity and poverty of man"—*i.e.*, the doctrine of creation and fall—and, related to this, the proclamation of salvation and the presentation of a path to salvation. This path leads, in the various religions, into greatly diverging directions. It can be placed under the exclusive direction of divine grace (as in Amida Buddhism and in Protestant Christianity); it can be left to the activity and initiative of man (as in Confucianism), or it can be characterized by a combination of both (as in Zen Buddhism and in the Roman Catholic combination of grace and merit). Finally, theology also includes among its various themes statements concerning the process and goal of history (eschatology), especially concerning the relation of secular history and history of salvation.

Functions of theology. The vastness of theological interests and aspects implies that theology can master the material with which it is confronted only within a broad spectrum of partial disciplines. Since theology is based on authority (revelation), and since this authority is documented in the Holy Scriptures (especially in Christianity), it is constrained to engage in philological and historical studies of these sources and, related to these studies, also with hermeneutical (critical interpretive) questions. This historical task broadens into a concern with the history and tradition of the religion that a particular theology represents. In this concern many difficult and controversial questions arise: whether and to what extent the canon (scriptural standard) of the sources of revelation is glossed over and modified by tradition and what normative value the modifying tradition has or should have. These problems play an important part in the relationship between Protestantism and Catholicism, even though the problems are also treated independently by each confession.

Controversial questions in theology

The question of truth posed by theology requires the constitution of a discipline that specifically concerns itself with fundamental questions (systematic theology). Its task can be determined in the following manner: (1) It has to develop the totality of religious teachings (dogmatics, or the doctrine of faith). (2) It has to interpret man's existence in the world and, related to this, to determine the norms (ethics derived from faith) for action in the world—*e.g.*, for the disposition toward one's fellow man and toward societal and political structures and institutions. (3) It further has to represent its claim to truth in the context of confrontation with other claims to truth and with other criteria of verification (apologetics, polemics). As part of this concern, theology's task is to explain reasonably, in view of historical relativism, the absolute claim of the truth that it represents. Related to this is the modern-day task of coordinating its doctrine of creation or its doctrine of the revelation of the transcendent (*e.g.*, the Christ event in Christianity) with the world view of modern natural science and its thesis of the immanency of being—*i.e.*, of being that is self-contained. Another aspect of this task is the confrontation with

other religions' claim to truth, which can lead to vastly different results: either—this is noted only as an example—it can lead to the thesis of the complementary positions of individual religions and therefore to tolerance (as for example in Hinduism as well as in some schools in the West) or to one's own religion's claim to be absolute (as in Christianity, at least among the most important of its representatives). But also, in the last mentioned situation, such a claim is widely modified. It can manifest itself by a total rejection of other religions as "devil's work," but it can also understand other religions as first steps to and as seeds of a religious development, the completion of which it knows itself to be.

The vast dimension of theological themes implies that theology is, with its many disciplines, a microcosmic image of the university. Even though it is a science in which the believer or the adherents of a religion explicate and critically analyze the truth that is represented by them, it nevertheless has to remain free within the framework of this committment, and it has to fulfil the responsibility of its scientific task on the basis of its own autonomy. The opposite of this freedom would arise when an institution (*e.g.*, the church) restricts this freedom with normative claims, forcing it therewith to assume ideological functions. The struggle concerning the freedom and limitations of theology—*i.e.*, concerning responsible criticism and authority—is a struggle that has accompanied the history of theology from the very beginnings to the present.

BIBLIOGRAPHY. FRIEDRICH SCHLEIERMACHER, *Schleiermachers kurze Darstellung des theologischen Studiums*, 2nd ed. (1830; Eng. trans., *Brief Outline on the Study of Theology*, 1850 and later), is still the best picture of theology as a whole and all its parts. KARL RAHNER and HERBERT VORGRIMLER, *Kleines theologisches Wörterbuch* (1961; Eng. trans., *Theological Dictionary*, 1965); and JOHN MACQUARRIE, *Twentieth-Century Religious Thought* (1963), together cover a vast range of topics and themes of theology, past and present. GERHARD VON RAD, *Theologie des Alten Testaments*, 2 vol. (1957–60; Eng. trans., *Old Testament Theology*, 2 vol., 1962–65); and RUDOLF BULTMANN, *Theologie des Neuen Testaments*, 2 vol. (1948–53; Eng. trans., *Theology of the New Testament*, 2 vol., 1952–55; 1-volume edition, 1965), are the most important texts dealing with Holy Scripture in modern times. MIRCEA ELIADE, *Le Mythe de l'éternel retour* (1949; Eng. trans., *Cosmos and History*, 1959); and OSCAR CULLMANN, *Christus und die Zeit*, 3rd rev. ed. (1962; Eng. trans., *Christ and Time*, 3rd rev. ed., 1962), deal with Christianity as a historical religion in contrast to non-historical interpretations of religion. ADOLF VON HARNACK, *Lehrbuch der Dogmengeschichte*, 3rd ed., 3 vol., 1893; Eng. trans., *History of Dogma*, 7 vol., 1900, reprinted 1961), is the classic study of the history of Christian theology in relation to Greek thought. The new disciplines of religious study, namely, the history and the phenomenology of religions, are introduced and illustrated by RUDOLF OTTO, *Das Heilige*, 9th ed. (1922; Eng. trans., *The Idea of the Holy*, 2nd ed., 1957); and *The History of Religions: Essays in Methodology*, ed. by MIRCEA ELIADE and JOSEPH KITAGAWA (1959). Modern theology, from the 18th century to the present, is treated in contrasting new ways by KARL BARTH, *Protestant Thought from Rousseau to Ritschl* (Eng. trans. 1959) and *Church Dogmatics*, 4 vol. (Eng. trans. 1936–61); and PAUL TILLICH, *Perspectives on 19th and 20th Century Protestant Theology* (1967) and *Systematic Theology*, 3 vol. (1951–63), are exhaustive treatments of the most fully developed theologies in Catholic and Protestant churches.

(H.Th.)

Theosophy

Theosophy is a religious philosophy with definite mystical concerns that can be traced to the ancient world but is of catalytic significance in religious thought in the 19th and 20th centuries. The term theosophy is derived from the Greek *theos*, "god," and *sophia*, "wisdom" and is usually translated as "divine wisdom." The literal translation of the term, however, indicates its meaning only in a general sense. Confusion may be avoided by a recognition of two usages of the word. In modern times it has been widely identified with the doctrines promoted by the Russian-born religious mystic Mme Helena Petrovna Blavatsky (1831–91) through the Theosophical Society, founded by her and others in 1875. The term may also be employed in a more general sense to refer to a certain strain of mystical thought to be found in such thinkers as the Greek philosophers Pythagoras (6th century BC) and Plato (5th–4th century BC); the Gnostic teachers (adherents of a dualistic religious-philosophical movement) Simon Magus (1st century AD) and Valentinus (2nd century AD); the Neoplatonist philosophers Plotinus (3rd century AD) and Proclus (5th century AD); the medieval north European mystics Meister Eckehart (*c.* 1260–*c.* 1328) and Nicholas of Cusa (1401–64); the Renaissance speculative mystics Paracelsus (*c.* 1490–1541) and Giordano Bruno (1548–1600); the German philosophical mystic Jakob Böhme (1575–1624); and the German Romantic philosopher Friedrich Schelling (1775–1854). The wide variety of viewpoints represented suggests the looseness of such a usage. Modern theosophists follow Mme Blavatsky in claiming to have revived this ancient mystical tradition in the modern era.

General characteristics of theosophical speculation

Nature and significance. Despite its diversity, theosophical speculation reveals certain common characteristics. The first of these is an emphasis on mystical experience. Whether ancient or modern, theosophical writers have agreed that a deeper spiritual reality exists and that man may establish direct contact with that reality through intuition, meditation, revelation, or some other state transcending man's normal consciousness. A second emphasis is that of esoteric doctrine. A distinction between an inner, or esoteric, teaching and an outer, or exoteric, teaching is commonly accepted, and much attention is devoted to deciphering the hidden meaning concealed in sacred texts. Modern theosophists claim that all the historic world religions, including Christianity, contain such an inner teaching. A third interest is that in occult phenomena. Most theosophical speculation reveals a fascination with supernatural or other extraordinary occurrences and with the achievement of higher psychic and spiritual powers. It is held that knowledge of the divine wisdom gives access to the mysteries of nature and man's deeper being. A fourth characteristic is that of a preference for monism—the view that reality is constituted of one principle, such as mind or spirit. Despite a recognition of basic distinctions between the exoteric and esoteric, between the phenomenal world and a higher spiritual reality, and between man and the divine, which suggests dualism, most theosophically inclined writers have affirmed an underlying, all-encompassing unity that subsumes all differentiation. Finally, theosophical speculation shows an affinity for religious and philosophical conceptions identified with Asian thought. The striking similarities between certain theosophical and Oriental doctrines have led to vigorous scholarly debate, particularly with regard to ancient and medieval thinkers. Though some scholars have attributed these similarities to the diffusion of Eastern conceptions westward, most now argue for a parallel but independent development. There is, however, no question about the validity of the claim of direct Asian influence upon modern theosophical thought, since Mme Blavatsky lived in India for a number of years and often expressed admiration for Oriental doctrines.

History, beliefs, and practices. *Theosophical speculation before 1875.* The beginnings of theosophical speculation may be traced back at least to Pythagoras in the 6th century BC. He founded a religious brotherhood at Croton in southern Italy, where he taught such doctrines as the transmigration of souls, the unity of all forms of life, and the importance of ascetic purification. Elements of theosophical speculation have also been traced in Plato's thought and in such early religious movements as the pre-Christian Greek philosophical-mystical movement known as Orphism and the heretical 2nd-century Christian dualistic and esoteric form of Gnosticism. The connection of theosophical speculation and Gnosticism would seem especially important since the latter had much influence on the early Christian Fathers. The Gnostics regarded the material world as intrinsically evil and believed that deliverance would come only through spiritual enlightenment.

Classical theosophical speculation

Classical theosophical speculation may be said to have climaxed in the works of Plotinus in the 3rd century AD. Inspired by Plato and the teachings of the 2nd-century philosopher Ammonius Saccas (who, like many great reformers, left no writings), he developed the Neoplatonic philosophy; after the death of Plotinus, his student Porphyry gathered and published his teachings in the *Enneads* (Concerning the One). Plotinus conceived of reality as an ideal world consisting of three principles, or hypostases: the One (*to hen*), the Intellect (nous), and the Soul (psychē). The three principles formed a descending hierarchy. The One, or the Good, embodied the supreme sphere of being, beyond human comprehension, transcendent to all differentiations and forms, and yet the source of all. Man was viewed as potentially divine through his participation in the One; he might achieve mystical union with the One through contemplation and self-purification.

With the increasing ascendancy of an antimystical orthodox Christian viewpoint in Europe during the Middle Ages, theosophical speculation tended to decline for a time. It surfaced again in the 13th century, however, in the sermons and writings of the great German mystic Meister Eckehart. Trained in the Dominican order and always an avowed Christian, his views nevertheless reveal certain theosophic overtones. One of his major doctrines was the distinction between God conceived in personal terms and God as the ultimate reality, which he called the Godhead. Believing that all words must fail in describing God, he was driven to the use of a negative terminology, sometimes referring to the deity as "Nothing." A number of Western students have noted the remarkable parallels between this "negative theology" and the Advaita Vedānta (nondualistic) system of the 9th-century Indian philosopher Śaṅkara. Describing Brahman, the ultimate reality, the follower of Vedānta declares in almost identical words, *"neti-neti,"* "not this, not that"—*i.e.*, that it cannot be conceived or expressed in terms of finite, existing things.

The revival of classical learning during the Renaissance in Europe led to the rediscovery of the writings of Plato and Plotinus, which in turn apparently encouraged a new burst of theosophical speculation. Most notable were Nicholas of Cusa, Paracelsus, and Giordano Bruno, whose writings reflect the curious Renaissance fusion of mysticism and materialism. The result was a flowering of investigations in alchemy, magic, and occultism. In addition to Platonism (dealing with the nature of reality) and Neoplatonism (dealing with levels of reality), there was also an intense interest in the Kabbala (a widespread Jewish mystical movement) and Hermeticism (a Hellenistic mystical, occultic, astrological, and alchemical movement). Bruno went so far as to affirm that Christ had been a magus (magician) and that the Hermetic religion of the ancient Egyptians was superior to Christianity.

In the period since the Renaissance, the two most significant names are those of the shoemaker and mystic Jakob Böhme, who died in the early 17th century, and the 19th-century German Romantic philosopher Friedrich Schelling. Drawing upon intense personal mystical experiences, Böhme developed a conception of God as the *Ungrund*, the primal ground of being, and a dialectical conception of reality as the interplay of opposites. "In yes and no all things subsist," he declared. Though his voluminous writings seem to suggest acquaintance with Plotinus and Meister Eckehart, he apparently came to these views largely on his own. Significantly, he entitled one of his works, *Six Theosophic Points*; the term theosophic is applied to his views more often than to those of any other Western mystic. A more systematic thinker than Böhme, Schelling recast much of the theosophic viewpoint within an idealistic and Romantic framework. At the same time he reaffirmed the mystical premise of all theosophical speculation—*i.e.*, that God must be experienced, must be known directly to be known at all.

The relationship of opposites

It should be noted that theosophical speculation has not been confined to Western thought. Indeed, the richest and most profound source of such views has been Indian thought, where it may be traced from the earliest Vedas (Hindu scriptures involving nature mysticism) through the *Upaniṣad* (philosophical-speculative scriptures) and the *Bhagavadgītā* ("The Lord's Song") to modern times. Where the theosophic current has been but one among many currents in the West, it has been the mainstream of Indian thought. Elements of theosophy may also be found in the other Asian religions, especially in Islāmic Ṣūfism, Buddhism, and Taoism.

The Theosophical Society. Since 1875, theosophy has been largely identified with the Theosophical Society founded in that year in New York City by Helena Petrovna Blavatsky and Henry Steel Olcott. A woman of noble Russian descent, Mme Blavatsky had immigrated to the United States in 1873 after many years of travel and occultist investigations throughout Europe and the Middle East. Olcott (1832–1907), an American lawyer, newspaperman, and student of spiritualism, soon fell under her sway. The two moved to India in 1878, eventually establishing their base of operations at Adyar, near Madras, which still serves as the international headquarters for the Theosophical Society today. During the later 19th century, branch societies were established throughout much of India and in the major cities of Europe. Mme Blavatsky, meanwhile, authored a series of often obscure works that have since been accepted as classic expositions of theosophical doctrine; best known are her two-volume *Isis Unveiled*, published in 1877, and *The Secret Doctrine*, also in two volumes, published in 1888.

The Theosophical Society affirms the following objectives: (1) to form a nucleus of the universal brotherhood of humanity, without distinction of race, creed, sex, caste, or colour; (2) to encourage the study of comparative religion, philosophy, and science; and (3) to investigate unexplained laws of nature and the powers latent in man. The society insists that it is not offering a new system of thought but merely underscoring certain universal concepts of God, nature, and man that have been known to wise men in all ages and that may be found in the teachings of all the great religions. One of the society's most controversial claims concerns the existence of a brotherhood of Great Masters or Adepts, who, it is asserted, have perfected themselves and are directing the spiritual evolution of humanity.

According to Mme Blavatsky, a theosophist accepts three fundamental principles:

The fundamental principles of the Theosophical Society

1. An Omnipresent, Eternal, Boundless, and Immutable Principle on which all speculation is impossible, since it transcends the power of human conception and could only be dwarfed by any human expression or similitude. It is beyond the range and reach of thought—in the words of *Māṇḍūkya* (an *Upaniṣad*), "unthinkable and unspeakable."

2. The Eternity of the Universe *in toto* as a boundless plane; periodically "the playground of numberless Universes incessantly manifesting and disappearing," called "the manifesting stars," and the "sparks of Eternity."

3. The fundamental identity of all Souls with the Universal Over-Soul, the latter being itself an aspect of the Unknown Root; and the obligatory pilgrimage for every soul—a spark of the former—through the Cycle of Incarnation (or "Necessity") in accordance with cyclic and karmic (causal) law, during the whole term (from *The Secret Doctrine*).

In addition to these principles, most modern theosophists subscribe to a rather elaborate cosmogony (theory of the origin of the universe). There are, it is believed, seven worlds or planes through which the universe evolves. In ascending order these are the physical plane; the emotional, or astral, plane; the mental plane; the intuitional, or Buddhic, plane; the spiritual, or Atmic, plane; the monadic, or Anupadaka, plane; and the divine, or Adi, plane. As a phase of this evolutionary process, it is held that man undergoes the same septenary (sevenfold) progression, eventually reaching perfection. Reincarnation and karma (the law of cause and effect) govern the evolution. Man must expect to undergo a series of rebirths or reincarnations in the course of his spiritual ascent since the law of evolution is determined by karma. Each action, desire, or thought produces a result. This is not, it is insisted, a

fatalistic viewpoint; each man is free to choose his own course. One's future life, however, will be determined by the actions in the present life. The result is that "As a man soweth, so shall he also reap."

Despite its beginnings in America, the Theosophical Society almost expired in the United States in the years following Mme Blavatsky's and Olcott's removal to India. During the 1880s and 1890s it was revived by William Q. Judge (1851–96), an Irish-born American mystic, who succeeded in making the American section the most active unit in the international movement. The American wing, however, was to be repeatedly disrupted by schisms in later years. Following Mme Blavatsky's death in 1891, tensions rapidly escalated between Judge and Olcott, culminating in the secession of the American movement from Indian control in 1895. After Judge's death in 1896, Katherine Tingley (1847–1929) succeeded to the headship of the American section; at her instigation the American headquarters was transferred to Point Loma in California and the focus of the movement's work recast along more practical lines. In 1950–51 the headquarters was moved to Pasadena, California. A new schism developed, with still a third group claiming to represent theosophy in America. Such sectarianism has declined in recent years.

Though Judge came to dominate the American work after 1891, Olcott maintained an uneasy control over the international movement. Upon his death in 1907, he was succeeded as president in India by the magnetic Englishwoman Annie Besant (1847–1933), whose leadership gave Indians a sense of pride in that they were exporting ideas of importance to the West. A forceful writer, her many books still provide one of the best expositions of theosophical belief. In 1911 she proclaimed Jiddu Krishnamurti, an obscure Indian youth, as the vehicle of a coming World Teacher, an act that led to much controversy. Krishnamurti subsequently renounced any claims to being a World Teacher and entered upon a career of writing and teaching. Since the 1920s he has spent much time in the United States and Europe, where his books have enjoyed considerable popularity. Though theosophical societies continue to exist, they have lost much of the vitality of their early years; the total membership of all divisions today is relatively small—*e.g.*, the Theosophical Society in America, with headquarters in Wheaton, Illinois, numbers about 5,000.

Influence of the Theosophical Society

Conclusion. The influence of the Theosophical Society has been rather significant, however, despite its small following. The movement has been a catalytic force in the 20th-century Asian revival of Buddhism and Hinduism and a pioneering agency in the promotion of greater Western acquaintance with Eastern thought. In the United States it has influenced a whole series of religious movements, including the Mighty I Am movement, Rosicrucianism, the Liberal Catholic Church, Psychiana, Unity, and sections of the New Thought movement. In the estimation of some scholars, no other single organization has done more to popularize Asian religious and philosophical ideas in the West than the Theosophical Society (see also NEW THOUGHT).

BIBLIOGRAPHY. Two classic works on Western mysticism that include much material relevant to an understanding of theosophical speculation are: EVELYN UNDERHILL, *Mysticism* (1911), and WILLIAM RALPH INGE, *Christian Mysticism* (1899). More recent studies include: RUDOLF OTTO, *Mysticism, East and West* (1932); SARVEPALLI RADHAKRISHNAN, *Eastern Religions and Western Thought* (1939); and R.C. ZAEHNER, *Mysticism, Sacred and Profane* (1957). For the Theosophical Society, see the old but still valuable account in J.N. FARQUHAR, *Modern Religious Movements in India*, pp. 209–291 (1915); for a recent full-scale history, see *The Theosophical Movement, 1875–1950* (1951). GERTRUDE WILLIAMS, *Priestess of the Occult: Madame Blavatsky* (1946), provides a modern critical biography of the central figure in the movement. For an exposition of the doctrines of the Theosophical Society, see MADAME BLAVATSKY, *The Secret Doctrine* (1888), and *The Key to Theosophy* (1889); ANNIE BESANT, *The Ancient Wisdom* (1897); and C.W. LEADBEATER, *An Outline of Theosophy* (1902). C.W. BRADEN, *These Also Believe* (1949), gives an excellent brief summary of the teachings. ALDOUS HUXLEY, *The Perennial Philosophy* (1946), provides evidence that theosophical thought remains very much alive in the 20th century.

(C.T.J.)

Therapeutics

Therapeutics, as the treatment and care of a patient for the purpose of combatting disease or injury, is concerned with the total management of the patient, including the supervision of diet and fluid intake; the employment of symptomatic and supportive measures to relieve pain and ease discomfort; the administration of drugs, vaccines, and antitoxins; the surgical repair or removal of diseased parts; the supply of artificial or natural tissues and organs; the use of drugs or irradiation; the application of physical agents such as heat and remedial exercises; nursing care; psychiatric treatment; the provision of activity for the development of muscle strength and motor skills; and the application of human sympathy and understanding, as well as the deployment of social services to cope with the social consequences and hardships with which disease is so frequently associated.

Classification by body systems and structures. Textbooks of therapeutics are segregated into those dealing with medical and those with surgical treatment. They deal with the various aspects of treatment primarily according to the body systems and structures. Thus, in books of medical treatment, besides chapters dealing with principles of treatment, antimicrobial therapy, corticosteroid therapy, and infectious diseases and immunization, there are chapters on diseases of the blood, diseases of the reticuloendothelial system, and leukemia; bleeding disorders and thrombosis; diseases of the heart and circulation; diseases of the alimentary tract; renal (kidney) diseases and disturbance of acid–base balance; metabolic and nutritional diseases; diseases of the nervous system; psychiatric diseases; diseases of the endocrine (ductless) glands; disorders of connective tissue, muscles, and joints; respiratory diseases; diseases of the skin; diseases of the eye; tropical diseases and infestations; venereal diseases; diseases of children; and domestic and industrial poisoning. Textbooks of medical therapeutics include advice on the prevention and management of diseases induced by drugs. Surgical treatment is generally considered in separate textbooks, and radiation therapy is generally included as a part of surgical treatment in textbooks.

Types of therapeutics

Classification by techniques. Therapeutics can also be considered under the various techniques and materials used, such as drugs, irradiation, surgery, physical therapy, occupational therapy, psychiatric treatment, and social therapy. This is the pattern that will be followed for the most part in this review. The most important and potent part of medical treatment is drug therapy, or clinical pharmacology.

Pharmacology embraces the physical and chemical properties, biochemical and physiological effects, mode of action, absorption, distribution, and excretion of drugs, and their therapeutic uses. The physician is interested not only in drugs that are useful in the prevention, diagnosis, and treatment of human disease—that is, in pharmacotherapeutics—but he is naturally also concerned with the biochemical and physiological effects of drugs and their mechanism of action and interaction—that is, pharmacodynamics.

The science of therapeutics. Medicine began with the Greeks, and the Greek physician Hippocrates (400 BC) is generally considered to have been the "father of medicine." Until as late as the latter part of the 19th century, therapeutics was entirely empirical and largely directed toward the relief of symptoms. At this time advances in experimental pathology and pharmacology began to establish therapeutics on a rational basis. Nevertheless, authority, tradition, and prejudice prevented the correct assessment of the value of many specific forms of therapy until the advent of the controlled clinical trial near the midpoint of the 20th century. In setting up such trials, researchers face the fact that two factors tend to prejudice the correct assessment of any form of treatment. The

Controlled clinical trial

first is the psychological effect on a patient of taking drugs, and the second is the observer error of the physician. The simple act of taking medicine may seem to be sufficient to improve the health of many persons, and the beneficial effects of treatment are likely to be more marked in persons with favourable attitudes toward doctors and medicine in general than in those who are skeptical. This is why in any clinical trial it is important that so-called dummy tablets with no pharmacological effect be introduced. Such a trial is called a blind trial. Doctors, too, are capable of suggesting to themselves that pharmacological effects have arisen from a dummy tablet, and if a doctor is involved in a therapeutic trial of a drug about which he is enthusiastic he is likely to make errors in assessing symptomatic improvement in patients known to have taken the drug. It is a natural wish of every doctor that his treatment should be successful, and this may even be projected into the conversation with the patient when he attempts to convince the patient that he has improved. Ideally, therefore, the assessing doctor should be unaware of which person in the trial is receiving an active drug and which is receiving the dummy tablet. Such a trial is called a double blind trial. Such complicated therapeutic trials were not necessary to establish the value of insulin in diabetes mellitus, streptomycin in tuberculosis, or penicillin in pneumonia. The value of these drugs was immediately apparent. Therapeutic problems are usually more complex, however, and a common problem is to assess the advantages of various types of drugs over their predecessors. If methods of treatment can be assessed in comparable groups of patients in a double blind fashion, the efficacy of a drug can be scientifically established. This is now common practice in the assessment of new forms of therapy that can be compared either with the previously established form of therapy or, if there is doubt about the efficacy of the previous form of treatment, with a dummy form of treatment.

Sources of drugs

In the early part of the 20th century most drugs were either (1) vegetable drugs obtained from leaves, roots, seeds, or barks—*e.g.*, belladonna (the active principle of which is the alkaloid atropine) and foxglove (the active principle of which is the glycoside digoxin); (2) mineral salts such as ferrous sulfate, potassium bromide, sodium chloride, or calcium gluconate; (3) animal products such as insulin, thyroid extracts, and animal extracts of some pituitary hormones, such as adrenocorticotrophic hormone.

More recently it has become possible to synthesize drugs, and most drugs used today do not occur in nature but are the product of the synthetic chemist.

Types of action

Mechanisms of drug action. Most drugs produce their effects by combining with enzymes, cell membranes, or other specialized functional components of cells called receptors. Interaction between drug and body cell alters the function of some cell component and causes biochemical or physiological effects. Subsequent events are called the effects of the drug. Drugs frequently have multiple effects. Digitalis, for example, affects three fundamental processes in the heart: there is an action on the contractile protein of the heart muscle fibre, an effect on the passage of electrolytes (substances that in solutions separate into positive and negative ions) through the muscle fibre membrane, and an effect on the utilization of energy by the muscle cell. Thus many drugs alter the course of disease by stimulating or depressing biochemical processes or physiological functions. Such drugs are called pharmacodynamic agents. Other drugs have effects on bacteria, viruses, or parasites without any significant effect on man: these drugs are called antimicrobial or chemotherapeutic agents.

Routes of administration of drugs. Drugs may be given (1) by mouth, (2) by injection into muscle tissue or subcutaneously (under the skin), or (3) by injection into a vein.

Drugs are usually given by mouth, and a few are absorbed in the mouth, but most are swallowed and absorbed through the stomach or small intestine. Occasionally a drug may be given as a suppository and absorbed through the rectum.

When a drug is given by injection into muscle tissue, its absorption is more rapid and more predictable, which is an advantage when patients are unconscious or uncooperative. Strict precautions are necessary to avoid introducing infection. Drugs can be injected subcutaneously (beneath the skin) if they are not irritants, which has the advantage that the patient can give himself the injection, as many diabetics do with their insulin. Intramuscular injections are given deep into muscle tissue, and it is almost impossible to use this method on oneself.

Intravenous injections are given directly into a vein, and only aqueous solutions of drugs are given in this way, which offers the advantage of a quick effect, particularly desirable when inducing anesthesia. On the other hand, the rapid access into the circulation makes the method dangerous enough that it is reserved for emergency situations or when a rapid effect is essential.

Decisions involved in the formulation of therapeutic regimen

THE ACTIVITY STATUS TO BE ASSIGNED

Before the advent of specific forms of therapy and before techniques were available for the study of the body's responses to disease, it was generally accepted that rest was beneficial in almost all disease states. During the past third of a century this view has been questioned, and it is now believed that rest, like all other facets of therapy, should be prescribed only when its advantages can be demonstrated. The benefits of rest can be summarized as follows:

1. Rest reduces the tissue demands for nutrients including oxygen, and it reduces the formation of metabolic waste products by these tissues.
2. Rest may permit healing to occur more rapidly (as in the healing of fractured bones).
3. Rest may permit compensatory mechanisms to come into effect (as in the development of collateral circulation after obstruction of an artery or vein).
4. Rest reduces the pain that results from movement of damaged or diseased tissues.

At the same time it has been realized that there are disadvantages of immobilizing tissues or of resting the whole body. Bed rest results in defective drainage of the lungs and bladder and in reduced spontaneous bowel actions. Minerals, including calcium, are lost from bones when they are rested.

Harmful effects of bed rest

The peripheral circulation of blood in veins stagnates, and as a result clotting may occur. If a person is immobile, pressure due to the weight of the body may result in damage to the skin and, ultimately, in bed sores. Local rest of limbs may result in wasting of muscles, loss of bone minerals, loss of dexterity of movement, and stiffening of joints and may ultimately lead to permanent contractures. Pressure ulceration of dependent parts may occur, and in many cases fluid collects in dependent parts if these are not regularly moved.

The value of rest in the treatment of many internal diseases has also been examined; it has been found, for example, that recovery from some conditions of the kidney and liver is not accelerated by resting in bed. Hence prolonged bed rest is no longer considered to be an essential part of the treatment of acute inflammation of the liver or the kidney. In general the person who is unwell will require rest in bed, and in certain circumstances rest may be beneficial for those who do not feel unwell. On most occasions, however, more is apparently lost by unnecessary rest than by continued activity.

THE DIET AND FLUID INTAKE

Opinions have also altered on the value of specific dietary regimens in therapy. There are certain essentials for an adequate diet in health and disease, and these may be particularly important during illness, when deviations are more likely to occur and when their consequences may be especially severe as a result of the body's abnormal requirements for nutrients. An adequate intake of calories is necessary to provide energy requirements. The contribution of protein, fat, and carbohydrate to the total calorie content is probably of secondary importance but may lead to malnutrition if grossly abnormal. An

adequate intake of certain essential dietary constituents must be maintained, although deficiencies can usually be tolerated for a short period. These essential substances include minerals (such as calcium and iron), salt, and the vitamins.

Diseases benefitted by specific diets

There are relatively few diseases in which specific diets are of proven benefit. A high content of certain dietary constituents may be required to replace abnormal losses as experienced in the protein-depletion types of intestinal and kidney disease and the salt-losing types of kidney and adrenal gland disease. On the other hand, it may be necessary to curtail certain dietary components. Thus a low intake of salt may be of great benefit in the treatment of heart failure and in some disorders of the liver and kidneys. Even normal quantities of protein may be harmful in other types of liver and kidney disease. Finally, there are a few rather unusual conditions in which an attempt must be made to eliminate a substance completely from the diet. Such substances include foods causing allergic reactions. A well-known example is shellfish, but there are less common sources of allergic reaction such as milk or gluten, the protein present in wheat and grain products. Rare and often familial inborn deficiencies of certain enzymes that are essential for the utilization of food constituents lead to accumulation of harmful substances when these foodstuffs are eaten. These conditions must be detected early in life before permanent harm is done, and treatment is usually by complete elimination of certain foods from the diet. Examples of such "inborn errors of metabolism" include phenylketonuria, in which the lack of a certain essential body enzyme leads to accumulation of injurious substances if the amino acid phenylalanine is ingested; this leads to brain damage and to permanent mental impairment. Another example is known as galactosemia, in which damage to the brain and eyes can occur if the sugar galactose is taken in the diet.

Although the proportion of the diet contributed by individual types of food is not particularly important in health, there are some conditions in which certain types of food must be restricted. The prime example is diabetes mellitus, a disease in which the body's handling of carbohydrates, and particularly of sugar, is impaired by an absolute or relative deficiency of insulin. Maintenance of a normal level of glucose in the blood is assisted by limiting the quantity of sugar and other carbohydrates taken in the diet.

The quantity and type of fluid in the diet are usually ignored in health, since they are adequately controlled by variations in thirst. The thirst mechanism is effective in controlling the intake of fluid, and the kidneys are able to retain or excrete fluid to maintain a delicate balance between intake and body requirements. In disease, however, either the thirst mechanism or the kidney function may be abnormal. The ill person may ignore his sensation of thirst and the unconscious person may be unaware of it; very sick persons may be unable to respond to their thirst by drinking fluids. Maintenance of a sufficient intake of fluids is then an essential part of therapy. Diseased kidneys may fail to conserve fluid, and dehydration can occur in spite of a normal intake of fluid. Alternatively, the kidneys may fail to excrete fluids, in which case the intake of fluid must be restricted. Very ill persons frequently receive fluid other than by mouth, by means of transfusion or by way of a tube passed through the mouth into the stomach. In these circumstances, the intake of fluid is not controlled by the thirst mechanism, and a careful record of fluid administration and of fluid excretion is necessary to avoid underhydration or overhydration.

Ineffective thirst mechanism

SYMPTOMATIC AND SUPPORTIVE MEASURES

Symptomatic and supportive measures are employed in therapy to relieve unpleasant symptoms and to maintain a person's general condition and morale during an illness. They may at times be the only therapeutic measures needed, for a great many illnesses require no specific treatment, and a majority of patients are cured without the intervention of the doctor. Relief of symptoms may result from specific therapy of the disease (such as the use of an antibacterial drug to treat a bacterial sore throat) or may require separate measures. These may in themselves be healing (such as immobilizing a broken bone in a plaster cast), but in other cases they may be potentially detrimental to the patient. Thus powerful pain-killing drugs may be required after severe injury, although they may carry the risk of causing unwanted effects such as reducing the level of consciousness or depressing the movements of the lungs. Certain symptoms may have to be relieved even if they are not primarily a part of the disease process. Important examples are anxiety and pain. Anxiety is almost unavoidable in the case of illness. It is often relieved by explanation, encouragement, and reassurance. Drugs that act upon the nervous system to suppress anxiety are being increasingly used for this purpose, and unwanted side effects from these drugs are becoming common. When anxiety is accepted as a normal response to illness, treatment with drugs may not be required. Pain is often relieved by measures such as rest for an inflamed or injured part but may, if severe, require drug treatment. Simple pain-killing drugs (analgesics) such as aspirin are widely used to treat minor pains. More severe pain is treated with a number of powerful drugs (such as pethidine or morphine), most of which have the additional property of causing drowsiness. If pain is confined to one region of the body, it is sometimes possible to interrupt the pain-carrying fibres that travel in peripheral nerves by injecting anesthetic drugs into the nerve itself or into the relevant area of the spinal cord. The many other symptoms that may arise during the course of an illness and may require treatment cannot be listed in full, but most are amenable to therapy with simple measures. There are occasions, however, when a physician will decide that a distressing symptom may have to remain untreated because the risk entailed in treatment may be greater than is justified by the severity of the underlying condition.

Relief of pain

Fever, a result of many diseased states, rarely requires treatment in itself, though on rare occasions, and particularly in children, the body temperature rises to a very high level and in these circumstances may cause damage, particularly to the brain. The body temperature can be reduced artificially by exposure of the body to cool air and by sponging with cold water. The normal response of the body to high fever is perspiration, however, and this in itself causes a reduction of body temperature by the heat lost when perspiration evaporates from the skin. Certain drugs, such as aspirin, have an antipyretic (antifever) effect and are often useful in viral infections for which no specific therapy is available.

Reduction of body temperature to subnormal levels (hypothermia) is a valuable aid to therapy in certain conditions. This treatment is based upon the observation that the requirements of the tissues for oxygen, and the rate at which they produce waste products, fall as the temperature is reduced. Thus tissues that are receiving a barely adequate oxygen supply or that are deficient in oxygen may survive longer at lower temperatures. The technique of induced hypothermia, for example, permits complete interruption of the blood flow to the brain during heart surgery or brain surgery for a period that would cause irreversible damage at normal temperature. The same technique has been employed to increase the time available for natural recovery after injury or loss of blood supply to the brain and to other tissues.

EMPLOYMENT OF SPECIFIC MEASURES

Although it is generally agreed that prevention is better than cure, preventive medicine is often neglected. Epidemiology is the study of disease patterns with the object of establishing the cause of disease. Once the cause of a disease is known, it may be possible to apply methods to ensure its prevention, often at relatively small cost. It is as a result of preventive methods that smallpox, cholera, poliomyelitis, diphtheria, and many other infectious diseases have largely been eliminated from Western communities. More recently, therefore, attention has focussed on preventive aspects of the noninfective diseases. Examination of cervical smears (specimens from the opening into the uterus) can detect cancer of the womb at an early and

therefore potentially curable stage. Population surveys and routine examinations of population groups that are relatively accessible, such as school children, pregnant mothers, old people in homes, and industrial groups, can detect diabetes mellitus, anemia, high blood pressure (hypertension), and breast cancer at an early stage.

Programs for preventive regimens depend on the local health situation in the country concerned. In African and Indian countries the main need is to combat the infectious diseases by better sanitation, the eradication of disease carriers (such as malaria-carrying mosquitoes), better education of the people, and immunization and vaccination programs. Infections conveyed by water or food are preventable by public health measures. Effective systems of sewage disposal and the provision of pure water have eradicated cholera and typhoid in many countries. Among the diseases controllable by active immunization are smallpox, diphtheria, whooping cough, poliomyelitis, tuberculosis, tetanus, typhoid, paratyphoid, cholera, yellow fever, and rabies, and to some extent even influenza.

Correction of environmental deficiencies

Preventive measures may be primarily concerned with the environment; these include better housing, clean water supply, adequate nutrition, and fluoridation of water. Such measures may alternatively be concerned primarily with the individual and involve immunization against infectious disease or testing for presymptomatic disease, such as routine X-rays for the detection of early tuberculosis or urine testing for diabetes mellitus.

Other measures considered in specific methods for the alleviation of disease include what is known as social medicine. Much disease has a social origin and is therefore caused in part by social factors: poverty, overcrowding, and chronic fatigue are especially relevant. Furthermore, disease has social consequences, and social services are an important part of the therapeutic program. These may include the provision of meals and nursing care for those ill at home without the necessary facilities available, the care of the young children of the sick mother, and even the provision of domestic help.

MODIFICATION OF REGIMENS TO FIT THEM TO THE SICK

The principles upon which treatment of most common illnesses is based are fairly well defined. Such treatment can be described as if it were applicable to all patients with this disease, but this is rarely the case. The skills of therapeutics consist not only of administering the recognized forms of treatment but also of modifying the treatment according to the individual patient. The following factors are among those that usually influence the exact form of therapy.

1. The severity of the illness and its impact upon the individual affect decisions, for example, as to the risks that should be taken in therapy, for many forms of effective modern treatment occasionally cause complications and must inevitably carry a degree of risk. Such considerations also affect the necessity for utilizing a kind of therapy that will lead to rapid cure, possibly with greater risk, as opposed to more leisurely treatment with less risk.

2. The age of the patient influences many decisions, such as the advantages of rest or of immobilization. Bed rest is particularly likely to lead to complications in the elderly and is difficult to enforce in children unless they are extremely ill. The response to certain drugs and the risk of side effects are also related to age, not only because of variations of dosage but also because of differences in susceptibility to certain complications. The response to irradiation of tissue depends to some extent upon age, and the risks of inducing cancerous changes as the result of X-rays are usually taken more seriously in children than in the elderly. At the extremes of life, anesthesia, necessary for surgery, carries an increased risk. The reaction to hospitalization varies greatly with age. Young children have been shown to suffer considerably from the deprivation of parental care while in the hospital, and old people frequently become confused and disorientated when they leave their normal environment. Age also raises ethical problems, such as the difficult decision as to whether or not intensive treatment should be given an elderly person who is suffering from a degenerative or ultimately fatal condition.

3. The effect of ethnic group, social class, and family background upon the outcome of the illness is usually considered. Many ethnic groups tolerate certain illnesses poorly or more poorly than others. Tuberculosis, for example, may be particularly dangerous in certain races. The social effects of absence from work during or after treatment and the effects of loss of earnings and of residual disability are also taken into account, as is the effect of the illness on the family of the patient.

Home and hospital care

4. The doctor has to consider the best place in which to carry out treatment. The majority of illnesses are satisfactorily treated while the ill person continues his day-to-day life or remains in his home with his family. When special medical or nursing care is required, a decision must be made as to whether he should be treated in a hospital or in a nursing home. This decision is made after consideration of family and personal preferences, financial implications, and the availability of adequate treatment elsewhere. The age of the patient is again important, old people and young children responding poorly to removal from their environment and their families, especially at times of illness. The decision as to the place of treatment will influence the treatment thereafter, for many forms of therapy, such as those involving transfusion or special procedures or observations, may be impractical at home.

5. The religious beliefs of patients may influence the choice of therapy, particularly in regard to such things as the attitudes of certain religions about therapeutic abortion or about blood transfusion.

6. The patient's attitude to his disease will also affect the type and place of therapy on many occasions. The apprehensive patient may feel more secure when in a hospital or may, on the other hand, have his anxieties increased by the need to enter a hospital. An excessive fear of surgical treatment may justify alternative nonsurgical forms of therapy.

7. The response to previous therapy may provide valuable guidance to the likely result of further treatment for the same or related conditions. This is of particular importance when complications or adverse effects have followed previous treatment, and unexpected or unusual response to therapy may recur if the treatment is repeated. In the case of allergies to drugs, for example, the reactions may be extremely severe if the drug is used again. Some forms of therapy carry an increased risk when carried out for a second or subsequent time. Examples are the cumulative toxicity of repeated administration of the antibiotic chloramphenicol, and risks resulting from the technical difficulties of operating for a second time on organs such as the thyroid. Such decisions are influenced to a great extent by the age of the patient.

8. Concurrent therapy is frequently a factor to be taken into account. There is an increasing awareness of the importance of interactions between different drugs in the body. Such interactions may increase, diminish, or otherwise alter the response to drugs given at the same time. Patients frequently take medicines for conditions other than that currently being investigated and treated. Important examples are the potentially dangerous interactions between some antidepressant drugs and many commonly used remedies, and the effect of barbiturate sleeping tablets upon the effectiveness of anticoagulant drugs. Previously established drug therapy must be taken into account in the choice of drugs in many illnesses.

9. Other diseases may be present. Many persons suffer from conditions other than the one under treatment, and these conditions may modify their response to subsequent forms of treatment. Examples are the preference for nonsurgical forms of treatment for patients with severe heart or lung disease, because of the risk of anesthesia and of complications in the postoperative period. Forms of treatment that require long periods of bed rest for old patients or for those with joint disease are avoided. Preexisting disease may also modify the response to drugs. Persons with diseases of the kidneys or liver commonly excrete or inactivate drugs more slowly than normal,

therefore require smaller doses for equivalent effect, and risk toxic effects if the drug is given in normal doses. Persons with chronic lung disease may develop sometimes fatal depression of their breathing when given doses of certain analgesics that have no such effect upon people with healthy lungs.

Major therapeutic techniques

SURGICAL TREATMENT

The great scope of modern surgery can only be suggested in this section. In general, surgical procedures can be categorized as follows:

Outline of surgical procedures

1. Repair of abnormalities resulting from:
   a. Congenital defects (*e.g.*, birthmarks, heart deformities)
   b. Trauma (*e.g.*, laceration of tissues, fracture of bones)
   c. Disease processes (*e.g.*, peptic ulcers, rheumatic scarring of heart valves)
   d. Degenerations (*e.g.*, hernias, prolapses)
2. Excision of abnormal tissues
   a. After trauma (*e.g.*, amputation of a severely damaged limb)
   b. After damage by disease (*e.g.*, removal of a kidney irreparably damaged by infection)
   c. Tumours, benign or malignant
3. Aspirations of collections of fluid
   Drainage of the contents of abscesses and cysts or of collections of fluid in body cavities.
4. Removal or bypass of obstructions to hollow organs
   a. Removal of an inhaled object from the lung or throat
   b. Relief of mechanical obstruction of the gut (due to tumour, torsion, or paralysis of movement of the gut)
   c. Relief of obstruction of blood vessels (by blood clot), kidneys and ureters (by stones), bladder (by enlargement of the prostate or stricture of the urethra)
   d. Relief of obstruction to the flow of cerebrospinal fluid (the various forms of hydrocephalus)
5. The supply of natural or artificial tissues and organs
   a. Natural tissues (skin grafts from other sites of the body; transplantation of kidneys or cornea or of segments of blood vessels from live or dead human donors)
   b. Artificial tissues (replacement of damaged or diseased tissues by artificial ones, such as artificial heart valves made of metal or plastic, metal or plastic artificial hip joints, synthetic grafts for blood vessels)

BIOLOGICAL THERAPY

Materials from human, animal, or plant sources have been used since the earliest days of therapeutics. During the last half-century an increasing number of therapeutic substances have been synthesized chemically, but a number of important materials are still obtainable only from biological sources.

Blood products. Human blood is used widely in therapy, either as whole blood or as one of the constituents of blood. Red blood cells, white blood cells, and platelets can be separated to some extent from whole blood and can be used for certain purposes. Plasma, which is all of the blood except its cells, is of great value in some situations because it can be stored for long periods. Some of the protein constituents of plasma have been separated from blood and used for special purposes, such as the treatment of bleeding disorders (*e.g.*, hemophilia) that result from deficiencies of these substances. Separation of blood components has the advantage that deficiencies can be remedied without the unnecessary administration of blood products that are not required by the patient. This also leads to more efficient usage of existing supplies of blood. Blood is most commonly used, however, as for transfusion to replace loss due to bleeding, and in these circumstances whole blood is usually preferred.

The products of blood serum (the blood minus its cells and coagulation factors) are used in medicine as a source of immune antibodies. Antibodies are produced by humans and animals as a response to infections. They circulate in the blood, and serum from the blood can be used to provide antibodies to prevent or counter these infections in man. Antibodies are known to reside in certain proteins of the blood (immunoglobulins), and concentrates of these proteins may be used to provide a high concentration of antibody in a small volume. Normal human serum has few applications in medicine, but serum collected from healthy people after their recovery from an infective illness may be of value in preventing or treating that illness in other people. More commonly, however, immunoglobulins concentrated from such serum are used. Immunoglobulin administered by injection is used on occasion for the prevention of certain virus diseases, including hepatitis (liver inflammation), measles, and chickenpox. Human immunoglobulin is also used in certain deficiency states in which normal immunoglobulins are reduced or absent from the blood. Persons with lower levels of immunoglobulins are unduly susceptible to infections, and this susceptibility can be overcome by administering concentrates of immunoglobulin from healthy people. Immune serum prepared in animals is used only in the treatment of tetanus and diphtheria, and its use is avoided if possible because of the risk of producing severe reactions to the foreign protein.

Immunoglobulins

Vaccines. Vaccines, produced in various ways from micro-organisms such as bacteria or viruses, are widely used in the prevention of infectious diseases. In general, vaccines consist either of (1) killed or inactivated micro-organisms (such as diphtheria, whooping cough, or influenza vaccines) or (2) living organisms that have been modified so that they can induce antibody production without producing disease (smallpox vaccination, oral poliomyelitis vaccines). In either case, the objective is to simulate a natural infection with these micro-organisms and thereby induce the formation of antibodies against them. The antibodies circulate in the blood and prevent further infection with that micro-organism or neutralize the effects of infection if this should occur.

PHARMACODYNAMIC THERAPY

Most of the drugs used in modern therapeutics can be looked upon as acting by stimulating or depressing physiological or biochemical processes within the body. The actions of drugs are often complex, and in many cases the exact mode of action is unknown. Any drug may have actions other than those desired in the context of its use.

A necessarily incomplete summary of some of the types of drug action utilized in therapeutics for diseases of different body systems follows.

The nervous system. *The brain.* Drugs that stimulate the central nervous system have relatively few uses in therapeutics. Drugs such as strychnine now have no applications in medicine but are of considerable historic interest. Stimulants are occasionally used to counter depression of the nervous system resulting from overdose of drugs. Drugs such as caffeine or amphetamine have a stimulant action upon the brain, and caffeine, for example, produces a more rapid and clearer flow of thought and allays drowsiness and fatigue. The amphetamine group of drugs has been used for this purpose in the past, but the danger of addiction limits their use.

Depression of brain activity is widely used in therapeutics. Sedatives reduce brain activity, hypnotics produce sleep, and anesthetics produce loss of consciousness. All act by inhibiting electrical activity within the brain, though the methods by which they work may vary widely. Probably the best known drugs of this type are the barbiturate drugs, which are used, in various dosage and preparations, as sedatives, hypnotics, or anesthetics.

Sedatives, hypnotics, and anesthetics

Selective or preponderant actions on certain parts of the brain or on certain types of brain activity are exerted by certain drugs.

Anticonvulsant drugs are used for the treatment or, more often, the prevention of epileptic attacks. The most widely used drugs of this type for this purpose include phenobarbital and hydantoinate drugs such as diphenylhydantoin.

Drugs are used to inhibit involuntary movements (*e.g.*, the drugs used in the treatment of Parkinson's disease). These include synthetic compounds related to atropine.

Many pain-killing drugs, analgesics, are known. These

drugs work by selectively or preponderantly inhibiting pain-receiving centres in the brain. Aspirin is an effective analgesic for minor pain, but more severe pain may require drugs with more powerful action, such as meperidine hydrochloride. The more powerful analgesic drugs, particularly those of the morphine group, produce addiction and are reserved for the treatment of severe pain. In addition to their analgesic action, they inhibit brain activity and produce drowsiness and sleep, or even coma.

In recent years many drugs have been introduced that have a specific antidepressant effect. In some cases the mode of action is known—for example, inhibition of brain enzymes by the monoamine oxidase inhibitor drugs—but in other cases the biochemical basis of antidepressant therapy remains uncertain.

A number of compounds are known to have a beneficial effect in psychotic states such as schizophrenia. The first of these compounds to be introduced, and one still widely used, is chlorpromazine, but many other compounds have been introduced since the discovery of this drug.

Peripheral nervous system. Local anesthetic drugs inhibit the conduction of impulses through peripheral nerves. They are usually used to inhibit pain sensations. The best known examples include procaine and lignocaine. These drugs are usually injected into the skin or tissues or in the vicinity of nerves that are conducting painful stimuli. Some local anesthetic drugs, such as cocaine, are effective when used locally in the eye, on mucous membranes, or on the skin.

The autonomic nervous system (visceral or vegetative nervous system) is widely distributed throughout the body and provides the innervation of the heart, blood vessels, endocrine glands, abdominal viscera, and smooth (nonvoluntary) muscles. The autonomic nervous system is composed of two divisions, the sympathetic and parasympathetic nervous systems. The sympathetic nervous system was originally so called because it coordinates bodily functions and teleologically is concerned with the responses to emergency situations in the external environment, such as the preparation for fight or flight. The mobilization of carbohydrate reserves and the increase in blood pressure and heart rate are preparatory measures. The parasympathetic nervous system, on the other hand, is concerned with bodily welfare at less stressful times and has its major influence on digestive glands.

Effector substances

Pharmacological stimulation of the autonomic nervous system is rarely used in therapeutics. The effector substances released where autonomic nerve fibres terminate on end organs have been isolated, however, and derivatives of these effector substances are widely used in medicine. These simulate the actions of the sympathetic or the parasympathetic nerves. The former type, the so-called sympathomimetic drugs, includes epinephrine and ephedrine, and parasympathomimetic drugs include acetylcholine and carbachol. Inhibition of the sympathetic nervous system is possible with a number of compounds acting in different ways. Inhibition of sympathetic activity acting on peripheral arteries forms the basis for most types of treatment for hypertension (elevated blood pressure) at the present time. Drugs have recently become available that selectively inhibit sympathetic activity on the heart, and these are of value in angina. Inhibition of parasympathetic activity is carried out with drugs of the atropine type. These drugs, among other effects, reduce the activity of the intestinal tract.

Relaxation of voluntary muscles. There are no clinically useful drugs that increase the power of muscles (except when weakness is due to the rare disease myasthenia gravis). Drugs that paralyze muscles are used to produce muscular relaxation during surgical operations. Curare is the best known drug of this type.

The cardiovascular system. *The heart.* Certain drugs influence the function of the heart in a number of different ways. Drugs that increase the power of contraction of the failing heart include drugs of the digitalis group. These are among the oldest drugs in medicine. As squill, they were used as medicines by the ancient Egyptians and by the Romans. Digitalis, derived from the foxglove plant, is mentioned in writings as early as 1250 and was introduced into medical treatment in 1785. Digitalis has a number of effects on the heart; one of its most valuable actions is to increase the power of muscular contraction of the failing heart. Many preparations are available, but digoxin is the one most commonly used.

Drugs can increase the rate of heartbeat. Drugs that mimic the activity of the sympathetic nervous system or inhibit parasympathetic nervous activity will, as a result, increase the heart rate. These drugs are of value in the occasional case in which the heartbeat is unduly slow.

Drugs can slow the heart rate. Drugs of the digitalis group slow the heart rate when the speed is unduly fast as a result of certain abnormalities of heart rhythm or as a result of failure of the heart. In the absence of heart failure or an abnormal rhythm, an excessively rapid heartbeat can be slowed by inhibiting sympathetic nervous activity or by stimulating parasympathetic activity, although the latter method is rarely used in practice.

Electrical conductivity of heart

Drugs are available that reduce the rate of electrical conduction within the heart. Electrical activity spreads through the heart from the upper part (the atria) to the lower part (the ventricles). In certain conditions, abnormally rapid contraction of the atria results in an excessive pulse rate. This abnormality can be controlled either by reducing the atrial activity or by reducing the rate of conduction of impulses within the conducting system of the heart. Digitalis drugs are of particular value in the latter respect.

Drugs are available that reduce electrical excitability of the heart. Electrical impulses that lead to the contraction of the heart muscle normally arise from a focus in the atria. If the cardiac muscle is unduly excitable, abnormal focusses of electrical activity may arise elsewhere and result in an abnormal heart rhythm. This may reduce the efficiency of the heart, produce heart failure, and even cause death. Electrical excitability of the heart may be reduced by a number of drugs.

Drugs can relieve cardiac pain. Cardiac (heart) pain results from insufficient arterial blood supply to the heart muscle. It can be relieved by using powerful analgesic drugs (such as morphine), but other preparations that are not analgesic as such are available that act by increasing the blood supply to the myocardium and reducing its oxygen needs.

The arteries. The calibre of medium and small arteries throughout the body can be varied as a result of activity of the sympathetic nervous system that causes constriction of small arteries. Arteries can be further constricted by the administration of sympathomimetic drugs, and these compounds are sometimes used to counter a fall in blood pressure. Arteries can be dilated by the use of drugs that oppose sympathetic activity. These drugs find their prime use in the treatment of hypertension. The earlier drugs of this type acted to inhibit both sympathetic and parasympathetic activity, but more recently drugs such as guanethidine and methyldopa have been developed that selectively inhibit sympathetic activity. These compounds effectively lower the blood pressure.

The respiratory system. Drugs acting upon the respiratory system include drugs that affect breathing, drugs that act upon coughs, and drugs that relieve obstruction of the air passages. Drugs that increase the breathing rate have few clinical applications. Nikethamide is occasionally used as a respiratory stimulant when respiration has been depressed as a result of overdose of other drugs or as a result of disease. Morphine and its derivatives are powerful depressants of respiration, but there are very few clinical situations in which depression of respiration is required.

Coughing results from irritation of the air passages and is a valuable protective reflex. It needs to be suppressed only when it is tiring and is serving no useful function. Few drugs are known with a specific cough-suppressant activity, and most of the effective cough suppressants are derived from the analgesics. Expectorants are drugs that act to liquefy sputum and hence ease its expectoration. Dehydration, one of the commonest causes of thick sputum, can be countered without the use of drugs.

Narrowing of the air passages is a feature of many

Opening obstructed air passages

illnesses (such as asthma and bronchitis). In the case of asthma this narrowing is potentially reversible, but many persons with bronchitis—inflammation of the bronchi—have irreversible obstruction of their air passages. Obstruction is frequently the result of infection that can be countered by the use of appropriate antibiotics. Spasm of the muscle of the bronchial wall may cause obstruction, however, and this may be reversed by treatment with sympathomimetic drugs (such as adrenaline). Asthmatic persons frequently develop constriction of bronchi as a result of allergic mechanisms. This constriction can be inhibited by anti-allergic drugs, but before these drugs are used it is necessary to attempt to remove the cause of the allergy from the patient's environment.

The digestive tract. Drugs that act upon the digestive tract include drugs that affect gastric acidity, drugs that stimulate or decrease activity of the lower bowel, and drugs that reduce or prevent vomiting. Since the pancreas is partially involved in the digestive process, it, too, is included in this section.

When ulcers in the stomach and duodenum arise from excessive production of acid by the stomach, they are cured and symptoms relieved by reduction of the gastric acidity. Most antacids (*e.g.*, sodium bicarbonate) act by chemically neutralizing gastric acid.

Cathartics, drugs used to stimulate contraction of the lower bowel and thereby produce a bowel action, are the most abused drugs in medical practice. Constipation, unless extremely severe, is rarely harmful, and the habit of taking drugs to produce a daily bowel action is usually condemned. Cathartics may act either by stimulating the lower bowel, by retaining fluids within the bowel, by increasing the bulk of the bowel contents, or by a lubricant action (as by mineral oils). The use of mineral oils (such as liquid paraffin) is potentially dangerous and has resulted in many complications.

Drugs that decrease the activity of the lower bowel are used in the treatment of diarrhea. Most of the effective drugs act by inhibiting the parasympathetic nervous system and are derived from atropine. Kaolin is an inert powder that increases the solidity of the stools in patients with diarrhea. In some cases, in which diarrhea has a specific cause (such as infection), specific treatment with antibiotic or other drugs is also required.

Vomiting is frequently a symptom of underlying disease and is not treated by nonspecific anti-emetics unless such disease has been excluded. Certain drugs have anti-emetic activity, among which are a number of antihistamine drugs and chlorpromazine and its derivatives.

Drugs that cause vomiting are rarely required in therapy but are occasionally used in an attempt to remove ingested poisons from the stomach. A strong solution of common salt is one of the most effective emetics and usually causes vomiting.

The pancreas. The pancreas has two main functions. It synthesizes and excretes enzymes for digestive processes. There are no drugs in clinical use that predictably increase or suppress this activity. The pancreas also produces insulin, essential for the metabolism of carbohydrates and lacking in many cases of diabetes mellitus. Insulin itself is used in therapy (see below *Substitution therapy*), and a number of drugs that increase the output of insulin by the pancreas are of value in treating diabetic persons who still have the potential to produce insulin from the pancreas.

Stimulation of the pancreas

The urinary tract. Drugs may affect or modify the function of the kidneys in a number of ways. Drugs that increase the flow of urine are known as diuretics and are used in treating conditions in which fluid is abnormally retained in the body. This may occur as a result of disease of the heart, the liver, or the kidneys themselves. Many available diuretics act at different sites within the kidney and can be used in combination to treat patients who have severe fluid retention. Drugs that reduce the flow of urine are of no clinical application, unless urine flow is abnormally high as a result of deficiency of pituitary antidiuretic hormone.

A number of drugs are known to alter the excretion of substances by the kidney. Among those that are of therapeutic value are probenecid, which not only increases the excretion of uric acid and can be used in the treatment of gout but also reduces the excretion of penicillin and is therefore used to aid penicillin therapy.

Physicians seldom prescribe drugs to cause contraction of the bladder, but when this is required parasympathomimetic drugs are used.

The blood-forming organs and the blood. No drugs are available that act by a pharmacological means to stimulate production of all formed elements of the blood. Abnormalities of the blood, and particularly of the red cells, may result from deficiency of iron, vitamin B_{12}, and folic acid, and in these circumstances replacement therapy with these compounds may correct the anemia.

Drugs that inhibit production of formed elements of the blood are used in the treatment of leukemia (excess of white cells) or polycythemia (excess of red cells).

Anticoagulants are widely used to inhibit clotting of blood in arteries and veins. The most widely used compounds act by interrupting the synthesis of substances that are essential for the clotting process.

The endocrine glands. Endocrine glands produce and secrete hormones that circulate in the bloodstream and have actions at many and distant sites in the body. Many endocrine glands, such as the thyroid, adrenal, and sex glands, are controlled by hormones released from the pituitary. Pituitary hormones available for clinical use can be used to stimulate the respective target glands. When overactivity of an endocrine gland is the result of pituitary overactivity, the pituitary gland itself is sometimes suppressed or destroyed by surgery or by radiation. Alternatively, it may involve less risk to the patient to control the activity of the target gland by direct surgical attack or by drugs. Many hormones have been isolated and in some cases synthesized; these are used in therapy to replace deficiencies.

The thyroid gland. Persons having an underactive thyroid gland are treated by administration of thyroid hormone. Overactivity of the thyroid gland may be treated with a number of antithyroid drugs that act by interfering with the chemical synthesis of thyroid hormone.

Adrenal (suprarenal) glands. The adrenal glands may be stimulated by giving the pituitary hormone (adrenocorticotropic hormone) or its synthetic equivalent. The adrenal glands produce a number of hormones, of which cortisol, the most important, is essential for life. Another hormone, aldosterone, is required to maintain a normal blood pressure. The production of cortisol can be inhibited only by suppressing the pituitary gland, but the effects of aldosterone can be counteracted by the use of the drug spironolactone. Corticosteroid drugs, which are synthetic derivatives of cortisol, have many actions in therapeutics dependent upon their anti-inflammatory effects and are also used to replace deficiencies of adrenal function.

The testes. The testicular hormone testosterone has been synthesized, for clinical use in the treatment of testicular deficiencies resulting either from damage or disease of the testes or from pituitary dysfunction.

The ovaries. Therapy with gonadotropins, hormones from the pituitary, has been effectively applied to the treatment of female infertility, since these hormones stimulate ovarian activity. It is possible to inhibit ovarian function by the use of ovarian hormones themselves, and various combinations of them are used as oral contraceptives. They act by inhibiting ovulation.

The pituitary. Several pituitary hormones are now available for therapeutic purposes. Adrenocorticotropic hormone (ACTH) stimulates the adrenal glands to produce cortisone. Growth hormone may be used to stimulate growth in children who are deficient in the natural pituitary hormone. Gonadotropins are used to treat infertility due to deficient ovulation. Vasopressin, the hormone of the posterior pituitary, is used to replace a deficiency of this hormone in the condition known as diabetes insipidus.

ACTH and growth hormone

Drugs that alter metabolic processes. Many drugs affect metabolic processes in the body. The use of insulin in the treatment of diabetes has been mentioned. Gout,

which is associated with excess production of uric acid, is sometimes treated with allopurinol, a drug that interrupts the synthesis of uric acid. High levels of cholesterol in the bloodstream, which may be associated with premature arterial degeneration, are often lowered by the use of the drug clofibrate. Vitamin D, like the other vitamins, has its main application in the treatment of specific vitamin deficiencies but may be used to correct abnormally low concentrations of calcium in the blood, even though they are not caused by a deficiency of this vitamin.

Drugs that act on inflammation. Certain drugs modify or suppress the inflammatory responses of the tissues to infection or other injury, and this action is widely used in therapy. Aspirin, though primarily an analgesic, has anti-inflammatory properties that are particularly valuable in the treatment of inflammation of the joints, as in rheumatic fever and rheumatoid arthritis. Other synthetic drugs have anti-inflammatory and analgesic properties and are of value in the treatment of joint disease.

Cortisol, the hormone produced naturally by the adrenal glands, has a powerful anti-inflammatory action and in addition modifies many types of allergic response. Many synthetic preparations, known as corticosteroids, also possess these properties. The most widely used at present are prednisone, prednisolone, cortisone, and hydrocortisone. These powerful drugs are effective in a wide range of disorders. They act either by suppressing inflammation or by interfering in some way with allergic or immune processes. Corticosteroids may be taken by mouth or by injection, and they are effective when applied to the skin, eyes, or mucous membranes. Complications of prolonged corticosteroid therapy are common, and prolonged therapy is usually avoided if a safer method of treatment is available or unless corticosteroid treatment is essential for survival or maintenance of health.

CHEMOTHERAPY

Definition of chemotherapy

The term chemotherapy is applied to the use of drugs that destroy micro-organisms or parasites in or on the body of the patient or inhibit their multiplication. Antimicrobial chemotherapeutic drugs usually act by selective inhibition of biochemical processes essential to the micro-organisms. Some of the toxic effects of these drugs on man are due to inhibition of similar processes in human cells. Chemotherapy is available against many bacteria, some viruses, some fungi, and many parasites.

Antibacterial drugs. Drugs effective against bacteria have been known since the development of penicillin in the 1940s. They differ in potency, range of activity, toxicity, and cost. In general, antibiotics can be divided into those that have activity against comparatively few bacteria (narrow spectrum) and those that are active against a larger number of bacteria (broad spectrum). The broad-spectrum antibiotics may be less effective against a particular type of micro-organism than a narrow-spectrum antibiotic to which it is sensitive.

The choice of antibacterial agent involves the physician in the consideration of several factors. Recovery from many bacterial infections occurs without antibacterial therapy; recovery may not always be hastened by such therapy. In some situations antibacterial drugs have been shown to delay cure, particularly in certain infections of the intestinal tract, such as cholera, and in carriers of typhoid bacilli. The choice of an antibiotic drug depends upon the known or suspected bacterium causing the infection, its known or anticipated range of antibiotic sensitivities, the severity of the infection, and the likely outcome of the illness without chemotherapy, as well as the known side effects of the available antibacterial drugs and the frequency with which they occur.

The efficacy of many antibacterial drugs has been reduced by the emergence of bacteria resistant to the action of antibiotics to which they were once sensitive. This is believed to be the result of excessive and incorrect use of antibacterial drugs, often for conditions that required no such therapy. The development of bacterial resistance can usually be avoided if adequate doses of drugs are given for a sufficient time and by the occasional combined use of two or more drugs. Bacterial resistance, which at one time threatened to remove the valuable weapon of antibiotic therapy from therapeutics, has now been checked by more judicious use of drugs and by the synthesis of many new antibacterial compounds. Nearly all bacterial infections may be effectively treated by one or more antibiotics; as a result primary bacterial infections now cause relatively few deaths in developed countries where these drugs are available. The length of time needed for antibiotic treatment depends upon a number of factors including the potency of the antibiotic and the ease with which it can gain access to the site of infection. Most acute infections are adequately treated by one or two weeks' antibiotic therapy; other infections, such as tuberculosis, may require prolonged treatment.

Antiviral drugs. Few antiviral drugs are available for therapeutic purposes, but it is likely that effective drugs will be developed within the next few years. It is likely that these drugs will be more effective when given before the development of symptoms and will therefore have a greater prophylactic than therapeutic value. Methisazone, recently introduced, has been shown to be highly effective in protecting persons who have come in contact with smallpox. Idoxuridine is a drug active against herpes virus (the cause of "cold sore" and other inflammations) and has been used to treat herpetic infections of the cornea of the eye. Of the large number of drugs known to be active against many viruses, most act by interfering with essential metabolic processes of viruses or of the cells that they infect. The great majority of the antiviral drugs tested have proved too toxic for clinical use, but increasing knowledge of the biochemistry of viruses and of their infections is expected to lead to the discovery of less toxic and more active agents.

Treating smallpox and herpes

Drugs active against fungus infections. Many fungi cause infections in man. Some troublesome infections of the skin are treated with the drug griseofulvin, and dangerous systemic fungus infections with amphotericin B. The fact that the importance of fungus infections in man has only recently been recognized probably accounts for the scarcity of drugs active against pathogenic fungi.

Antiparasitic agents. A large number of parasitic agents infect man, and specific therapy is available against many of these. This therapy is used in conjunction with such measures as the eradication of mosquitoes for the control of malaria and the control of animal carriers of other diseases. Drugs have therefore been used partly to kill carriers such as insects and also as prophylaxis and therapy of infection. Antimalarial drugs are used as prophylaxis when regular administration is required throughout the period of exposure or for the treatment of established malaria. Drugs are also available for the treatment of amebiasis, trypanosomiasis, and many other parasitic diseases.

SUBSTITUTION THERAPY

The replacement of substances in which the body is deficient forms an important part of therapy.

Restoration of substances lost from the body. Loss of blood occurs from bleeding, and loss of fluids from severe diarrhea or vomiting. Minerals and proteins may be lost because of kidney or bowel disease. The method of replacement usually depends on the nature of the loss. Blood, for example, cannot be given by mouth.

Deficiencies of dietary constituents. These deficiencies may occur as a result of inadequate intake in the diet, impaired absorption of substances from the intestinal tract, or excessive bodily requirements for certain dietary constituents. Inadequate intake of essential substances can sometimes be corrected by improving the diet, but often it is necessary to administer pure preparations of the deficient substance or substances. Examples are vitamin deficiencies or deficiency of iron, both of which may, on occasion, result from inadequate intake. Poor absorption of substances present in normal concentrations in the diet may result from disease of the intestinal tract or from removal of parts of the intestines by surgery. It is rarely possible to correct this type of deficiency by increasing the intake of foods rich in the deficient substances, and treatment consists of administering these

Iron deficiencies

substances in pure form. If absorption is severely disturbed, it may be necessary to give such replacements by injection. Deficiencies in calcium, potassium, iron, vitamin B_{12}, and folic acid may all occur as a result of impaired absorption from the gut. Increased requirements for certain dietary constituents may occur during pregnancy or during periods of rapid growth, and this may lead to deficiencies. Supplements of pure preparations of the deficient substance are usually used in treatment. An example is the treatment of the increased demand for iron, folic acid, and calcium during pregnancy.

Deficiencies of hormones can, in most cases, be corrected by the administration of a synthetic or semisynthetic preparation of the hormone that is lacking. Preparations are available of thyroid, adrenal, testicular and ovarian hormones, and of some of the pituitary hormones. Insulin is administered by injection for the treatment of diabetes mellitus, a condition in which the production of insulin by the pancreas is insufficient to maintain a normal level of glucose in the blood.

RADIATION THERAPY

Forms of radiation

Radiation therapy is the treatment of disease by ionizing radiation (radiation that forms positively and negatively charged particles in the substance that it encounters). X-rays, gamma rays, and corpuscular radiation such as alpha or beta rays all have the ability to produce ionization in living matter. There is no fundamental difference in these forms of radiation, whether they are produced in modern generators such as linear accelerators or whether they are emitted by radioactive elements. It is the energy of the radiation that is important, because penetration into the tissues depends on the energy. The effects of irradiation are destructive. Some cells are killed directly and in others the ability to reproduce is destroyed. Cells that are rapidly growing and reproducing are more vulnerable to irradiation than those that are less actively dividing. Hence, the most important practical applications for radiation therapy are in the treatment of cancer. The object of radiation therapy is to provide adequate and uniform irradiation of a tumour while sparing healthy tissue. This requires accurate localization of the tumour and precise distribution of the irradiation. As cancer is second only to heart disease as the most common cause of death, the uses of radiation therapy are numerous. Nevertheless, surgery remains the first line of attack in most localized cancers, and radiation therapy is generally reserved for those cases not amenable to direct surgery. Radiation therapy is also used in certain nonmalignant disorders, which include certain skin conditions, and in some rheumatic disorders; radiation from radioactive isotopes (forms that emit radiation while changing to a different element) is used for the treatment of certain cases of overactivity of the thyroid gland and in some patients with polycythemia, in which the bone marrow produces too many blood cells.

Local irradiation to an organ or tissue can be achieved by the oral or intravenous administration of certain radioactive isotopes that are concentrated in that particular organ. Iodine, for example, is almost selectively concentrated in the thyroid gland. When the radioactive form of iodine is administered (iodine-131 is commonly used), it is concentrated in the gland and emits beta particles. The particles are completely absorbed within the thyroid, causing ionization in its tissues. This destroys a proportion of the thyroid cells and, when an appropriate dose is given, can restore a hyperactive gland to normal. Radioactive iodine can also be used for certain types of thyroid cancer, though surgery and external irradiation are more appropriate in most cases. Phosphorus is concentrated in bone, for bone is the major phosphate pool in the body. When radioactive phosphorus (phosphorus-32) is given intravenously, it is concentrated in bone; the beta particles emitted irradiate the bone marrow. When an appropriate dose is given, this will control certain states of bone marrow overactivity, in which the bone marrow production of red cells is excessive. Several radioactive isotopes can be made up into needles for implantation so that the emission of radiation can be utilized locally. Radium in this form has long been used for the treatment of cancer of the neck of the womb. Radioactive tantalum, because it can be bent into any shape or form, is particularly useful for implantation as wire into curved surfaces such as the bladder, for the treatment of local cancer.

PHYSICAL THERAPY

Physical agents such as heat, cold, muscular exercises, and faradic current (an unsymmetrical alternating current) to stimulate wasted muscles are of greatest use in patients with the rheumatic diseases and with certain neurological disorders, in which muscle wasting occurs after damage to its nerve supply.

Uses of heat

Heat, which relieves pain by its action as a counterirritant, can be applied in a variety of ways—the heat lamp, electric pad, and warm baths. Generalized heat is particularly advantageous for the patient with rheumatoid arthritis with extensive joint involvement and also has the advantage of stimulating the circulation. Infrared waves, short waves, and ultrasonic waves are electromagnetic waves that penetrate the skin and warm the deeper tissues and require more sophisticated equipment and greater skill. Short waves are high-frequency alternating currents that produce heat by causing rapid oscillation of ions in the patient's tissues. Ultrasonic waves are sound waves with a very high frequency that are undetectable by the human ear. Faradism is an electric current that will stimulate motor nerves and cause tetanic contraction of muscle. It thus will stimulate wasted muscles to recover.

Remedial exercises may be active or passive. Passive exercises are used to promote the mobilization of stiff or inflamed joints and to prevent deformities. Even acutely inflamed and painful joints should be put through as full a range of movements as pain permits. As soon as possible, patients with arthritis should progress to active exercises so that muscle tone is maintained. Hydrotherapy in the form of supervised exercises in a warm pool plays an important part in the modern treatment of arthritis. The warmth relaxes the muscles, and the buoyant effect of the water makes movement easier.

OCCUPATIONAL THERAPY

Occupational therapy is the treatment of physical or mental disorders by the use of occupation or recreation, with the object of promoting recovery or creating new habits and of preventing deterioration. That work helps to maintain health is generally recognized; it is also of value in disease, especially in the more chronic disorders and in psychiatric illnesses; it is particularly important in children. Doctors recognize that it is important to relieve the boredom and to stimulate the interest of the chronically ill person and to promote self-confidence in the depressed schizophrenic patient. Occupational therapy in the form of craft work and recreational activities plays a large part in the recovery of such patients.

Occupational therapy may also help to mobilize stiff joints and to increase muscle power by graduated exercises and work under supervision. Remedial occupational therapy aims to minimize the disability that may follow illness or injury and help the patient prepare himself for other useful employment if he is unable to return to his previous industry. Such treatment is particularly useful to the person who has suffered injury in an accident and also to the person with arthritis. Many of the physical measures already considered form part of this treatment, and the remainder may be summarized as rehabilitation. Unstable joints may require splinting or other support. Deformities are prevented and remedial exercises practiced to make full use of the undamaged muscle. Basketry, carpentry, pottery, and others of the less physically demanding crafts may be taught and practiced.

BIBLIOGRAPHY. C.W.H. HAVARD (ed.), *Fundamentals of Current Medical Treatment*, 3rd ed. (1970), covers the whole field of medical treatment; a selected bibliography is provided at the end of each chapter. D.R. LAURENCE, *Clinical Pharmacology*, 3rd ed. (1966), is intended for medical students, with references given at the end of each chapter. *Cecil-Loeb Textbook of Medicine*, 12th ed. by P.B. BEESON and W. MCDER-

MOTT (1967), is a medical classic not confined to therapeutics; covers the etiology, diagnosis, and treatment of disease. (C.W.H.H./J.E.St.)

Thermionic Devices

Thermionic devices convert heat directly into electricity by means of thermionic emission—the ejection of electrons from a heated surface—rather than by changing it first to some other form of energy. Heat for the device is supplied by chemical, solar, or nuclear sources. It differs somewhat from the vacuum diode, primarily in the source of heat for the cathode.

Thermionic emission is the liberation of electrons from a hot cathode, or emitter. The emitted electrons travel through a vacuum or gas-filled space to a cool anode, or collector. Useful electrical power can be extracted by a load—a resistor or other impedance device—connected between the cathode and anode. The phenomenon was first observed in the middle of the 18th century by Charles DuFay, a French experimenter, who noted that gas near a heated solid conducts electricity. In 1853 Edmund Becquerel, a French physicist, reported that a measurable electric current could be produced by a potential of a few volts in air if the air was heated between hot platinum electrodes. Toward the end of the 19th century in Germany, Julius Elster and Hans Geitel, experimenting on a sealed device that contained two electrodes, noted that charges flowed from the heated electrode to the cooled electrode.

Thermionic emission was identified by Thomas A. Edison in 1883 when he observed that a current passed from a heated filament of an incandescent electric lamp to a conductor in the same glass bulb. Later, W.H. Preece and J.A. Fleming, two English scientists, showed that this effect was produced by electrons flowing through the vacuum from the heated cathode to the anode. J.J. Thomson, an English physicist, in 1897 recognized that electrons exist in solids and described thermionic emission as the "boiling off" of free electrons from solids into a vacuum cavity (see also ELECTRON TUBE).

Thermionic work function

Another English physicist, O.W. Richardson, in 1916 identified the thermionic work function (a measure of the energy required for an electron to free itself from the surface of the metal) and determined emission current density with the aid of kinetic theory. His theory was subsequently corrected by S. Dushman, a U.S. scientist (1930), following the discovery by Enrico Fermi of electron properties in metals (1927). The basic expression for emission current is thus called the Richardson-Dushman equation.

The development of thermionic converters was delayed until the 1950s when the impetus of space exploration promoted renewed interest. A vacuum thermionic converter and the cesium-filled thermionic converter were developed shortly after 1955.

EFFICIENCIES

A thermionic converter is a device with a heated electron emitter (cathode) electrically insulated from a cooled collector (anode), with the gap between them either a vacuum or filled with a metallic vapour. The elements are placed in a gas-tight envelope, with provisions for connecting a heat source to the cathode, a coolant to the anode, and electrical leads to a load.

Typically, the emitter operates at a temperature near 2,000° K (1,727° C), and the collector at 1,000° K (727° C).

The operation of a thermionic converter is influenced by a number of physical characteristics:

Fermi energy. The Fermi energy, or Fermi level, of a solid is the maximum energy that electrons in a solid may reach, even at absolute zero, because of the crowding of electrons.

Work function. The work function is the energy that must be imparted to an electron near the Fermi level of a solid to get the electron out of the solid into a cavity. The work function of tungsten, a typical material for emitters, is 4.52 electron volts (eV), but a collector work function of 0.6 eV has been obtained.

Ionization potential. The ionization potential is the energy that must be imparted to an atom to remove an atomic electron and move it an infinite distance away, making it a free electron. The atom is then said to be ionized.

Thermionic current density. The thermionic current density J_e of a solid is given by the Richardson-Dushman equation in the form:

$$J_e = AT^2 \exp(-1.6 \times 10^{-19} \Psi / kT) \text{ amperes/cm}^2$$

based on the projected area of the electrode, in which $A = 120.4$ amperes per square centimetre °K² for an ideal metal, for T in degrees Kelvin; Ψ is the work function in electron volts; k is the Boltzmann constant, with the numerical value 1.38×10^{-23} joule/°K. (If the temperature T is measured in degrees Kelvin, the quantity kT has the dimensions of an energy and is usually called the thermal energy.) At 300° K (room temperature), $kT/1.6 \times 10^{-19} = 0.0259$ electron volt. Among real materials, A varies: 60.2 for tungsten, molybdenum, and tantalum; 330 for zirconium; 17,000 for platinum; 1.4 for alumina; 1.1×10^{-5} for magnesia.

THE VACUUM CONVERTER

In a thermionic converter with a vacuum gap between the electrodes, the electron gas is boiled out of the heated cathode at a high temperature and passed through the vacuum to a colder anode. The electron gas is then condensed at the anode, which is cooled to maintain a lower temperature than the cathode. The electron gas then passes through the external circuit and back to the cathode side to deliver electric power.

Electrons pass through a retarding electrostatic field. The base line corresponds to the potential of the electron in the cathode or the emitter. Heat lifts some of these electrons over the work function barrier at the surface of the emitter, Ψ_E. As soon as an electron escapes the surface of the emitter, it enters into the vacuum gap with other emitted electrons, encountering a retarding potential or space charge potential because of repulsion by other electrons in the gap. Only those electrons with initially sufficient energy to pass over the peak of the potential can reach the anode side. The anode also emits at its temperature, but the net electron flow is from the cathode to the anode (or collector), whose work function is Ψ_c. The net output voltage is V, given by the difference in electric potentials produced by these work functions and after deducting the space charge potential.

To limit the space charge effect, the vacuum gap or interelectrode spacing has to be 0.001 inch (0.025 millimetre) or less. With both electrode surfaces of tungsten impregnated with oxides of barium, aluminum, and calcium, a maximum current density of three amperes per square centimetre can be obtained with a cathode temperature of 2,308° F and an anode temperature of 1,000° F. These conditions yield a maximum output of one watt per square centimetre at 0.7 volts, giving an efficiency of 12 to 13 percent. An output of 10 to 30 watts per square centimetre at 15 percent efficiency is obtainable.

Reduction of space charge effect

Because of the limitations of the vacuum converter and the difficulty in maintaining a small gap (down to 0.0004 inch [0.01 millimetre]), various methods of reducing space charge have been studied. Space charge can be reduced by suitably applied magnetic fields and auxiliary electric fields; by introducing another grid, as in the triode; and by neutralizing the space charge with metallic vapour. The last has proven to be by far the most successful.

GAS-NEUTRALIZED CONVERTERS

The most efficient thermionic converters are filled with a cesium vapour, chosen because of its low ionization potential (3.87 eV). Other metals, such as rubidium and potassium, produce similar results. Metals with a high ionization potential permit a high collector temperature and still have less back emission of electrons compared to cesium. Emitter materials of tungsten, molybdenum, tantalum, and rhenium have been tested. A collector of molybdenum is common. Heat lifts some of the thermionic

electrons over the work function barrier at the surface of the emitter. As soon as an electron escapes, it is accelerated by the potential created by cesium ions just outside of the emitter (emitter sheath drop). A small portion of these electrons helps produce cesium ions, Cs^+, but the majority flows through the nearly neutral plasma (equal number of Cs^+ ions and electrons) to the collector, a slight energy loss resulting from the collision with ions and atoms of cesium. The loss is reduced by keeping the gap between the electrodes small.

Cesium vapour contributes to satisfactory performance because (1) cesium ions neutralize the space charge effect of electrons; (2) adsorbed cesium produces a low work function of the collector Ψ_c, thus providing greater output voltage; (3) adsorbed cesium in the emitter adjusts its work function to permit an optimum number of electrons to escape.

The cesium pressure is controlled by a liquid cesium reservoir in the converter system. Depending on the cesium pressure used, there may be two different designs:

High- and low-pressure devices

1. High-pressure devices. When cesium pressure is several millimetres of mercury, the cathode is covered by cesium. A small interelectrode spacing of one mil is required to limit the loss from back scattering of electrons. A suitable cathode temperature is in the 1,500° to 1,800° C range.

2. Low-pressure devices. A low cesium pressure of 10^{-2} millimetres of mercury or lower, in conjunction with high emitter temperature of above 1,800° C, results in a cesium-free cathode. A larger interelectrode spacing (from two to ten mils) is permissible because of negligible electron scattering. In a low-pressure device with the emitter temperature lowered to 1,200° C, arcing occurs and ions are generated by impact ionization of cesium. Part of the electric energy output is dissipated in the arc (called "ball of fire").

The thermionic converter is a low-voltage, high-current device. A typical cesium vapour-filled device, with cylindrical electrodes one inch (25.4 millimetres) long and one-half inch (12.7 millimetres) in diameter, produces 0.7 volt at 70 amperes; a flat converter 1¼ inch (31.8 millimetres) in diameter, heated by focussed solar energy, produces 1.3 volts at 64 amperes. In laboratory units, 15 to 17 percent efficiency has been achieved; units with 20 percent efficiency are easily built.

DEVICES AND APPLICATIONS

The fact that a thermionic converter is a high-temperature heat engine suggests various applications: an electrical power source for space vehicles; a device for utilizing high temperatures, such as the initial high-temperature steam, utilizing a maximum temperature higher than the permissible steam temperature, in a nuclear power plant; a compact power plant for mobile or stationary applications; and a compact portable electrical generating system.

The heat for a thermionic device may come from any convenient source, and may be nuclear, chemical, or solar in origin. Nuclear fuel is attractive because of the large energy yield per pound of fuel and because the high temperature at which the heat energy can be delivered matches the desirable temperatures in thermionic converters. Because of critical mass, minimum economical unit capacity is limited when heat is supplied by nuclear fission. In the form uranium dioxide, UO_2, uranium-233 is preferred to uranium-235, the minimum for both being around a 50-kilowatt level. Control is similar to that of fission nuclear reactors (*q.v.*). When a fuel element is needed for emitters, a combination of carbides such as UC-ZrC (uranium carbide-zirconium carbide) or uranium carbide alone is used. For low unit capacity below one kilowatt and up to the multikilowatt range, radioactive isotopes may be employed for heating. If low cost, penetrating radiation, and long life are important, cobalt-60, strontium-90, and cesium-137 in the form of cobalt metal, strontium oxide, strontium difluoride, and strontium titanate may be employed. For short-lived application, cerium-144 and rubidium-106 in the form of the cerium oxide may be used; for long-lived weak radiation, plutonium-238 in the form of the oxide or promethium-147 may be used; and for short-lived, weak radiation, gaseous krypton-85, polonium-210, or curium-242 may be used.

Designs may take the form of in-reactor or out-of-reactor systems. The latter simplifies problems of constructing the enclosure to avoid permanent change in dimensions (creep) and rupture due to the extremes of temperature and radiation environment inside the reactor. The in-reactor system, however, is more compact. The successful use of nuclear thermionic devices depends upon the containing and maintaining of the dimensional stability of the isotope and fission heat source. Reactor lifetime is limited by the reactivity of fuel or fuel element swelling.

Solar-powered thermionic systems are designed mainly for space applications. Combustion heated systems are designed for ground and power plant applications.

In spacecraft. Thermionic devices can be applied in space as uncomplicated and lightweight power sources in the following manner:

1. For electrostatic or electromagnetic propulsion. This may require units from 1,000 to 10,000 kilowatt of electric power (kWe). The most likely design would be a thermionic converter in a reactor, with liquid-metal heat transfer to the radiator.

2. Space auxiliary power for manned spacecraft. The power demand would range from 10 to 50 kWe and could be met with a thermionic converter on the surface of a reactor.

3. Instrumentation and control. Requiring up to 10 kWe, the choice could be a solar-heated thermionic converter or an isotope-heated system.

When selecting a nuclear source for a space mission, both fuel and launch costs must be considered. Around 100 kW, cobalt-60 shows promise as a leading heat source for multikilowatt power in space. A cobalt-60 kernel with shielding will prevent loss of the radioactive material by diffusion or chemical attack. Its weight is comparable to a plutonium-238 heat source and costs are substantially lower.

The fast spectrum reactor

A typical thermionic reactor element for space applications is the so-called fast spectrum (of neutrons) flashlight reactor, having a wet cell thermionic fuel element with the sheath insulator in a cesium environment (cesium is isolated from the sheath insulator in the dry cell). Subassemblies of cells, containing emitters of one diode and collectors of the next, are enclosed in a long bilayer type of insulator and sheath. A three-cell series-connected diode has approximately 20 square centimetres of emitter area for 300 watts (140 amperes at 2.1 volts) normally. A full length element consists of 10 to 12 diodes in series for 1 kW at 8 volts. The fuel elements are assembled to form a cylindrical core. For 100 kWe the overall size is 24 in. (61 cm) diameter × 26 in. (66 cm) high, and 2,400 lb weight (7,200 lb total, including radiation shield and auxiliaries). A single coolant loop flows through the reactor at a liquid metal temperature of 600° to 700° C. Other concepts are moderated "flashlight" reactor with a fuelled moderator element such as uranium zirconium hydride, providing a reduced minimum critical size; externally fuelled coolants in tubes, a unit cell "pancake" (flat) concept; out-of-core, using a heat pipe (see HEAT EXCHANGERS) with a reactor of uranium nitride or tungsten and gas as a heat transfer fluid; and a direct-radiating reactor with the anode arranged outside of the reactor for radiation into space.

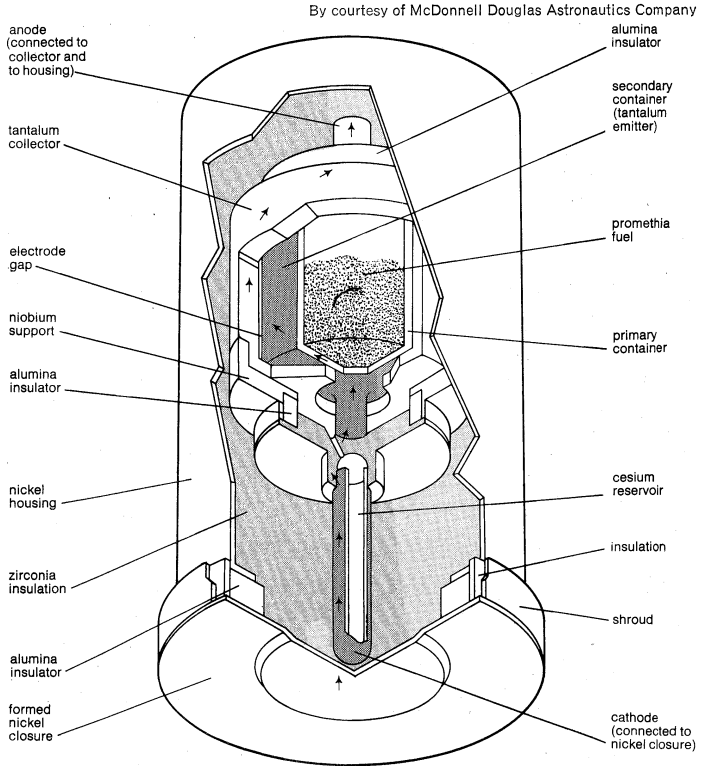
A 108-watt thermionic generator of 7.6 percent efficiency for space applications has been tested for 3,000 hours.

Solar-powered thermionic generator modules, with five converters in each module (4.33 cm^2 emitter area yielding 8 watts/cm^2 at 2,000° K), have been constructed. The emitter is tantalum and the collector is molybdenum, with two-mil spacing using low-pressure cesium. Each module is heated by a solar concentrator measuring five feet in diameter. The specific power is 440 lb/kW for a 1.5 kW total. Although technically demonstrated and proven for a two-year lifetime, this solar-heated device was not employed.

For a space propulsion system of 1,000 kWe of power, both a nuclear steam-turbine power plant and a nuclear

thermionic power plant have been proposed. Since the only cooling available is by radiation into space, the condenser, or cooler surface area, can be made smaller as the condenser temperature is increased. A realistic condenser temperature could be 400° K because the strength of the turbine blades limit inlet temperature to 1,000° K. The top or cathode temperature of a thermionic system could be 2,000° K, and the anode or cooler temperature 1,200° K.

Aside from other considerations, the radiator area of such a thermionic power plant would be only 1/81 as large as that in a steam power plant.



Comparison with other energy conversion devices

Unlike conventional heat power devices—such as Rankine cycle, Brayton cycle, and Stirling cycle power plants—thermionic devices, like other direct energy conversion devices, have no rotating or reciprocating parts, thus eliminating the need for attended operation. Other advantages include the ability to tolerate large acceleration higher than 30 times the force of gravity, low system weight, and the fact that efficiency of operation is largely independent of unit capacity.

When compared to other direct energy conversion devices (fuel cells, thermoelectric devices, solar cells, MHD [magnetohydrodynamic] generators), thermionic devices have the lowest specific weight: 1 lb per kWe is practical, compared to 1,000 for solar cells, 250 for thermoelectric devices, and 100 for chemical fuel cells. Thermionic devices are best suited for high temperatures (1,500° K, compared to the 800° C maximum temperature for a thermoelectric system). In a nuclear isotope space power system of 4 kWe, a thermionic system has highest efficiency (10–12 percent), smallest radiator area (20–25 ft^2), and lowest system weight. A thermionic system with the converters in the core of a reactor has a specific weight of 7 lb/kWe for the 100- to 1,000-kWe range, including shielding.

When utilizing solar heat, a thermionic system with a solar concentrator is again less than one-half the weight of a solar-cell system of similar capacity.

Ground power stations. Thermionic devices can be employed effectively in ground power stations. Energy in the form of electricity can be extracted from high-temperature steam by a thermionic converter during the process of lowering the temperature to that required for the steam turbine (maximum 700° C). This is called "topping," and the technique can increase power output by 20 percent or more.

Flame-heated thermionic converters have been developed for 5 to 200 watts. The combustion chamber is a silicon carbide-coated molybdenum cup, the outside acting as an emitter. With an emitter area of 6 cm^2, 5 watts/cm^2 were produced at 1,300° C. A 70-watt unit using a silicon carbide envelope, impermeable to combustion products, has functioned for 1,200 hours. Portable units, a 300- to 600-watt backpack and 1- to 3-kW base-site power system, have also been produced.

For power generation, a nuclear thermionic system does not differ markedly from that of a fossil fuel system. The treatment and removal of fission products are similar in all nuclear reactors.

A large quantity of fission products is generated in a nuclear fuel element in a year of operation. Disposal methods depend on the type of fuel and emitter materials, operating temperature, and design. Gaseous and volatile fission products may be removed directly from the emitter and the interelectrode space through an exhaust system, by diffusion through the emitter or by venting from the emitter. Some build up of fission product concentration in the cesium is tolerable because of the small electron scattering cross section of xenon, the most abundant fission product.

For ground applications the fission products are treated as in any nuclear reactor system.

Inaccessible regions other than space. Nuclear-fuelled thermoelectric systems have been selected for use in remote radio stations, but for the power range, thermionic systems could serve as well. A small nuclear thermionic electric power source is particularly useful in remote locations.

Isotope-powered converter

Among developments of special interest is the ISOMITE unit. This isotope battery (see the Figure) is a relatively low-temperature thermionic converter powered by a radioisotope. It operates at a very low cesium pressure, about 10^{-3} to 10^{-2} torr (millimetres of mercury). Power ranges are 100 μW, 10 mW, and up to 1 W, fuelled by promethium-147 oxide Pm_2O_3. Typical data are as given in the Table.

Typical Characteristics of an Isotope-Powered Thermionic Converter

output	1 μW	10 mW
Total heat output (W)	0.27	3.6
Curies of activity	750	10^4
Fuel capsule diameter (cm)	0.71	1.76
Emitter area (cm^2)	3.0	14.6
Interelectrode spacing (cm)	0.013	0.0063
Total volume (cm^3)	0.28	4.28
Total weight (gm)	11	87
Emitter temperature (° K)	780	870
Collector temperature (° K)	700	703
Collector work function (eV)	1.42	1.48
Maximum power (mW)	0.780 at 0.1 V	19 at 0.145 V
Efficiency (percent)	0.29	0.55

Battery life is normally five years; with plutonium-238 (Pu-238) fuel, 10 years of life can be expected.

A small power unit such as this has many applications, such as a satellite power source for deep space probes, in underwater power supplies, and in remote terrestrial applications.

LIMITATIONS

Thermionic converters lack moving parts, but there are sources of deterioration in the devices. Vapour pressure of the emitter material, for example, produces evaporation or sputtering. Also, the electrode materials are subject to creep (permanent change in mechanical dimensions) and to rupture under thermal cycling and from stress corrosion.

Some form of power conditioning is usually needed in a thermionic converter to change direct-current (dc) to alternating-current (ac) electricity. Dc can be changed to ac

by applying a small modulating signal or by switching, using an electromagnetic field or plasma injection.

FUTURE POSSIBILITIES

In large power applications for space (above 1,000 kWe), the nuclear thermionic system appears to have advantages over a vapour cycle turbine system, partly because of its inherent compactness.

In terrestrial nuclear power systems thermionic conversion is superior to either the magnetohydrodynamic (MHD) generator or the thermoelectric system for power plant topping. With fossil power, however, the MHD system may be a more attractive topping technique.

Extensive undersea applications, both small power and large power, still await development. For this use the thermionic converter is substantially more efficient than the thermoelectric system.

Thermodynamics, Principles of

Thermodynamics is that part of physical science that is concerned with the conditions that material systems may assume and the changes in conditions that may occur either spontaneously or as a result of interactions between systems, including interactions such as heat, which cannot be described in terms of mechanics. It is basic to the distinction between mechanics and thermodynamics that according to mechanics all the energy of a system in any state is convertible to work, whereas according to thermodynamics only a fraction of the energy of a system in most states is convertible to work without other effects. The scope of thermodynamics has been steadily broadening since early in the 19th century as a result of a better understanding that has grown up of its underlying principles.

The word thermodynamics was derived from the Greek words *thermē* ("heat") and *dynamis* ("force"). The beginnings of the study of thermodynamics are found in the early 19th century in the study of the motive power of heat; that is, the capability of hot bodies to produce mechanical work. These early studies revealed several underlying principles, the most important of which are the first and second laws of thermodynamics. The discovery and clear enunciation in 1850 of the two laws by Rudolf Julius Clausius, a German mathematician and physicist, broadened greatly the scope of the subject. Throughout the rest of the 19th century it developed into a science, now known as classical thermodynamics, concerned primarily with physical systems in or passing through stable equilibrium states (the terms system and state are defined below). More recently thermodynamics has been extended to include physical systems in nonequilibrium states.

Although the development of thermodynamics, in contrast to other aspects of the study of physics, has progressed without regard to the details of the microscopic structures of physical systems, many scientists, beginning with Ludwig Eduard Boltzmann, Austrian physicist, have felt that the laws of thermodynamics might be justified and explained by means of detailed microscopic descriptions of matter and the laws of mechanics (classical or quantum) and statistics. Work in this direction has resulted in the development of the branch of thermodynamics known as statistical thermodynamics, which, though it plays an important role in the evaluation of properties of systems, has not achieved one of its original goals, namely, the derivation of the laws of thermodynamics from the laws of mechanics. In particular, it now appears that the second law of thermodynamics is an independent law of nature. This particular point will be clarified below.

This article is divided into two parts. In the first part, the general principles of thermodynamics that apply to any physical system in any state—and the corollaries of these principles—are presented without reference to the detailed microscopic structure of matter. The presentation, therefore, encompasses both classical and nonequilibrium thermodynamics. In the second part, the detailed microscopic structures of physical systems are considered, and the states of such systems are discussed in the light of the laws of both quantum mechanics and thermodynamics. Quantum mechanics and thermodynamics are shown to be complementary parts of physical science, and they are neither separable nor are they derivable one from the other.

This article is divided into the following sections:

I. Brief history of classical thermodynamics
II. Basic concepts and laws of thermodynamics
  Systems, states, and properties
  Work and nonwork
  First law
  Second law
  Entropy
  Stable equilibrium
III. Simple systems
  Stable equilibrium states
  Maxwell relations
  Phase rule
  Simple one-component systems
  Simple multicomponent systems
  Bulk flow
  Chemical reactions
  Availability functions
  Negative temperature
  Third law
IV. Force fields
  Nonrelativistic effects
  Relativistic effects in a gravity field
V. Steady rate processes
  Approach to mutual stable equilibrium
  Flow of a substance through a barrier
VI. Statistical thermodynamics
  Gibbsian statistics
  Quantum statistical thermodynamics
  Statistics of grand systems
VII. Concluding remarks

I. Brief history of classical thermodynamics

Temperature is probably the earliest thermodynamic concept to attain operational status. Early in the 17th century Galileo, an Italian astronomer and physicist, devised a thermoscope that was a rudimentary thermometer. Soon thereafter a liquid-expansion thermometer with bulb and stem, open at the top, was devised in France by Jean Ray. In 1640 the grand duke Ferdinand II of Tuscany, one of the founders of the Florentine Academy of Experiment, invented the sealed-stem alcohol thermometer. Such devices were put to clinical (determining degrees of fever), agricultural (incubation), and meteorological uses.

Early attempts to measure temperature

The purpose of these instruments was to measure a quantity, that had as yet been undefined, that was more objective in nature than the physiological sensations of hotness and coldness. An equilibrium concept was probably involved; namely, that all bodies exposed to the same atmosphere would ultimately attain the same degree of hotness or coldness, despite any contrary evidence of the senses. An associated concept of the equilibrium concept was that temperature is a driving potential that causes some influence to pass from one body to another of unequal hotness or coldness. Thus, when a body is taken from a warm room to the cold outdoors, its length begins immediately to decrease.

What was it that passed from one body to another at different temperatures? Was it temperature itself that was

transmitted? The English philosopher and scientist Francis Bacon as early as 1620, and the Florentine Academy a few years later, began to make this distinction between this influence and temperature; but it was more than a century before Joseph Black, a chemist at the University of Glasgow, in 1770 made the distinction sharply. He showed by mixing equal masses of pairs of liquids of different temperatures that the temperatures of the two substances often changed by radically different amounts. Indeed, a large change in temperature of a solid body produced no change at all in the temperature of a mixture of ice and water or of water and steam. Temperature was not necessarily conserved or even transmitted in the process.

Black established the science of calorimetry, which led to the establishment of the caloric theory, based upon the following postulates: (1) Caloric is an all-pervading elastic fluid, the particles of which repel one another strongly. (2) Particles of caloric are attracted by particles of matter. (3) Caloric is conserved. (4) Caloric is either sensible (*i.e.*, change in caloric is associated with change in temperature) or latent. (5) Caloric has weight. These postulates were intended to account for expansion and contraction upon heating and cooling, variations in heat capacity, calorimetry, latent heat, and gain in weight of certain metals when heated in air (calcined). Frictional heating was subsequently accounted for by postulating that friction reduced the attraction between caloric and matter.

Toward the end of the 18th century, Count Rumford (Benjamin Thompson), an expatriate American colonial engineer and physicist, attacked the validity of the caloric theory on the basis of experiments intended to show that caloric could be created and, therefore, was not conserved. More refined measurements on the generation of heat by frictional work were made nearly a half century later by an English physicist, James Prescott Joule.

Carnot's heat engine

In 1824 Sadi Carnot, a French military engineer, introduced the concept of the heat-engine cycle, a concept that permitted a sharp distinction to be made between interactions of systems and changes in their states. Carnot then proved from conservation of caloric and the impossibility of the production of work without compensating changes in the environment that (1) a reversible cyclic engine is the most efficient possible means of producing work from heat, and (2) all reversible cyclic engines operating between the same pair of heat reservoirs must have the same efficiency. Although the proof, as it turned out, was invalid, Clausius asserted in 1850 that Carnot's principle is itself a basic postulate and is, in effect, what came to be known as the second law of thermodynamics.

In the decade of the 1840s Joule laid the foundations of the first law of thermodynamics by showing that the amount of work required to bring about a given change of state is independent of the kind of work (whether mechanical, electric, or magnetic), the rate of doing work, or the method of delivering it. Joule concluded that work can be converted into heat, with a fixed ratio of one to the other, and that heat can be converted into work. In 1844 Julius Robert von Mayer, a German physicist, postulated that in a work-producing cycle the heat introduced must exceed the heat rejected by an amount proportional to the work. He deduced the value of the proportionality constant from calculation of cycles in a gaseous system.

In 1849 Lord Kelvin (William Thomson), an engineer of Glasgow, pointed out the conflict between the caloric basis of Carnot's arguments and the conclusions reached by Joule. In 1850 Clausius resolved the difficulty by stating explicitly the first and second laws of thermodynamics. Within a few years Clausius defined and named the property entropy that is conserved in all reversible processes, and derived from the second law the principle of increase of entropy.

The first law was stated by Clausius as follows: In all cases in which work is produced by the agency of heat, a quantity of heat is consumed that is proportional to the work done; and, conversely, by the expenditure of an equal quantity of work, an equal quantity of heat is produced. He applied this statement to a cyclic process in a system (a concept with which he credits Carnot) in order to obtain a statement of the first law in terms of work and heat without reference to alteration in the state of the system. This led naturally to a definition of the property energy—called mechanical energy by Kelvin and contracted to energy by J. Willard Gibbs, an American mathematician and physicist. Clausius stated the second law in the following terms: A passage of heat from a colder to a hotter body cannot take place without compensation.

Clausius' paper of 1850 marked the birth of the science of thermodynamics. Immediately thereafter, Kelvin, who had previously displayed an interest in the theory of temperature, proposed and discussed various definitions for thermodynamic temperature scales, including the one that now bears his name. James Clerk Maxwell, a physicist of Edinburgh and Cambridge, averred that two bodies each equal in temperature to a third body are equal in temperature to each other. This statement, which is sometimes called the zeroth law of thermodynamics, is an incomplete version of a condition for equilibrium, subsequently derived by Gibbs and others, that is a corollary of the second law. Maxwell also devised a number of mathematical relations that now bear his name. Kelvin and Max Planck, a German physicist, later restated the second law, so as to avoid the undefined term compensation used by Clausius, in terms of the impossibility of a perpetual-motion machine of the second kind (see below).

In the years 1873–78 Gibbs published three papers that proved to be definitive as regards the conditions for equilibrium. These papers provided a mathematical method so orderly and systematic that they have served as the foundations of physical chemistry and many subsequent applications of classical thermodynamics.

At the turn of the century, the French mathematician Henri Poincaré addressed the problem of definition of temperature and heat and the statement of the first and second laws. In 1909 Constantin Carathéodory, a Greek mathematician teaching in Germany, presented an alternative logical structure in which he shunned use of the term heat. It is closest in method and spirit to that used here. He states the two laws as follows: First, an extensive property exists the increment in which is the work received by the system while surrounded by an adiabatic wall (an adiabatic wall being one that permits only work interactions between the system and its surroundings). Second, in the neighbourhood of any prescribed initial state are states that cannot be reached by an adiabatic process.

In 1918 Walther Nernst, a Nobel-Prize winning chemist of Germany, stated the Nernst heat theorem, treated below, which is essentially the third law of thermodynamics, which rounds out the exposition of classical thermodynamics by providing a common base for values of entropy for all atoms or molecules that can be formed from simpler species.

II. Basic concepts and laws of thermodynamics

SYSTEMS, STATES, AND PROPERTIES

The description of physical phenomena is based on the concept of state of a system and the changes of state that occur either spontaneously or because of interactions with other systems. Knowledge of the states of a system is equivalent to knowledge of the outcomes of all possible observations on the system; namely, observations of all its properties.

The term system means any identifiable collection of matter that can be separated from everything else by a well-defined surface so that changes in everything else need not affect the condition of the collection. Examples of systems are a number of water molecules confined within a watertight container, a thermonuclear plasma (a special collection of charged particles) confined by a suitably designed magnetic field, and the vapour of a solid within a cavity in the solid.

The particles of a system may have a finite rest mass, as do molecules, atoms, or electrons, or zero rest mass, as do photons. The number of particles of a system can be large, as in a cubic centimetre of tungsten, or small, as in a hydrogen atom.

At any instant of time a system is in a condition called a state, which encompasses all that can be said about the results of any measurements or observations that can be performed on the system at that time. The state at a given instant of time determines the properties of the system. A property is any quantity the value of which depends upon the state but not the history of the system. For a given state the value of a property can be determined by some type of measurement (some physical operation or test). When the values of all properties of two states are identical, the two states are identical; otherwise they are different.

Because of unavoidable quantum mechanical considerations, a simple measurement, no matter how nearly perfect, will not yield the precise value for a property. In general, a very large number of measurements of the same kind is required to yield the precise value, each measurement performed on a duplicate of the system in the given state and each yielding a different result. The value of a property is defined, therefore, as the sum of all the results of the measurements of the property divided by the number of measurements (in other words, the arithmetic average or expectation value of all the results of the measurements of the property). It will be shown below that a state can be described by a set of weighting factors, or probabilities, that enter into the evaluation of all properties.

Measurements and values compared

Although an indefinite number of properties can be associated with a state, the values of these properties are not all independent of each other. The number of independent properties is finite and is either small or large, depending on the type of state in question; that is, on whether or not it is a stable equilibrium state. The meaning of the terms that define the various types of states will be given below.

WORK AND NONWORK

An interaction between two systems such that whatever happens in each of the interacting systems could have been brought about while the sole effect external to each system was the change in level of a mass in a gravity field will be defined as work; that is, work is an interaction that must satisfy a test: each of the interacting systems is separately required to experience the same changes as in the actual interaction, but, through alteration of circumstances external to that system, the effect outside of it is solely the rise or fall of a mass. If this test can be satisfied in the case of both systems, then the original interaction is work.

It can be shown from experimental evidence that the following interactions conform to the definition just cited and are, therefore, work interactions: (1) the displacement of a point on the boundary of a system at which point a force is exerted in the direction of the displacement by another system (this is essentially the definition of work in mechanics, which is less general than the one given here, which covers interactions other than those considered in mechanics; the present definition implies that the force applied on a body by a stationary force field, such as gravity or an electrostatic field, results in no work, even though the body is in motion—for example, freely falling); (2) the electromagnetic interactions between primary and secondary coils of a transformer; and (3) the exchange of radiation emitted by lasers. Such radiation consists of wave particles, which are in order relative to each other as contrasted with those, for example, from an incandescent lamp, which are randomly arranged. On the other hand, it can be shown by virtue of the second law that the exchange of radiation between a hot system and a cold system (such as blackbody radiation) does not conform to the requirement stated in the definition of work and is not, therefore, a work interaction.

Work is one of several distinguishable types of interaction that can occur between two systems. Any interaction that is not work will be hereinafter called nonwork. A special type of nonwork interaction that will be treated below in detail is a heat interaction. In general, an interaction is fully specified if the exact sequence of states, called the path, of each of the interacting systems is specified. In turn, the path of one of the systems and the interactions that occur specify the process experienced by the system. In an interaction that satisfies the definition of work, each system is said to be experiencing an adiabatic process.

The state and, therefore, the values of the properties of a system can change either spontaneously or as a result of interactions with other systems. During changes of state the values of certain properties are subject to limitations imposed by the laws of physics. The limitations imposed by thermodynamics are consequences of the first and second laws, which will be stated here in an unusually general way.

FIRST LAW

The first law is a statement of existence of a property called energy. It is based on the concept of work and can be stated as follows: For any process involving no effects external to the system except displacement of a mass between specified levels in a gravity field, the magnitude of that mass is fixed by the end states of the system and is independent of the details of the process. This law has many implications or corollaries, some of which are as follows.

1. *Uniqueness of work values.* By virtue of the first law a unique number can be assigned to a work interaction between two systems. This number is n when n arbitrarily selected units of mass are displaced between two arbitrarily specified levels in a gravity field. The sign of work is selected positive when work is done by a system—that is, when the sole external effect would be the rise of a weight.

Consequences of the first law

2. *Definition of energy.* By virtue of the first law, the work in an adiabatic process depends on the initial and final, or end, states only. It follows that a property of a system can be defined, called energy, such that its change of value between states A_1 and A_2 is equal to the work W_{12}^a involved in an adiabatic process that has A_1 and A_2 as end states. In terms of symbols, if E_1 and E_2 denote the energies of states A_1 and A_2, respectively, and W_{12}^a the work done in any adiabatic process connecting A_1 and A_2, the difference $E_2 - E_1$ is equal to the negative of W_{12}^a; *i.e.*,

$$E_2 - E_1 = -W_{12}^a. \tag{1}$$

Energy is only partially defined by equation (1) because the difference between E_1 and E_2 does not specify the values of E_1 and E_2. An arbitrary value such as zero, however, can be assigned to E_0 of some reference state A_0, so that the energies of all other states are fixed by equation (1).

It will be shown below that by virtue of the second law of thermodynamics certain interactions that cause change of energy cannot be described as work. The corresponding process is, by definition, a nonadiabatic process. Because energy is a property, the energy change associated with any nonadiabatic process will equal numerically the work in any adiabatic process between the same end states.

Because work values are additive, energy is an additive or extensive property; that is, the energy of a whole is equal to the sum of the energies of its parts.

3. *Conservation of energy.* The magnitude of the work in an adiabatic process can be positive, negative, or zero, depending on the end states of the process, but zero adiabatic work does not necessarily imply identical end states. An adiabatic zero-work change of state may occur spontaneously in a system, as, for example, when an electrical capacitor discharges through an internal resistor. During such a process, equation (1) requires that the energy of the system remain invariant. This is the so-called law of conservation of energy, which is a consequence of the first law of thermodynamics. The

first law, on the other hand, cannot be deduced from the law of conservation of energy.

A system that experiences an adiabatic, zero-work process is said to be isolated from all other systems in the environment.

4. *Impossibility of perpetual-motion machine of the first kind.* A perpetual-motion machine of the first kind (PMM1) is any system that undergoes a cycle and has no external effect except the rise of a weight. The term cycle (or cyclic process) is defined as a process in which the initial and final states of the system are identical.

By virtue of the first law, the work of an adiabatic cycle must be equal to zero and, therefore, a PMM1 is impossible.

5. *The first law and relativity.* According to the general theory of relativity, the energy E of a system is equal to the product of its mass m and the square of the speed of light c in a vacuum, namely,

$$E = mc^2. \qquad (2)$$

By virtue of the first law, the energy E of an isolated system is conserved. Therefore, equation (2) requires that the mass m of the system is also conserved, regardless of the processes occurring within the system (such as chemical reactions, nuclear reactions, and creation and annihilation of particles). Moreover, if the energy of a system is altered by virtue of an adiabatic or nonadiabatic interaction, the mass of the system must also be altered in accordance with equation (2). In most applications the energy transferred to or from a system is so much smaller than the total energy mc^2 of the system that the change in mass is negligible.

Conservation of mass

SECOND LAW

The second law is a statement of existence of stable equilibrium states and of special processes that connect these states to others. More than the first law, the second law distinguishes thermodynamics from other parts of physics. Because it has far-reaching implications concerning the properties and behaviour of matter, it is frequently invoked in discussions of philosophy as well as in discussions of physics.

Of the many statements of the second law, those of Clausius, Planck, and Carathéodory are the most notable. All of these statements imply the existence of a stable equilibrium state for given values of energy, the number of particles, and the constraints (see below)—an implication that is here taken to be the essential element of the second law.

The term equilibrium state means a state that does not change with time while the system is isolated from all other systems in the environment. Equilibrium state is sometimes confused with steady state: a steady state does not change with time even though the system, rather than being isolated, is interacting with other systems.

If a system is in an equilibrium state, a finite change of state may be caused by interactions with the environment, including those that leave no finite net effects in the environment. Several types of equilibrium states can be distinguished. Among these is the stable equilibrium state for which a finite change of state cannot occur, regardless of interactions that leave no net effects in the environment.

Consistent with its nature, a system might assume any one of a set of possible states, but some of the possible states may be prohibited by restrictions imposed by the environment. These restrictions are called constraints. For example, a given amount of gas may assume any of a large number of states. The same amount of gas, however, confined in a gas-tight container of fixed volume is restricted to states with volumes smaller than or equal to the volume inside the container. The possible states of the system that are consistent with the constraints will be called allowed states.

Constraints on systems

The second law can now be stated as follows: Among all the allowed states of a system with given values of energy, numbers of particles, and constraints, one and only one is a stable equilibrium state. Such a state can be reached from any other allowed state of the same energy, numbers of particles, and constraints and leave no effects on the state of the environment.

The second law cannot be derived from the laws of mechanics (either classical or quantum). The second law asserts that a stable equilibrium state exists for each value of the energy, whereas in mechanics the only stable state is that of minimum energy, what is known as the ground state.

Some corollaries of the second law are as follows.

1. *State principle.* By virtue of the second law, stable equilibrium states exist, and a unique stable equilibrium state corresponds to each set of values of energy, numbers of particles, and constraints. The uniqueness implies the following corollary: the value of any property of a system in a stable equilibrium state may be expressed as a function of the values of the energy, numbers of particles, and constraints only. This corollary is known as the state principle.

2. *Reversible and irreversible processes.* A process is reversible if the system and its environment can be restored to their initial states, except for differences of smaller order of magnitude than the maximum changes that occur during the process.

According to the second law, a system may start from any allowed state and reach the corresponding stable equilibrium state with no net effect on the environment. Such a process could not be reversible. For if it were, the system, starting from the stable equilibrium state, could undergo a process that ends at another state with no net effect on the environment. This conclusion, however, violates the definition of a stable equilibrium state. It follows that irreversible processes exist.

3. *Impossibility of perpetual-motion machine of the second kind.* It can be shown from the definition of a stable equilibrium state that a system in such a state can receive but cannot produce work. The plausibility of this corollary will be evident from the observation that work can always be used to change from any state to a nonequilibrium state by creating relative velocity of parts or compression to a smaller volume. If a system in a stable equilibrium state were to produce work, that work could be used to cause the system itself to end in a nonequilibrium state with no net effects on the environment—contrary to the definition of its initial state.

This corollary applies strictly only to systems of which the energy can be increased indefinitely, such as any system with particles free to move from one place to another or any system with translational degrees of freedom. Most practical systems satisfy this requirement. The generalization to systems that do not satisfy the requirement, such as a nuclear-spin system, is discussed below under *Negative temperature.*

A perpetual-motion machine of the second kind (PMM2) is any device that would deliver net work; *i.e.*, raise an external weight, while undergoing a cycle and interacting with a single system in a stable equilibrium state. A perpetual-motion machine of the second kind is a device that permits a system to violate the corollary stated above and is, therefore, impossible.

Prior to the discussion of the fourth corollary, it is necessary to define the terms mutual stable equilibrium and reservoir. Two systems A and B are said to be in mutual stable equilibrium if the combined system AB is in a stable equilibrium state. It can be readily verified that if two systems are in mutual stable equilibrium, each system must be in a stable equilibrium state. Moreover, if the two systems are brought into communication so that interactions are not prohibited, no interactions will occur unless the allowed states of at least one of the systems are altered.

Reservoirs as systems

A reservoir R is a special kind of a system that provides useful reference states for applications of the second law and satisfies the following conditions: (1) it is closed to the transfer of rest mass—*i.e.*, its boundaries cannot be crossed by material particles; (2) its constraints are invariant with time—for example, its volume has the same value at all times; (3) it passes through stable equilibrium states only; and (4) in the course of finite interactions it remains in mutual stable equilibrium with a dupli-

cate of itself that experiences no such interactions. An example of a reservoir is a mixture of solid, liquid, and vapour water in mutual stable equilibrium while enclosed in a container.

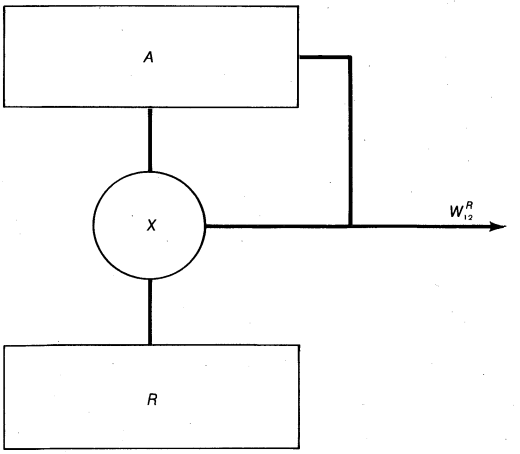

Figure 1: Production of work by a system A interacting with a reservoir R through an intermediate device X (see text).

4. *Work done reversibly by a system in combination with a reservoir.* A system A in combination with a reservoir R can experience a work interaction with other systems either directly or through an intermediate device X, or both, while X is undergoing a cyclic process (Figure 1). During this work interaction no rest mass is exchanged between A and R while the state of A changes from A_1 to A_2. The work done is denoted by W_{12}^R for processes in general and by $(W_{12}^R)_{rev}$ for processes that are reversible.

By virtue of the second law it can be shown that for a given change of state from A_1 to A_2, the work $(W_{12}^R)_{rev}$ is the same for all reversible processes and for all reservoirs in mutual stable equilibrium with each other; that is, $(W_{12}^R)_{rev}$ is fixed by the end states A_1 and A_2. Moreover, W_{12}^R cannot exceed $(W_{12}^R)_{rev}$ when both correspond to the same change of state from A_1 to A_2.

ENTROPY

The two laws of thermodynamics imply the existence of a property called entropy that is conserved in all reversible processes. Its definition is based on another property called available work.

Available work. Because for a given system and reservoir $(W_{12}^R)_{rev}$ depends on the end states of the system only, a property can be defined called available work (symbolized Ω, omega), such that its change of value between states A_1 and A_2 is equal to the work $(W_{12}^R)_{rev}$; that is (using the symbol $\equiv$ to imply definition),

$$(\Omega_2 - \Omega_1) \equiv -(W_{12}^R)_{rev}. \tag{3}$$

It can be easily verified that available work is an additive or extensive property.

Definition of entropy. Because both energy and available work are extensive properties, the difference between them is also an extensive property. Entropy will be defined as the extensive property S the change of which, DS, in a change of state is equal to a positive constant c_R times the difference between the corresponding changes of energy DE and available work $D\Omega$ evaluated with respect to a standard reservoir. This definition can be written in the form of an equation; *i.e.*,

$$DS \equiv c_R\,(DE - D\Omega). \tag{4}$$

The symbol D denotes a change, finite or infinitesimal, in magnitude of the property the symbol of which it precedes.

The standard reservoir may be chosen to be a mixture of solid, liquid, and vapour water in mutual stable equilibrium, and an arbitrary value, as explained below, may be assigned to the constant c_R. Subject to subsequent considerations, an arbitrary value may be assigned to the entropy of an arbitrarily selected reference state of the system. Thereafter, by means of equation (4), a value may be found for any state, equilibrium or nonequilibrium, once values for E and Ω have been determined by appropriate measurements.

Entropy changes in adiabatic processes. If the process from state A_1 to state A_2 in system A is adiabatic—that is, system A experiences only work interactions—then the work done by A must, by equation (1), equal the decrease in the energy of A. For a reversible adiabatic process the work done must, by equation (3), also equal the decrease in available work, so that the difference between the decrease in energy and the decrease in available work must be equal to zero. It follows from equation (4) that for a reversible adiabatic process the entropy change of the system is equal to zero; that is, the entropy is invariant. Moreover, because the fourth corollary states that the work for any adiabatic process cannot exceed that for the reversible adiabatic process, it follows that for an adiabatic process in general the entropy change must be greater than or at least equal to zero. In terms of symbols these conclusions can be written as

$$(DS)_{rev}^a = 0, \text{ for reversible adiabatic processes,} \tag{5}$$

and

$$(DS)^a \geq 0, \text{ for adiabatic processes} \tag{6}$$

(the symbol $>$ means "greater than," and $\geq$ means "greater than or equal to").

Principle of increase of entropy. When equation (6) is applied to any process in an isolated system—*i.e.*, to an adiabatic process for which the work is zero—it becomes

$$DS \text{ (isolated)} \geq 0. \tag{7}$$

Thus, the entropy of an isolated system may remain constant or may increase, but a decrease of entropy in an isolated system is impossible. Because any process in any system may be conceptually changed to a process in an isolated system by including in the isolated system all systems with which the original system interacts, the conclusion represented by equation (7) is of great generality. Equation (7) is known as the principle of increase of entropy, although it may be more strictly said to be the principle of the impossibility of a decrease of entropy. According to this principle, whenever any process occurs in nature, the total entropy of all systems involved in the process must either increase or, if the process is reversible, remain constant.

STABLE EQUILIBRIUM

Criterion for stable equilibrium. Changes of state in an isolated system can occur only until the system reaches the unique stable equilibrium state consistent with the given values of energy, numbers of particles, and constraints. It follows from equation (7) that the entropy of the stable equilibrium state must be larger than that of any equilibrium or nonequilibrium state with the same values of energy, numbers of different particles, and constraints. By the same token, a criterion for stable equilibrium is that the entropy should be at its maximum value for fixed values of energy, numbers of particles, and constraints.

Equations relating properties for stable equilibrium states. By virtue of the state principle, the simplest illustrations of the laws of thermodynamics are provided by applications to systems in or passing through stable equilibrium states. For the properties and the relations between properties of systems in such states can be expressed by means of relatively simple mathematical forms.

The term numbers of particles, as used in the state principle, implies certain species of particles. The set of species selected must be a minimum set in terms of which the composition of all allowed states may be described. Such a minimum set of species, which will be unique in the number of members for a given system regardless of the choice of species to make up the set, is called a set of components.

For a system A with given fixed values E of energy,

$n_1, n_2, \ldots, n_k$ of the numbers of particles of components 1, 2, . . . , k of the set of k components, and $\beta_1, \beta_2, \ldots, \beta_s$ of constraints 1, 2, . . . , s of the set of s constraints, the uniqueness of the corresponding stable equilibrium state implies that the value of any property of A in that state must be fully and uniquely determined by the given fixed values. Moreover, for all stable equilibrium states, the values of a property F may be expressed as a mathematical function having a single value for each single set of values $E, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s$,

$$F = F(E, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s). \quad (8)$$

Several relations like equation (8) for several properties may be manipulated mathematically to express the values of any property as a function of the values of any set of independent properties of stable equilibrium states. A set of independent properties is such that the value of each property in the set can be varied without affecting the values of the remaining properties in the set.

Expressions for entropy and energy

Two functions of interest to subsequent considerations are those that relate the values of entropy S to the values of $E, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s$, and the values of energy E to the values of $S, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s$. These functions are denoted as

$$S = S(E, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s) \quad (9)$$

and

$$E = E(S, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s). \quad (10)$$

In general, the change of entropy per unit change of energy, or of any of the numbers of particles, or of any of the constraints can be evaluated with the help of equation (9). The same remark applies to energy and equation (10). Such changes are called partial derivatives and are used to define a number of useful properties that have meaning for stable equilibrium states only.

Mutual stable equilibrium of closed systems. If two systems A and B that are closed to the transfer of rest mass taken together constitute a system in a stable equilibrium state, then the entropy of that system must be at a maximum for the value of its energy. One of the consequences of this requirement will be seen from a possible variation—a conceptual alteration of state consistent with the description of the system and the constraints imposed on it and its parts A and B by the environment —in which the energy of A is increased by a small amount denoted by dE_A, and that of B is decreased by the same amount, while both A and B pass through stable equilibrium states without changes of values of their constraints. The entropy of part A is correspondingly altered by the amount dS_A. This amount can be expressed as

$$dS_A = \left(\frac{\partial S_A}{\partial E_A}\right)_{n,\beta} dE_A,$$

in which $(\partial S_A/\partial E_A)_{n,\beta}$ denotes the rate of change of S_A per unit change of E_A as A passes through stable equilibrium states while its numbers of particles (n) and its constraints (β) are held constant, namely, the partial derivative of S_A with respect to E_A. A similar expression can be written for the entropy change dS_B of B, so that the alteration dS of combined system AB is given by the expression

$$dS = \left(\frac{\partial S_A}{\partial E_A}\right)_{n,\beta} dE_A + \left(\frac{\partial S_B}{\partial E_B}\right)_{n,\beta} dE_B. \quad (11)$$

It can be shown that if the entropy S is to be at a maximum for the given fixed value of energy $E_A + E_B$ of the combined system AB and for both positive and negative variations dE_A, then it is necessary that the two partial derivatives $(\partial S_A/\partial E_A)_{n,\beta}$ and $(\partial S_B/\partial E_B)_{n,\beta}$ be equal to each other, namely,

$$\left(\frac{\partial S_A}{\partial E_A}\right)_{n,\beta} = \left(\frac{\partial S_B}{\partial E_B}\right)_{n,\beta}. \quad (12)$$

The quantity $(\partial S/\partial E)_{n,\beta}$ of a system may be thought of as a potential that governs the tendency of energy to pass from one system to another. It can be shown that it is a "capturing tendency" in that if

$$\left(\frac{\partial S_A}{\partial E_A}\right)_{n,\beta} > \left(\frac{\partial S_B}{\partial E_B}\right)_{n,\beta},$$

"Capturing" and "escaping" tendencies

then dE_A may be greater than zero (energy may pass from system B to system A) in an actual process but not less than zero (because less than zero would be contrary to the principle of increase of entropy). Conversely, the reciprocal quantity $(\partial E/\partial S)_{n,\beta}$ may be thought of as an "escaping tendency."

Temperature. The potential that governs the flow of energy is called temperature. A scale of temperature may be defined in terms of any function of $(\partial S/\partial E)_{n,\beta}$ or $(\partial E/\partial S)_{n,\beta}$ that continuously increases or decreases with either. The scale commonly used in thermodynamics is the Kelvin scale of temperature. It is denoted by T and defined as

$$T \equiv \left(\frac{\partial E}{\partial S}\right)_{n,\beta}, \quad (13)$$

so that T becomes a measure of the escaping tendency of energy. The necessary condition, equation (12), for mutual stable equilibrium between two systems A and B is equivalent to an equality between the temperatures T_A and T_B of A and B, namely,

$$T_A = T_B. \quad (14)$$

From the observations that the work produced by the combination of systems A, X, and R used in the definition of entropy change is the decrease in energy of the combination AR and that for a reversible process the entropy of that combination is conserved, it is readily shown that the constant c_R in equation (4) is equal to the partial rate or derivative $(\partial S_R/\partial E_R)_{n,\beta}$ of the entropy of the reservoir R or the inverse of the temperature T_R of the reservoir. Because the magnitude of constant c_R is arbitrary, a selection of a value for it for a simple reservoir fixes not only the scale of entropy but also that of the Kelvin temperature. By international agreement the value of T for solid, liquid, and vapour water in mutual stable equilibrium is 273.16° K. Among the reasons for the selection of this five-digit figure is that it causes the temperature interval between the freezing and boiling points of water under a pressure of one atmosphere to be almost exactly 100 degrees. If any other reservoir R' is used with X and A, the change in entropy found from equation (4) for a change in state of system A from A_1 to A_2 will be the same as that found using R if constant $c_{R'}$ is taken equal to the inverse temperature of the reservoir R'.

Entropy constant

When the number 273.15 is subtracted from the value of any given Kelvin temperature T, the result will be the Celsius temperature t, or t (degrees Celsius) $\equiv T - 273.15$.

Heat. An argument will now be outlined to prove that certain nonwork interactions are entirely distinguishable from work in that no fraction of any one such interaction will satisfy the definition of work.

If two systems A and B are in stable equilibrium states and each is under constant constraints, but they are not in mutual stable equilibrium, then an interaction could occur between them. By virtue of the third corollary of the second law, any such interaction must be a nonwork interaction; that is, its effects on at least one system, say A, could not have been produced while the sole external effect was the rise of a weight. In general, however, the effects on A could be produced while weights external to A are raised and, in addition, a change of state of B takes place. It can be shown that maximum work will be delivered to the weights if the process is carried out reversibly and each system passes through stable equilibrium states. A reversible cyclic device X (Figure 2) interposed between systems A and B will permit these conditions to be fulfilled. The device X may produce work, but the reversible interactions experienced by A with X and X with B cannot be work by virtue of corollary 3 of the second law.

For the reversible process just described it can be shown from the functions that relate energy to entropy and other independent properties that the work δW that will

be delivered to the weights is equal to the negative of the energy change dE_A of system A times the ratio $(T_A - T_B)/T_A$. This conclusion can be written as an equation; *i.e.*,

$$\delta W = -\frac{T_A - T_B}{T_A} dE_A. \tag{15}$$

In equation (15), the symbol d denotes an infinitesimal change of the value of a property, whereas δ denotes an infinitesimal amount of a quantity that is not a property or state function. Work is not a property of any system, and therefore δW is the appropriate way to indicate an infinitesimal amount of W.

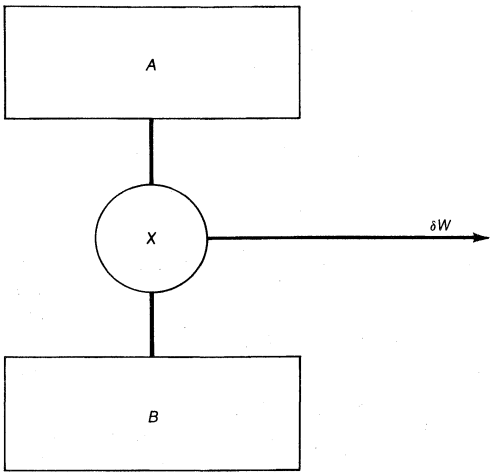

Figure 2: Production of work by a reversible cyclic device X that undergoes reversible nonwork interactions with systems A and B (see text).

Because dE_A is a measure of the magnitude of the interaction experienced by A with X, equation (15) expresses the work produced as a fraction of the magnitude of that interaction. As systems A and B approach mutual stable equilibrium, temperatures T_A and T_B approach equality, a necessary condition, and the fraction that represents the ratio of δW over dE_A approaches zero; that is, the work that can be obtained from the interaction between A and B through X becomes a vanishingly small fraction of the magnitude of the interaction. Moreover, it can be shown that then the interactions between A and X and between X and B are exactly equal, and each may be expressed as a product of temperature and entropy change $T_A\,dS_A$ and $T_B\,dS_B$.

In the limit, therefore, as T_A approaches T_B, the cyclic device X is no longer required, and the nature of the interaction approaches something completely distinguishable from work. It is this special kind of interaction that is called heat and denoted by the symbol Q. Moreover, for any process for which a system passes only through stable equilibrium states of fixed constraints and for a change of state corresponding to changes dS in entropy and dE in energy, the infinitesimal amount of heat $(\delta Q)_{rev}$ received by the system is given by the relations

$$(\delta Q)_{rev} = TdS = dE. \tag{16}$$

If the interacting systems pass only through stable equilibrium states, then the process will be reversible.

Heat is not a property of a system. Accordingly, the symbol δQ is used to denote an infinitesimal amount of heat but not the change in value of a property. Nor is heat contained within a system. Being an interaction, its magnitude depends upon the arbitrary selection of boundaries between systems.

Meaning of heat

The term heat is used here in a special sense that is quite foreign to the popular conception of its meaning. A different term might have been used were it not for the historical association of the word heat with thermodynamics. It will be observed from the context that the word heat is reserved here for a very special kind of interaction between systems, which only by virtue of the second law is entirely distinguishable from all other kinds of interactions, including the special kind called work. If a less restrictive definition had been used, then some of the relations between heat and entropy given here would not always hold.

Heat and flow of entropy. When a heat interaction occurs between two systems A and B that pass through stable equilibrium states, the process is reversible. For the combined system AB the process may be considered an adiabatic process for which the work is zero, so that, in accordance with equations (5) and (7) expressed in terms of subsystems A and B, $DS_A + DS_B = 0$. Because, from equation (16), DS_A is equal to $(\delta Q_A/T)_{rev}$ and different from zero, the heat interaction is associated with a flow of entropy from A to B if heat flows from A to B and conversely. By way of contrast, work in a reversible process leaves the entropies of the interacting systems unaltered.

To system B may be added a part that is not in a stable equilibrium state and that may experience an irreversible process without affecting the state of the other part or the interaction between A and B. Although the process as a whole is no longer reversible, the interaction is the same as before and could appropriately be called heat. A flow of entropy from A to B is still associated with the flow of heat from A to B, but the increase of entropy in B exceeds the amount that has flowed from A; that is, the statement $dS > \delta Q/T$ may be written for the irreversible process, and

$$dS \geq \frac{\delta Q}{T} \tag{17}$$

for processes in general.

For an adiabatic process equation (17) reduces to equation (6). For other processes equation (17) will apply provided that the only nonwork interactions are heat; that is, at least locally where the interaction occurs, the behaviour on each side of the boundary is the same as if both systems were passing through stable equilibrium states, with identifiable temperatures, and the process was reversible. It can readily be shown that certain nonwork interactions when used in place of δQ will not satisfy equation (17).

Inequality of Clausius. An inequality that was first stated by Clausius bears his name. It is as follows: For an irreversible cycle the sum of ratios, each of which is a heat δQ received by the system divided by the temperature T at which the heat is received, is always less than zero. When each amount of heat δQ is very small, the sum of the ratios $\delta Q/T$ can be represented by a cyclic integral, and the inequality of Clausius is given by the relation

$$\left(\oint \frac{\delta Q}{T}\right)_{irrev} < 0. \tag{18}$$

(The symbol $\oint$ means to integrate over a closed path, the complete cycle.) The inequality of Clausius follows directly when the inequality of equation (17) is applied to each step of an irreversible cycle and summed up for all the steps, because dS, being the change in a property, sums up to zero. Application of the inequality of Clausius is restricted, of course, to processes for which all nonwork interactions are heat.

Work, heat, and change of energy. If work and heat interactions occur successively, then the total energy change dE will be the sum of the work effect $(-\delta W)$ and the heat effect δQ; or, by equations (1) and (16),

$$dE = \delta Q - \delta W, \tag{19}$$

the minus sign resulting from the conventions regarding the signs for heat and work.

In practice it is not always necessary that work and heat should be successive in time. For example, if simply by shifting a boundary between systems a process can be made either adiabatic or heat only, then simultaneous heat and work are identifiable and may be used together in equation (19).

Expression (19) for change of energy is applicable, of course, only to those processes for which the interactions are identifiable as heat and work. Because heat and work are limiting cases of actual processes, equation (19) is strictly applicable only where all interactions have been carried to these limits.

Reversible cyclic engine. By reference to the definition of heat, it will be observed that the reversible interactions between A and X and between X and B in Figure 2 are heat interactions in which one part of X is in equilibrium with A and another part with B, whether or not A and B are close to mutual stable equilibrium. Because the process for the combined system AXB is adiabatic, it can be shown that the heat δQ_B received by B is equal to the heat δQ_A received by A times the negative of the ratio T_B/T_A; namely,

$$\delta Q_B = -\frac{T_B}{T_A}\delta Q_A. \tag{20}$$

The work produced by cyclic device X is, by equation (19), equal to the negative of the sum $\delta Q_A + \delta Q_B$, and, because of equation (20),

$$\delta W = -\delta Q_A - \delta Q_B = \frac{T_A - T_B}{T_A}(-\delta Q_A). \tag{21}$$

It is seen from equation (21) that X will produce positive work if $T_A > T_B$ and $\delta Q_A < 0$; that is, if heat flows from the hotter system to X and from X to the cooler system. The efficiency η with which X converts to work the heat it receives from the hotter system is thus

$$\eta = \frac{T_A - T_B}{T_A}. \tag{22}$$

Reversible cyclic engines

This quantity is called the Carnot efficiency after Carnot, who, before the discovery of the first and second laws of thermodynamics, made the following statements concerning the efficiency of engines working between reservoirs at specified levels of temperature: The efficiency of a reversible engine has a fixed value that is the same for all reversible engines and is greater than that of any irreversible engine.

An example of a reversible cycle in which a system receives all heat at one temperature and rejects all heat at another with reversible adiabatic changes between the two temperatures is the Carnot cycle, devised by Carnot. Its efficiency is given by equation (22).

Work-producing systems and devices. A problem of economic and social importance in heat engineering is the production of work to be used for practical purposes such as lifting weights, driving electric generators, propelling vehicles, or operating cutting tools. Work can be obtained from any system that is not in a stable equilibrium state as it changes toward a stable equilibrium state without changes in constraints. For example, work may be obtained by lowering a weight inside a closed system while causing—through appropriate levers, belts, and pulleys—a weight to rise outside. The production of work need not end until the internal weight has reached the lowest position in the gravity field that the configuration of the system permits. Similarly, an electric storage battery may produce work until it is completely discharged. The maximum work that can be produced by the system adiabatically will be obtained if the process is executed reversibly—that is, at constant entropy. By virtue of the second law the maximum work is only a fraction of the energy of the system. This fraction is larger the farther the system is initially from stable equilibrium; *i.e.*, the larger the difference between the maximum entropy corresponding to the initial energy and the entropy of the initial nonstable state. The fraction is equal to zero when the difference in entropy just described is equal to zero—namely, when the system is initially in a stable equilibrium state.

On the other hand, a system in any state, including a stable equilibrium state, can produce work when combined with a system in the environment that passes through stable equilibrium states but is not in mutual stable equilibrium with the first. The maximum work that can be obtained is the maximum possible decrease in the available work when the system in the environment acts as a reservoir, or it is the maximum possible decrease of one of the other availability functions discussed below when other conditions are imposed by the environment. In order to obtain this maximum, the work-producing process must be completely reversible. For example, if the system with the elevated weight described in the preceding paragraph is at a higher or lower temperature than the atmosphere, then further work may be obtained by interposing a Carnot heat engine between the system and the atmosphere, so that the system is gradually cooled or heated to the temperature of the atmosphere as heat flows to the engine and produces work. If the whole process is executed reversibly, then the maximum possible work will be produced.

The greatest sources of work are fuels found in nature that are either not themselves in stable equilibrium states—for example, uranium in a reactor—or are not in mutual stable equilibrium with the atmosphere from which they have been isolated in the course of geologic history—for example, the fossil fuels coal and petroleum. In either case, the maximum work can be obtained only by a reversible approach to stable equilibrium or mutual stable equilibrium.

In the case of uranium, a reversible nuclear reaction is required; for the fossil fuels, a reversible chemical reaction. A close approximation to a reversible chemical reaction is found in lead storage batteries used in automobiles for starting and for lighting. No close approximation to a reversible nuclear reaction has yet been realized in practice, although in principle such a reaction is possible.

Because the cost of work includes not only fuel costs but also capital costs that usually increase as irreversibility in the process is reduced, the economical means of producing work may in some respects depart radically from the reversible means. For example, in fossil-fueled central power stations, fuel and oxygen in the air enter into an irreversible chemical reaction that raises the temperature of the resulting products by about 2,000 degrees on the Kelvin scale and reduces the work available by about one quarter. Energy from these hot products is then transferred irreversibly across a large temperature difference to appear as heat added to liquid and vapour water that is the working fluid of a heat engine. The loss in work available is again about one quarter of that of the original fuel and air. Irreversibility in the heat-engine cycle accounts for another 10 percent, so that about 40 percent is actually realized as work delivered to the electrical distribution system.

Economical production of work

A Carnot cycle is an obvious but usually impractical means to produce work from heat interactions with hot products of chemical or nuclear reactions. Most commonly used is the Rankine cycle, in which heat is used to generate vapour from a liquid; the vapour is expanded through a work-producing engine, condensed to liquid as it rejects heat to the environment, and pumped back into the vapour generator. The Stirling cycle, which has had only limited application, passes through gaseous states only.

III. Simple systems

STABLE EQUILIBRIUM STATES

A closed simple system is one in which the numbers of particles of the various components are fixed and the only constraint provided by the environment is an upper value for the volume of the system. By virtue of the state principle, volume (regardless of shape) and energy become sufficient to determine a stable equilibrium state, and the number of independent properties is two. A system that is not influenced by capillarity and external force fields is a simple system. These conditions may be satisfied despite capillarity and gravity fields if homogeneous parts of the system are large, so as to have small surface-to-volume ratio, yet shallow in the vertical direction of the gravity field and free of electric and magnetic fields created by external bodies.

Definition of a simple system

For stable equilibrium states of a closed simple system, entropy S or any other property can be regarded as fixed by the two independent properties volume V and energy

U; therefore, S can be expressed as a function of V and U of the form

$$S = S(V,U). \tag{23}$$

For a number of reasons the energy E of a simple system is denoted by a different symbol U and is called the internal energy. Alternatively, equation (23) may be solved for U in terms of S and V to give

$$U = U(S,V). \tag{24}$$

The energy change dU between two neighbouring stable equilibrium states can be expressed in terms of the corresponding entropy and volume changes, dS and dV, respectively, by means of the relation

$$dU = \left(\frac{\partial U}{\partial S}\right)_V dS + \left(\frac{\partial U}{\partial V}\right)_S dV. \tag{25}$$

The first partial differential coefficient has already been identified (by equation 13) as the Kelvin temperature. The second is the rate of energy change (the rate of receiving work) with change in volume in reversible adiabatic compression or expansion. It can be shown to be the negative of the pressure p that the system exerts on constraining walls. Substitution of the temperature T and the pressure p in equation (25) results in the equation

$$dU = TdS - pdV, \tag{26}$$

in which the first term in the right-hand member represents the heat and the second the work of a reversible process. It may be observed, however, that equation (26) holds for any change between neighbouring stable equilibrium states regardless of the nature of the process, because it is a relation between properties and changes in values of properties. But for the general process, the terms (TdS) and ($-pdV$) are not in general equal to the respective heat and work that may be involved in the process.

By means of the criterion of stable equilibrium and equation (26), it can be shown that not only the temperature but also the pressure must be uniform throughout a simple system in a stable equilibrium state.

Representation of states on diagrams. Because a stable equilibrium state in a simple system is determined by two independent properties, all such states may be represented by points on a surface in a space in which two of the three coordinates represent independent properties and the third the dependent property. Alternatively, the traces of planes of constant value of one property may be shown on a two-dimensional chart in which the coordinates represent the other two properties. Two common choices of the latter class are pressure–volume (p–V) and temperature–entropy (T–S) charts. An example of the former is shown in Figure 3 (left), with traces of planes of constant temperature from the pressure–volume–temperature space and of planes of constant entropy from the pressure–volume–entropy space. On the p–V chart the area under a curve of states represents the work done on a slowly moving piston that confines the fluid in a cylinder. On the T–S chart (Figure 3 [right]) the area under the curve represents the heat received by the system in a reversible process passing through the states represented by the curve. Because the change of energy of a system undergoing a cycle is equal to zero, it is seen from equation (19) that the cyclic integral $\oint \delta Q$ must be equal to the cyclic integral $\oint \delta W$. For a reversible cycle, TdS may be substituted for δQ and pdV for δW so that

$$\oint TdS = \oint pdV. \tag{27}$$

For any cycle, therefore, the area enclosed by the representation on the T–S chart is equal to that on the p–V chart; for example, the areas enclosed by the representations of the Carnot cycle in the p–V and T–S charts (Figure 4 [left] and 4 [right]) are equal.

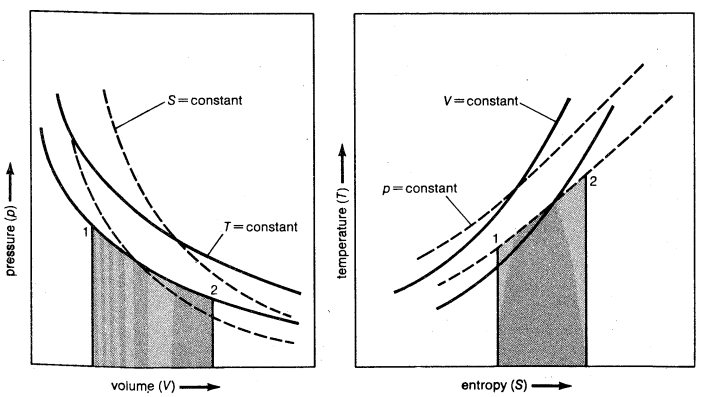

Figure 3: *Relationships between thermodynamic properties of systems.*
(Left) Relationships of pressure and volume of systems maintained at fixed temperature *(T)* or at fixed entropy *(S)*.
(Right) Relationships between temperature and entropy of systems maintained at fixed pressure *(p)* or at fixed volume *(V)*.

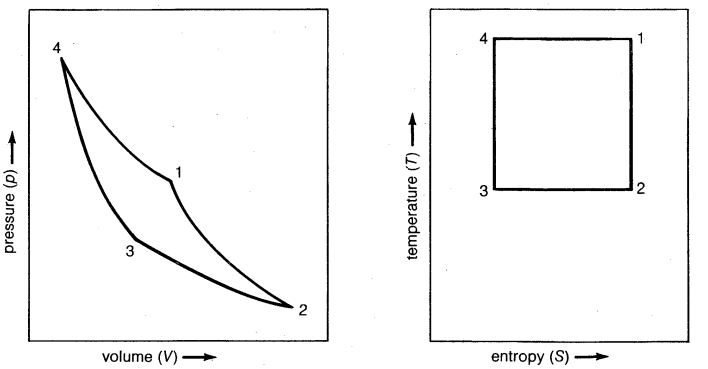

Figure 4: *Relationship between work done and heat received by a fluid undergoing a Carnot cycle.*
The lines from state 1 to state 2 represent reversible and adiabatic expansion of the fluid; from 2 to 3, reversible compression at fixed temperature accompanied by heat rejection; from 3 to 4, reversible and adiabatic compression; from 4 to 1, reversible expansion at fixed temperature accompanied by heat reception. The enclosed area (left) represents the net work done by the fluid during the complete cycle; it is exactly equal to the enclosed area (right) that represents the net heat flow to the fluid.

Reversible constant-pressure process. The reversible process at constant pressure, because of its practical importance, warrants special consideration. Because for constant pressure the change in the product pV is also p times the change in V, pdV, it can be shown that the expression for the heat $(\delta Q)_p$ received by the system is equal to the change of an extensive property called enthalpy, which is defined by the relation $H \equiv U + pV$; that is,

Enthalpy

$$(\delta Q)_p = dH. \tag{28}$$

Thus, in any heating of a simple system in such a way (for example, under a piston loaded by a weight) that its boundary expands slowly as it maintains constant pressure, the enthalpy of the system increases by the amount of heat added.

MAXWELL RELATIONS

For a closed simple system that assumes only stable equilibrium states, it can be shown that the partial derivative $(\partial T/\partial V)_S$ is equal to the negative of the partial derivative $(\partial p/\partial S)_V$, thus,

$$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V.$$

This relation is one of the Maxwell relations, named for the man who first stated them.

Enthalpy, Helmholtz free energy, and Gibbs free energy are, respectively, defined as follows:

$$H \equiv U + pV, \tag{29}$$
$$\Psi \equiv U - TS, \tag{30}$$
$$Z \equiv H - TS. \tag{31}$$

These properties can be manipulated mathematically to obtain the following equations:

$$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V, \tag{32}$$

$$\left(\frac{\partial T}{\partial p}\right)_S = \left(\frac{\partial V}{\partial S}\right)_p, \tag{33}$$

$$\left(\frac{\partial S}{\partial V}\right)_T = \left(\frac{\partial p}{\partial T}\right)_V, \tag{34}$$

$$\left(\frac{\partial S}{\partial p}\right)_T = -\left(\frac{\partial V}{\partial T}\right)_p. \tag{35}$$

These equations are Maxwell relations. They relate the entropy to the relatively easily measured properties pressure, volume, and temperature.

PHASE RULE

An intensive property of system A is defined as a property of which the value at a spatial point in a part of A approaches a limit independent of the size of the part as the size is reduced until it can no longer be identified as a system. As a system is subdivided into smaller and smaller parts, at some point a part becomes so small as compared with the extent of force fields between the parts that it is no longer isolatable and may not, therefore, be considered a system.

For certain stable equilibrium states of a simple system, parts of the system may assume different values of intensive properties; for example, liquid and vapour water may coexist in mutual stable equilibrium for which liquid and vapour parts have the same pressure and temperature but radically different densities. Each such part is called a phase. More generally, a phase of a system is the collection of all homogeneous parts open to the transfer of rest mass and having identical values of their intensive properties.

In the absence of chemical reactions and membranes that are permeable to one substance and not to another, the number of components of a phase of a multiphase system will be identical with the number of molecular species present in the whole system. As soon, however, as a chemical reaction is permitted in which some of these species may be formed from others, then the number of components is reduced by one.

A closed simple system has two independent properties; a simple system open to the transfer of rest mass will have these same two plus the number n of components for the system, because the quantity of each component may be independently varied. On the other hand, the number of independent properties of the same simple open system is also equal to the sum $F + r$, in which F denotes the number of independent intensive phase properties and r the number of phases, because the F intensive properties fix the intensive states of the phases, and the r masses of the r phases fix the size of the system. From these remarks it follows that F is given by the relation

$$F = n + 2 - r. \tag{36}$$

The Gibbs phase rule

This is the phase rule of Gibbs. It reveals, for example, that for a single-component open system, such as water, the number of independent intensive properties may be 2, 1, or 0 if the number of phases present is 1, 2, or 3, respectively. Thus, for water vapour, temperature and pressure are independent properties; *i.e.*, after the value of one is arbitrarily selected, the value of the other may be arbitrarily selected. For coexisting liquid and vapour, either pressure or temperature may be considered the independent property; for coexisting solid, liquid, and vapour (the triple point), the values of all intensive phase properties are fixed by the nature of the substance, and the value of none may be arbitrarily selected.

SIMPLE ONE-COMPONENT SYSTEMS

Phases. All systems that consist of a single pure molecular species, such as argon, oxygen, or water, exhibit largely common patterns of coexisting phases. A closed system of this kind, being a simple system, has two independent properties and the relationships between properties for stable equilibrium states may therefore be shown as a surface in three-dimensional space. The projection of one such surface onto the pressure–temperature plane is shown in Figure 5 (top) and onto a pressure–volume plane in Figure 5 (bottom). It will be evident from these

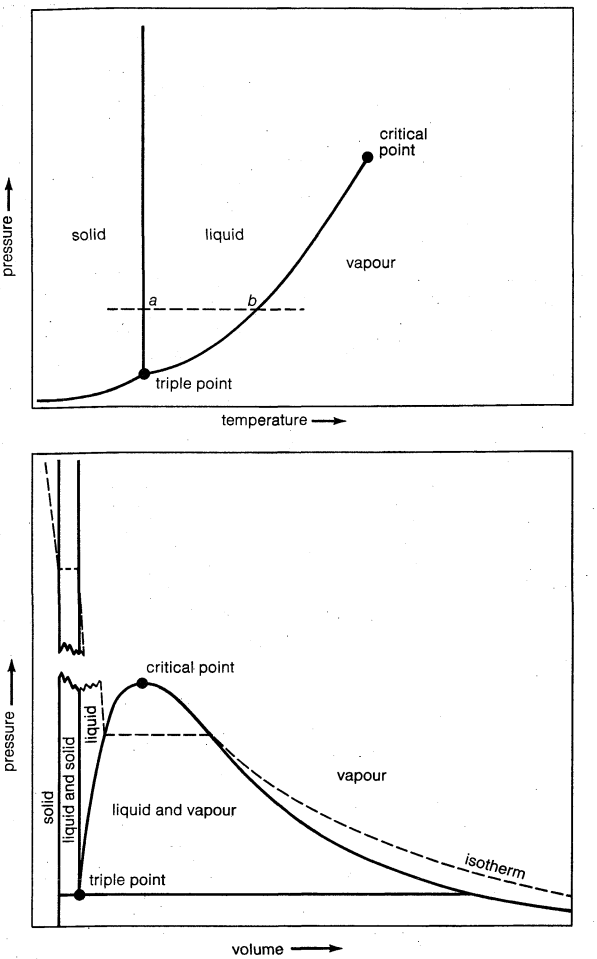

Figure 5: *Relationships between phases of a pure substance.* (Top) The horizontal broken line through *a* and *b* represents the effects of absorption of heat by a substance at a constant pressure. (Bottom) The broken line from lower right to upper left represents the effects of compressing a substance, initially entirely vaporous, while keeping the temperature fixed (an isothermal process).

figures that the solid may be heated under constant pressure until some liquid appears. Further heating increases the proportion of liquid present at constant temperature until the solid vanishes, leaving only liquid. Further heating increases the temperature of the liquid until vaporization begins, provided that the pressure is less than the critical pressure. Continued heating increases the proportion of vapour present at constant temperature until the liquid vanishes, leaving only vapour. The vapour may then be raised in temperature indefinitely or until chemical dissociation destroys the assumed purity of the molecular species.

At the critical pressure the coexisting liquid and vapour states are identical, and the vaporization process contracts to an infinitesimal process. At higher pressures no vaporization occurs. It becomes clear, then, that liquid and vapour states differ in degree rather than in kind, because any liquid state can be transformed to any vapour state by a process for which the system remains in a single-phase condition throughout. The same cannot be said of the transition from solid states to either liquid or vapour states.

Processes at constant volume and at constant pressure. When a simple system is heated at constant volume, no work occurs at the boundaries, so that the heat, according to equation (23), is equal to the increase in energy as

Heat capacities

well as to the product of temperature and increase in entropy:

$$(\delta Q)_V = dU = TdS.$$

The heat of a constant-volume process is therefore equal to the area under the curve on a temperature–entropy chart. The constant-volume heat capacity is defined in terms of the partial derivatives of energy and entropy as follows:

$$C_V \equiv \left(\frac{\partial U}{\partial T}\right)_V = T\left(\frac{\partial S}{\partial T}\right)_V; \tag{37}$$

and the constant-volume specific-heat capacity is defined similarly as

$$c_v \equiv \left(\frac{\partial u}{\partial T}\right)_v = T\left(\frac{\partial s}{\partial T}\right)_v, \tag{38}$$

in which lowercase letters denote values per unit of mass or per mole. By reference to equation (28) it will be seen by analogy that the corresponding definitions of heat capacities at constant pressure are as follows:

$$C_p \equiv \left(\frac{\partial H}{\partial T}\right)_p = T\left(\frac{\partial S}{\partial T}\right)_p \tag{39}$$

and

$$c_p \equiv \left(\frac{\partial h}{\partial T}\right)_p = T\left(\frac{\partial s}{\partial T}\right)_p. \tag{40}$$

By means of Maxwell relations it can be shown that the difference between the two heat capacities is given by the product of two partial derivatives, both of which are fixed entirely by the relation between p, V, and T:

$$C_p - C_V = T\left(\frac{\partial p}{\partial T}\right)_V\left(\frac{\partial V}{\partial T}\right)_p. \tag{41}$$

When a phase change occurs during constant-pressure heating or cooling, the temperature is unchanged by the heating or cooling as long as both phases are present. The heat required in such a process to change a unit mass from one phase to the other is equal, according to equation (28), to an increase in enthalpy. It is called the latent heat of that phase change. Thus, a latent heat of fusion h_{jl}, a latent heat of vaporization h_{fg}, and a latent heat of sublimation h_{ik} can be defined by means of the relations

$$h_{jl} = h_l - h_j = T(s_l - s_j), \tag{42}$$
$$h_{fg} = h_g - h_f = T(s_g - s_f), \tag{43}$$
$$h_{ik} = h_k - h_i = T(s_k - s_i), \tag{44}$$

in which subscripts j, l, f, g, i, and k refer, respectively, to solid in equilibrium with liquid, liquid in equilibrium with solid, liquid in equilibrium with vapour, vapour in equilibrium with liquid, solid in equilibrium with vapour, and vapour in equilibrium with solid.

In a two-phase region the change in any extensive property is directly proportional to the corresponding change in any other for a fixed value of temperature, and the pressure is a function of temperature only. From these observations and Maxwell relations (33) or (34), it follows that the rate of change of pressure with temperature change for a two-phase mixture is equal to the ratio of the entropy change to the volume change when a fixed quantity of the substance is changed from one phase to the other—*e.g.*, from liquid state to vapour state. Alternatively, the ratio of enthalpy change to volume change gives the rate of change of pressure with change in the natural logarithm (ln) of temperature:

The Clapeyron relation

$$\frac{dp}{dT} = \frac{s_2 - s_1}{v_2 - v_1} \tag{45}$$

$$\frac{dp}{d(\ln T)} = T\frac{dp}{dT} = \frac{h_2 - h_1}{v_2 - v_1}. \tag{46}$$

These equations are used to express the Clapeyron relation.

Equation of state. The mathematical relation between the pressure, volume, and temperature for stable equilibrium states of a closed simple system is called its equation of state. Although it will be subsequently shown to be a relation that does not completely specify the nature of the system, the mathematical relation is an important one because the three properties it relates are relatively easily measured.

Experimentally it is found that the relation between the pressure, volume, and temperature of a system is extremely complicated. No explicit mathematical expression has ever been devised that represents all the stable equilibrium states of any one simple system. Instead, equations have been proposed, each of which represents some limited range of states of a particular system. The complexity of equations of state ranges from that for a perfect gas with a single constant to those for liquid and vapour states, of which that for water is an example, which often have between 10 and 100 constants, the values of which must be determined so as to fit experimental data.

For the range of liquid and vapour states of a pure molecular species, the general pattern of the p-v-T relation is best shown by drawing a graph of the quantity pv/RT versus the ratio of pressure to critical pressure. If v is taken to be the specific volume (the volume per unit mass) and R is chosen so that pv/RT becomes unity at zero pressure and infinite specific volume for any temperature, then a coincidence occurs: pv/RT is unity for every temperature for that substance, provided only that the specific volume is infinitely large. The constant R is called the gas constant of the molecular species.

The molecular weight of oxygen is 32 and the molecular weight M for any species is inversely proportional to the gas constant R of the molecular species. Thus, the molecular weight M of any species can be defined as 32 times the ratio of the gas constant of oxygen and the gas constant of the species:

$$M \equiv 32\frac{R\ (\text{for } O_2)}{R}. \tag{47}$$

It follows that the volume occupied by a molecular weight of a gas at very low pressure is the same for all gases for any selected pair of values of p and T. Moreover it is directly proportional to T and inversely proportional to p.

The product of molecular weight M and gas constant R is the same for all gases and is called the universal gas constant (denoted by $\mathbf{R}$). The result is an equation, called the perfect-gas equation of state, that appears frequently in the literature of thermodynamics; that is,

The universal gas constant

$$pv/RT = 1, \tag{48}$$

in which v is the volume occupied by one molecular weight, or one mole, of gas.

The equation of state (48) applies, therefore, to any pure molecular species in states for which the specific volume is extremely large and the pressure, at finite temperature, is therefore extremely small. It holds within 2 percent for water vapour at a pressure of one atmosphere and with correspondingly better precision as the pressure is lowered. A gas that conforms to equation (48) is called a semiperfect gas.

By means of Maxwell relations and equation (23) it can be shown in the case of a semiperfect gas that internal energy, enthalpy, and both heat capacities are functions of temperature only and are independent of the effects of volume or pressure. Moreover, the difference $c_p - c_v$ between the specific-heat capacities is equal to the gas constant R when all three quantities are defined in terms of unit mass or, alternatively, in terms of molecular weight.

When quantum effects are not important, an approximate expression for the specific-heat capacity may be obtained from statistical thermodynamics. It is

$$c_v = \frac{f}{2}R, \tag{49}$$

in which f denotes the number of active degrees of freedom of the molecule (the number of independent ways in which the space configuration of the molecule may change). For a mass concentrated in a point, f would be three (corresponding to the three directions of translation), and c_v would be $3R/2$. With spatial distribution of the mass, additional degrees of freedom appear by

virtue of rotation and vibration of the molecule. The number of such degrees of freedom active in a molecule depends, in accordance with quantum theory, on the temperature. In Table 1 are shown the molal heat capacities of several gases at room temperature along with the corresponding number of degrees of freedom $c_v/(\frac{1}{2}R)$. For a monatomic gas this number of degrees of freedom proves to be three almost exactly; for diatomic gases it is nearly five (corresponding to two degrees of rotational freedom); and for more complex molecules, a number in excess of five, which implies vibrational degrees of freedom. For all except the monatomic molecule, the value of c_v increases with temperature as new degrees of freedom become active.

Table 1: Molal Specific Heat Capacities of Gases at Room Temperature

	c_v	c_p	$c_v/(\frac{1}{2}R)$	$c_p/(\frac{1}{2}R)$	$k = c_p/c_v$
He*	2.979	4.965	3.000	5.000	1.667
H_2	4.88	6.87	4.92	6.91	1.406
O_2	5.02	7.00	5.05	7.04	1.406
N_2	4.97	6.96	5.01	7.00	1.400
CO	4.97	6.96	5.01	7.00	1.400
H_2O	6.02	8.01	6.07	8.06	1.330
CO_2	6.81	8.80	6.86	8.85	1.292

*And all other monatomic gases.

The expressions for energy, enthalpy, and entropy of a semiperfect gas are as follows:

$$u = \int_{T_0}^{T} c_v dT + u(T_0), \tag{50}$$

$$h = \int_{T_0}^{T} c_p dT + u(T_0) + RT_0, \tag{51}$$

$$s = \int_{T_0}^{T} c_v \frac{dT}{T} + R \ln \frac{v}{v_0} + s(T_0, v_0)$$

$$= \int_{T_0}^{T} c_p \frac{dT}{T} - R \ln \frac{p}{p_0} + s(T_0, p_0); \tag{52}$$

in these equations the subscript 0 refers to an arbitrarily selected state.

Perfect gas

The perfect gas is a special case of the semiperfect gas —namely, that for which the heat capacities are independent of temperature. The integrals of the previous expressions can now be resolved to give the following:

$$u = c_v(T - T_0), \tag{53}$$

$$h = c_pT - c_vT_0, \tag{54}$$

$$s = c_v \ln \frac{T}{T_0} + R \ln \frac{v}{v_0} + s_0$$

$$= c_p \ln \frac{T}{T_0} - R \ln \frac{p}{p_0} + s_0, \tag{55}$$

in which s_0 denotes the arbitrary value of s at T_0 (for which u is zero) and at p_0.

For a reversible adiabatic process in a perfect gas, the following relations hold: $pv^k = \text{constant}$, $Tv^{k-1} = \text{constant}$, and $pT^{-k/(k-1)} = \text{constant}$, and k is the ratio c_p/c_v.

In 1873 the Dutch physicist Johannes van der Waals proposed the following equation, which in a qualitative way describes the liquid and vapour states of a pure species:

Van der Waals' equation

$$p = \frac{RT}{v - b} - \frac{a}{v^2}, \tag{56}$$

in which a and b are constants for any one species. Not only does this equation approach that of the semiperfect gas as v goes to infinity, but the equation also provides for a region of coexisting states that is capped by a critical state, as in actual substances. Below the temperature T_c (equal to $8a/27Rb$), three values of v correspond to each value of p. Pairs of high-volume and low-volume states, such as P and R (Figure 6), may be found at each pressure–temperature combination. The one pair for which the areas $PQbP$ and $QaRQ$ are equal can be shown to be the pair that can coexist in mutual stable equilibrium.

An approximate justification of the van der Waals equation can be made based in part on the Newtonian equation of motion for a collection of particles having the following characteristics: (1) the particles are uniform rigid spheres; (2) their diameters are appreciable fractions of the mean distances between them, except at infinite specific volume; and (3) they exert finite attractive forces, which vary with the distance between them, as well as infinite repulsive forces upon contact.

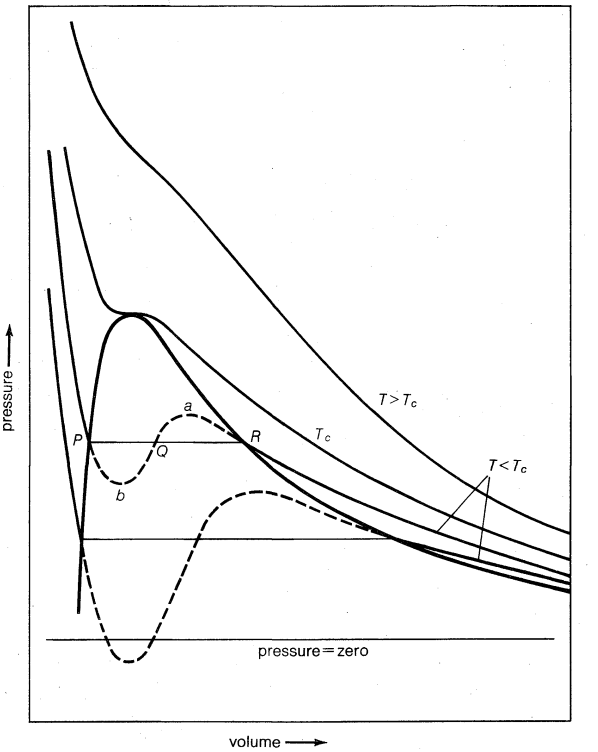

Figure 6: Relations between pressure *(p)* and volume *(v)* of liquid and vapour states of a pure molecular species at different temperatures according to the van der Waals equation (see text).

Equations of state, by proper assignment of values of constants, can be made to represent quantitatively (as contrasted with qualitatively for the van der Waals equation) the properties of many molecular species with fair precision. An equation has been developed that represents the properties of water within the precision of virtually all experimental measurements on liquid and vapour water.

A general type of equation of state, which can be made to fit almost any range of gaseous states at the expense of indefinite increase in the number of constants, is the virial form. It may be written as

Virial equations of state

$$\frac{pv}{RT} = 1 + B\rho + C\rho^2 + D\rho^3 + \ldots, \tag{57}$$

in which ρ denotes the density, and the coefficients B, C, D, . . . , called the second, third, fourth, . . . virial coefficients, are functions of temperature only. Substantial progress has been made in determining the forms of the functions B and C for the simpler molecular structures by means of models of the structure and force fields between them.

Critical point. In recent decades the relationships between the various properties of a pure molecular species at and near the critical point have been the subject of many studies. It appears from these that certain mathematical singularities occur at the critical point, including an infinite value for the heat capacity at constant volume, which indicate that no continuous equation (such as the van der Waals equation) relating pressure, volume, and temperature can represent the actual variation in these

properties for states closer than a few degrees in temperature to the critical point. A so-called scaling law has been devised to cope with the mathematics of this region.

Fundamental equations. As was implied above by the development of the equation of state for a semiperfect gas, such an equation alone is not adequate to yield the values of energy u, enthalpy h, and entropy s. It must be supplemented by a knowledge of the variation of heat capacity with temperature.

A type of equation for which any of the properties p,T,u,v,s (or any algebraic combination of these) not explicit in it are found by differentiation is called a fundamental equation, and the corresponding function has been called a characteristic function. For a simple system, the four characteristic functions—specific energy u, specific enthalpy h, specific Helmholtz free energy ψ, and specific Gibbs free energy ζ—are expressed in terms of fundamental equations as follows:

$$u = u(v,s),\ T = \left(\frac{\partial u}{\partial s}\right)_v,\ p = -\left(\frac{\partial u}{\partial v}\right)_s, \tag{58}$$

$$h = h(p,s),\ T = \left(\frac{\partial h}{\partial s}\right)_p,\ v = \left(\frac{\partial h}{\partial p}\right)_s, \tag{59}$$

$$\psi = \psi(v,T),\ p = \left(\frac{\partial \psi}{\partial v}\right)_T,\ s = -\left(\frac{\partial \psi}{\partial T}\right)_v, \tag{60}$$

$$\zeta = \zeta(p,T),\ v = \left(\frac{\partial \zeta}{\partial p}\right)_T,\ s = -\left(\frac{\partial \zeta}{\partial T}\right)_p, \tag{61}$$

where the specific Helmholtz free energy ψ and the specific Gibbs free energy ζ are defined by

$$\psi \equiv u - Ts \text{ and } \zeta \equiv h - Ts. \tag{62}$$

SIMPLE MULTICOMPONENT SYSTEMS

Gibbs equation. The change of entropy dS between neighbouring stable equilibrium states of a simple system open to the transfer of rest mass can be expressed in terms of the corresponding change of energy dU, volume dV, and number of particles dn_i ($i = 1,2,\ldots,k$) of the k components in the system. By use of equation (9) it can be shown that the expression for dS involves partial derivatives as coefficients that multiply the changes in the independent properties U, V, n_1, n_2, . . . , n_k:

$$dS = \left(\frac{\partial S}{\partial U}\right)_{V,n} dU + \left(\frac{\partial S}{\partial V}\right)_{U,n} dV + \left(\frac{\partial S}{\partial n_1}\right)_{U,V,n} dn_1 + \ldots + \left(\frac{\partial S}{\partial n_k}\right)_{U,V,n} dn_k, \tag{63}$$

in which subscript n denotes all of n_1, n_2, . . . , n_k that can be held constant. Upon identifying, as in equation (23), the first two partial derivatives in terms of pressure p and temperature T and introducing a new quality μ_i to be defined shortly, equation (63) becomes what is called the Gibbs equation:

$$dS = \frac{1}{T}dU + \frac{p}{T}dV - \frac{\mu_1}{T}dn_1 - \ldots - \frac{\mu_k}{T}dn_k. \tag{64}$$

Chemical potential

The quantity μ_i, which is called the chemical potential of component i in the system, is defined as follows:

$$\mu_i \equiv -T\left(\frac{\partial S}{\partial n_i}\right)_{U,V,n} \text{ for } i = 1,2,\ldots k. \tag{65}$$

Mutual stable equilibrium. Upon seeking the conditions that must be satisfied in order that two or more phases should be in mutual stable equilibrium while open to transfer of rest mass between them, it is unnecessary to consider any states for which any one phase would be in a nonequilibrium state if it were suddenly isolated. It is unnecessary because any change of state that could occur spontaneously while the phase was isolated would be one of many allowed changes of state when it was not isolated and would, therefore, serve as an indication that at least one spontaneous change is possible and that equilibrium does not exist.

It is sufficient, therefore, to consider only those states for which the individual phases are in stable equilibrium states when isolated. The Gibbs equation provides a general statement of the change of entropy of a simple phase that may exchange component substances with neighbouring phases as it passes through stable equilibrium states. If the formation of any new part unlike the existing parts is prohibited by the definition of the phase, then a set of stable equilibrium states is prescribed for which the Gibbs equation expresses changes in entropy between states in the set.

A heterogeneous system may be considered to be made up of several homogeneous phases, within each of which the formation of a new part is prohibited as proposed above. The states that these phases may assume consistent with mutual stable equilibrium may now be found by seeking out the state of maximum entropy of the whole system for a given volume and energy. This kind of procedure was used above to show that the phases of such a system must have equal temperatures. By similar reasoning it can now be shown that the phases must have equal pressures and equal values of the chemical potential μ_i of each component i present in all the phases. That is, among the necessary conditions for stable equilibrium of a multiphase simple system (*i.e.*, in the absence of force fields and capillarity) is uniformity throughout the multiphase system of temperature, pressure, and chemical potential of each component present in all the phases.

Of these conditions the one most open to exception is equality of pressure. In order for it to apply, an encroachment of the volume of each phase upon every other, for constant energy and composition of each phase, must be an allowed variation in state of the system. Wherever phases are separated by a rigid boundary, which may be permeable to one or more components, then equality of pressure between such phases is not necessary to mutual stable equilibrium.

If two phases are separated by a wall that is permeable to some components but not permeable to others, then equality of chemical potential of those other components across the wall is not necessary. An exception can be made as regards the potentials T, p, and μ_i in cases in which a transfer of energy, volume, and component i can occur at stable equilibrium in one direction but not in the other direction. Then a condition for mutual stable equilibrium becomes, because entropy is to be maximized, that the temperature in the phase that can receive energy but cannot supply it may be greater than or equal to the temperature in phases that can both receive and supply energy. Similar statements can be made in regard to pressure and the transfer of volume and in regard to chemical potential of component i and the transfer of that component.

These statements imply that potentials T, p, and μ_i are escaping tendencies for energy, volume, and component i, respectively. For equilibrium each escaping tendency must be balanced as between phases, unless the escape of one flux has reached its upper limit for a phase so that no further escape is possible. For such a phase it is necessary for equilibrium that the escaping tendency be not less than in other phases, but it may be more. This consideration is relevant for certain quantum effects at low temperature, for two phases separated by a movable solid boundary that has come up against a stop and behind which the pressure may be greater than in front (but not less), and for exhaustion of a phase as regards one component.

From the definitions of enthalpy H (29), Helmholtz free energy Ψ (30), and Gibbs free energy Z (31), it is readily shown that the chemical potential can be expressed in alternative forms; that is,

$$\mu_i = \left(\frac{\partial U}{\partial n_i}\right)_{V,S,n} = \left(\frac{\partial H}{\partial n_i}\right)_{p,S,n} = \left(\frac{\partial \Psi}{\partial n_i}\right)_{V,T,n} = \left(\frac{\partial Z}{\partial n_i}\right)_{p,T,n} \tag{66}$$

The last of these is known as the partial Gibbs free energy ζ_i of component i in the phase. In view of the definition of Z, μ_i may also be expressed in terms of the partial enthalpy h_i and the partial entropy s_i; thus,

$$\mu_i = \left(\frac{\partial Z}{\partial n_i}\right)_{p,T,n} = \left(\frac{\partial H}{\partial n_i}\right)_{p,T,n} - T\left(\frac{\partial S}{\partial n_i}\right)_{p,T,n}$$

$$= \zeta_i = h_i - Ts_i. \tag{67}$$

In general, lowercase symbols with subscript i denote the partial property. For a phase of pure component i, any partial property is identical with the corresponding specific property—that is, the value of the property per unit mass, which is here taken to be the mole. The chemical potential of a component i in a mixture containing i is equal to the specific Gibbs free energy of i in a phase of pure i in equilibrium with the mixture through a membrane permeable to i alone.

A semipermeable membrane such as the one just proposed is one across which the pressure need not be balanced for equilibrium. By definition of the membrane, encroachment of the mixture phase into the volume of the pure phase cannot occur, but the reverse encroachment can occur. The membrane must, of course, have sufficient structural strength to support the pressure difference.

The expression for the chemical potential of a semiperfect gas in terms of temperature and pressure is found from equations (67), (51), and (52). It proves to be the sum of a simple function of pressure p and temperature T plus a relatively complicated function $f_i(T)$ of temperature as follows:

$$\mu_i = RT \ln p + f_i(T), \tag{68}$$

in which the function $f_i(T)$ is different for different semiperfect gases i. For a given temperature, however, equation 68 indicates that the chemical potential increases with increase in pressure. That is, temperature being fixed, the escaping tendency increases as the pressure increases.

Three equations will be recorded here but not derived.

1. The Gibbs equation as an expression for the change in Gibbs free energy of a phase between neighbouring stable equilibrium states:

$$d\mathrm{Z} = Vdp - SdT + \sum_i \mu_i\, dn_i. \tag{69}$$

In the equation the short notation $\sum_i \mu_i\, dn_i$ has been used to denote $\mu_1 dn_1 + \mu_2 dn_2 + \cdots + \mu_k dn_k$, in which subscript $i = 1, 2, \ldots, k$ denotes a component substance.

2. The Gibbs free energy as a summation of products of chemical potentials and numbers of moles of component substances i of a phase:

$$\mathrm{Z} = \sum_i \mu_i n_i. \tag{70}$$

Gibbs–Duhem equation

3. The Gibbs–Duhem equation, which relates for a phase the changes between stable equilibrium states in temperature, pressure, and numbers of moles of components:

$$SdT - Vdp + \sum_i n_i\, d\mu_i = 0. \tag{71}$$

Mixtures of gases. *Gibbs–Dalton rule for mixtures.* Gibbs revised the earlier rule of the 18th- and 19th-century English physicist John Dalton for determining the properties of a mixture of gases from the properties of the pure components. Two equivalent statements of the Gibbs–Dalton rule for mixtures are as follows: (1) The pressure in a mixture of different gases is equal to the sum of the pressures of the different gases as existing each by itself at the temperature of the mixture and with the same value of the chemical potential as it has in the mixture. (2) The pressure of a mixture of different gases is equal to the sum of the pressures of the pure components each existing as a phase in equilibrium with the mixture through a membrane permeable to the component.

Using single subscripts to refer to components in the mixture and double subscripts to refer to pure component phases, the Gibbs–Dalton rule takes the form

$$p = p_{11} + p_{22} + p_{33} + \cdots \tag{72}$$

for

$$T = T_{11} = T_{22} = \ldots, \tag{73}$$

and

$$\mu_1 = \mu_{11}, \mu_2 = \mu_{22}, \ldots. \tag{74}$$

In this notation p_1 would have no "operational" meaning because no instrument has been devised that can measure the pressure of component 1 when it is part of a mixture.

It can now be shown from the Gibbs–Dalton rule and the Gibbs–Duhem equation that the number c_i of mass units of component i in unit volume of the mixture (the concentration c_i of i in the mixture) is equal to the density ρ_{ii} or the inverse of the specific volume v_{ii} of i in the pure phase in mutual stable equilibrium with the mixture. The concentration c_i denotes the ratio of mass n_i of i in the mixture to the volume v of the mixture. It follows immediately that the density ρ (or $1/v$) of the mixture is the sum of the densities ρ_{ii} (or $1/v_{ii}$) of the pure phases.

Further application of the Gibbs–Duhem equation yields the following expressions for extensive properties:

$$U = nu = \sum_i n_i u_{ii},$$

$$H = nh = \sum_i n_i h_{ii},$$

$$S = ns = \sum_i n_i s_{ii},$$

$$\Psi = n\psi = \sum_i n_i \psi_{ii}, \text{ and}$$

$$\mathrm{Z} = n\zeta = \sum_i n_i \zeta_{ii} = \sum_i n_i \mu_{ii} = \sum_i n_i \mu_i. \tag{75}$$

In these equations the mass n_i of component i in the mixture will be identical with n_{ii} the mass of i in the pure phase if the volume of the pure phase ii that is in mutual stable equilibrium with the mixture is made equal to the volume of the mixture. The result is in accord with Dalton's concept that each component behaves as if it were present alone.

A further conclusion that can be reached is that a Gibbs–Dalton mixture of semiperfect gases is itself a semiperfect gas. That is, for the mixture the ratio pv/RT is equal to unity if v is the volume per mole of all components and R the universal gas constant. If a specific gas constant is used and v is the volume per unit mass, then the mixture behaves as a semiperfect gas with a molecular weight M that is the mass m of the mixture divided by the total number n of moles of all components. It is also the average of the molecular weights M_i of the components, each weighted proportionately to the mole fraction y_i of that component in the mixture:

$$M = \frac{m}{n} = \sum_i y_i M_i.$$

Mixing gases. Some further results of the Gibbs–Dalton rule will be given here without proof. If a number of pure species are confined by thin partitions in separate parts of an insulated volume V in such quantities that their pressures are equal when their temperatures are equal, then when the partitions are removed (or destroyed), the gases will mix irreversibly without change in temperature, pressure, energy, or enthalpy. The change of entropy ΔS is greater than zero, as is appropriate for an adiabatic irreversible process. It is given by the negative of the product of the number n of moles of all components multiplied by the gas constant R and a mean logarithmic mole fraction:

$$\Delta S = -nR \sum_i y_i \ln y_i, \tag{76}$$

in which y_i denotes the mole fraction of the species i in the final mixture. Both the Helmholtz free energy and the Gibbs free energy decrease in the mixing process.

The Gibbs–Dalton rule holds in regions of state in which the pressure is low relative to the critical pressure of every component. Outside these regions an equation of state for a mixture may be devised from the equations of state of its components, with varying degrees of precision, by means of certain combining rules. One of these rules, proposed by the 19th- and 20th-century French physicist Émile-Hilaire Amagat, states that the volume of a mix-

ture is the sum of the volumes of the pure components—each at the pressure and temperature of the mixture. A 20th-century U.S. chemist, James Alexander Beattie, later proposed a rule of more general application that prescribes how the coefficients in the Beattie–Bridgman equations for the pure components may be combined in order to obtain the corresponding coefficients for the mixture.

Vapour pressures of pure liquids. The vapour of a pure species may be in mutual stable equilibrium with its liquid at a flat interface at the normal or saturation vapour pressure corresponding to its temperature. The vapour may also, however, be in mutual stable equilibrium at a nonwetting porous wall that is permeable to vapour but not to liquid or at a curved interface, either of which can support a pressure difference between liquid and vapour. The effect of change in pressure of the liquid on the corresponding vapour pressure is called the Poynting effect. It is found by equating chemical potentials of liquid and vapour. For an incompressible liquid and a semiperfect vapour, the Poynting effect proves to be approximately proportional to the change in pressure on the liquid. For water at 40° C (104° F) the equilibrium pressure of the vapour increases by 1 percent when the pressure on the liquid is increased by a factor of 200.

The Poynting effect

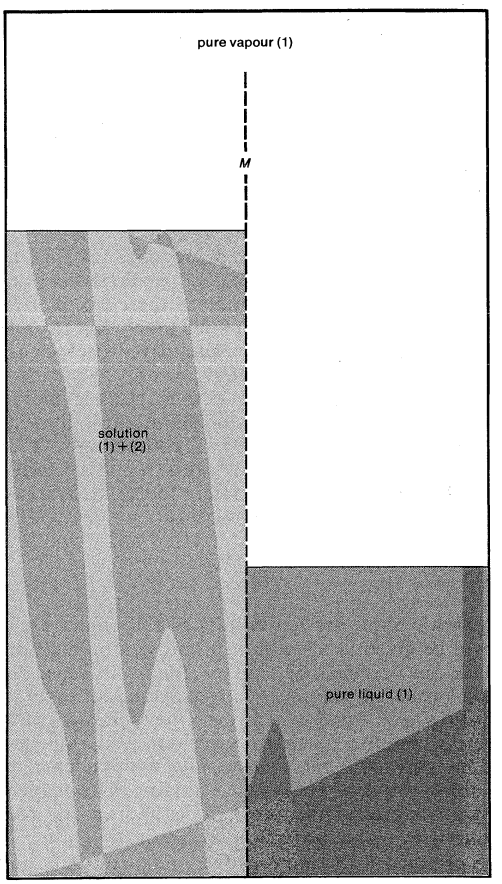

Figure 7: Equilibrium between a pure volatile liquid (1), a solution of nonvolatile substance (2) in liquid (1), and the vapour of substance (1). Substance (1) can pass through the membrane (*M*), but substance (2) cannot. The difference in the vapour pressures of solvent and solution causes the liquid levels to be unequal. The difference in pressure between pure liquid and solution is called the osmotic pressure (see text).

Ideal solutions. When a solute is added to a volatile solvent, the volatility of the solvent is reduced. The effect is to reduce the pressure of solvent vapour that is in equilibrium with the liquid in proportion to the reduction in the mole fraction of solvent in the solution. Thus the effect on the volatility is the same for equal numbers of moles of different solutes in solution, the mole being measured as described by equation (47). This observation, which holds only for dilute or ideal solutions, is expressed in Raoult's rule. The rule states that at given pressure p and temperature T the pressure p_1^v of pure solvent vapour in equilibrium with the solution is equal to the product of the mole fraction x_1 of solvent in the solution and the vapour pressure p_1° of pure liquid solvent at the pressure and temperature of the solution. By ignoring the small Poynting effect on the vapour pressure of the solvent, the rule of boiling-point raising may be derived from Raoult's rule by mathematical deduction. It is that the rate of change of boiling temperature T with mole fraction x_2 of solute 2, as solute is added to a dilute solution, is equal to the rate of change of boiling temperature of pure solvent 1 with the logarithm of the pressure p_1° on the pure solvent. The mathematical statement of the rule of boiling-point raising is given by the relation

Raoult's rule

$$\left(\frac{\partial T}{\partial x_2}\right)_{x_2 \to 0} = \left[\frac{dT}{d(\ln p_1^\circ)}\right]_{x_2 = 0}. \qquad (77)$$

For water at 25° C (77° F) the value of $(\partial T/\partial x_2)$ is about 17° C (31° F) or, more practically, 0.17° C for each mole percent of solute regardless of the nature of the solute.

Figure 7 depicts a container in which volatile solvent liquid 1 is separated from a solution containing nonvolatile solute 2 by a wall M permeable to 1 only. The wall extends only part way to the top, leaving a vapour space with free access of vapour 1 from one liquid surface to the other. Because the pressure of vapour in mutual stable equilibrium with the solution is less, by Raoult's rule, than that in equilibrium with the pure solvent, the height of the solution surface must be greater than that of the pure liquid by enough to provide the appropriate hydrostatic head of vapour between them. The corresponding hydrostatic head of liquid, of course, is much greater and accounts, except for the head of vapour, for a substantial difference between the pressure of the solution and the pressure of the solvent with which it is in equilibrium through the semipermeable wall. This difference in pressure, which is required to prevent migration of solvent into the solution, is called osmotic pressure. With the usual approximations for a dilute solution and a perfect vapour, it can be shown by equating chemical potentials of solvent across the wall that the osmotic pressure P is approximately equal to the product of gas constant R, temperature T, and number of moles c_2 of solute per unit volume of solution.

Osmotic pressure

By means of the Gibbs–Duhem equation (71) and the assumption of perfect vapours for the two components of a binary solution, it can be shown that Raoult's rule requires that the pressure p_2^v of solute vapour in equilibrium with a solution is proportional to the mole fraction x_2 of solute in the solution; that is, p_2^v is equal to

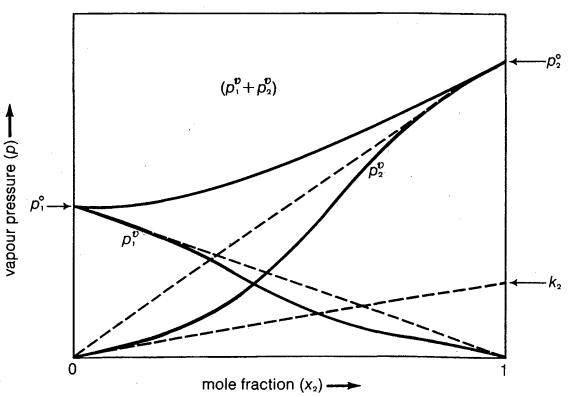

Figure 8: Variation of vapour pressure above solutions of two completely miscible volatile substances, 1 and 2, from pure 1 ($x_2 = 0$, $P_1^v = p_1^\circ$) to pure substance 2 ($x_2 = 1$, $P_2^v = p_2^\circ$). The Henry's rule constant, k_2, is shown as the tangent to the graph of p_2^v at $x_2 = 0$.

k_2x_2, k_2 being a constant of proportionality. This relation is known as Henry's rule. Unlike Raoult's rule, in which the coefficient of x_1 is the vapour pressure of the pure solvent, the proportionality constant k_2 bears no simple relation to the properties of the components. Of course, if Raoult's and Henry's rules were to hold over the whole range of x_2 from 0 to 1, then k_2 would be the vapour pressure of pure solute. In general, however, the laws hold only for dilute solutions; that is, for x_2 nearly zero. An example of the variation of vapour pressures of a binary mixture of two completely miscible volatile species is shown in Figure 8, in which the distinction between Henry's rule constant k_2 and the vapour pressure p_2° of pure solute is made evident.

Equation (68) for the chemical potential of a semiperfect gas can be used in combination with Raoult's and Henry's rules to show that any change in chemical potential of solvent in a solution between two states at the same temperature is proportional to the change in $RT \ln x_1$. Similarly, the change in chemical potential of solute is proportional to change in $RT \ln x_2$. Expressions for the chemical potentials, therefore, are

$$\mu_1 = RT \ln x_1 + \mu_1^\circ \tag{78}$$

$$\mu_2 = RT \ln x_2 + \mu_2^\circ, \tag{79}$$

in which μ_1° is the chemical potential of pure solvent ($x_1 = 1$) at the pressure and temperature of the solution. The quantity μ_2° is the chemical potential of pure solute in a hypothetical ideal-solution state for which x_2 is unity. Equations (78) and (79) indicate that the logarithm of the mole fraction of a component is the measure of the escaping tendency of that component.

When to an ideal solution at a given pressure and temperature is added some pure solvent starting from the same pressure and temperature, it can be shown that the total volume occupied by solution and solvent remains unchanged by the process of dissolving. Similar statements may be made concerning the total energy and total enthalpy. One consequence is that no heat flows to or from the fluids during this process of solution; thus, the heat of solution is zero, and the process is adiabatic. The total entropy, on the other hand, increases during the process of solution, as would be expected from equation (6) for an irreversible adiabatic process. In general, a similar addition of pure solute to an ideal solution will result in change in total volume, energy, and enthalpy, and the heat of solution will not be zero. The change in volume, energy, and enthalpy per unit of solute added will be independent of the composition of the solution over the range of ideality.

BULK FLOW

A kind of transfer of matter in which each elementary piece of the flowing fluid can be considered to be a closed and separable system bounded by a prescribed surface is called bulk flow. Contrasting with this definition is transfer of material by molecular diffusion, in which the flowing molecules cannot be considered to be closed and separable systems.

Figure 9 shows a system A enclosed within a fixed boundary σ and an infinitesimal adjacent mass dm separated from A by a part of σ that is penetrable by A. The mass dm may be pushed across σ to join the larger mass inside. The work done by the surroundings on the combined system comprising A and dm will be equal to the product $pvdm$—namely, the pressure p multiplied by the specific volume v and the mass dm. This statement must be qualified by limiting it to slow motion of the boundary of dm and to zero shear effects in the fluid.

It can now be shown from equation (19) that the change in energy found within the boundary σ is the initial value of $E + pV$ for the mass dm, or $(e + pv)\,dm$, e denoting energy per unit mass. To this must be added any heat δQ that crosses the boundary of the combined system, and from it must be subtracted any work δW_x, called shaft work, that crosses boundary σ by virtue of

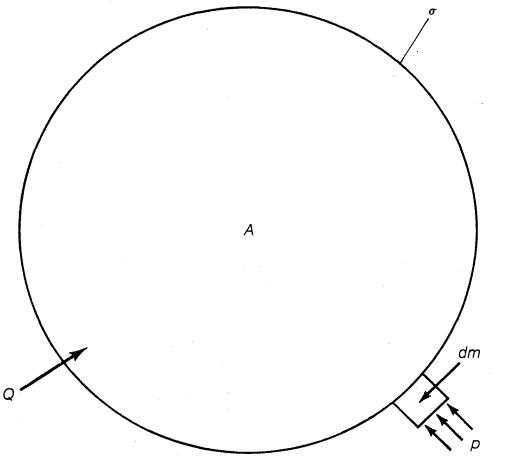

Figure 9: Schematic calculation of the change in energy of system resulting from the introduction of additional mass (see text).

torque in a rotating shaft or the equivalent. The corresponding statement for the energy change dE within σ when an infinitesimal mass of fluid dm crosses σ is

$$dE = (e + pv)dm + \delta Q - \delta W_x. \tag{80}$$

Equation (80) is sufficiently general to apply to otherwise simple systems that may change level in a gravity field and that depart from equilibrium to the extent that elementary parts acquire the uniform velocity ϕ. Then it may be shown by consideration of work in adiabatic processes that the energy e of unit mass is the sum of the internal energy u, the kinetic energy $\phi^2/2$, and the gravity potential energy gz for height z above a datum level $z = 0$, g denoting the gravity constant, which has the dimensions of acceleration:

$$e = u + \frac{\phi^2}{2} + gz. \tag{81}$$

Equation (80) may now be repeated after substituting the enthalpy symbol h for $u + pv$:

$$dE = (h + \frac{\phi^2}{2} + gz)\,dm + \delta Q - \delta W_x. \tag{82}$$

A special case of the problem of bulk flow is one for which inward flow and outward flow occur, each in one or more channels, and the state of the fluid within the control volume is the same at all times. The state of the control volume for which this assumption holds is called a steady state, and the flow condition is called steady flow. A simple example with single entry and single exit is shown in Figure 10. It would apply to a boiler, for which W_x is zero, and to a steam turbine, for which Q is nearly zero, as well as to many other engineering devices.

Steady flow

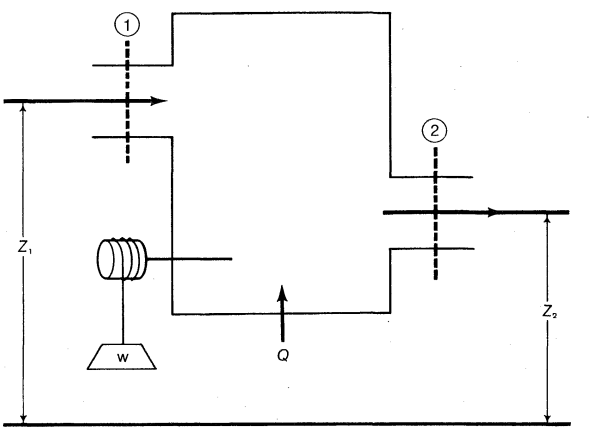

Figure 10: A system in a steady state in which the state of the fluid between boundaries 1 and 2 is the same at all times. The net mass flux across the entire boundary of the system must be zero. The heights of boundaries 1 and 2 above a datum are denoted Z_1 and Z_2 (see text).

The condition of steady state requires that dE be zero. The value of $(h + \frac{\phi^2}{2} + gz)dm$ is then summed up over all entry and exit conditions. For the simple example of Figure 10, equation (82) indicates that the difference between $(h + \frac{\phi^2}{2} + gz)$ at entry and exit when added to the heat Q' and shaft work W_x' passing inward across σ for each unit of mass entering must equal zero:

$$(h + \frac{\phi^2}{2} + gz)_1 - (h + \frac{\phi^2}{2} + gz)_2 + Q' - W_x' = 0. \quad (83)$$

CHEMICAL REACTIONS

Stable equilibrium states. An isolated closed simple system in which chemical reactions occur will attain a stable equilibrium state if the reactions are left uninhibited to proceed as far as they will. Such a state is fixed by two independent properties such as energy and volume or temperature and volume, and it is called a state of chemical equilibrium. Among the properties of the chemical equilibrium state fixed by the two independent properties are the proportions of the molecular species present.

When a chemical reaction proceeds at such a rate that chemical equilibrium is not achieved, each state passed through may be considered, for the purposes of analysis, to be a stable equilibrium state for which an anticatalyst has prevented chemical reaction. Between these states the system may experience chemical reaction in such degree as to produce a certain chemical aggregation in a second state different from that in the first. These states may be considered to have been achieved by successively removing and replacing an agent, such as an anticatalyst, that prohibits a chemical reaction. In the presence of such an agent each stable equilibrium state would correspond to a different set of proportions of species that would constitute a system with its own set of allowed states. To identify the state, therefore, it is necessary to add to the two independent properties required by the state principle an additional property that identifies the system. For example, for a mixture of molecules of nitrogen (N_2), hydrogen (H_2), and ammonia (NH_3) and the chemical reaction of formation of ammonia from the elements N_2 and H_2,

$$\frac{1}{2}N_2 + \frac{3}{2}H_2 \rightleftarrows NH_3,$$

the energy, volume, and some measure of the degree to which this reaction has proceeded in one direction or the other would be required to identify the system and its stable equilibrium state.

Heat in chemical reactions. For any chemical reaction in a simple system, for which heat Q and work W are the only interactions, the energy change ΔE is given, according to equation (19), by the difference between heat and work: $\Delta E = Q - W$. For a chemical reaction in a system held at constant volume, the heat $(Q)_V$, in the absence of other interactions, is given by the increment in energy:

$$(Q)_V = \Delta E. \quad (84)$$

For a chemical reaction in a system held at constant pressure, the heat $(Q)_p$ is given by the increment in enthalpy:

$$(Q)_p = \Delta H. \quad (85)$$

For steady flow between entry section 1 and exit section 2, the heat interaction, in view of equation (83), is the increase in enthalpy $H_2 - H_1$ between the two sections plus any shaft work W_x:

$$Q = H_2 - H_1 + W_x.$$

For a chemical reaction at constant volume in an isolated system, no change in energy occurs despite the large change in temperature that is usually observed, as may be seen from equation (84) in which $(Q)_V$ (and therefore ΔE) is equal to zero for an isolated system.

When values are sought in the literature for the properties E and H for use in the preceding equations or for S and Z for use in other equations, it is found that for different molecular species they are not available on a common base—that is, an arbitrarily selected zero state is used for each separate species independently of that for any other. It is necessary, therefore, to supplement data for the molecular species with data on change in values of properties when each species is formed from the chemical elements without change in pressure or temperature.

Equilibrium between chemically reacting species. Included in the description of a system is the set of possible states that the system may assume. The choice of this set is often arbitrary and may be made to suit convenience in approximating a real system and its behaviour. For example, a system consisting of a mixture of hydrogen and oxygen gases may or may not have included among its possible states those in which water has been formed by chemical reaction.

The description of a multicomponent system may or may not permit a certain chemical reaction in which some species are formed from others. Whenever a reaction is permitted that was not permitted before, the number of components, each of which must be independently variable, decreases by one. Moreover, one new kind of change of state is introduced—namely, a variation in which certain species leave phases in which they are actual components to form other species in phases in which these others are actual components.

From O.A. Hougen, K.M. Watson, and R.A. Ragatz, *Chemical Process Principles*, 2nd ed. (1957), used with permission of John Wiley and Sons, Inc.

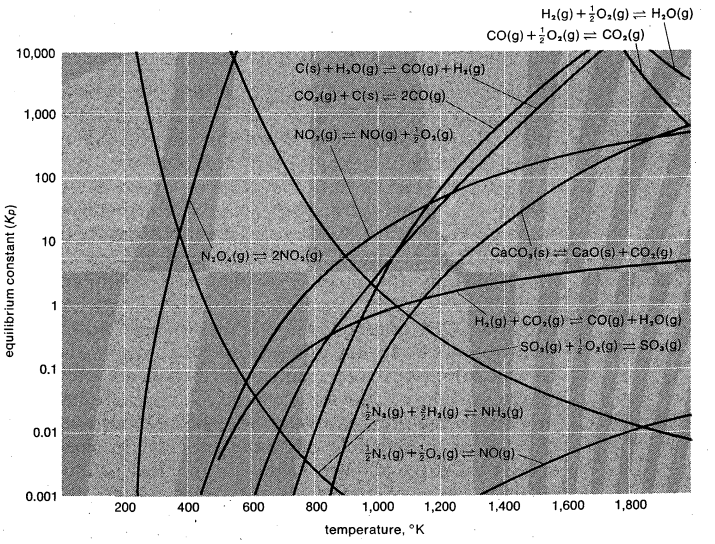

Figure 11: Variation in equilibrium constant, K_P, with variation in temperature for several chemical reactions (see text).

For a reaction such that a moles of A combine with b moles of B, etc., to form k moles of K plus l moles of L, etc., the stoichiometric (chemical-reaction) statement is

$$aA + bB + \ldots \rightleftarrows kK + lL + \ldots. \quad (86)$$

This statement implies that the change Δn_A in number of moles of species A resulting from the reaction, when divided by the coefficient a, is numerically identical with similar quotients for the other species; *i.e.*,

$$\frac{\Delta n_A}{a} = \frac{\Delta n_B}{b} = \ldots = -\frac{\Delta n_K}{k} = -\frac{\Delta n_L}{l} = \ldots = -\Delta\xi. \quad (87)$$

The common value of the ratios, sometimes called the degree of reaction, is denoted by $\Delta\xi$. The stable equilibrium state in a system for which reaction (86) is allowed must be the state for which the entropy is at a maximum for all the states having given values of energy and volume of each phase. By reference to the Gibbs equation (64), it can be shown that this maximum is attained when the chemical potentials $\mu_A, \mu_B, \ldots, \mu_K, \mu_L, \ldots$ of species $A, B, \ldots K, L, \ldots$ are related as in the following equation, which is called the equation of chemical equilibrium:

$$a\mu_A + b\mu_B + \ldots - k\mu_K - l\mu_L - \ldots = 0. \quad (88)$$

Because for each component of a Gibbs–Dalton mixture

of semiperfect gases the chemical potential may be simply expressed, as in equation (68), in terms of the logarithm of the partial pressure of the species in the mixture, the condition for stable equilibrium becomes such that a product of powers of the partial pressures p_A, p_B, . . . , p_K, p_L, . . . is the same for a given temperature regardless of the proportions of the components that make up the mixture. This product is called the equilibrium constant in terms of pressure. For reaction (86) it is given by

$$\frac{p_K^k p_L^l \cdots}{p_A^a p_B^b \cdots} = K_p(T). \tag{89}$$

The variation of K_p with variation in temperature for a number of familiar reactions is shown in Figure 11.

Equilibrium constants

For a chemical reaction among the components of an ideal solution, a similar equilibrium constant is found for which the mole fraction x_I of component I is substituted in equation (89) for the partial pressure of component I:

$$\frac{x_K^k x_L^l \cdots}{x_A^a x_B^b \cdots} = K_x(T). \tag{90}$$

When a gas mixture is not a Gibbs–Dalton mixture or a solution is not ideal, then a property called the fugacity takes the place of pressure in equation (89), and one called activity takes the place of mole fraction in (90). (For the definitions of these properties, see SOLUTIONS AND SOLUBILITY.)

Because each of these so-called equilibrium constants changes with change in temperature, some knowledge of the rate of change of the value of K with temperature is of great value. This rate is expressed most simply as the rate of change of ln K with temperature, and it proves to be equal to the quotient of the change in enthalpy when the reaction occurs at constant pressure and temperature and the product RT^2. In non-ideal mixtures (or solutions) the change in enthalpy must be measured between a reactants state for which the fugacity (or activity) of each reactant species is unity and a product state for which the fugacity (or activity) of each product is unity:

$$[d(\ln K_\alpha)/dT]_p = \frac{\Delta H^\circ}{RT^2}. \tag{91}$$

AVAILABILITY FUNCTIONS

The economic and engineering importance of a system in a given state is often determined by its available work Ω_R with reference to ambient systems as a reservoir. The function Ω_R, which was used above to introduce and define entropy, proves to be one of a number of availability functions (all of which were stated or implied by Gibbs in his papers of 1873 and 1877–78).

The decrease in Ω_R between two states of a system is the maximum work that can be obtained from the system and a reservoir at T_0, no net changes of state occurring in any other systems aside from, for example, the rise of an external weight. The maximum work is also the value of the work produced by system and reservoir in a reversible process and is a value common to all reversible processes joining the two prescribed states of the system. In view of equation (4) and the definition of the entropy constant c_R, the decrease in available work Ω_R may now be identified as the decrease in the quantity $(E - T_0S)$, in which the subscript 0 is introduced to refer to the reservoir. The value of Ω_R itself may be taken to be the maximum possible decrease in $(E - T_0S)$, which is also the decrease when the system changes to a state of mutual stable equilibrium with the reservoir.

If the system is surrounded by an atmosphere at temperature T_0 that applies a constant pressure p_0 at all interfaces with other systems, then some of the work discussed in the previous paragraph is associated with change in volume of the atmosphere. The net maximum useful work, $(W_u)_{max}$, that can be delivered by system and atmosphere to other things for a change from state 1 of the system to state 2, no net changes in state occurring in any other things aside from the rise of a weight, is given by the decrease in an availability function Φ defined as $E + P_0V - T_0S$:

$$(W_u)_{max} = \Phi_1 - \Phi_2.$$

The function Φ is useful in evaluating the performance of a work-producing device that changes volume as it uses up its capacity for doing work.

A less well known availability function is that for a system exposed as before to a large reservoir at fixed pressure p_0 and temperature T_0 with which the system can exchange (through permeable or semipermeable membranes) component species; that is, transfer of these species can occur until the chemical potential of each in the system equals that in the reservoir. This availability function, denoted by Ξ, has a minimum value of zero. It is given by the relation

$$\Xi \equiv E + p_0V - T_0S - \sum_i \mu_{i0} n_i, \tag{92}$$

μ_{i0} denoting the chemical potential of component i in the reservoir.

NEGATIVE TEMPERATURE

In the interest of simplicity, the third corollary of the second law was stated above as follows: A system in a stable equilibrium state can receive but cannot produce work. Although this statement is satisfactory for all ordinary systems, which are also called normal systems, recent developments in the theory of nuclear spins—the spinning of neutrons and protons of the atomic nucleus that contributes to both the angular momentum and the magnetic moment of the atom—have shown that some systems, which will be called special systems, in stable equilibrium states can produce work but cannot receive work.

Characteristics of special systems

A special system requires the following characteristics: (1) the energy of its allowed states has a finite upper limit; and (2) it must be coextensive in space with another system that shields it from work interactions that would change its volume or the velocity of its parts. For example, a lithium fluoride crystal may be considered to contain two distinct systems occupying the same space. The first, a special system, consists of the nuclear spins of the atoms of the crystal and has the energy of these spins. The second, a normal system, consists of the same atoms in the crystal, but its energy does not include that of the nuclear spins of the atoms. The stable equilibrium states of the two systems can be identified and distinguished because each comes to equilibrium in itself much more rapidly than they together approach mutual stable equilibrium.

It can be shown by reference to the second law of thermodynamics that for a closed special system the entropy–energy diagram is as shown in Figure 12. The

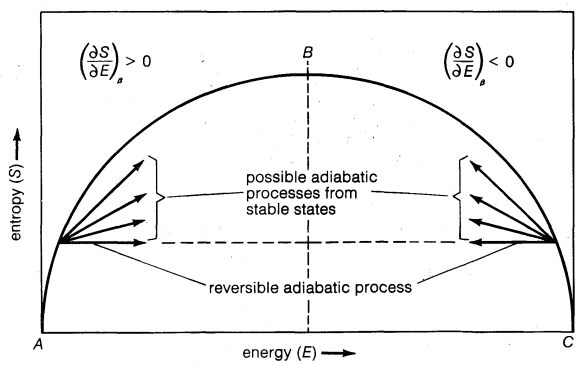

Figure 12: Entropy-energy diagram for a closed special system, for which negative absolute temperatures exist (see text).

curve ABC represents stable equilibrium states as well as the upper boundary for the region of all allowed states for given values of constraints β. Normal stable equilibrium states, which a special system may assume, are those on the AB part of the curve. Special stable equilibrium states are those on the BC part of the curve, and for these special equilibrium states the energy decreases with increase of entropy. In view of the definition of tempera-

ture (equation [13]), the temperature is therefore represented by a negative number.

The significance of negative temperatures on the scale of hotness and coldness can best be described in terms of the reciprocal Kelvin scale τ, in which $\tau \equiv 1/T$. The possible range of values of τ is from minus infinity to plus infinity, with the hottest temperature possible at minus infinity and the coldest temperature possible at plus infinity. Thus, negative temperatures correspond to hotter levels (the direction of heat flow being from hot to cold) than plus infinity on the Kelvin scale. The so-called absolute zero on the Kelvin scale becomes plus infinity on the τ scale of temperature.

THIRD LAW

Valid calorimetric experiments at temperatures near zero on the Kelvin scale invariably are in accord with the following postulate, which is the third law of classical thermodynamics: The entropy of any finite system approaches a noninfinite value as the temperature on the Kelvin scale approaches zero.

States to which the third law is applied

The third law applies only to stable equilibrium states and implies that the heat capacity at constant constraints must go to zero at zero temperature. It follows that a substance cannot be treated as a perfect gas at temperatures near zero, because for a perfect gas the specific heat capacity at constant volume is constant, and the entropy, as given by equation (55), approaches minus infinity. For crystalline substances near zero temperature, the variation of heat capacity is often found to be proportional to T^n, n being greater than unity.

From the third law in combination with the second law, it can be shown that for any finite system all paths of stable equilibrium states for fixed values of constraints β_i must converge on a single value of entropy as they approach zero temperature, as shown in Figure 13.

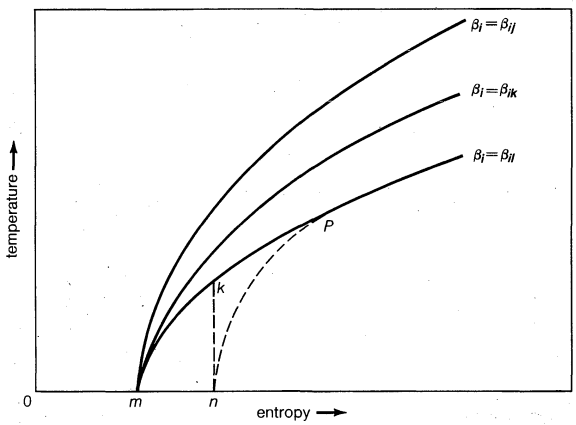

Figure 13: Convergence of values of entropy of stable equilibrium states of a system upon a single value at very low temperatures, as postulated by the third law of thermodynamics. For a given value β_{il} of constraint β_i, *Pm* represents stable equilibrium states and *Pn* metastable states (see text).

From the curve of stable equilibrium states for constant values β_{il} of constraints β_i, a branching may occur, as shown by *Pn* of Figure 13, but the states along *Pn* cannot be stable equilibrium states. They may be metastable or unstable, and the constant-entropy process *nk* from one of these states to the corresponding stable equilibrium state can be neither reversible nor adiabatic. Moreover, the change at zero temperature from n to m may be a spontaneous irreversible change to a stable equilibrium state. It follows that, as the temperature approaches zero, the magnitude of the entropy change in any isothermal reversible process approaches zero. This is the Nernst heat theorem, named for the Nobel-Prize winning German chemist, which is a corollary of the third law as stated above. An equivalent statement is that, as the temperature approaches zero, the magnitude of the entropy change between any pair of stable equilibrium states at the same temperature approaches zero.

Nernst heat theorem

Because the change between stable equilibrium states may involve a change in value of a constraint, such as the volume, all states that can coexist in stable equilibrium at zero temperature must have the same minimum value of the entropy for the same mass. Moreover, if a system consisting of chemically reacting species can be brought into a stable equilibrium state by imposing appropriate electrostatic forces in an electrolytic cell, then the system must have the same minimum value of entropy whether in the reactants state or the products state.

It is appropriate now to assign the value zero to the minimum value of the entropy for a given system. The energy at any finite temperature for given values of constraints β may be found from the experimentally determined relation between the heat capacity C_β and temperature by integrating the product $C_\beta dT$ from temperature zero to temperature T:

$$[E - E_{(T=0)}]_\beta = \sum_{T=0}^{T=T} C_\beta dT.$$

Similarly, the entropy at any finite temperature may be found by integrating the product $(C_\beta/T)dT$:

$$S_\beta = \sum_{T=0}^{T=T} \frac{C_\beta}{T} dT.$$

It is possible, therefore, to determine the values of Gibbs free energy $(E + pV - TS)$ for chemically reacting species at some standard pressure and temperature and, from these values, the conditions for chemical equilibrium, including the equilibrium constants—all without experimental values for the chemical reaction as such between the species.

IV. Force fields

NONRELATIVISTIC EFFECTS

When to the conditions for a simple system, gravitational, electrical, and magnetic constraints in the form of applied force fields are added, an additional term appears in the Gibbs equation for each additional constraint. Each added term is a product similar to the product pdV in that it represents the work done in a reversible process in which the value of a constraint is varied.

When a gravity field is applied to a system of mass small enough so that the field is affected by it only negligibly, a gravity potential γ may be defined as the increase in energy per unit mass of an elementary system as it is moved from a reference level ($\gamma = 0$) to the given level while entropy, number of particles, and volume constraint are held constant. The Gibbs equation (64) for a system of mass m then becomes

$$dS = \frac{1}{T}[dE + pdV - \sum_i \mu_i dn_i - md\gamma]. \qquad (93)$$

A simple and familiar condition for stable equilibrium that can be deduced from the Gibbs equation in form (93) is that for an otherwise simple fluid system in a gravity field, the rate of change of pressure with vertical distance is proportional to the density of the fluid. The proportionality factor proves to be g, the so-called acceleration of gravity.

A modification of the Gibbs equation similar to but more complicated than that given above for a gravity field has been devised to apply to a dielectric material, a material of which the electrically charged component species cannot move from one position in the material to another as it changes between neighbouring stable equilibrium states in an electric field between the plates of a capacitor. Another has been devised for a magnetic material in a magnetic field. (They will not be given here.)

RELATIVISTIC EFFECTS IN A GRAVITY FIELD

In an extremely intense gravity field, relativistic effects cannot be ignored. By combining the Einstein relation between energy and mass ($E = mc^2$) with the first and second laws, the following two conclusions are reached: (1) For stable equilibrium in a vertical column, it is necessary, as in nonrelativistic systems, that the temperature, $(\partial E/\partial S)_{n\beta}$, be uniform. (2) If a system is held at

constant volume and lifted reversibly and adiabatically —that is, at constant entropy S—the pressure and temperature of the system both increase. More specifically, the increase in the natural logarithm of the pressure when the system is lifted from the level at which the gravity potential γ is arbitrarily assigned the value zero to a level at which it has the value γ is equal to the quotient of γ and the square of the speed of light c. A similar statement holds for temperature. Since the square of the speed of light c is a very large number, the effect on pressure and temperature will be small except in very intense gravitational fields.

The relation between temperature and gravity potential may be derived by consideration of a cycle in which a pure molecular species in a triple-point state (for example, solid, liquid, and vapour in mutual stable equilibrium) is lifted reversibly, adiabatically, and at constant volume from the reference level $\gamma = 0$ to the level γ, heated reversibly at constant temperature, lowered reversibly and adiabatically to $\gamma = 0$, and cooled to the original state. Because of the increase in mass in the heating process, the work of descent will exceed the work of ascent. The efficiency of this cycle may then be equated to that of a Carnot cycle in terms of temperature, as in equation (22), to obtain the desired relation.

V. Steady rate processes

Many applications of thermodynamics involve interactions between systems some or all of which are passing through nonequilibrium states. For example, chemical and nuclear reactions and flow of energy and matter are processes occurring in systems passing through nonequilibrium states.

Problems of analysis of nonequilibrium states

The analysis of nonequilibrium states is more difficult, both conceptually and numerically, than that of stable equilibrium states. For example, because the number of properties required for the description of nonequilibrium states is larger than that for stable equilibrium states, the mathematical relations between properties are correspondingly more complicated.

In the interest of simplicity, the following applications are restricted to systems in steady states having fixed time rates of change of extensive properties. These applications will be called steady rate processes.

APPROACH TO MUTUAL STABLE EQUILIBRIUM

If two systems I and II are each in a stable equilibrium state but not in mutual stable equilibrium, a process in which they change toward mutual stable equilibrium will occur if they are connected by an intermediate system M. Depending upon the nature of the three systems and their states, the process that occurs may be caused by the transfer through M of energy alone or of matter with energy. The rate at which such transfer occurs will depend upon the initial departure from mutual stable equilibrium of systems I and II. By means of the first and second laws of thermodynamics and one additional postulate to them, a number of useful relationships between rates and potential differences or gradients may be determined for a substantial variety of rate processes, most of which are irreversible.

Generally it is possible to conceive of the process in M as being caused by two systems I and II, each of which would immediately assume a stable equilibrium state if the communication with M were suddenly stopped. To meet this requirement, the conductivity of matter or energy in I and II must be very great, so that whatever the influence on I of interaction through M with II, that influence will be felt uniformly through I and similarly with II. If the region is fluid, this result could be attained by minimal stirring of the fluid.

Under these circumstances, values of properties may be assigned to I and II. Region M, on the other hand, is in a nonequilibrium state. Nevertheless, values of intensive properties such as temperature and chemical potential of component i can be assigned to a point A in the region M by the method of local isolation. This method consists of isolating a region comprising point A and measuring the intensive property for this region when it reaches a stable equilibrium state. The value of the property in the limit as the size of the region is reduced to the smallest consistent with isolation may be taken to be the value at point A.

Region M will be assumed to be in a steady state; that is, the rate of change of any intensive property of I, II, or M is negligible. Extensive properties of I and II, on the other hand, may change at a finite rate, and any such rate is called a flux. Thus, an energy flux J_u is defined as the negative of the change of energy of I per unit time and, because of steady state in M, the change of energy of II per unit time:

$$J_u \equiv -\frac{dU_I}{dt} = \frac{dU_{II}}{dt}. \tag{94}$$

Similarly a flux of component i is denoted by J_i and is given by

$$J_i \equiv -\frac{dn_{iI}}{dt} = \frac{dn_{iII}}{dt}. \tag{95}$$

Under the steady-state conditions assumed and with I and II each held at constant volume, any one flux must depend upon those differences in intensive properties between I and II that measure the departure from stable equilibrium. Among these may be differences in temperature, pressure, mole fraction of component i, potential of component i, etc. The choice of differences that is made is governed by the postulate to be employed. It is made by expressing the rate of entropy generation in the process in terms of the Gibbs equation and using the resulting expression to define conjugate pairs of fluxes and forces. Each flux is then expressed in terms of all the forces so defined.

The region M between I and II may be subdivided into vertical laminas dM, over any face of which, for interaction in one direction only, the values of all intensive properties are uniform. For any one lamina, therefore, constant-volume stable equilibrium regions I and II may be substituted for material adjoining M without altering the process in the lamina (Figure 14).

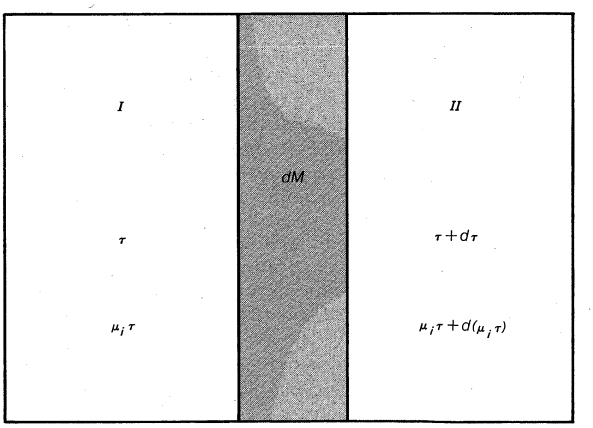

Figure 14: Two systems, *I* and *II*, each in stable equilibrium but not in mutual stable equilibrium, interacting through a thin intermediate system *dM*, which is in a nonequilibrium state. The symbol τ represents the quantity $1/T$, the reciprocal of the absolute temperature (see text).

For steady state in dM the rate of entropy generation in the process will be wholly accounted for by changes of entropy in I and II. Because the Gibbs equation (64) states the entropy change of a phase such as I or II in terms of the temperature, chemical potentials of components, change in energy, and change in masses of components, it will yield an expression for the rate of entropy change in terms of temperature, chemical potentials, and rates of change of energy and masses. These rates of change are the fluxes, J_u and J_i, of energy and of component, as indicated above. Because of the steady-state condition these fluxes may prove to be identical for regions I and II, but they will differ at most only infinitesimally for an infinitesimal thickness of the lamina dM.

The rate of entropy generation in the whole process is

found by summing for regions *I* and *II* the rates of entropy change, one of which will be negative and the other positive, to get an infinitesimal difference between two finite rates. This rate of entropy generation will then be the sum of products of fluxes and differences between *I* and *II* of potentials. These products are $J_u d(1/T)$ and $J_i d(-\mu_i/T)$, symbol d denoting the difference between the value in *II* and the value in *I* of the potential in parentheses. Thus the expression for the rate of entropy generation $d\dot{S}$ is

$$d\dot{S} = J_u\, d\left(\frac{1}{T}\right) + \sum_i J_i\, d\left(-\frac{\mu_i}{T}\right), \qquad (96)$$

in which $\sum_i$ denotes summation over all component substances $i = 1, 2, \ldots k$.

This last expression serves the purpose of identifying conjugate fluxes and forces; that is, for energy flux J_u the difference $d(1/T)$ is the conjugate force, etc.

Each flux J_u, J_i of equation (96) is a function of the state of one of the stable equilibrium regions *I* or *II* and of the forces $d(1/T)$, $d(-\mu_i/T)$, with the further condition that, whatever the state, the flux will be zero when all forces are zero—that is, for mutual stable equilibrium. Purely mathematical considerations indicate that the functional relation between a flux such as J_u and the forces $d(1/T)$, $d(-\mu_i/T)$ is a very simple one, provided that the fluxes are small; *i.e.*, provided that the departure from mutual stable equilibrium is small. This functional relation is that the flux is equal to the sum of terms each consisting of a force multiplied by a coefficient L. From thermodynamic considerations it can be shown that the magnitudes of the coefficients L are fixed once the nature and states of regions *I* and *M* are fixed. They are independent of the magnitudes of the forces $d(1/T)$ and $d(-\mu_i/T)$. The functional relation is thus given by

$$J_u = L_{uu}\, d\left(\frac{1}{T}\right) + \sum_i L_{ui}\, d\left(-\frac{\mu_i}{T}\right) \qquad (97)$$

$$J_i = L_{iu}\, d\left(\frac{1}{T}\right) + \sum_i L_{ii}\, d\left(-\frac{\mu_i}{T}\right), \qquad (98)$$

in which the first subscript on an L refers to the flux and the second to the force term in which it appears. Although exceptions to them may doubtless be found, these equations are of general application to rate processes and become increasingly valid the more nearly all the fluxes approach zero. They are known as phenomenological equations, and the coefficients L are known as conductivities.

The Onsager reciprocal relation

The Onsager reciprocal relation, the additional postulate referred to above, is as follows: The matrix of coefficients L of a set of equations such as (97) and (98), in which conjugate pairs of fluxes and forces are identified through expression (96) for the rate of entropy production, is symmetrical; that is,

$$L_{ij} = L_{ji} \text{ for } i, j = u, 1, 2 \ldots . \qquad (99)$$

Lars Onsager, a Norwegian–American theoretical chemist, stated this new law in 1931 in an argument based on a principle of statistical mechanics called the principle of microscopic reversibility and a postulate that is closely related to the second law of thermodynamics. The new law was subsequently shown to be of general application in irreversible processes and was extended to a wide variety of phenomena.

Phenomenological equations

The phenomenological equations reduce to special forms for various special systems and force conditions and are known under different names. For example, Fourier's law of heat conduction (for the 19th-century French mathematician and physicist Jean-Baptiste Fourier), Ohm's law of electric current flow (for the 19th-century German physicist Georg Simon Ohm), Fick's law of neutral particle diffusion (for the 19th-century German physiologist Adolf Eugen Fick), and the law of ambipolar diffusion of positive and negative charges are all special cases of the linear phenomenological equations. The constants appearing in the laws just cited, such as electric resistance in Ohm's law, may be expressed easily in terms of the conductivities L of the phenomenological equations.

FLOW OF A SUBSTANCE THROUGH A BARRIER

A relatively simple application of the thermodynamics of rate processes is to the flow of a single-component substance through a barrier *M* under conditions such that the phenomenological equations (97) and (98) are valid. An example would be the flow of helium through a rubber membrane between two stable equilibrium regions *I* and *II*. The Onsager reciprocal relation is simply that $L_{u1} = L_{1u}$, subscript 1 referring to helium.

The two forces are the differences across the membrane $d(1/T)$ and $d(\mu_1/T)$. When the flux of helium is zero, then the difference $d(1/T)$ causes its conjugate energy to flow downgrade in temperature and upgrade in $1/T$. When the temperature difference and $d(1/T)$ are zero, then its conjugate helium will flow downgrade in chemical potential and in μ_1/T. Each of these forces, however, tends to cause its nonconjugate flux, as well as its conjugate flux, in one or the other direction. This behaviour is called coupling. In the absence of coupling, the coefficients L_{u1} and L_{1u} would both be zero.

By virtue of coupling, the two forces may be set in relation to each other so as to stop the flow of helium because of a balance between the opposing influences of the two forces. Such a steady state will be attained spontaneously if a temperature difference is maintained between *I* and *II* for a long enough period of time while the volumes of *I* and *II* are held constant. The flow of helium will eventually cease—or at least approach zero as a limit as time proceeds. A flow of energy will persist, however, in the steady-state condition by virtue of the temperature difference.

It can be seen from the second phenomenological equation (98) that the ratio L_{1u}/L_{11} is equal to the ratio of forces $d(\mu_1/T)/d(1/T)$ when J_1 is zero. From the two equations (97) and (98) taken together it can be seen that the ratio L_{u1}/L_{11} is equal to the ratio of fluxes J_u/J_1 when $d(1/T)$ is zero. Because the Onsager reciprocal relation requires that L_{1u} be equal to L_{u1}, it follows that the ratio of forces when J_1 is zero must equal the ratio of fluxes when the temperatures of *I* and *II* are equal.

By means of a simple thermodynamic analysis, the ratio of forces $d(\mu_1/T)/d(1/T)$ may be expressed in terms of the ratio of pressure difference to temperature difference dp/dT, which then proves to be proportional to the excess of J_u/J_1 for dT equal to zero over the enthalpy h_1 of helium in region *I*. The actual relation is

$$\left(\frac{dp}{dT}\right)_{J_1=0} = -\frac{1}{v_1 T}\left[\left(\frac{J_u}{J_1}\right)_{dT=0} - h_1\right]. \qquad (100)$$

This relation gives the ratio of the pressure gradient to the temperature gradient for which the particle flow is stopped. Because it can be shown that for simple bulk flow J_u/J_1 is h_1 for fluid crossing any section in which the temperature is uniform in the direction of flow, it follows from equation (100) that bulk flow may be stopped even in a temperature gradient by zero pressure gradient. Whenever the energy flux per unit particle flux differs from h_1 in constant-temperature flow, then a pressure gradient is necessary to stop flow in a temperature gradient.

The Knudsen effect

Application of equation (100) to the flow of a perfect gas may be made for a porous plug with pore sizes very small compared with the mean distance travelled by gas molecules between collisions or compared to flow between emitting and receiving surfaces separated by a distance that is very small compared with the mean distance between collisions. For both of these the result is the same and can be shown to be

$$\left(\frac{dp}{dT}\right)_{J_1=0} = \frac{1}{2}\frac{p}{T} \qquad (101)$$

or, for a finite length,

$$\left[\frac{p^I}{p^{II}} = \sqrt{\frac{T^I}{T^{II}}}\right]_{J_1=0}. \qquad (102)$$

These relations describe what is known as the Knudsen effect.

The excess over the enthalpy flux of the energy flux across the barrier per unit of matter flowing when dT is zero is called the heat of transport and is denoted by q_1^*:

$$q_1^* \equiv \left(\frac{J_u}{J_1}\right)_{dT=0} - h_1. \tag{103}$$

It is the direct heat interaction that must be provided between regions *II* and *I* (Figure 14) when one unit of mass flows from *I* to *II* through *M* if the temperatures of *I* and *II* are to be maintained equal. Its magnitude can be found, in accordance with (100), by a measurement of the ratio dp/dT that corresponds to a flux J_1 of zero. The value found in this way for the heat of transport through a rubber membrane for nitrogen is —260 calories per gram mole and for hydrogen +100.

VI. Statistical thermodynamics

Early mechanical theories of heat

The mechanical theory of heat was developed concurrently with thermodynamics. It relates heat to changes in the motion of the atoms and molecules of matter. The history of the theory can be traced back to the Greek philosophers Democritus (*c.* 400 BC) and Epicurus (*c.* 300 BC). The French philosopher Pierre Gassendi developed in the 17th century a theory in which all material phenomena are attributable to the indestructible motion of atoms. Although the English philosopher Robert Hooke, the German philosopher and mathematician Gottfried Wilhelm Leibniz, and the Swiss mathematician and physicist Daniel Bernoulli improved upon it in the 17th and 18th centuries the theory was not firmly established until Joule demonstrated experimentally in the 19th century, that a quantitative relation exists between heat and work when they produce identical effects.

After Joule's demonstration the theory developed rapidly into a science of major importance that became known as statistical mechanics or statistical thermodynamics. Its subject is the relation between the laws of thermodynamics and the details of the structure of matter. Its development, which can be traced through Hermann Ludwig Ferdinand von Helmholtz, a German physicist and anatomist; Clausius; Maxwell; and Boltzmann, culminated in the work of Gibbs, who in 1901 presented an exposition of statistical thermodynamics that excels in completeness, rigour, and generality. Although the exposition of Gibbs is stated in terms of classical mechanics, it is better adapted to quantum mechanics, which in some ways it anticipates.

Perhaps because Gibbs's contribution was not fully understood, a less general and less rigorous molecular statistics prevailed in the literature, with few exceptions, until after World War II.

GIBBSIAN STATISTICS

According to classical mechanics, the state of a system having N degrees of freedom (independent ways in which the space configuration of the system may change) is fully specified by the values of N position coordinates $q_1, q_2, \ldots, q_N$, and N momentum coordinates $p_1, p_2, \ldots, p_N$. For example, the state of a system consisting of n point particles (particles without internal structure and therefore without internal degrees of freedom) is specified if the position coordinates along three Cartesian axes x, y, and z and the corresponding momentum coordinates along these same axes for each of the particles are specified. For such a system the number N of the degrees of freedom is equal to three times the number n of the particles of the system.

The position of a particle in space may be represented geometrically by a point in three-dimensional space having coordinates x, y, and z. The state of the particle involves not only the values of the coordinates x, y, and z but also the values of momentum component (which fixes the velocity component) p_x in the x direction, p_y in the y direction, and p_z in the z direction. These considerations suggest a mental extension of the concept of space to six dimensions, having coordinates x, y, z, p_x, p_y, and p_z. The state of the particle could then be completely described by a point in the six-dimensional space for which the values of x, y, z, p_x, p_y, and p_z are appropriately fixed.

The particle just discussed is said to have three degrees of freedom, and its state can be represented by a point in a six-dimensional space. A collection of two such particles might have six degrees of freedom, and the representation of its state would call for a 12-dimensional space. The number of degrees of freedom of a more complex system is the number of independent kinds of displacement to which it is subject. The state of such a system having N degrees of freedom may be represented geometrically in classical mechanics by a point in $2N$-dimensional space having as coordinates $q_1, q_2, \ldots, q_N$, $p_1, p_2, \ldots, p_N$. This $2N$-dimensional space was called by Gibbs phase space.

Phase space

According to Gibbs, the term thermodynamic state of a system with N degrees of freedom does not necessarily correspond to a unique point in phase space, but to a set of probabilities of the system being in any one of the allowed points consistent with the constraints imposed on the system. Because any set of allowed states in classical mechanics forms a continuum, Gibbs introduced a probability density or distribution P, which he called the coefficient of probability, such that the product $P dq_1 dq_2 \ldots dq_N dp_1 dp_2 \ldots dp_N$ is equal to the probability of the system being in states having values of coordinates between q_1 and $q_1 + dq_1$, q_2 and $q_2 + dq_2, \ldots, q_N$ and $q_N + dq_N$ and values of momenta between p_1 and $p_1 + dp_1$, p_2 and $p_2 + dp_2, \ldots$, and p_N and $p_N + dp_N$. For a given thermodynamic state, the distribution P will be a corresponding function of q's and p's. Furthermore, because a system must be at some one of the allowed states, the sum of all the probabilities must always be equal to unity or, by the same token, the integral of the distribution P over all q's and p's must be always equal to unity.

Various types of thermodynamic states correspond to particular mathematical forms of the distribution P. For example, Gibbs assumed without proof that, for the stable equilibrium states of a system with N degrees of freedom, the coefficient of probability P corresponding to the state $q_1, q_2, \ldots, q_N, p_1, p_2 \ldots, p_N$ of energy ε is equal to the number 2.718282 (the base of natural logarithms) raised to the $(\Psi - \varepsilon)/\Theta$ power, in which Ψ and Θ are constants; in other words, P is given by the exponential relation

$$P = \exp\left(\frac{\Psi - \varepsilon}{\Theta}\right). \tag{104}$$

He called this distribution of probabilities a canonical distribution. Further discussion of Gibbsian statistics will be omitted because the quantum statistical thermodynamics discussed below, though based on Gibbsian ideas, is more complete.

QUANTUM STATISTICAL THERMODYNAMICS

Definition of state. In contrast to classical mechanics, a fundamental premise of quantum mechanics is that at a given time the most that can be said about results of measurements on a system is the probability of finding particular values of properties, such as coordinates and momenta, rather than the particular values that will be observed. This premise reflects the principle of indeterminacy first introduced by the German physicist Werner Heisenberg. It requires a description of the state of a system in terms of probabilities.

The principles of quantum mechanics may be stated by means of a number of mathematical formulations. Among these, the best known are the wave formulation by the German physicist Erwin Schrödinger, the vector formulation by the English physicist P.A.M. Dirac, and the matrix formulation by Heisenberg. The matrix formulation is especially suited to the exposition of quantum statistical thermodynamics and is adopted below (for a discussion of matrices in general, see the article ALGEBRA, LINEAR AND MULTILINEAR).

Any property of a system that in classical mechanics

Matrices and eigenvalues

may be expressed as a function of position and momentum coordinates is expressed in quantum mechanics by a matrix. For example, the Hamiltonian function of classical mechanics, which is the energy of the system, is represented by the Hamiltonian matrix. Matrix representations are used also for properties (such as spin) that have no classical analogue. The method of calculation of elements of matrices is specified by the principles of quantum mechanics.

Each matrix possesses eigenvalues; that is, a set of numbers that can be found by solving the characteristic equation of the matrix. The eigenvalues of the matrix of a property are real, as distinguished from complex, in the mathematical sense. Each one corresponds to a possible outcome of a measurement of the property performed on the system. For example, a measurement of the energy of a system in a given condition will yield any one of the real eigenvalues of the Hamiltonian matrix of the system. The number of eigenvalues of a property may be either finite, as with spin, or infinite, as with energy for most systems.

According to quantum mechanics, it is impossible to predict from knowledge of the condition of a system which eigenvalue a measurement will yield. Instead, the most that can be said at any instant of time is the probability that a measurement will yield a given eigenvalue.

The state of a system is defined as the set of all probabilities for the outcomes of all measurements that may be performed at a given instant of time. That is, the state of a system is represented by Table 2, in which $\overline{F}$, $\overline{G}$,

Table 2: State of a System

property	$\overline{F}$	$\overline{G}$	$\overline{H}$	
Probabilities	$W(F_1)$	$W(G_1)$	$W(H_1)$	...
	$W(F_2)$	$W(G_2)$	$W(H_2)$	...
	•	•	•	
	•	•	•	
	•	•	•	

$\overline{H}$, . . . denote observable properties and in which $W(F_1)$ denotes the probability that any one measurement of property $\overline{F}$ will yield the eigenvalue F_1, . . . , $W(G_1)$ denotes the probability that any one measurement of property $\overline{G}$ will yield the eigenvalue G_1, . . . and so forth. It can be shown that these probabilities can be combined to form a matrix $[\rho]$, called the density matrix or statistical matrix. Conversely, a systematic procedure exists for determining from a given density matrix $[\rho]$ the probability $W(E_n)$ that a measurement of energy corresponding to the Hamiltonian matrix $[E]$ will yield the energy eigenvalue E_n of $[E]$. Again, the procedure yields the probability $W(F_m)$ that a measurement of property $\overline{F}$ corresponding to matrix $[F]$ will yield the eigenvalue F_m of $[F]$.

Expectation values of properties. Because measurements of a property $\overline{F}$ of a system in a given state yield different eigenvalues F_m, each with a probability $W(F_m)$ specified by the density matrix $[\rho]$ that represents the state, an expectation value or simply a value of the property corresponding to the given state is defined as the weighted average of the various possible eigenvalues, each eigenvalue being weighted by the probability that it will be observed. Symbolically, the value F of a property $\overline{F}$ may be represented as a sum over many terms, each of which is the product of a probability $W(F_m)$ and the eigenvalue F_m; that is,

$$F = \sum_m W(F_m)F_m, \tag{105}$$

in which the symbol $\sum_m$ denotes summation over all eigenvalues, and each eigenvalue is represented by a different symbol (different value of the subscript m) even when two or more eigenvalues have the same value. (For some matrices several distinct eigenvalues may have identical numerical values. The eigenvalues are then called degenerate.)

Reversible equation of motion. Quantum mechanics provides an equation, called the equation of motion, from which can be found the rate of change of the density matrix $[\rho]$ with time for each of the numerous processes that are reversible and adiabatic. The equation will not be given here.

Conditions for equilibrium are found from the equation of motion. If the eigenvalues of the density matrix $[\rho]$ for an equilibrium state are denoted by $x_1, x_2, \ldots, x_m, \ldots$ and the eigenvalues of the Hamiltonian matrix $[E]$ by $E_1, E_2, \ldots, E_m, \ldots$, it can be shown that, in the absence of irreversibilities, a necessary and sufficient condition for equilibrium is that the first eigenvalue x_1 be equal to the probability $W(E_1)$, that a measurement of the energy will yield the first eigenvalue E_1, the second eigenvalue x_2 be equal to $W(E_2)$, etc. Moreover, for equilibrium states the expectation value of the energy E can be expressed as a sum of terms each of which is the product of x_m and E_m; that is,

$$E = \sum_m x_m E_m. \tag{106}$$

General expression for entropy. According to the first and second laws of thermodynamics, entropy is a property or state function of a system. Moreover, it must be invariant in any reversible adiabatic process. From these two conditions and the requirement that it is an extensive property, the expectation value S of entropy can be shown to be proportional to a mean of the natural logarithms of the eigenvalues of the density matrix. When $y_1, y_2, \ldots, y_m, \ldots$ denote the eigenvalues of the density matrix $[\rho]$ (corresponding to an arbitrary state, which is not necessarily equilibrium or stable equilibrium), the mean is calculated by weighting each $\ln y_m$ with the value y_m. In mathematical form this statement is expressed

$$S = -k \sum_m y_m \ln y_m, \tag{107}$$

in which k is a universal constant that proves to be the Boltzmann constant.

Pure states. A pure state is defined as one for which the eigenvalues of the density matrix $[\rho]$ are all equal to zero, except for one that is equal to unity. It follows from equation (107) that the entropy of a pure state is equal to zero.

It can be shown that any pure state may be described also by means of a wave function of quantum mechanics; and, conversely, states that can be described by wave functions correspond to zero entropy. In general, however, the entropy of a system is not equal to zero, and the state of the system cannot in general, therefore, be described by a wave function.

Stable equilibrium states. In the language of quantum statistical thermodynamics, the criterion for stable equilibrium (see above *Stable equilibrium*) implies that the density matrix for a stable equilibrium state be such that the entropy (equation [107]) is at its maximum for given expectation values of energy and numbers of particles. When this criterion is applied to a system of which the numbers of particles are known without uncertainty (the probability of the value for the number of particles of a given kind that is found by a measurement is unity), it yields the eigenvalues $x_1^\circ, x_2^\circ, \ldots, x_m^\circ, \ldots$ for the stable equilibrium states as functions of the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ of the Hamiltonian matrix of the system and the temperature of the stable equilibrium state in question. The various mathematical functions are as follows:

$$x_1^\circ = \frac{\exp(-E_1/kT)}{\sum_m \exp(-E_m/kT)}; x_2^\circ = \frac{\exp(-E_2/kT)}{\sum_m \exp(-E_m/kT)}; \ldots \tag{108}$$

$$T \equiv \left(\frac{\partial E}{\partial S}\right)_\beta, \tag{109}$$

$$E = \sum_m x_m^\circ E_m = \frac{\sum_m E_m \exp(-E_m/kT)}{\sum_m \exp(-E_m/kT)}, \tag{110}$$

and

$$S = -k \sum_m x_m^\circ \ln x_m^\circ$$
$$= k \ln [\sum_m \exp(-E_m/kT)] + \frac{E}{T}. \quad (111)$$

Because the eigenvalues $x_1, x_2, \ldots, x_m, \ldots$ of the density matrix for any equilibrium state and, therefore, the eigenvalues $x_1^\circ, x_2^\circ \ldots, x_m^\circ, \ldots$ of the density matrix for any stable equilibrium state represent probabilities that measurements of energy will yield eigenvalues $E_1, E_2, \ldots, E_m, \ldots$, respectively, equation (108) can be thought of as analogous to the canonical distribution postulated by Gibbs, provided that the two constants Θ and Ψ in equation (104) are expressed in terms of the temperature T and the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$. It can be shown that Θ and Ψ are given by the relations

$$\Theta = kT \quad (112)$$

and

$$\Psi = kT \ln [\sum_m \exp(-E_m/kT)]. \quad (113)$$

It can be readily verified from equations (111) and (113) that the function Ψ is equal to the Helmholtz free energy of the system; *i.e.*, equal to $E - TS$. Moreover, because the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ are in general functions of the values of the constraints, the Helmholtz free energy Ψ is a function of temperature and the constraints and, therefore, a characteristic function. This means that in quantum statistical thermodynamics the problem of evaluating the properties of any system with numbers of particles that are known without uncertainty and in a stable equilibrium state reduces to the problem of evaluating the energy eigenvalues as functions of the constraints. The evaluation of the energy eigenvalues is a difficult mathematical task that has been carried out for only a very few systems. The difficulty, however, is in the calculation rather than in the conception of the evaluation.

The canonical partition function

The quantity Q_c, called the canonical partition function, is defined as the sum of $\exp(-E_1/kT)$, $\exp(-E_2/kT)$, $\exp(-E_3/kT)$, etc. It appears in the expressions for many properties of systems in stable equilibrium states. For example, because

$$Q_c \equiv \sum_m \exp(-E_m/kT), \quad (114)$$

it follows that the probability x_m° of observing an energy eigenvalue E_m is the quotient of $\exp(-E_m/kT)$ and Q_c, that the Helmholtz free energy per mole is the product of (kT) and the logarithm of Q_c, and that the entropy is the sum of the product $k \ln Q_c$ of k and logarithm of Q_c and the quotient E/T of the expectation value of the energy and the temperature:

$$x_m^\circ = \frac{\exp(-E_m/kT)}{Q_c}; \Psi = kT \ln Q_c; \text{ and } S = k \ln Q_c + \frac{E}{T}.$$

STATISTICS OF GRAND SYSTEMS

Stable equilibrium states. In many systems the numbers of particles may be uncertain either because the system is open to the transfer of rest mass or because particles can be created and annihilated within the system. The terminology of Gibbs suggests that such systems be called grand systems.

By definition, uncertainty in the numbers of particles means that measurements of these numbers for a grand system in a given state yield different particle-number eigenvalues. This uncertainty is analogous to that associated in general with the energy. It follows that an expectation value rather than a dispersion-free value (that is, rather than a unique value that is observed as a result of every measurement) is assigned to the number of particles of each component of a state of a grand system. Without discussion of the matrix formalism for grand systems, some results applicable to stable equilibrium states will be given.

A stable equilibrium state of a grand system is fully described by the set of eigenvalues $x_1^\circ, x_2^\circ, \ldots, x_m^\circ, \ldots$ of the density matrix that maximizes the entropy of the system at given expectation values of energy, numbers of particles of the components, and constraints. The mth eigenvalue x_m° is equal to the probability that a suitable measurement will yield the mth energy eigenvalue E_m and the mth number-of-particle eigenvalues $n_{1m}, n_{2m}, \ldots, n_{km}$ for the set of k components of the system. It can be expressed as a function of the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ of the Hamiltonian matrix of the system, the eigenvalues $n_{11}, n_{12}, \ldots, n_{1m}, \ldots$ of the number of particles of component number one, the eigenvalues $n_{21}, n_{22}, \ldots, n_{2m}, \ldots$ of the number of particles of component number two, ..., the total potential $\mu_1, \mu_2, \ldots, \mu_k$ of the k components 1,2, ... k, and the temperature T of the stable equilibrium state in question. It is given by the relation

$$x_m^\circ = \frac{\exp[(n_{1m}\mu_1 + n_{2m}\mu_2 + \ldots + n_{km}\mu_k - E_m)/kT]}{\sum_m \exp[(n_{1m}\mu_1 + n_{2m}\mu_2 + \ldots + n_{km}\mu_k - E_m)/kT]}. \quad (115)$$

The sum in the denominator of (115) is called the grand partition function Q_g; *i.e.*,

$$Q_g \equiv \sum_m \exp[(n_{1m}\mu_1 + n_{2m}\mu_2 + \ldots + n_{km}\mu_k - E_m)/kT]. \quad (116)$$

It appears in many relations between properties for grand systems in stable equilibrium states. For example, for a grand system with volume V as the only independent constraint, the equation of state is given by the relation

$$pV/kT = \ln Q_g. \quad (117)$$

Equation (117) applies to grand systems in gaseous, liquid, or solid states.

The one-particle approximation for one-component systems. Because of mathematical difficulties, the energy eigenvalues of most systems can be computed only approximately. A class of approximations that consists in expressing each energy eigenvalue of the system as a sum of energy eigenvalues of suitably defined subsystems, each having one particle only, is called the one-particle approximation. It is valid for some crystals and for dilute gases at such low densities that short-range interparticle forces (forces between two particles that act only when the two particles are very near each other) can be neglected, and long-range forces on each particle are independent of the positions of other particles. Some results of the analysis applicable to dilute gases will be given below.

In the context of the one-particle approximation, each of the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ of a dilute gas having one component only (namely, consisting of a number of particles of a single type) is expressed as a sum of terms such that each term is a positive integer multiplied by an energy eigenvalue of a system that has one particle only and for which the eigenvalues can be evaluated. For example, if $\nu_{m1}, \nu_{m2}, \ldots, \nu_{mj}, \ldots$ denote the positive integers that appear in the sum for the mth eigenvalue E_m and $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_j, \ldots$, the energy eigenvalues of the system with the one particle, then E_m is given by the relation

$$E_m = \nu_{m1}\varepsilon_1 + \nu_{m2}\varepsilon_2 + \ldots + \nu_{mj}\varepsilon_j + \ldots$$
$$= \sum_j \nu_{mj}\varepsilon_j \text{ for all values of } m. \quad (118)$$

Equation (118) is interpreted as meaning that of the n_m particles associated with the energy eigenvalue E_m, ν_{m1} have energy ε_1, ν_{m2} have energy $\varepsilon_2, \ldots, \nu_{mj}$ have energy $\varepsilon_j, \ldots$. From this interpretation it follows that the sum of all the positive integers $\nu_{m1}, \nu_{m2}, \ldots, \nu_{mj}, \ldots$ must be equal to n_m; *i.e.*,

$$\nu_{m1} + \nu_{m2} + \ldots + \nu_{mj} + \ldots = \sum_j \nu_{mj} = n_m. \quad (119)$$

Fermions and bosons

The values that each integer ν_{mj} can assume are restricted by the nature of the particles in question. For certain particles, called fermions, each ν_{mj} may be either zero or unity for all values of the subscripts m and j; *i.e.*, for any energy eigenvalue E_m of the overall system and any energy eigenvalue ε_j of the auxiliary one-particle sys-

tem. For example, because electrons are fermions a grand system consisting of electrons has, for a state with an energy eigenvalue E_m, at most one electron of one-particle energy eigenvalue ε_j. (This restriction is equivalent to Pauli's exclusion principle of atomic physics.) On the other hand, for certain particles called bosons, each of the integers ν_{mj} may have any positive integral value as well as the value zero. In a grand system consisting of photons—which are bosons—in a state with energy eigenvalue E_m, any number of photons from zero to n_m may have a particular energy ε_j.

When the allowed numerical values of the integers ν_{mj} are considered, the properties of a dilute gas in a stable equilibrium state can be expressed as functions of the one-particle energy eigenvalues $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_j, \ldots$ rather than the eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ of the overall system.

For example, the expectation or average value ν_j of the number of particles that can be thought of as having one-particle energy ε_j—namely, the expectation value ν_j of the integers $\nu_{1j}, \nu_{2j}, \ldots, \nu_{mj}, \ldots$—is defined as the sum of terms each being an integer ν_{mj} multiplied by the probability x_m° that a suitable measurement will yield the energy eigenvalue E_m.

It can be shown that, if μ denotes the total potential of the single component of the grand system, then ν_j is given by the relations

$$\nu_j = \sum_m x_m^\circ \nu_{jm} = \frac{1}{\exp[(\varepsilon_j - \mu)/kT] + 1} \quad \text{for fermions} \qquad (120)$$

and

$$\nu_j = \sum_m x_m^\circ \nu_{jm} = \frac{1}{\exp[(\varepsilon_j - \mu)/kT] - 1} \quad \text{for bosons.} \qquad (121)$$

Relation (120) is called the Fermi–Dirac distribution, and the corresponding dilute gas is said to obey Fermi–Dirac statistics. Relation (121) is called the Bose–Einstein distribution, and the corresponding dilute gas is said to obey Bose–Einstein statistics.

Again, for a system with volume V as the only constraint, it can be shown that the equation of state, (117), and the expectation value n of the number of particles are given by the relations

$$\frac{pV}{kT} = \sum_j \ln \{1 \pm \exp[(\mu - \varepsilon_j)/kT]\}^{\pm 1} \qquad (122)$$

and

$$n = \sum_j \{[\exp(\varepsilon_j - \mu)/kT] \pm 1\}^{-1}, \qquad (123)$$

in which the plus sign in $\pm$ applies to fermions and the minus sign to bosons.

Fundamental equation for one-component simple systems. For a system for which both sets of eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ and $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_j, \ldots$ are functions of volume V only, equations (122) and (123) indicate that p and n are functions of volume V, temperature T, and potential μ only. In principle, the p and n functions can be combined so as to eliminate volume V and obtain a fundamental equation that gives the total potential as a function of n, p, and T. But because equations (122) and (123) are transcendental, the derivation of such a fundamental equation is a difficult mathematical task. Under certain conditions it can be done with the aid of some approximations that are additional to the one-particle approximation.

For example, for a dilute gas in which the molecules have three translational degrees of freedom and of which the temperature is sufficiently high and pressure sufficiently low, it can be shown that the potential μ can be approximated by the expression

$$\mu = kT\ln p - \frac{5}{2}kT\ln T - kT\ln q_s - kT\ln\frac{k(2\pi mk)^{3/2}}{\hbar^3}, \qquad (124)$$

in which m denotes the mass of each particle of the system; $\hbar$, an alternate form of Planck's constant; and q_s, the partition function associated with the energy eigenvalues $\bar{\varepsilon}_i$ for the internal structure of each molecule:

$$q_s = \sum_i \exp(-\bar{\varepsilon}_i/kT).$$

Such a gas is called a semiperfect gas. Consistent with the relations found for a semiperfect gas above without reference to the detailed structure of the molecules of the system, its fundamental equation is independent of n. This result reflects conformity with the definition of a simple system, which excludes capillarity. In contrast with equation (68), equation (124) gives the chemical potential per particle instead of per mole. It includes, therefore, the Boltzmann constant k, which is related to a single molecule and which is equal to the universal gas constant R divided by the number of molecules contained in a mole. Boltzmann constant

As indicated earlier, the heat capacities of a semiperfect gas are functions of temperature. From equation (124) may be found the following expressions for specific heat capacities per molecule:

$$c_p = \frac{5}{2}k + 2kT\frac{\partial \ln q_s}{\partial T} + kT^2\frac{\partial^2 \ln q_s}{\partial T^2}$$

and

$$c_v = \frac{3}{2}k + 2kT\frac{\partial \ln q_s}{\partial T} + kT^2\frac{\partial^2 \ln q_s}{\partial T^2},$$

in which $\partial^2 \ln q_s/\partial T^2$ denotes the partial derivative of $\partial \ln q_s/\partial T$ with respect to T. Because q_s is a function of T, both specific heat capacities are functions of T.

A particular semiperfect gas is one for which c_p and c_v are independent of temperature. As stated above, such a gas is called a perfect gas. A gas behaves as a perfect gas either when the molecules have no internal structure, so that q_s is unity, or when q_s can be approximated by the product $g\exp(-\bar{\varepsilon}_0/kT)$, in which g and $\bar{\varepsilon}_0$ are constants.

Electronegativity of atoms and molecules. An atom or a molecule may be regarded as a grand system with electrons as its only component particles because it can exchange energy and electrons while reacting chemically with other atoms and molecules.

An atom A of atomic number z contains z units of positive electric charge in addition to its electrons. It has all the energy eigenvalues of the neutral atom and of each of the multiply (positively) charged ionized atoms. Consideration will be limited to atoms having energy eigenvalues corresponding to a singly charged negative ion; *i.e.*, an ion with $z + 1$ electrons.

The eigenvalues n_i of the number of electrons in atom A are such that

$$n_i = i = 0, 1, 2, \ldots, z, z + 1;$$

that is, the atom can be fully ionized ($i = 0$), partially ionized ($i<z$), neutral ($i = z$), or singly negatively charged ($i = z + 1$).

For each n_i a number g_{i_0} of energy eigenvalues will have the minimum numerical value E_{i_0}, in which g_{i_0} may be one or greater than one. Each of the g_{i_0} identical eigenvalues E_{i_0} represents the energy of the so-called ground state of A with exactly n_i electrons. Moreover, an infinite number of energy eigenvalues E_{ij} ($j = 1, 2, \ldots$), each with a multiplicity or degeneracy g_{ij}, correspond to the excited states for each n_i.

For a stable equilibrium state at temperature T, the expectation value n of the number of electrons of the atom is given in terms of the above notation by the relation

$$n = \frac{\sum_{i,j} n_i g_{ij} \exp[(n_i\mu - E_{ij})/kT]}{\sum_{i,j} g_{ij} \exp[(n_i\mu - E_{ij})/kT]}, \qquad (125)$$

in which the symbol $\sum_{i,j}$ denotes a double summation, one over all values of i from zero to $z + 1$ and the other over all values of j from zero to infinity. The number n may assume any value between 0 and $z + 1$, although n_i can assume only integral values.

For given n and T values equation (125) can be solved for the value of the potential μ. Although the solution is numerically tedious, some general results are readily established: (1) For a fully ionized state (that is, for the minimum value $n = 0$) μ is minus infinity, and for a singly charged negative-ion state (that is, for the maximum value $n = z + 1$) μ is plus infinity, both for all

values of T. Such extreme values of μ are always obtained when the value of the number of particles of the grand system is either minimum or maximum. They are consistent with the interpretation of the potential μ as an escaping tendency. (2) For values of n in the range between z and $z + 1$, the potential μ is positive. For all other values the potential μ is negative. (3) For a neutral atom state (that is, for $n = z$), in the limit as T approaches zero, μ is equal to one-half the difference between the energy eigenvalues of the ground states of the singly charged negative ion and the singly charged positive ion. It can also be written in the form

$$\mu = -\frac{I_1 + A_1}{2}, \tag{126}$$

in which I_1 and A_1 are, respectively, the first ionization energy and the electron affinity of the atom. For example, for the hydrogen atom the first (and only) ionization energy is equal to 13.6, the electron affinity is 0.7, and, therefore, the potential μ is -7.15, all in electron-volt units.

Since μ is a measure of the escaping tendency, $-\mu$ is a measure of a capturing tendency or power to attract. The power of an atom to attract electrons is called the electronegativity of the atom. The preceding analysis indicates that electronegativity can be identified with the potential $-\mu$ of electrons in an atom, and its value can be computed by means of statistical thermodynamics. Similar results can be obtained for molecules and for solid surfaces.

VII. Concluding remarks

The concepts of a system and states of a system adopted throughout this article are more general than are usually adopted in the science of thermodynamics. In the first part of the article, in which the microscopic structure of the particles that constitute the system is ignored, the many relations for systems in stable equilibrium states that are well-known to classical thermodynamics are derived. The method, however, lends itself well to the treatment of states other than stable equilibrium inasmuch as the values of entropy may be found for such states.

In the second part, the microscopic structure is brought into consideration but without loss of the concept of an unambiguous stable equilibrium state. This result is achieved through the quantum-mechanical interpretation of measurement as an operation that yields definite eigenvalues with certain probabilities. The results are, first, many relations familiar to statistical mechanics that permit evaluation of properties of a system from the known structure of the particles and, secondly, a means of applying the laws of thermodynamics to systems that are large or small, simple or complex. The limitation of thermodynamics, frequently applied in the past, to macroscopic systems no longer applies. To illustrate this generality, thermodynamic ideas are applied above to a single atom in order to discover the meaning of the previously recognized quantity electronegativity.

Thermoelectric Devices

Thermoelectric devices are devices that either convert heat directly into electricity—in the case of thermoelectric generators—or provide cooling by passing an electric current through appropriate materials—in the case of thermoelectric refrigerators. Both devices are based on thermoelectric effects involving interactions between the flow of heat and of electricity through solid bodies. Although the effects themselves were discovered in the first half of the 19th century, it is only in recent years that the devices based on them have begun to compete with conventional generators and refrigerators. The growing knowledge of solid-state physics in general, and semiconducting materials in particular, has made possible such applications as a refrigerator the size of a thimble and a nuclear-powered generator on the Moon to provide electrical power for equipment that sends moonquake information back to the Earth.

The Seebeck and Peltier effects

The two most important thermoelectric effects are the Seebeck effect and the Peltier effect. In the Seebeck effect, an electrical current or voltage is produced in a circuit made of two different conducting materials if the two junctions (points of contact) are held at different temperatures. The flow of heat from the hot to the cold junction gives rise to an electrical current; this effect is the basis for thermoelectric generation of electricity from heat. In the Peltier effect, when a direct electric current flows through a circuit made of two different conductors, one junction between the two materials is cooled while the other is heated, depending on the direction of current flow. This effect, which may be considered the inverse of the Seebeck effect, is the basis for thermoelectric refrigeration.

A major advantage of thermoelectric devices is that they involve only the motion of heat and electricity, rather than the motion of mechanical parts as in rotating machinery such as turbines, dynamos, motors, or compressors used in more familiar generators and refrigerators. The major disadvantages of thermoelectric devices are that they are often less efficient to operate and more expensive to produce than conventional machines and so are usually used in specialized applications rather than as replacements for large-scale power generating plants or air-conditioning equipment.

HISTORY

Thomas Johann Seebeck, a German physicist, discovered the effect which bears his name in 1821. He found

that a magnetic compass needle held close to a circuit made of two different conductors was deflected (indicating a flow of current) when the two junctions in the circuit were held at different temperatures.

The second major thermoelectric effect was discovered in 1834 by Jean-Charles-Athanase Peltier, a French watchmaker turned scientist, who, when he passed a current through the junction between two conductors, observed that heat was either absorbed or was emitted at the junction, depending on the direction of the current flow.

The thermodynamic relationship between these two thermoelectric effects was established by the English physicist Lord Kelvin (William Thomson) in 1857. He also discovered a third effect, related to the other two but more difficult to detect. The Thomson effect is the absorption or evolution of heat when an electrical current flows in a uniform conductor along which there is a temperature gradient.

The Seebeck effect is the basis for the thermocouple, a device that is widely used to measure temperatures. This was the only application of thermoelectricity for more than a century after the discoveries of Seebeck and Peltier. The theory of thermoelectric power generation was developed by a German scientist, E. Altenkirch, in 1909. In the following year he calculated the performance that could be achieved with thermoelectric refrigeration and heating, though useful devices based on his calculations were not feasible with the materials available at that time. In the multiplication of research efforts on semiconductor materials that followed the invention of the transistor in 1947, it was realized that these materials are best suited for thermoelectric applications. In the Soviet Union, Abram F. Ioffe and a group in Leningrad made important contributions to the field and, in the early 1950s, produced some of the first useful generators and refrigerators using semiconductors such as bismuth telluride (a compound of the elements bismuth and tellurium represented by the chemical formula Bi_2Te_3). In England, H.J. Goldsmid and his coworkers independently discovered that bismuth telluride could produce useful cooling. They achieved a temperature drop of 40° C (72° F) below room temperature in 1955 and 65° C (117° C) in 1958. In another independent effort, a group in the United States discovered that lead telluride (PbTe) and related semiconductors could be used effectively for thermoelectric generators.

Basic materials

These materials—bismuth telluride and lead telluride—remain the basis of thermoelectric materials most widely used for refrigeration and electric-power generation today. As a result of extensive materials research in many laboratories around the world in the 1950s and 1960s, only two other important materials were developed. Alloys of silicon and germanium, investigated in 1962, were found to be useful at higher temperatures, and bismuth–antimony alloys, investigated in 1962–63, were found best for use at low temperatures.

BASIC PRINCIPLES

Thermoelectric effects. The thermoelectric effects are concerned with the interactions between the flow of heat and of electricity in conducting solids. A very familiar effect is the production of heat in a wire when an electrical current flows through it, as in an electric heater or toaster. This phenomenon is called Joule heating; the amount of heat is proportional to the square of the current and is independent of the direction of the current flow. Although Joule heating is not itself a thermoelectric effect, it does, however, play an important role in thermoelectric devices.

In Figure 1, the flow of heat and the flow of electrical current through a conductor (A) are associated with two driving forces, the temperature difference along the conductor and the voltage applied to the ends of the conductor. The current is proportional to the applied voltage and inversely proportional to the resistivity of the material—*i.e.*, its opposition to flow of electricity. Resistivity is denoted by the Greek letter rho (ρ). Similarly, the heat flow from the hotter to the colder regions of a material is proportional to the temperature gradient and to the thermal conductivity of the material—that is, its ability to conduct heat. This quantity is represented by the Greek letter kappa (κ).

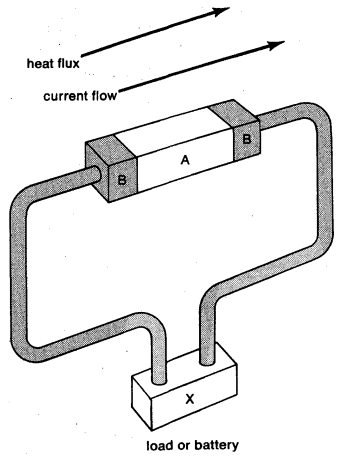

Figure 1: Basic thermoelectric circuit (see text).

In the first thermoelectric effect, a voltage is produced by the temperature gradient, the magnitude of the voltage depending on a characteristic of the material known as the Seebeck coefficient (S), expressed in volts per degree Celsius. This coefficient is often called the thermoelectric power, and it is usually measured in microvolts (10^{-6} volt) per degree Celsius. This voltage can be of either polarity, depending on the material.

According to the second thermoelectric effect, there is a flow of heat proportional to the electrical current and depending on a characteristic of the material known as the Peltier coefficient (Greek pi, π). This heat flow, unlike Joule heating, can be in either direction, depending on the material (π, like S, can be positive or negative), and the heat flow reverses when the current is reversed. The thermoelectric coefficients S and π have been defined here as properties of a particular material, but the observation of these effects depends on the presence of junctions between two different materials, A and B. If the two junctions between A and B in Figure 1 are at different temperatures, then there is a voltage developed across A and a voltage developed across B. If X is a voltmeter in the circuit, it will read the difference between these voltages.

If X in Figure 1 is a battery that drives a current around the circuit, then a quantity of heat flows across each unit of cross-sectional area of A, and a different quantity flows in B. At the junctions, there is a difference of heat flow that is absorbed at one junction (cooling) and evolved at the other (heating) depending on the direction of current flow. In effect, heat is removed from one junction and delivered to the other. The circuit acts as a heat pump—that is, it pumps heat from one junction to the other if the two materials are different.

In the Peltier experiment, if the two junctions are at different temperatures and the Peltier coefficient of material A varies with temperature, then the heat absorbed at one junction will not be the same as that evolved at the other. The difference must appear within the material A. This is the Thomson effect, the third thermoelectric effect, which is the absorption or emission of heat in a single material at a rate proportional to the current flow and the temperature gradient.

Thomson effect

The Thomson coefficient is proportional to the change of the Peltier coefficient with temperature. The first two thermoelectric effects are also related to each other. The laws of thermodynamics lead to the "Kelvin relation," which states that, for any material, the Peltier coefficient is equal to the product of the Seebeck coefficient and the absolute temperature: $\pi = ST$.

Electronic origin. The origin of the thermoelectric effects can be understood in terms of the motion of the electrons or holes (a hole is equivalent to a positive

charge, as it results from the absence of an electron) that carry the electrical current in a conductor. For a detailed discussion of these effects, see the articles ELECTRICITY; and THERMODYNAMICS, PRINCIPLES OF.

The Seebeck coefficient is small in most metals, typically a few microvolts (10^{-6} volt) per degree Celsius. Semiconductors (materials which are neither good electrical conductors nor good insulators) have much larger values of the coefficient, in the range of hundreds or thousands of microvolts per degree Celsius. A semiconductor material is made *n*-type (*i.e.*, given an excess of negative charges) by the addition of a small amount of impurity that introduces an excess of electrons in the crystalline structure of the semiconductor. The addition of an impurity that produces a deficiency of electrons, or holes, yields *p*-type (*i.e.*, with an excess of positive charges) material. A junction between *n*-type and *p*-type material is called a *p-n* (or *n-p*) junction.

The number of excess electrons or holes determines the electrical resistivity of a metal or semiconductor. In general, the larger the concentration of carriers, the lower the resistivity. The resistivity of a semiconductor is much higher than that of most metals, since it contains fewer charge carriers.

Thermal conduction

Thermal conduction also depends on these carriers, increasing with increasing concentrations of electrons or holes. In metals, most of the heat is carried by the electrons or holes. In any solid, heat is also carried from hot to cold regions by the vibrations of the atoms about their normal positions in the crystal structure or lattice. This so-called lattice thermal conductivity is the most important mechanism operating in semiconductors with small numbers of electrons or holes—less than one per 10,000 atoms.

Basic thermoelectric devices. Semiconductors have relatively large thermoelectric powers and are thus preferable to metals as the active materials for most thermoelectric applications. In a basic device, two bars of semiconductor, called thermoelements, one *n*-type and one *p*-type, are joined with metal connections into a circuit, as shown in Figure 2. In an elementary refrigerator, X is a battery that drives an electron current around the circuit, as shown. Cooling occurs at both junctions J_2 and J_3, so that the *n*-type and *p*-type effects are added, Heat is evolved at junctions J_1 and J_4. If these are kept near room temperature by attaching air-cooled fins or a water-cooled heat sink (a device for disposing of heat), then the cooled junctions will be well below room temperature. With the best available semiconductors, arranged in this simple circuit, if the hot junctions are maintained at 20° C (68° F), the cold junctions can reach −50° C (−58° F), a difference of 70° C (126° F). Much lower temperatures can be achieved by "cascading" a thermoelectric refrigerator, an effect that is achieved by building several stages, each of which acts as the heat sink for the next.

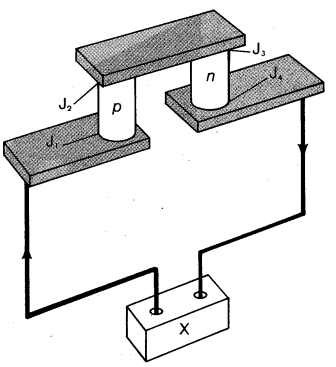

Figure 2: An elementary thermoelectric device (see text).

In an elementary thermoelectric generator, X in Figure 2 is an electrical load such as a motor or an electronic circuit. If the top junctions, J_2 and J_3, are heated while the lower junctions, J_1 and J_4, are kept near room temperature, a current will flow through the load. Again the effects of the two types of semiconductor are added, and increased conversion efficiency is obtained. With the best available materials, heat can be converted into electrical energy with an efficiency near 10 percent, or somewhat higher if several stages are cascaded.

Figure of merit. In both types of device, the performance depends on the properties of the two semiconducting materials. In a refrigerator, the Peltier effect (and therefore, by the Kelvin relation, the thermoelectric power S) must be large to maximize the cooling effect; the resistivity (ρ) must be small to minimize Joule heating; and the thermal conductivity (κ) must be small so that a large temperature difference can be maintained. Similarly, in a generator, a large thermoelectric power (S) is required to maximize the voltage produced by the temperature gradient; a small ρ results in minimum waste of electrical power by Joule heating; and low κ prevents the heat from flowing wastefully through the thermoelements.

In either device, when the efficiency or performance is calculated, the material parameters always occur in a certain combination: $Z = S^2/\kappa\rho$, where Z is known as the figure of merit since the device efficiency improves with increasing Z. This equation states that the figure of merit of a semiconductor material is given by the square of its Seebeck coefficient divided by the product of its resistivity and its thermal conductivity.

If both materials have properties that are identical except for the sign of S, this figure of merit (Z) applies to each material separately and also to the couple as a whole. If the properties are different, Z for the couple must be calculated.

The figure of merit enters, along with the absolute temperatures of operation of the device, into various calculations of device perfromance. Important characteristics are as follows:

1. Efficiency of a generator, symbolized by the Greek letter eta (η), is the ratio of the maximum electrical power delivered to a load to the rate of heat flow through the thermoelements. For infinitely large Z, this becomes the maximum efficiency attainable in thermodynamic theory—the so-called Carnot efficiency—and is always less than 100 percent.
2. The maximum temperature difference (symbolized ΔT_{max}) that can be achieved with a single-stage refrigerator which is one-half the product of the figure of merit and the square of the cold junction temperature: $\Delta T_{max} = \frac{1}{2}ZT_c^2$.
3. The coefficient of performance of a refrigerator is the ratio of the heat removed from a load to the electrical power used in the device. For infinitely large Z this becomes the thermodynamic limiting efficiency, which can be larger than 100 percent because electricity is being used to pump heat from one place to another, not to generate heat.

The improved performance that can be achieved in multiple-stage devices can also be expressed in terms of Z and the various temperatures involved.

THERMOELECTRIC MATERIALS

In order to maximize the figure of merit, it is necessary first to choose the best semiconducting materials and then to control their properties by proper additions of impurities. The first obvious advantage of semiconductors is their large available thermoelectric powers, both *n*-type and *p*-type. Since the smaller the density of electrons or holes is, the larger the Seebeck coefficient will be; the addition of impurities is minimized to increase the figures of merit. If, however, the density of the charge carriers (electrons or holes) becomes too low, the electrical resistivity will rise so high that the figure of merit is reduced. The figure of merit therefore reaches a maximum at some intermediate density of electrons or holes, which is about one per 10,000 atoms, or 10^{19} per cubic centimetre. The Seebeck coefficient is then near 200 microvolts per degree Celsius.

Some thermal conductivity at this level is due to the charge carriers, but in most semiconductors even more

Figure of Merit of Various Semiconductor Materials

material	conductivity type	figure of merit $Z\ (1{,}000°\ K)^{-1}$	at temperature $T(°K)$
Bi_2Te_3	*n*	2.8	300

88% Bi + 12% Sb + magnetic field	*n*	8.6	100

heat is carried by the vibrating atoms, in the phenomenon called lattice thermal conductivity. Lattice thermal conductivity can vary by a factor of 1,000 between different semiconductors (semiconducting diamonds have the highest room temperature thermal conductivity known; silver antimony telluride, $AgSbTe_2$, conducts heat almost as poorly as glass or plastics). Lattice thermal conductivity is, therefore, the most important variable in selecting the optimum thermoelectric material.

Materials made up of heavy atoms generally have low lattice thermal conductivities. For this reason, compound semiconductors such as bismuth telluride and lead telluride are useful thermoelectric materials (lead and bismuth are the heaviest of the common nonradioactive elements).

Effect of atomic disarrangement on thermal conductivity

Another factor that influences thermal conductivity is the orderliness of the atomic arrangement in the crystals that make up the material. Disordered solids, such as glasses, have lower thermal conductivities than do perfectly ordered crystals. Disorder may be introduced into crystals by mixing two similar materials. If the atoms involved are different in their masses but chemically similar (*i.e.*, if they come from the same column of the periodic table), then the resultant alloyed material will have electronic properties similar to those of the pure materials, but the lattice thermal conductivity may be as much as ten times lower. In bismuth telluride, replacing some of the bismuth atoms with antimony or of tellurium with selenium gives rise to useful improvements in the figure of merit, as shown in the Table. Similar results are obtained by alloying lead telluride with lead selenide or germanium telluride. In these materials, the excess electrons for negative-type behaviour are obtained by adding a very small amount of an element, such as iodine, that takes the place of tellurium in the crystal but has one more electron per atom. Small additions of elements with fewer electrons, such as cadmium, result in positive-type conductivity.

The bismuth telluride–antimony telluride–bismuth selenide system provides the best available materials for use in refrigerators, and these are also used in generators that operate over a fairly small range above room temperature, up to about 200° C (400° F). For generators that have their hot junctions up to 500° C (900° F), lead telluride-based materials are best. At higher temperatures, the figure of merit of these materials drops to very low values because the thermoelectric power decreases. For high-temperature use, different semiconductor alloys are used. Alloys of silicon and germanium, the semiconductors most commonly used for transistors, are the best available materials for use up to 1,000° C (1,800° F).

At temperatures far below room temperature, another group of materials, bismuth–antimony alloys (*e.g.*, 88 percent bismuth, 12 percent antimony), are best. In the range from −200° to −100°C (−330° to −150° F) they have larger figure-of-merit values than any other known materials, and, in single crystals of these alloys, a properly oriented magnetic field can raise the figure of merit even higher.

Greatest efficiency in a thermoelectric generator is obtained by operating with the largest possible temperature difference between junctions. It would be useful to fabricate the hottest sections of the device using silicon–germanium alloys, the intermediate sections with lead telluride, and the sections near room temperature with bismuth–telluride alloys. For practical reasons, commercial generators are usually made as single-stage devices using a single material, the choice depending on the range of temperatures to be used.

APPLICATIONS

Temperature measurement. The oldest and most familiar thermoelectric device is the thermocouple that is used to measure temperature. In the circuit of Figure 1, if one junction between the two different conductors is held at a known temperature, then the voltage developed by the Seebeck effect and measured by the meter at X will depend on the temperature of the other junction. If this dependence is calibrated using known temperatures, such as the melting points of pure substances, this simple circuit provides a convenient and accurate means of temperature measurement.

Principles of the thermocouple

Efficiency of energy conversion is not important in this application, and the materials A and B are most useful in the form of long fine wires; the materials used, therefore, are usually metals rather than brittle semiconductors. Material B, for example, may be copper and material A an alloy known as constantan, composed of 60 percent copper and 40 percent nickel. With these metals, the measured voltage for temperatures near room temperature is about 40 microvolts per degree Celsius. With the reference junction held at 0° C (32° F) in an ice-water bath, if the measuring junction is at the temperature of boiling water (100° C, 212° F), the meter reads 4.28 millivolts. For high temperatures up to 1,700° C (3,100° F) thermocouples of platinum and platinum–13 percent rhodium are commonly used. Other alloys can be used for very low temperatures—*i.e.*, down to a few degrees above absolute zero.

Metallic thermocouples are commonly used in laboratories and in industry to measure and control temperatures. They are particularly convenient for remote sensing of high temperatures in furnaces or other inaccessible or hazardous locations. Their electrical output is ideal for electronic temperature-controlling equipment.

Thermopiles

A thermopile is a group of thermocouples connected electrically in series and thermally in parallel so that the Seebeck voltages produced by a temperature difference are added for increased sensitivity. Thermopiles have been used to measure radiant heat by detecting the temperature rise of a blackened cap which is heated by the radiation.

Metallic thermopiles can also be used in thermoelectric generators for applications in which economy and simplicity are more important than efficiency. Thus, in an experimental telephone repeater for use in remote regions where no electricity was available, heat from burning propane gas was converted into electrical power using a thermoelectric generator made with many metallic wires. A few watts of power were obtained in this experiment with 0.5 percent efficiency in 1954. Ten years later, in a similar application, 200 watts were generated at about 5 percent efficiency, using semiconductor thermoelements. This generator provided power for a microwave repeater on a mountain peak, where the propane tanks were replenished only twice a year.

Thermoelectric generators. Thermoelectric generators have several advantages over more conventional ma-

chines for converting heat into electricity. First, they have no moving parts to suffer wear and require maintenance. Second, they are silent and vibration free. Third, they can be scaled down to very small size with no loss of efficiency. Large steam generating plants have efficiencies as high as 40 percent, but the efficiency drops drastically as they are reduced in size. For power requirements up to a few kilowatts, the 5 to 10 percent efficiencies obtained with thermoelectric generators are at least as high as those of steam generators or internal combustion engines.

There are a number of applications in which these advantages can be used today, in spite of the relatively high initial costs. These include remote terrestrial equipment with moderate power requirements, such as the telephone repeaters mentioned above, unattended lighthouses and navigation buoys, and Arctic weather stations. Heat for these applications may be provided by burning any kind of available fuel or by nuclear energy. Power for space applications can also be provided by thermoelectric generators with nuclear or solar energy as the heat source. Some typical applications are described below.

Kerosene lamp generator. In some remote areas of the Soviet Union, no electricity is available and kerosene lamps are used for home lighting. These lamps also provide a useful quantity of heat which can be converted into electrical power for radio receivers or even transmitters. A cylindrical arrangement of thermoelements is mounted over the glass chimney of such a lamp. The hot combustion gases heat the inner junctions while the outer junctions are cooled by a set of cooling fins with large surface area. The temperature difference of about 300° C (540° F) results in a few watts of electrical power for the radio. Similar generators developed in the United States are used in remote areas of many of the world's underdeveloped countries.

In Leningrad, where the first kerosene lamp generator was developed, larger generators have also been built for use in the far north. These use all types of fuel, from gasoline to firewood. One such generator provides 200 watts of electrical power for communications use and consumes about two kilograms (4.4 pounds) of firewood per hour.

Liquid- or gas-fuelled (portable) generators. A number of companies have developed thermoelectric generators in the 10- to 100-watt range. The fuel for these is typically propane, kerosene, or gasoline, burned either with a conventional flame or in a flameless "catalytic burner." The thermoelements are made with bismuth telluride, lead telluride, or silicon–germanium alloys, and the operating temperature range is matched to the choice of materials. Natural air convection is usually used to cool the cold junctions. The measured efficiency of such a generator may be only 4 percent, although the materials are capable of 10 percent conversion efficiency. The extra loss occurs in the burners, which may deliver only 40 percent of the heat theoretically obtainable from the burning fuel. In spite of the need for engineering improvements, such generators are already competitive in efficiency and in weight with portable gasoline internal combustion generators.

Generators of this type are used in many countries for communications applications. Another important use is in corrosion protection of oil and gas pipelines. Corrosion is an electrochemical process and is greatly reduced if the vulnerable metal is kept at an appropriate electrical potential with respect to its surroundings. Using a negligible amount of fuel from the pipeline, a thermoelectric generator provides this electrical potential.

Nuclear-powered generators. Heat produced by the decay of radioisotopes (see RADIOISOTOPES, APPLICATIONS OF) or by a small nuclear reactor (*q.v.*) has been converted into electricity for various space and terrestrial applications. In the U.S. SNAP program (Systems for Nuclear Auxiliary Power), the various generators are designed SNAP-3, SNAP-10A, etc.

SNAP series of thermoelectric generators

In the radioisotope power sources, a radioactive material with a reasonably long half-life (the length of time it takes the radioactivity to decrease to half its initial value) is carefully sealed inside a metal container so that none of the decay particles can escape. As it absorbs the energy produced by the radioactive decay, the container is heated to a high temperature. The thermoelements surround this hot container and they, in turn, are surrounded by cooling fins which dissipate heat either by air or water convection or by radiation into space. Some useful radioisotopes are strontium-90, polonium-210, plutonium-238, and curium-242.

One American generator is a 60-watt strontium-90-fuelled device that uses lead telluride thermoelements to provide power for a floating weather station contained in a large buoy. Similar generators have been installed in automatic weather stations near the North and South poles, where the entire units, buried in snow, are designed to operate unattended for two years and to transmit weather data automatically every six hours.

In England, similar generators using plutonium-238 and silicon–germanium thermoelements, provide a few watts of power for bright pulsed marine lights in inaccessible unmanned lighthouses.

Since 1961, when a grapefruit-sized radioisotope-fuelled generator was the first thermoelectric device to orbit the Earth, there have been several similar generators used in a variety of space applications. One used plutonium-238 and lead telluride thermoelements to provide 2.5 watts of power. A much more ambitious device has produced over 500 watts using a nuclear reactor heat source and a silicon–germanium thermoelectric generator.

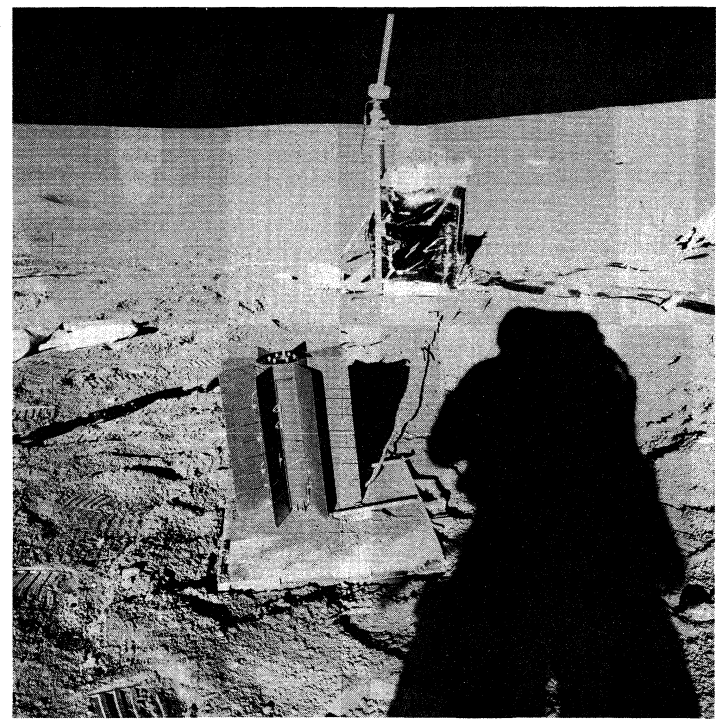

Figure 3: (Foreground) Radioisotope thermoelectric generator installed on the moon in 1971. Astronaut's shadow is on the lower right. Some of the equipment powered by this generator is visible in the background.

In one successful space application a radioisotope-fuelled generator was placed on the surface of the Moon on November 19, 1969, and in 1971 it was still performing perfectly in powering a number of lunar experiments and radio transmission equipment. In the generator, plutonium-238 provides 1,500 watts of heat at 600° C (1,100° F) at the hot junctions of the lead telluride thermoelements, and a large finned beryllium radiator cools the cold junctions to about 275° C (530° F; there is no air for convection cooling). The electrical output is about 75 watts, corresponding to 5 percent efficiency. This generator is expected to provide about 65 watts of power after ten years of operation, the drop being due only to the decay of the radioisotope and not to the deterioration

Generator on the Moon

of the thermoelectric device. Similar generators have been placed on the Moon in several Moon landings since 1963 (see Figure 3).

Solar generators. Experimental thermoelectric generators have been used as alternatives to solar batteries to convert sunlight into electricity. These generators, for use in space applications, are of two types. In the first, large panels, rolled or folded during launching, are extended in space to capture sunlight on one surface and radiate heat from the other. In the second type, a large mirror is deployed in space to concentrate sunlight onto a compact generator. This type sometimes includes some form of heat storage such as a meltable solid that gives up its stored heat during dark periods to provide continuous power without storage batteries. Besides this continuous power capability, the advantages of solar thermoelectric generators are their light weight and resistance to radiation damage.

Special applications. There are a number of special applications besides communications and navigation in which thermoelectric generators have been used.

A very widespread but seldom appreciated use for tiny thermoelectric generators is in the automatic control system of home gas furnaces in which heat from a pilot flame is used to generate an electrical current by means of lead telluride thermoelements. This current is used to hold the main gas valve open against a closing force. If the pilot flame should go out, the current is no longer generated and the valve automatically closes, providing a "fail safe" operation.

In electronics, a small bismuth telluride generator has been used to convert alternating current electricity via heat into smooth, ripple-free direct current for special components. It has also been demonstrated that such a generator can be used to convert direct current at one voltage to direct current at a different voltage.

In a medical application, a tiny radioisotope thermoelectric generator has been implanted in the human body to provide power for an implanted electronic "pacemaker," which triggers the heart beat of patients suffering from tachycardia. This eliminates the need for repeated operations to replace the batteries normally used. It is expected that they will have a life of up to 10 years.

Thermoelectric refrigerators. The advantages and disadvantages of thermoelectric refrigerators are similar to those mentioned above for generators. The absence of moving parts leads to greater reliability and silent operation. The available efficiency, or coefficient of performance, is lower than that of large mechanical refrigerators or air conditioners, but it is the best available for small, special-purpose coolers.

Bismuth telluride alloys are used in all of the thermoelectric cooling devices developed in England, Japan, the United States, the Soviet Union, and several other countries. Single-stage coolers can achieve a temperature drop of about 70° C (126° F) below room temperature. With a small second stage on a larger first stage (for example, a single couple with its hot junctions cooled by eight similar couples), a temperature drop greater than 100° C (180° F) can be achieved. Using eight stages, the coldest three of which make use of the magnetically enhanced Peltier effect in bismuth–antimony alloys mentioned above, a temperature drop of 171° C (308° F) below room temperature has been achieved in an experimental device. This is more than halfway down toward absolute zero.

Single-stage and multistage coolers

Small-scale cooling and temperature control. The most important applications of thermoelectric cooling devices are in the area of small-scale special instruments for laboratory and industrial use. In electronics, spot coolers have been used to improve the performance of many solid-state devices, including transistors, lasers, light-emitting diodes, and microwave parametric amplifiers. The eight-stage device mentioned above was designed to cool a tiny, ultrasensitive infrared detector.

Small ovens are often used to control the temperature of such devices as quartz crystal oscillators to within one-thousandth of a degree at a fixed temperature well above the maximum ambient temperature. Thermoelectrically cooled chambers are used instead of these ovens to achieve the same control at room temperature or below to improve the long-term performance of these oscillators. In such temperature-control devices, active heating as well as cooling can be achieved by reversing the current through the thermoelements.

When metallic thermocouples are used for precise temperature measurement, as described above, the reference junction is usually maintained at exactly 0° C (32° F) in an ice water bath. This inconvenient bath has been replaced by a thermoelectrically cooled water cell, which automatically keeps a constant mixture of ice and water and needs no maintenance. When some of the water freezes in this cell, it increases in volume, and the expansion is used to operate a switch on the cooling device so that a fixed ratio of ice to water is maintained.

In oil-pumped vacuum systems, the vacuum can be improved by using a "cold trap" in the form of a thermoelectrically cooled baffle between the pump and the vacuum chamber to condense the residual oil vapours.

An early application that makes use of a single semiconductor couple is an automatic dew-point hygrometer, in which a tiny polished silver mirror reflects a beam of light away from a detector; when the mirror is cooled to the dew point by the thermoelements, droplets of water form on the mirror and reflect light into the detector. The temperature of the mirror is recorded, and the current in the thermoelements is automatically reversed; the dew evaporates and the procedure is repeated.

In biological research, thermoelectric coolers have been used for maintaining specimens such as blood plasma, antibiotics, and sperm cells at low temperatures during storage and transport. Other applications include freezing-point determinations of biological fluids, refrigeration of microtome platforms to freeze tissues that are to be sliced into very thin microscopic specimens, and cold probes to stimulate individual nerve cells within a living cat's brain.

Biological applications

Large-scale refrigeration. Because of their high cost, thermoelectric refrigerators have not made any large impact on the consumer market. Many demonstration units have been developed, however, and, in a few cases, these have been produced for actual use because of their special advantages. Among the demonstrations have been full-sized household refrigerator-freezers and smaller refrigerators for use in boats and trailers, water coolers, and room air conditioners. In large-scale uses, at least one building in the United States, the Johnson Wax Building in Wisconsin, was completely air conditioned with thermoelectric cooling panels because standard units could not be conveniently installed. In one hotel, every room has been equipped with its own thermoelectric ice maker, more for the novelty of the device than for its economic advantages. The largest thermoelectric devices made have been nine-ton submarine air conditioners built for the United States Navy. In this application, noiseless operation was the most important advantage.

Thermoelectric heating. Any thermoelectric cooling device can act as a heater if the current through the thermoelements is reversed. In the temperature-control devices mentioned above, this heating mode is often used, as well as the cooling mode. Consumer applications that use both heating and cooling have also been demonstrated. A thermoelectric baby-bottle cooler, for instance, has been designed with a built-in clock. At a preset time, the current in the cooler can be reversed so that the bottle is warmed to the ideal drinking temperature by the time the alarm wakes the baby's mother. In a thermoelectric "hostess cart" or "buffet bar," heating and cooling are used simultaneously in two adjacent compartments of a rolling cart, to keep food hot or cold, ready to serve.

The same air conditioner that cools a house in the summer can be used to heat it during the winter. A large thermoelectric heat pump can move heat either into the house or out of it, depending on the direction of current flow through the device. In either direction, the efficiency can be greater than 100 percent if the temperature difference to be achieved is not too large. In mild climates, this type of home heating could, therefore, be more eco-

nomical to operate than normal electrical heating. Again, as in most large-scale applications, the initial cost of the device is relatively high.

Future prospects. Thermoelectric devices in ever-increasing numbers will continue to be used in various small-scale specialized applications for which they are ideally suited. Many large-scale applications have been suggested, from home heating and air conditioning to central power plants and automotive generators to replace internal combustion engines. These schemes will become practical only if further research in solid-state physics leads to new, inexpensive materials with much larger values for the thermoelectric figure of merit than those presently available.

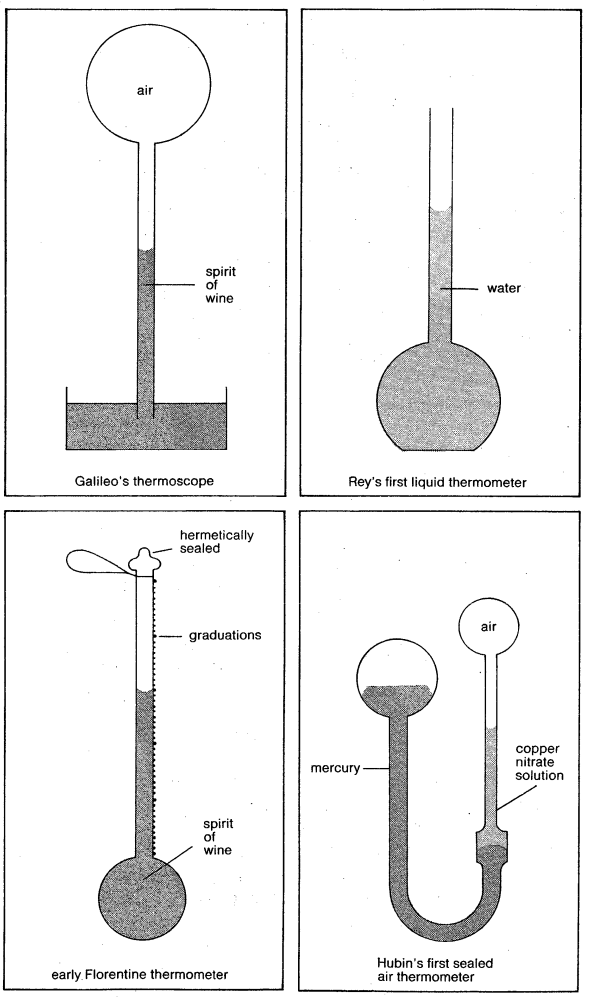
Thermometry

Thermometry is the science of measuring temperature. Any instrument used for this purpose is a thermometer. Pyrometry, a special case of thermometry, is, loosely, the science of measuring high temperatures. The term pyrometry has undergone a gradual change in meaning since its introduction in 1731 until it now usually refers to radiation thermometry (measurement of heat radiated from a body), even though recent infrared-radiation pyrometers are not restricted to high-temperature measurements.

There are many definitions of temperature (see HEAT; THERMODYNAMICS, PRINCIPLES OF). In lay terms, temperature is a measure of the hotness or coldness of a system, or a measure of the ability of a system to transfer heat to another system. More scientifically, it may be defined as the property of a system that determines whether it is in thermal equilibrium with other systems. If two isolated systems at different temperatures are placed in intimate contact (*e.g.*, a piece of hot metal in a pail of cold water), the hotter system will transfer heat to the colder until both are at the same temperature, intermediate between their original temperatures; that is, until thermal equilibrium is reached. Temperature is not a measure of the total quantity of heat in a system.



Temperature is one of the seven basic physical quantities in terms of which all other physical quantities are defined. It differs from the others (such as length and mass) by being "intensive," whereas the others are all "extensive." Length, for example, is additive: two separate one-metre lengths placed end to end establish a two-metre length. Temperature, being intensive, is not additive, however: one litre of water at 20° C (68° F) added to another litre of water at 20° C gives two litres of water still at 20° C. This phenomenon has fundamental implications for the establishment of a practical scale of temperatures. The scale or its unit cannot be established at a single temperature and extrapolated to others; it must be carefully defined over the whole range of temperatures.

Importance of thermometry

Temperature measurement and control play an integral role in a wide variety of industrial, scientific, and domestic activities. Those industries where the need is especially obvious include agriculture, aircraft and automobile industries, heating and air conditioning, refrigeration, electronics industries, mining and metallurgy, manufacturing. A familiar and important application of precise thermometry in science is in medicine. Domestically, nearly every household has at least one thermometer, be it on the furnace or the kitchen range.

HISTORY OF THERMOMETRY

Early history. Although the ancient Greeks conceived of degrees of hot and cold and performed various simple experiments which could, in retrospect, have formed the basis of a thermometer, not until the late 16th century did the first thermoscope appear; most authorities attribute its invention to the Italian scientist Galileo (Galilei), probably in 1592. Probably not provided with a scale, the thermoscope measured only changes in temperature and these only qualitatively (see illustration, top left). Galileo's thermoscope consisted simply of a large glass bulb with a long, narrow, openmouthed neck inverted over a vessel of coloured water or spirit of wine (alcohol). After some air had been driven out of the bulb, the liquid rose a short distance into the neck; subsequent changes in the temperature of the bulb produced expansion or contraction of the air in it, which in turn produced changes in the level of the liquid in the neck. The idea of providing such a thermoscope with a scale, thus producing a thermometer, probably originated with Sanctorius Sanctorius, a colleague of Galileo, in 1611. He noted the level at which the liquid stood when the bulb was surrounded by melting snow and again when it was heated by a candle and divided the intervening distance into 110 equal parts.

Early thermometers.

By 1632 Jean Rey, a French physician, apparently unaware of the earlier Italian work, had invented the first thermometer with a liquid instead of air as the indicating

fluid (see illustration, top right). He simply filled a flask having a long, slender neck with water until the liquid level lay in the neck. Changes in the temperature of the bulb produced corresponding changes in the liquid level.

In succeeding years the sensitivity of these thermometers to barometric pressure was observed. This difficulty was first overcome in about 1644 by the grand duke Ferdinand II of Tuscany, who conceived the idea of hermetically sealing the end of a liquid-filled thermometer of the Rey type (see illustration, bottom left). Ferdinand contributed further to the advance of thermometry by promoting the establishment in 1657 of the Accademia del Cimento in Florence. During the ten years of its existence this society conducted extensive thermometric experiments while its workmen became highly skilled in the manufacture of thermometers of reproducible dimensions. These Florentine thermometers were widely used for over a century, some surviving to the present. The Accademia was also among the first to try mercury in its thermometers, although spirit of wine was preferred because of its larger expansion coefficient; *i.e.*, because it expanded more in response to increases in temperature.

The first mercury thermometer

These advances in liquid-in-glass thermometry did not preclude continued study of air thermometers. In Paris in 1672 Hubin (given name unknown) invented the first air thermometer to be independent of atmospheric pressure by adding a sealed bulb to the open end of a two-liquid U-tube barometer (see illustration, bottom right). A sealed air thermometer was similarly constructed from a three-liquid barometer in 1695 by Guillaume Amontons, a French physicist who studied seriously the principles of its operation. These were important developments, leading in the 19th century to fundamental studies in gas thermometry.

Development of temperature scales. For the next century, thermometry was devoted largely to the attainment of reproducible temperature scales to enable measurements made with different thermometers, in different locations, or at different times to be directly comparable. The list of contributors to these advancements includes many of the most famous names of science, such as the Englishmen Robert Boyle and Sir Isaac Newton and the Dutch Christiaan Huygens. By the early 18th century as many as 35 temperature scales had been devised, most of them based upon one or other of two principles: (1) calibration of the thermometer at two temperatures to establish two fiduciary marks, division of the interval between them into equal parts, and linear extrapolation beyond the fiduciary marks, or (2) calibration of the thermometer at one temperature with subsequent scale divisions based upon the calculated expansion of the fluid in it. The first of these is simpler to apply, is more precise, was then the widest used, and in a more general form is the basis of practical temperature scales to this day. The second provides to some extent a fundamental rather than an empirical scale and may be considered the forerunner of the absolute temperature scale.

The two principles of thermometer scales

Fahrenheit scale. Of these diverse scales only a few survived, one of the best known having its foundations in the work of the Danish astronomer Ole Rømer. For several years before his death in 1710, Rømer turned his attention to thermometry. He calibrated his standard thermometers according to principle (1) above, assigning the value 60 (degrees) to the boiling point of water and 7½ (later 8) to the melting point of ice, these serving as his two fixed points. For his meteorological observations he seldom used the upper part of his scale, and therefore he changed his upper reference temperature to that of blood heat, labelling it 22½. Rømer's scale is important only insofar as it influenced Daniel Gabriel Fahrenheit, a Dutch instrument maker of German descent. Fahrenheit became justly famous in the period 1700–30 for the quality of his mercury thermometers and for the agreement among them when they were calibrated on his scale. Preferring finer scale divisions than Rømer used, he chose 32 for the melting point of ice and 96 for blood heat. On this scale he determined the boiling point of water to be 212 degrees, although he did not use it as one of his fixed points. The Fahrenheit scale commonly used in the English-speaking world today derives from the original one but uses 32 and 212 rather than 32 and 96 for its two fixed points. Thus, the unit of temperature (Fahrenheit degree, ° F) on this scale is 1/180 of the difference between the boiling and freezing points of water. It is a tribute to the skill of Fahrenheit that the presently accepted value for the body temperature of a healthy person (98.6° F) is so consistent with his original scale.

Réaumur scale. At about the same time (1730), a scale based on principle (2) above was developed by the French scientist René-Antoine Ferchault de Réaumur. Though it is not absolutely clear how he proceeded, it seems he chose for his thermometric fluid spirit of wine diluted with some particular amount of water, assigned 0° Re to its level at the freezing point of water, and graduated the thermometer so 1° was 1/1000 of the total volume occupied by the fluid at 0° Re. The alcohol was so diluted as to boil at about 80° Re, but because of confused reporting it was believed that this was the boiling point of water. Thus, what has been handed down as the Réaumur scale uses 0° Re as the freezing and 80° Re as the boiling point of water. But for this historical accident Réaumur might have been credited with establishing the first centigrade scale (*i.e.*, one with the fundamental interval divided into 100 parts), because, on his original scale, the boiling point of water would have been near 100° Re. The Réaumur scale found widest acceptance in Germany.

Celsius scale. The first truly centigrade scale is generally attributed to the Swedish astronomer Anders Celsius in 1742. Earlier workers, including Fahrenheit, had already been aware that the temperature of boiling water is dependent upon atmospheric pressure, but Celsius was the first to allow for this explicitly in his calibrations. For his scale he assigned 0° to the level at which the mercury stood when the thermometer bulb was immersed in water boiling at a particular barometric reading and 100° to the level when the bulb was immersed in melting snow. Shortly thereafter the inverted form of Celsius' scale (*i.e.*, 0° for the freezing point and 100° for the boiling point of water) made its appearance in Sweden and in France. It later spread throughout most of the world and was known for two centuries as the centigrade scale until, in 1948, the name of Celsius was officially attached to it.

Absolute temperature scale. All of the temperature scales described above are essentially empirical. The basis for a fundamental scale, however, had already been laid by experiments on the properties of gases. In 1661 Robert Boyle observed that the product of the pressure (P) and volume (V) of a given quantity of air at constant temperature was constant over a moderately wide range of pressures. What is now known as Boyle's law may therefore be written

Boyle's law

$$PV = \text{constant.}$$

Further experiments many years later showed that Boyle's law is only approximately true except in the limit of very low pressures, in which case it is exactly true for all gases.

In about 1800, Jacques-Alexandre-César Charles and Joseph-Louis Gay-Lussac concluded from independent experiments that the volume occupied by any gas increases linearly with increase in temperature when the gas is maintained at constant pressure. Known as Charles's law, this result may be expressed in the form

$$V = V_0 (1 + \alpha t),$$

where V is the volume at temperature t° C, V_0 is the volume at 0° C (32° F), and the constant symbolized by the Greek letter alpha, α, is the coefficient of thermal expansion. According to Charles and Gay-Lussac, α has the same value for every gas; just as before, the law is only approximate but becomes exact in the limit of low pressures, in which case α has the value 0.003661 = 1/273.15. If this value is inserted in the above equation, it follows that, when $t = -273.15$° C, the gas has no volume at all. For this reason the temperature −273.15° C is called the absolute zero; no lower temperature is possible. This statement of zero volume should not be interpreted literally; what it approximately means is that at

−273.15° C the molecules comprising the gas are so tightly packed that no space is left between them. In practice, all substances at this temperature are in the liquid or solid state, for which the law no longer applies anyway.

If now a new temperature scale is defined so that temperatures T on it are given by $T = t + 273.15$, Charles's law may be rewritten in the form

$$\frac{V}{T} = \text{constant}.$$

This, when combined with Boyle's law, results in the general gas law (see GASEOUS STATE)

$$\frac{PV}{T} = \text{constant}.$$

It is evident from this equation that, if either the pressure or the volume of a given quantity of gas is held constant, measurement of the other may be used to determine temperature. This condition is the basis of the gas thermometer. A gas for which the general gas law holds is called ideal, or perfect; the scale on which the temperature T was defined is called the absolute temperature scale, or the ideal-gas temperature scale.

Ideal gas

Kelvin scale. Because no real gas behaves exactly as an ideal gas, most of the early experiments utilizing these principles produced slightly different scales, not only for different gases but also for the constant pressure and constant volume modes of operation. The need remained for a truly fundamental temperature scale independent of the properties of any particular substance. This need was met by the British physicist William Thomson (later Lord Kelvin), who proposed in 1848 to define a thermodynamic temperature scale in terms of the efficiency of an ideal heat engine described by the French physicist Sadi Carnot in 1824 (see THERMODYNAMICS, PRINCIPLES OF). A heat engine may be described as a machine that converts heat into mechanical work, such as a steam or an internal-combustion engine. To produce continuous work, the machine performs a given cycle of operations over and over again. Any heat engine operates on the principle that during one part of its cycle the working substance absorbs heat from a reservoir at a high temperature, and during another part, after using some of this heat to do the work, it rejects a lesser quantity of heat to a reservoir at a lower temperature. In the case of the steam engine, for example, the working substance is water vapour, the high-temperature reservoir is the boiler, and the low-temperature reservoir is the condenser. No heat engine can be perfectly efficient; *i.e.*, can convert all of the heat extracted from the high-temperature reservoir into useful work. Carnot's contribution was to show that his ideal engine worked at the maximum possible efficiency and, further, that this efficiency was independent of the nature of the working substance and dependent only upon the temperatures of the two reservoirs.

Thomson (Lord Kelvin) showed that for the Carnot engine, if Q_1 units (joules) of heat are extracted from the hot reservoir and Q_2 joules of heat are returned to the cold reservoir, a temperature scale could be defined such that

$$\frac{T_1}{T_2} = \frac{Q_1}{Q_2},$$

where T_1 and T_2 are the temperatures assigned to the hot and cold reservoirs, respectively, on his thermodynamic temperature scale. This is often also called the Kelvin scale, in his honour. Thomson went on to establish that the temperatures so defined are identical with those defined by the ideal-gas laws; *i.e.*, the absolute and thermodynamic temperature scales are the same.

Establishment of the Kelvin unit

To establish the size of the unit on the Kelvin scale, Thomson pointed out that in principle one temperature could be defined arbitrarily, and, by the above equation, all others would be measured in terms of it. This was impractical in his day. As an alternative and to keep the scale compatible with those already in use, he accepted the Celsius principle of setting the difference between the freezing and boiling points of water equal to 100 kelvins (the name now used for the unit on the Kelvin scale). Thus, the kelvin (symbol K without the degree sign °) has the same magnitude as the degree Celsius, and the two scales are related by

$$T\,(\text{K}) = t(^\circ\text{C}) + 273.15.$$

(The degree sign is still occasionally used with the symbol K when referring to temperatures or temperature differences on the kelvin scale.)

This definition of the kelvin suffers the disadvantage that the position of the two fundamental reference points relative to the absolute zero (*i.e.*, the number 273.15) must be determined by experiment. Suppose this value can be found to within 0.01° K; then the freezing point of water on the Kelvin scale (273.15° K) is uncertain by about one part in 27,000. A very low temperature, such as the boiling point of liquid helium (4.2° K), however, is uncertain by about one part in 400. For scientific work such a large uncertainty in converting from one scale to the other is undesirable. For this reason Kelvin's first proposal for defining the kelvin is preferred.

Rankine scale. It is of course possible to set up an absolute temperature scale with a degree the same size as the Fahrenheit degree. If this is done, the absolute zero is found to occur at −459.67° F. The absolute Fahrenheit scale is defined by setting $T(^\circ\text{R}) = t(^\circ\text{F}) + 459.67$; it bears the same relation to the Kelvin scale as the Fahrenheit does to the Celsius. This scale is commonly called the Rankine scale, in honour of W.J.M. Rankine, a famous 19th-century Scottish engineer and one of the founders of the science of thermodynamics.

Advances in thermometer technology. Coincident with these fundamental developments, advances in thermometer technology continued. Any property of a substance that changes with temperature may in principle form the basis of a thermometer; properties other than the expansion of liquids and gases are capable of higher sensitivity and wider range. The English scientist Sir Humphry Davy reported in 1821 that the electrical resistance of a metal is dependent upon temperature. The German scientist Sir William Siemens proposed in 1871 to exploit this phenomenon to build an electric resistance thermometer. His choice of platinum for the material of the sensor was superb; as perfected by the British physicist Hugh Longbourne Callendar and others, the platinum resistance thermometer is the most stable and accurate thermometer available. It is described in detail later; at this point it is important for the role it plays in the present International Practical Temperature Scale, below.

Another electric thermometer, called a thermocouple, is based upon the discovery by Thomas Johann Seebeck in Germany in 1822 that an electric current is generated in a simple closed circuit consisting of two dissimilar metals (*e.g.*, copper and iron) when the two junctions are held at different temperatures. Thermocouples (also described below) composed of platinum and an alloy of 10 percent rhodium in platinum have been developed into precise instruments, especially for reading high temperatures; they, too, form a part of the International Practical Temperature Scale.

That the temperature of a hot object might be measured by suitably sampling the heat it radiates was recognized by the 19th century. Various theoretical attempts to establish a relation between the emitted radiation and the temperature of the object culminated in 1900 in the famous law of the German physicist Max Planck. For the very special case of a blackbody (*i.e.*, a body that totally absorbs all of the radiation incident upon it), Planck developed the equation

Planck's law

$$L_\lambda(T) = c_1\lambda^{-5}/(e^{c_2/\lambda T} - 1),$$

where $L_\lambda(T)$ is the spectral radiance of the source (*i.e.*, the energy radiated per unit time per unit of projected area per unit solid angle at a fixed wavelength symbolized by the Greek letter lambda, λ), T is the thermodynamic temperature, and c_1 and c_2 are the first and second radiation constants, respectively. Not only has this law been found to describe the spectral distribution of the energy emitted by a blackbody accurately, but it

also marked the beginning of the quantum theory of radiation. For his discovery Planck received the Nobel Prize for Physics in 1918. It is important that the same temperature appears in Planck's equation as in Kelvin's thermodynamic scale, so that radiation thermometry, in addition to gas thermometry, provides a practical means of measuring thermodynamic temperatures. Planck's law as applied to a particular radiation thermometer, the optical pyrometer, is also an integral part of the International Practical Temperature Scale.

International temperature scales. Although the thermodynamic scale as propounded by Kelvin was recognized as fundamental, there were practical difficulties in using it. Gas thermometers were cumbersome and unsuited to many applications. Furthermore, in many cases, knowledge of the thermodynamic temperature was not as important as the precise reproduction of temperature or temperature intervals on some practical scale. A multiplicity of such scales was obviously undesirable. Thus, in 1927 all countries adhering to the International Committee on Weights and Measures adopted the International Temperature Scale. This scale was defined basically by extending the principle (1) listed earlier. Because of improvements in measurements and techniques, the International Temperature Scale was replaced in 1948 by the International Practical Temperature Scale of 1948 (IPTS-48), in 1960 by a revised version, and in 1968 by the currently used International Practical Temperature Scale of 1968 (IPTS-68).

The IPTS-68 recognizes the thermodynamic temperature as the basic temperature and defines its unit (the kelvin) to be 1/273.16 of the triple point (equilibrium among the solid, liquid, and vapour phases) of water (see the Table). The IPTS-68 itself is so constructed as to closely approximate thermodynamic temperatures; its unit is also called the kelvin, or the degree Celsius, which has the same size. Temperature (T_{68}) on the IPTS-68 is defined by assigning numerical values to 11 reproducible fixed points and interpolating between them in prescribed ways. The IPTS-68 is not defined below −259.34° C. The 11 fixed points of the IPTS-68 and their assigned temperatures are listed in the Table.

Defining Fixed Points of the International Practical Temperature Scale of 1968*

fixed point	T_{68} (°K)	t_{68} (°C)
Equilibrium among the solid, liquid, and vapour phases of equilibrium hydrogen (triple point of equilibrium hydrogen)	13.81	−259.34
Equilibrium between the liquid and vapour phases of equilibrium hydrogen at a pressure of 33,330.6 newtons per square metre (25/76 standard atmosphere)	17.042	−256.108
Equilibrium between the liquid and vapour phases of equilibrium hydrogen (boiling point of equilibrium hydrogen)	20.28	−252.87
Equilibrium between the liquid and vapour phases of neon (boiling point of neon)	27.102	−246.048
Equilibrium among the solid, liquid, and vapour phases of oxygen (triple point of oxygen)	54.361	−218.789
Equilibrium between the liquid and vapour phases of oxygen (boiling point of oxygen)	90.188	−182.962
Equilibrium among the solid, liquid, and vapour phases of water (triple point of water)	273.16	0.01
Equilibrium between the liquid and vapour phases of water (boiling point of water)	373.15	100.00
Equilibrium between the solid and liquid phases of zinc (freezing point of zinc)	692.73	419.58
Equilibrium between the solid and liquid phases of silver (freezing point of silver)	1,235.08	961.93
Equilibrium between the solid and liquid phases of gold (freezing point of gold)	1,337.58	1,064.43

*All of the assigned boiling and freezing point temperatures are for a pressure of one standard atmosphere (101,325 newtons per square metre). The freezing point of tin (t_{68} = 231.9681° C) may be used as an alternative to the boiling point of water.

An important but subtle point regarding these scales is worth noting. By definition, the unit for thermodynamic temperatures is the same in all temperature regions; this is not necessarily so for the IPTS-68. Even if the temperatures assigned to the fixed points are their true thermodynamic values, it has not yet been established that the assigned interpolating formulas will exactly reproduce thermodynamic temperatures except above the gold point. Thus, the unit on the practical scale may not be constant; a degree in one temperature region may be of different size from that in another. Hence, the accurate determination of thermodynamic temperatures in all temperature regions is the major task of modern thermometry.

METHODS OF TEMPERATURE MEASUREMENT

Temperature measurements are required over such a wide range and in such a wide variety of situations that a very large number of types of thermometers have been developed. The principles of the more important of these are outlined below. Many considerations influence the choice of thermometer for a particular task, among them cost, durability, size, speed of response, accuracy, sensitivity, and temperature range.

Gas. Gases are used in several ways as thermometric fluids. In the gas thermometer they provide the best means of measuring thermodynamic temperatures over the wide range from about −263° to 1,000° C (−441° to 1,800° F). Only for very low temperatures, however, is the gas thermometer a practical measuring device.

The three forms of the gas thermometer. The gas thermometer may be constructed in one of three forms: constant-volume, in which the pressure of a given quantity of gas confined to a constant volume is measured as a function of temperature; constant-pressure, in which the volume of a given quantity of gas maintained at constant pressure is measured as a function of temperature; and constant-temperature, in which both the pressure and volume of a given quantity of gas at temperature T are measured and then measured again when a known fraction of this gas has been transferred to a reference volume. In all three cases one of the temperatures is a known reference (frequently the triple point of water), and the others are determined relative to it. Most gas thermometers in use are of the first type. In a typical installation a quartz or metal bulb containing the gas is held at a constant temperature and connected to a pressure-measuring device through a complex network of capillary tubing. An appropriate standard IPTS-68 thermometer placed so as to be at the same temperature as the bulb allows a direct comparison of the practical with the thermodynamic scale. The gas is usually helium, especially at low temperatures, but hydrogen, nitrogen, argon, and others have been used at high temperatures.

Factors leading to error

A number of small but important effects must be considered if accurate temperatures are to be obtained. The volume of the bulb itself, for example, and hence of the gas in it changes with temperature; the amount of change can be calculated if the thermal-expansion coefficient (fractional increase in volume for a 1° C rise in temperature) of the material of the bulb is known; metals are preferred over glasses in this regard. Again, a small portion of gas is not in the bulb but in the connecting capillary, which usually is exposed to a temperature gradient. This volume and its temperature distribution must be measured. Many possibilities for errors arise. Perhaps the most important are adsorption of gas on and desorption of gas from the walls of the bulb. These result in the nature and quantity of the gas not being constant. The uncertainties in temperatures measured with very good gas thermometers vary from a few thousandths of a degree below 100° C to a few tenths of a degree at 1,000° C.

Vapour-pressure thermometry. Gases are also used in vapour-pressure thermometry. From thermodynamic principles the equilibrium pressure of the vapour over a liquid surface may be related to thermodynamic temperature by an equation involving the latent heat of

vaporization and the heat capacity of the substance. If the latter two quantities are known, then measurement of the vapour pressure will determine thermodynamic temperature; if not, the pressure–temperature relation may be established by gas thermometry and subsequently used for practical vapour-pressure thermometry. These thermometers are used only at cryogenic (very low) temperatures with high-purity gases such as helium, hydrogen, neon, and nitrogen as the working fluids. From 0.2 to 5.2° K, helium-vapour-pressure scales are recommended by the IPTS-68. Because the vapour pressure is independent of volume, the thermometers are easier to use than gas thermometers, but their ranges are discontinuous—from the triple to the boiling point of each fluid.

Filled-system thermometers. Both gases and vapours are used in industrial filled-system thermometers. In the usual construction the fluid (gas alone or liquid plus vapour) is contained in a bulb that connects through a capillary to an indicating device. Changes in the temperature of the bulb are transmitted by changes in pressure of the gas or vapour to the indicator. Gas-filled thermometers commonly contain nitrogen; the liquid in a vapour-pressure thermometer is chosen to suit the temperature range desired.

Liquid. In the early 1970s, as in the past, more liquid-in-glass thermometers than any other type were being manufactured. Their popularity arises from their simplicity, low cost, long lifetime, wide temperature range, and general applicability. The basic instrument is not significantly different from those of the 17th century. It consists of a glass bulb connected to a closed, graduated capillary; a liquid (almost invariably mercury) fills the bulb and part of the capillary, while the remainder of the capillary is commonly filled with dry nitrogen. The liquid level rises in the capillary when the bulb temperature increases because the mercury expands more than the glass containing it. The freezing point of mercury (−39° C [−38° F]) determines the lower limit of the mercury-in-glass thermometer; the softening point of the glass determines the upper limit. Hard borosilicate-glass thermometers may reach almost 600° C and quartz higher, provided the nitrogen pressure is sufficiently high to prevent boiling or significant evaporation of the mercury. Coloured organic liquids are used below −39° C: alcohol will reach −80° C and pentane −200° C.

For accurate work these thermometers must be used in their intended manner. They may be designed to have all of the bulb and liquid column at the temperature to be measured (total immersion), all of the bulb and a specified portion of the column (partial immersion), or the entire thermometer (complete immersion). If some portion of the liquid column is not at its prescribed temperature, the observed reading may be corrected for the length of emergent stem. A thermometer with a separated mercury column will read incorrectly. The column may usually be reunited by cooling the bulb until all of the mercury has retracted into it. These thermometers also exhibit small amounts of hysteresis (they will read differently when cooled down to a specific temperature than when warmed up to that same temperature) and dimensional instability. The very best of them are capable of reading temperatures to within a few thousandths of a degree.

Clinical thermometers

Liquid-in-glass thermometers are manufactured in many special forms. The clinical thermometer has a constriction in the bore to prevent the mercury from retreating from its maximum reading when the thermometer is removed from the body. The thermometer must then be shaken to return the mercury to the bulb. The mercury column in an oceanographic reversing thermometer is arranged to separate when inverted; the amount of separated mercury indicates the temperature at the time of inversion. Another type indicates both the minimum and maximum temperatures reached in a given time interval.

Liquids are also used in liquid-filled thermometers (similar to gas-filled ones) in which the temperature indications are produced by changes in the volume of the liquid.

Electrical resistance. *Platinum resistance thermometer.* The basic principle of the platinum resistance thermometer has already been described. Over a very wide temperature range, from 0° to 630° C, the thermometer's electrical resistance is related to temperature on the IPTS-68 by a rather complex equation. Below 0° C the relationship is even more complicated. The great value of the platinum resistance thermometer lies in the fact that, once calibrated, its readings are reproducible to a high degree of accuracy. The platinum in standard thermometers must be free from mechanical strain and have a minimum purity of about 99.995 percent. The most successful design has platinum wire of about 0.08-millimetre (0.003-inch) diameter wound as a bifilar (two-strand) helix on a mica support, the whole being about four millimetres (0.2 inch) in diameter and 20 millimetres (0.8 inch) long with a resistance at 0° C of about 25 ohms. This sensor is mounted in the bottom of a glass or quartz sheath about 40 centimetres (16 inches) long, with fine gold lead wires extending from it to the head of the sheath. Its resistance is measured when a small current (usually less than 0.002 ampere) is passed through it. This construction is suitable from about −180° to 500° C (glass sheath) or 650° C (quartz sheath). For lower temperatures the sensor is encapsulated in a short, close-fitting metal sheath; for higher, designs incorporating ceramic supports and capable of reaching 1,100° C were being developed in the 1970s. For accurate measurements the platinum thermometer must be annealed at about 450° C for several hours at frequent intervals. It is fragile and must never be subjected to rough handling. In laboratory research these thermometers may attain an accuracy approaching 0.0001° C. More rugged designs, capable of lesser accuracy, are used industrially. Because platinum thermometers are expensive, other metal resistance thermometers, notably copper and nickel, have also been developed. Copper is limited to temperatures below 120° C, nickel to below 300° C. Neither is as stable or accurate as platinum.

Cryogenic electrical resistance thermometers. Other types of electrical resistance thermometers are suitable for cryogenic temperature measurements. One is the small (less than two-watt) carbon resistor commonly used in electronic circuitry. Its resistance increases rapidly with decreasing temperature, so that at very low temperatures it forms a sensitive, moderately stable thermometer. Different resistors are chosen for different small portions of the range from below 1° K to above 50° K.

Semiconductor thermometers

Semiconductor thermometers, in particular germanium thermometers, are the most important cryogenic electrical resistance thermometers. High-purity germanium has too high and constant an electrical resistance to be useful in itself for thermometry. When it is doped with minute quantities of an impurity such as arsenic, however, its resistance is very much lower and highly temperature-dependent (see SEMICONDUCTOR DEVICES). Like carbon and in contrast to metals, the resistance increases with decreasing temperature. Germanium thermometers are useful from about 0.2° to 50° K but especially from 0.2° to 20° K, where the platinum-thermometer sensitivity is very low. In this range reproducibility with 0.001° K can be obtained. A typical germanium thermometer is a small crystal enclosed in a helium-filled cylindrical platinum shell about three millimetres (0.1 inch) in diameter and 12 millimetres (0.5 inch) long with fine gold lead wires protruding.

Another class of semiconductor resistance thermometer is thermistors, which are usually small beads or cylinders about one millimetre in diameter composed of a mixture of complex metal oxides. Different thermistors suitable for various temperatures from 4° K to 300° C are manufactured; it is preferable to operate any one thermistor over a narrow range. At room temperature they are ten times more sensitive than platinum thermometers but much less stable; at cryogenic temperatures they are inferior to carbon or germanium. Germanium and platinum thermometers are expensive, however, whereas carbon and thermistors are cheap; where their lower accuracies suffice, they are widely used.

Thermocouples. Thermocouples are among the most important thermometers. The basic thermocouple con-

sists simply of two wires of different materials joined together at one end (the hot junction), connected to separate copper lead wires at the other (the cold junction), with the leads connected to a voltage-measuring device. The wires are enclosed in a nonconducting sheath (cloth, rubber, ceramic) to insulate them electrically from one another. If necessary, a considerable length of thermocouple extending from and including the hot junction is placed in a ceramic or metal tube for protection from the environment. A temperature difference between the hot and cold junctions develops a small voltage; thus, when the cold junction is maintained at a known reference temperature (frequently 0° C), the voltage is a measure of the temperature of the hot junction. Typical sensitivities are ten to 60 microvolts per degree Celsius. Thermocouples may be used from very low (1° K) to very high (3,000° C) temperatures—a wider range than any other type.

Innumerable combinations of wires have served as thermocouples. The most important one for laboratory use is platinum, 10 percent rhodium–platinum, with a range from −50° to 1,600° C. Because platinum is costly, however, the largest number of industrial thermocouples employ such base metals as iron, copper, and various alloys.

Rugged, long-lasting, and suitable for continuous recording or control of temperature, thermocouples are perhaps the most widely used industrial thermometers. Their lifetime is dependent upon many things, chief of which are embrittlement, from oxidation or reduction, and contamination (see also THERMOELECTRIC DEVICES).

The sonic pyrometer

A thermocouple is also the sensor in a sonic pyrometer, which is designed to measure the temperature of slowly moving hot gases. A portion of the gas, drawn over a radiation-shielded thermocouple probe at sonic speed to give good convective heat transfer to the probe, is subsequently returned to the gas stream. Variations are applied in pneumatic, aspiration, and subsonic pyrometers.

Radiation. Radiation thermometers have the distinct advantage that they need not touch the material the temperature of which they are measuring; their greatest application is in the field of high temperatures. The most important such thermometer is the disappearing filament optical pyrometer, in which an objective lens produces an image of the source in the plane of the tungsten filament of a small battery-powered lamp. The filament current is varied until the filament and the source image appear equally bright when viewed through an eyepiece lens and a red filter. The source temperature is obtained from a previous calibration of the pyrometer lamp (brightness versus lamp current). The red filter and the eye sensitivity together restrict the observed radiation to a very narrow wavelength band. For temperatures above about 1,500° C the source brightness is first attenuated by a neutral glass filter before the match is made. In recent forms of this instrument a photoelectric detector replaces the eye, an extremely narrow band interference filter (which may transmit an infrared rather than visible wavelengths) replaces the red filter, and the brightnesses are matched automatically by an electronic mechanism as the source and lamp are alternately focussed on the detector.

The optical pyrometer measures an apparent, or brightness, temperature and not the true one, unless the source is a blackbody. If the emissivity of the source (*i.e.*, the ratio of the energy the source radiates to that which a blackbody at the same temperature would radiate) is known, the true temperature may be obtained from the measured brightness temperature. Two-wavelength or multiwavelength pyrometers attempt to eliminate this emissivity correction by measuring the ratio of the source brightnesses at two or more widely separated wavelengths. They have been successful only for special applications.

In contrast to these monochromatic instruments, a total-radiation pyrometer accepts approximately the whole spectrum of energy radiated by the source, which is usually simply focussed on the pyrometer's detector. Though not as accurate as an optical pyrometer, it can measure much lower temperatures (below 200° C) where the radiation lies wholly in the infrared. Radiation pyrometers are widely used in industry for continuous recording and control of temperatures. Infrared pyrometers manufactured with photodetectors respond to a broad wavelength band of infrared radiation but not to the whole spectrum. Their operation is similar to that of a total-radiation pyrometer. Both of these types also require emissivity corrections.

Spectroscopic thermometry

Another class of radiation phenomena forms the basis of spectroscopic thermometry. Extremely high temperature gaseous sources emit radiation in discrete spectral lines or in groups of closely spaced lines rather than (or in addition to) over a continuous spectral range. The source temperature may be estimated by studying the intensities, or widths, of these lines, by measuring the ratio of the intensities of a line and the continuum at the same wavelength, or by observing the absorption by the gas of blackbody radiation transmitted through it. These techniques are applied, for example, in determining the temperatures of flames, plasmas (ionized gases), and stars. In comparison with more conventional thermometry, the accuracy is very low.

Other methods. *Bimetal.* The bimetal strip, one of the most rugged and maintenance-free of all thermometers, consists simply of two pieces of different metals bonded together and rigidly fixed at one end. When this compound strip is heated, one metal expands more than the other, thus causing a rotary motion of its free end. A pointer affixed thereto moves across a graduated scale to indicate temperatures. Because the sensitivity of this thermometer is determined in part by the length of the strip, it is frequently wound in a spiral to obtain reasonable length in a compact unit. One of the metals is generally invar, an iron–nickel alloy with a very small thermal-expansion coefficient. The other may be brass or an iron or nickel alloy. The bimetallic strip is similar in range to that of liquid-in-glass, though less accurate; it is not as fragile, and it is simpler to read. It is commonly used in thermostats and similar control devices.

Acoustic. The velocity at which a sound wave travels through a medium is dependent upon its temperature; instruments that measure temperature from a determination of the velocity of sound are called acoustic thermometers. Those that operate at frequencies above the range of human hearing are designated ultrasonic interferometers. Acoustic thermometry is an important supplement to gas thermometry, because it allows independent determinations of thermodynamic temperatures, especially from 2° to 40° K.

In most acoustic thermometers a sound-wave generator such as a fixed-frequency audio oscillator or a resonating quartz-crystal ultrasonic oscillator sets up standing waves in a variable-length cylindrical cavity having precisely parallel end faces and containing helium at a known pressure. The change in the number of nodes in the cavity when its length is changed by a precisely measured amount determines the wavelength (symbolized by the Greek letter lambda, λ) of the wave; this, together with the known oscillator frequency (f), gives the wave velocity from $W = \lambda f$. By repeating the measurement at different pressures and extrapolating to zero pressure, the wavelength at zero pressure is obtained, allowing the temperature to be calculated from a theoretical relation between the wave velocity and the temperature of an ideal gas. In this way temperatures may be measured to accuracies of $\pm 0.005°$ K.

A practical type of ultrasonic thermometer having high resolution from about −20° to 300° C uses the linear temperature dependency of the frequency of a resonating quartz crystal. It is calibrated by comparison with a platinum resistance thermometer.

Magnetic. Gas, acoustic, and vapour-pressure thermometers become less sensitive with decreasing temperature, so that their useful lower limit is about 1° K; magnetic thermometers, on the other hand, become more sensitive with decreasing temperature and are therefore important for establishing thermodynamic temperatures from 1° to about 0.002° K. These thermometers employ the temperature dependency of the magnetic susceptibili-

ty (χ)—*i.e.*, a parameter that indicates the extent to which a material is susceptible to magnetization—of paramagnetic salts, which is expressed by

$$\chi = \frac{C}{T - \theta},$$

where C and θ (theta) are constants. Cerium magnesium nitrate obeys this relation down to about 0.006° K. Below that point the equation defines a magnetic temperature, which must be related to thermodynamic temperature by some kind of auxiliary measurements. The susceptibility is usually determined by placing a spherical single crystal or a small cylindrical powdered specimen of the salt inside a coil, the mutual inductance of which is measured with an alternating-current bridge. The constants C and θ are determined above 1° K by comparison with another type of thermometer and the equation extrapolated below.

Magnetic thermometers with other salts (*e.g.*, gadolinium sulfate) make convenient interpolating instruments from 1° to 30° K. They are calibrated at two or three temperatures over the range, and intervening temperatures are interpolated using the above or some other simple relation between χ and T. It is interesting that the extension of this principle to nuclear magnetism (as distinct from atomic paramagnetism) will measure the lowest temperatures yet attained, below 10^{-5}° K.

Thermal noise. In any electrical conductor the electrons move about randomly, the extent of their motion increasing with temperature. Because they are charged particles, their motion produces a small fluctuating voltage; it commonly manifests itself, for example, as noise or static in electronic circuits. From thermodynamic principles it has been shown that this thermal-noise voltage is systematically related to temperature. A thermal-noise thermometer takes advantage of this relationship to measure thermodynamic temperatures. Generally, two platinum resistors connected to an electronic amplifier are used, the first at a known reference temperature and the second at an unknown temperature. The noise generated in the two resistors is compared, and one is attenuated until they are equal. Or, alternatively, one resistance may be varied until the noise voltages are equal. In either case an inherent difficulty is to separate the noise generated in the amplifier itself from that generated in the resistors. Variations of these techniques have been proposed; *e.g.*, rather than attenuate the noise from the resistor at the higher temperature, one may inject noise into the one at the lower temperature, with the advantage of reducing the dependence upon amplifier noise. Noise thermometers may be operated at temperatures from a few degrees Kelvin to above 1,000° C.

Pyroelectric. Crystals of certain solids, such as tourmaline and triglycine sulfate, exhibit spontaneous polarization when their temperature is changed (*i.e.*, they become electrically charged with opposite faces having charges of opposite polarity). The magnitude and polarity of the induced voltage is dependent upon the magnitude and direction of the temperature change. This phenomenon, called pyroelectricity, has been suggested as the basis of a differential thermometer but had not yet been fully exploited in the early 1970s. Extreme sensitivity is clearly possible, for in some materials a 1° C temperature change generates several hundred volts. Temperature changes smaller than 10^{-5}° C have been measured in this way, and 10^{-7}° C appears possible. Pyroelectric thermometers will not measure temperature itself, because the voltage gradually disappears when the crystal is maintained at constant temperature.

The phenomenon of pyroelectricity

Gas viscosity. A gas-viscosity thermometer depends upon the resistance offered by a capillary tube to the flow of gas through it. In one such device the flow of argon through a variable-length capillary at a reference temperature is matched to the flow through a ceramic capillary at a high temperature as sensed by a differential manometer (pressure-measuring instrument). At balance, the pressure drop along both capillaries is the same, and under these conditions a simple equation relates the resistance of the reference capillary to the temperature of the ceramic capillary. The temperature is then obtained from an independent calibration of the instrument.

Temperature indicators. Certain materials give one single indication of a temperature. Crayons or paints that melt or change colour within a very small temperature range may be applied to any surface and will indicate when the surface reaches a specified temperature. Pellets that melt and tapes that turn black are similarly applied. More than 100 such temperatures between 40° and 1,800° C may be measured in this way by suitable choice of indicator. The accuracy is typically within 1 percent. Pyrometric cones, small clay cones, their axes inclined slightly from the vertical, soften and bend at particular temperatures and are much used in the ceramic industries. Cholesteric liquid crystals, which indicate temperature by changing their colour, differ from the other indicators in that the colour change is reversible, and the crystals may traverse a range of colours to indicate more than one temperature. Sensitivity is high; a 0.1° C temperature change is detectable.

Thermography. Thermography, or mapping of external temperature distributions over extended areas, can be accomplished with the indicators described above or by photography, especially with infrared-sensitive emulsions. Scanning and recording with infrared pyrometers is common in meteorological applications. Another method employs phosphors that emit visible light when irradiated with ultraviolet. The intensity of the emitted radiation is temperature-dependent. The phosphor may be painted on a surface, irradiated, and the temperature distribution observed visually or photographed.

Mapping internal temperature distributions

Shadowgraph, Schlieren, and interferometer techniques when applied to transparent mediums, such as high-temperature gases, can be employed to map internal temperature distributions. These techniques exploit the temperature dependence of the index of refraction, that property determining the direction and velocity with which a light ray traverses a medium. In the shadowgraph and Schlieren techniques an extended uniform beam of light is shone through the medium; temperature gradients within cause small displacements of individual rays within the beam. These effects are reproduced as variations in the intensity of the emergent beam and may be displayed by suitable projection on a screen or photographic plate, where they appear as shadows. In the interferometer an initial monochromatic beam is split so that only one portion traverses the medium, is subsequently reunited, and is then projected on a screen. Interference fringes, indicating contours of constant temperature, result from the velocity changes undergone by the individual rays in one beam relative to those in the other. This method is capable of quantitative evaluation.

BIBLIOGRAPHY. The most complete references for thermometry, covering all phases of the subject and giving extensive bibliographies, is the series, *Temperature: Its Measurement and Control in Science and Industry*, 4 vol. (1941–72). Among textbooks dealing in whole or in part with some part of thermometry, two that give the most complete coverage are H.D. BAKER, E.A. RYDER, and N.H. BAKER, *Temperature Measurement in Engineering*, 2 vol. (1953–61); and M. TERNY, *La Mesure des températures au laboratoire et dans l'industrie* (1962). A review emphasizing measurements of reasonably high precision is R.E. BEDFORD, T.M. DAUPHINEE, and H. PRESTON-THOMAS, "Temperature Measurement," in *Tools and Techniques in Physical Metallurgy*," ed. by F. WEINBERG vol. 1, ch. 1 (1970). Cryogenic thermometry is ably reviewed in C.A. SWENSON, "Low Temperature Thermometry, 1 to 30 K," *Critical Reviews in Solid State Sciences*, 1:99–136 (1970). Two excellent accounts of the history of thermometry are H.C. BOLTON, *Evolution of the Thermometer: 1592–1743* (1900); and W.E.K. MIDDLETON, *A History of the Thermometer and its Uses in Meteorology* (1966). Two extensive bibliographies of research papers dealing with all phases of thermometry published from 1953 through 1962 are C. HALPERN and R.J. MOFFAT, "Bibliography of Temperature Measurement: January 1953 to June 1960," *National Bureau of Standards Monograph 27* (1961); and C. HALPERN, "Bibliography of Temperature Measurement: July 1960 to December 1962," *ibid.*, suppl. 1 (1963). The complete text of the IPTS-68 appears in "The International Practical Temperature Scale of 1968," *Metrologia*, 5:35–44 (1969).

Thermoreception

Thermoreception is a process in which different levels of heat energy (temperatures) are detected by living things.

GENERAL FEATURES

Adaptive function. Temperature has a profound influence upon living organisms. Active life among animals is feasible only within a narrow range of body temperatures, the extremes being about 0° C and 45° C. On the Fahrenheit scale the same range is 32° F and 113° F. Limitations depend on the freezing of tissues at the lower temperature and on the chemical alteration of body proteins at the higher end of the range. Within these limits the metabolic rate of the animal tends to increase and decrease in parallel with its body temperature.

Body temperature and metabolism among more highly evolved animals (*e.g.*, birds and mammals) are relatively independent of direct thermal influences from the environment. Such animals can maintain considerable inner physiological stability under changing environmental conditions (see HOMEOSTASIS) and are adaptable to substantial geographic and seasonal temperature fluctuations. A polar bear, for example, can function both in a zoo during summer heat and on an ice floe in frigid Arctic waters. This kind of flexibility is supported by the function of specific sensory structures called thermoreceptors (or thermosensors), which enable the animal to detect thermal changes and to adjust accordingly.

Temperature of the body directly reflects that of the environment among cold-blooded (poikilothermic) animals, such as insects, snakes, and lizards. These creatures maintain safe body temperatures mainly by moving into locations of favourable temperature (*e.g.*, in the shade of a desert rock). Warm-blooded (homoiothermic) organisms, such as the polar bear, normally keep practically constant body temperature, independent of environment. Homoiothermic animals, including man, are able to control their body temperature not only by moving into favourable environments but also through the internal regulatory (autonomic) effects of the nervous system on heat production and loss. Such autonomic adjustments depend on lower brain centres; the behavioral (movement) responses require the function of the brain's outer layers (the cerebral cortex).

Cold-blooded and warm-blooded animals

A variety of behavioral responses is elicited through stimulation of thermoreceptors, including changes in body posture that help regulate heat loss and the huddling together of a group of animals in cold weather. In some species, thermoreceptors are also involved in food location and sexual activities. Bloodsucking insects, such as mosquitoes, are attracted by thermal (infrared) radiations of warm-blooded hosts; such snakes as pit vipers can locate warm prey at considerable distance by means of extremely sensitive infrared receptors. Man has achieved the widest range of adaptability to extremes in temperature, since his technology allows him to protect himself under a considerable variety of thermal conditions on earth and even in outer space.

Perceptual aspects of thermoreception are found in evidence that man and other animals have conscious temperature sensations and emotional experiences of thermal comfort and discomfort (see FATIGUE; SENSORY RECEPTION, HUMAN). The effects of temperature on productive efficiency and behaviour (*e.g.*, on one's ability to think) have led to the installation of heat-regulating equipment in homes, public buildings, factories, and similar shelters for people, livestock, and other animals.

Thermoreception can be studied in different ways: (1) on the basis of reports of temperature sensations and thermal comfort by human subjects; (2) through observations of behavioral responses to variations in temperature by all kinds of animals; (3) by the measurement of compensatory autonomic responses (*e.g.*, sweating or panting) to thermal disturbances in the environment; and (4) by recording electrical impulses generated in the nerve fibres of thermoreceptors in laboratory animals and human subjects.

General properties of thermoreceptors. The concept of thermoreceptors derives from studies of human sensory physiology, in particular from the discovery reported in 1882 that thermal sensations are associated with stimulation of localized sensory spots in the skin. Detailed investigations reveal a distinction between hot spots and cold spots; that is, specific places in the human skin that are selectively sensitive to warm stimuli or to cold. To this extent the different thermoreceptors exhibit sensory specificity. Modern neurophysiological methods show thermoreceptors also to be biophysically specific, in that they include nerve endings that are excited only by or primarily by thermal stimuli.

Early investigations of thermoreception

Extending far beyond the context of conscious temperature sensation as reported by humans, the biophysical definition holds for any thermoreceptive structure. Clearly, electrical responses from thermoreceptors are observable whether conscious sensations are reported by the animal (as in the case of a person) or whether they are not (as in the case of a laboratory rat). Although they are closely related, the concepts of sensory and biophysical specificity are not identical, the criterion being the quality of inner experience (sensation) in the first case and the quality of the neurally effective stimulus in the second. To make the distinction clear, a receptor that is neurally excited by cooling as well as by the application of a chemical (*e.g.*, menthol) might be classified only as a specific (cold) thermoreceptor in terms of human sensation; biophysically, however, it manifestly is a chemoreceptor as well (see CHEMORECEPTION).

Most of the modern understanding of thermoreceptors is based on biophysical (electrophysiological) investigations. This approach, introduced in 1936 for recording the electrical signals from single thermosensitive nerve fibres in the tongue of the cat, had been applied by 1960 to similar recordings from single thermoreceptors in the skin of human subjects. Such investigations are made by dissecting single nerve fibres under the microscope and placing them on electrodes or by inserting very fine wires (*e.g.*, tungsten microelectrodes) directly into the intact nerve or receptor. As in the case of other sensory nerve fibres, the electrical signals generated by the activity of thermoreceptors are brief impulses of about one millisecond duration and roughly constant amplitude. They follow in a more or less regular sequence, modulations (changes) in the frequency of which reflect differences in the intensity of the stimulus. (Frequency modulation is widely applied in such devices as radios for information processing.) Sensory structures are called specific thermoreceptors if they respond biophysically to temperature stimuli yet are practically insensitive to such other kinds of stimulation as mechanical pressure.

The general properties of thermoreceptors in the external parts of the body are found to be similar for any species of animals investigated. Thermoreceptors can be divided into well-defined classes as cold and as warm receptors. At constant temperatures (within an appropriate range), cold receptors are continuously active electrically, the frequency of the steady discharge (static response) depending on temperature. In most cases the static activity reaches a maximum at temperatures between 20° and 30° C (68° and 86° F). On sudden cooling to a lower temperature level, the cold receptors respond with a transient increase in frequency (dynamic response); if the lower temperature is maintained, the frequency drops to a level of static discharge in adaptation. When the receptor is warmed up again, a transient decrease in electrical activity is seen, after which the frequency rises again and finally adapts to the initial static value. Warm receptors are also continuously active at constant temperatures, with a maximum at 41° to 46° C (about 106° to 115° F). On sudden temperature changes, warm receptors respond in the opposite direction from that of cold receptors, temporarily overshooting adaptation frequency on warming and showing transient inhibition on cooling. Thermoreceptors are thus selectively sensitive to specific ranges of temperature as well as to rate of temperature change.

Cold receptors and warm receptors

Some receptor cells in the skin of fishes and amphibians respond both to mechanical and to thermal stimulation. In the skin of cat, monkey, and man, receptors have been

found that are excited both by mechanical stimuli and by cooling. It seems, however, that these nerve endings are primarily mechanoreceptors (see MECHANORECEPTION), their sensitivity to cooling being much lower than that of specific cold receptors.

THERMORECEPTION IN INVERTEBRATES

Insects placed on a surface that provides a temperature gradient (warmer at one end and cooler at the other) often congregate in a narrow band of temperature, providing behavioral evidence of sensitive thermoreception. Honeybees (*Apis mellifera*) normally choose a temperature range of 35° ± 1.5° C (95° ± 2.7° F); when repeatedly replaced at the warm end of the gradient, individual bees follow their average chosen temperature within ±0.25° C (±0.45° F). Bees also accurately regulate temperature in the hive between 35° and 36° C (95° and 97° F) by behavioral patterns (*e.g.*, beating wings to circulate air) in the brood season.

Among invertebrates other than arthropods, the leech (*Hirudo medicinalis*) can make temperature discriminations with an accuracy of 1° C (about 2° F). The slug (*Agriolimax reticulatus*) reacts at temperatures below 21° C (70° F) by increased locomotor activity in response to 0.3° C (0.5° F) cooling over a period of five minutes.

The temperature sensitivity of bloodsucking arthropods (*e.g.*, lice) is considerably greater than that of nearly all other arthropods; the warmth of the victim's body is the primary influence in stimulating and guiding such blood feeders. The so-called castorbean tick (*Ixodes ricinus*), which sucks blood from sheep, responds when its front legs, which are the primary site of thermal sensitivity, are warmed up by 0.5° C (0.9° F). The bloodsucking assassin bug (*Rhodnius prolixus*) responds with direct movement toward any warm stimuli; *e.g.*, when a glass tube warmed 15° C (27°F) above air temperature is kept within about four centimetres (1.5 inches) of its antennae. Similarly, mosquitoes (*Aedes aegypti*) fly readily to a warm, odourless, inanimate surface as if it were that of a warm-blooded creature. The mosquito's antennae are probably the site of the thermosensors, and the animals manifest sensitivity to changes in air temperature of about 0.5° C. In most insects the thermoreceptors appear to be located in the antennae, since they show impairment of thermoreceptive behaviour when part or all of the antennae are removed. Behavioral studies represent a rather gross method of localizing thermosensitive structures, however. A more direct approach to thermoreceptor function in insects has been achieved by electrophysiological methods. Microelectrodes with tips of very small diameter are inserted near the presumed thermosensitive cells. Any electrical nerve impulses elicited by temperature stimuli are amplified and recorded. This method permits, for example, the study and identification in various insects of receptors that are sensitive to cooling. Cockroaches (*Periplaneta americana*) have two whiplike antennae consisting of 120 to 180 ring-shaped segments that grow thinner and longer with increasing distance from the animal's head. There are about 20 cold receptors per antenna; these are located on the thicker segments (Figure 1), with rarely more than one per segment. Each cold receptor consists of a delicate hairlike structure (sensillum) emerging from a ring-shaped wall. The cold sensilla are mechanically protected by large bristles covering the segments of the antenna. At constant temperatures the cold receptor is continuously active, the average maximum frequency of its discharge being about 16 impulses per second at a temperature near 28° C (82° F). At higher and lower temperatures, the steady frequency becomes lower. When the receptor is rapidly cooled, its discharge frequency rises steeply up to 300 impulses per second and then declines gradually to a much lower constant level. On rapid warming, the opposite response is seen; *i.e.*, there is a transient inhibition of the receptor discharge, followed by a gradual restoration of the steady activity. The cold receptor is thus sensitive to constant temperatures as well as to the rate of temperature changes.

Studies with microelectrodes

From *Zeitschrift fur Vergleichender Physiologie* (1968)

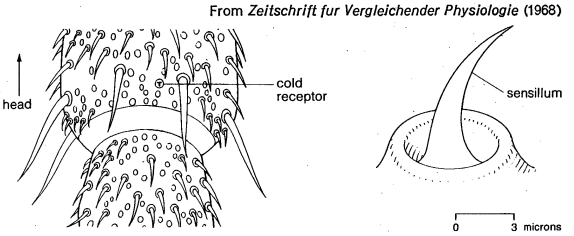

Figure 1: (Left) Portion of cockroach antenna showing location of cold receptor. (Right) Magnification of a single cold receptor of a cockroach.

Caterpillars of various moths (*Lasiocampidae, Saturniidae, Sphingidae*) have cold-receptor cells in their antennae and mouthparts (maxillary palps). Electrophysiological investigations with microelectrodes suggest that just three receptor cells located in the third antennal segment and probably not more than one receptor cell in the maxillary palp are sensitive to cooling. At constant room temperatures, static neural activity from such cells is observed; this activity increases in frequency when the temperature is lowered. During rapid cooling, the frequency rises steeply to a transient maximum of up to 300 impulses per second, while rapid warming produces a temporary inhibition of the discharge. Since only a few cells out of the 20 or 30 that comprise the thermoreceptor structure exhibit the typical electrical response to cooling, specific thermoreceptive function among caterpillars is strongly indicated.

Electrophysiological evidence for the presence of thermosensitive structures also is available for the antennae of honeybees and of migratory locusts (*Locusta migratoria migratorioides*). Temperature-induced changes in the spontaneous electrical activity within the central nervous system of honeybees also have been recorded. Other sensory structures in these animals also can be influenced by temperature, but their primary functions appear to be chemoreceptive or mechanoreceptive.

THERMORECEPTION IN VERTEBRATES

Fish. Many species of modern bony fish (teleosts) are sensitive to very small changes of temperature of the water in which they live. Various marine teleosts, such as the cod (*Gadus gadus*), have been trained to swim half out of water up a long sloping trough in response to changes of as little as 0.03° to 0.07° C (0.05° to 0.13° F) in the temperature of the water flowing over them.

More detailed conditioning experiments with freshwater fish show that they can distinguish warm from cold, discrimination being made on the basis of thermal change rather than on absolute temperature. Temperature sensitivity persists in these animals when the nerve supplying the lateral line (see MECHANORECEPTION) is cut but is abolished after transection of the spinal cord. When freshwater fish are trained to seek food in response to a change in water temperature, they are found to discriminate differences of less than 0.1° C (0.2° F). Goldfish (*Carassius*) have been trained to discriminate between warm and cold metal rods placed in their tanks. Consistent responses are obtained only when the rod is at least 2° C (3.5° F) colder or warmer than the water. Practically the whole surface of the fish, including the fins, is found to be thermosensitive. This mode of temperature discrimination need not be ascribed to the function of specific thermoreceptors; it could depend on skin receptors that are sensitive to combined mechanical and thermal stimulation. Indeed, electrophysiological recordings from nerve fibres originating in the skin of fish support the latter view. Changes in the electrical activity of these fibres are elicited only when the skin is touched by some solid object; yet the frequency of this mechanically elicited neural discharge is heavily influenced by the temperature of the object used in touching the fish.

Temperature discrimination in goldfish

Elasmobranchs, such as rays and sharks, have distinctive sense organs, called ampullae of Lorenzini, that are highly sensitive to cooling. These organs consist of small capsules within the animal's head that have canals ending at the skin surface. The capsules and their canals are filled

with a jellylike substance, sensory-receptor cells being situated within each capsule. Recordings of impulses from single nerve fibres supplying the ampullae of Lorenzini in rays (*Raja*) and dogfish (*Scyliorhinus*) reveal steady activity of the receptors at constant temperatures between 0° and 30° C (32° and 86° F), the average frequency maximum appearing near 19° C (66° F). Rapid cooling causes transient overshooting of the stabilized discharge frequency, while rapid warming produces transient inhibition of the impulses. In some single fibres, cooling by 3° C (5.5° F) leads the frequency to overshoot by about 100 impulses per second. It remains an open question, however, whether the ampullae of Lorenzini are to be called specific thermoreceptors, since they also respond to mechanical stimuli and to weak electrical currents.

Amphibians and reptiles. Rattlesnakes (*Crotalus*) and related species of pit vipers (Viperidae) have a pair of facial pits (Figure 2), sense organs on the head below and in front of the eyes, which are most sensitive thermo-

From *Journal of Physiology* (1956)

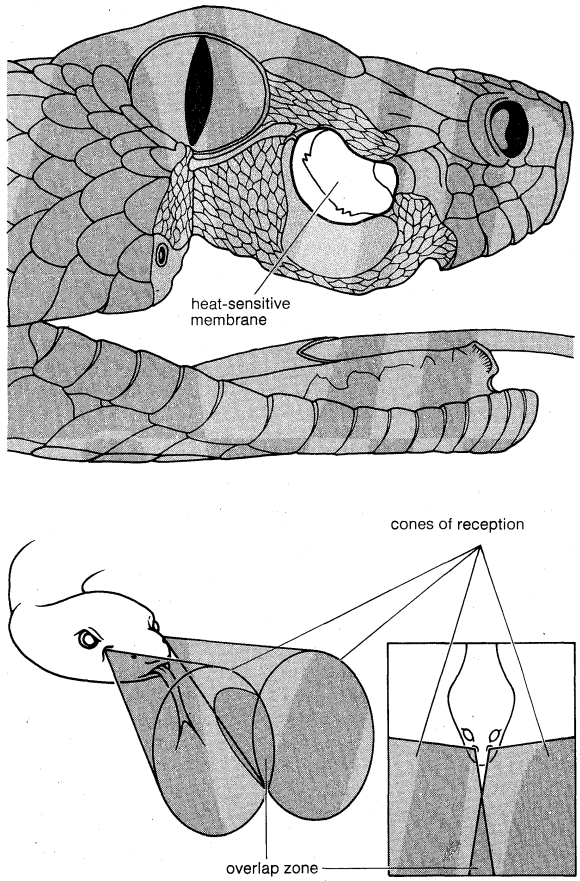

Figure 2: (Top) Partially dissected head of rattlesnake showing heat-sensitive membrane inside pit organ. (Bottom) Cones of reception, directions from which heat energy can be detected (see text).

receptors indeed. The pit organs act as directional distance receptors and make it possible for the reptile to strike at warm prey even when the snake's eyes and nose are covered and its tongue has been cut off. Each pit is a cavity about five millimetres deep, equally as wide at the bottom, and narrowing toward the opening at the surface of the head. Inside and separated from the bottom by a narrow air space is a densely innervated membrane of about ten microns thickness stretching between the walls of the pit. A direct connection between the air space beneath the membrane and the open air maintains equal pressure on both sides of the membrane. Warm-sensitive receptors distributed over the membrane consist of tree-like structures of uninsulated (unmyelinated) nerve fibres. Infrared radiation (heat energy) reaches the membrane from an external source through the narrow opening of the pit, permitting the snake not only to detect heat but also to localize coarsely the position of the stimulus. The fields of direction (cones of reception) from which each pit can receive infrared radiation from the environment extend to the front and sides of the head, with a narrow zone of overlap in the middle, as shown in Figure 2.

Under resting conditions, there is an irregular, steady discharge of nerve impulses from the pit organ. Rapid warming by as little as 0.002° C (0.004° F) at the nerve endings elicits a significant increase in impulse frequency; cooling produces an inhibition of the resting discharge. In contrast to the warmth receptors in mammals, the reptile's pit receptors are practically insensitive to steady temperatures, despite their high sensitivity to rate of thermal change. The distinctive consequence in the snake's adaptive behaviour is that gradual variations in air temperature tend to occur without detection, only the more rapid changes in infrared radiation being discriminated. Sensitivity to rapid temperature changes is enhanced by the very limited heat capacity of the receptive membrane (since it is so thin). When an animal that is 10° C (18° F) warmer than the environmental background appears for half a second at a distance of 40 centimetres (about 16 inches) in front of the snake, the heat energy radiated is enough to elevate significantly the frequency of receptor discharge in the pit organ. Indeed, behavioral experiments show that under these conditions the snake is able to discover warm prey through the victim's infrared radiations.

Detection of warmth of their prey by snakes

As poikilotherms, reptiles have practically no internal neural or metabolic mechanisms for maintaining their body temperature within physiologically safe limits. Nevertheless, such reptiles as snakes and lizards are able to keep their body temperature near these safe levels through behavioral regulation (*i.e.*, by moving to cooler or warmer places as necessary). The body temperatures of two samples of lizards (*Sceloporus magister* and *Cnemidophorus tesselatus*), for example, were found to be 34.9° ± 0.6° C (94.8° ± 1.1° F) and 41.3° ± 0.2° C (106.3° ± 0.4° F), respectively, although the average air temperatures were 33° C (91° F). Highly accurate regulation is recorded for a snake (*Crotalus cerastes*) that moved partially in and out of its burrow into the sun to maintain a body temperature of 31° to 32° C (88° to 90° F) over several hours. The desert iguana (*Dipsosaurus dorsalis*) regulates its body temperature largely by behavioral mechanisms to achieve and hold body temperatures near 38.5° C (101.3° F). These adjustments by iguanas include postural orientation to solar radiation both inside and outside burrows and altered thermal contact of the body surface with the soil. Although supporting direct evidence remains to be more fully developed, it appears that reptiles have thermosensitive nerve structures in the brain as well as in the skin.

There is some electrophysiological evidence of thermal sensitivity among amphibians, but only to relatively large temperature changes. The lateral-line organs in frogs (*Xenopus laevis*), which, as in fish, are sensitive to minute water turbulence, also respond to static temperatures and to temperature changes. Whether these responses have any adaptive, behavioral significance for temperature detection remains to be demonstrated. It has been reported, however, that a frog placed in a pan of cool water will not jump out as the pan is heated, if the temperature changes are gradual enough. Indeed, frogs are recorded to remain in the water this way until they are boiled to death.

Birds. Birds are homoiothermic, normally maintaining their body temperature within a range of less than 1° C (2° F). Investigations of temperature regulation in birds suggest the existence of thermosensors both in the lower part of the brain (hypothalamus) and in the skin.

Direct electrophysiological evidence of thermoreceptors has been obtained in the tongues of chickens and in the skin of pigeons by recording from individual fibres of nerves serving the receptors. At a constant temperature of 20° C (68° F), a high level of static activity was observed for cold receptors in the chicken's tongue. When

the temperature of the tongue was maintained at 44° C (111° F), individual cold fibres showed a low, steady-state frequency of two to four impulses per second. A temperature drop of 9° C (16° F) was found to elicit an initial response of 30 impulses per second, which gradually declined to a new static frequency of eight impulses per second. Rewarming of the tongue resulted in a cessation of detectable electrical activity for several seconds; no specific warm receptors were found. There is some electrophysiological evidence of cold and warm receptors in the skin of pigeons.

Mound building to regulate nest temperatures

Megapodes, large-footed birds such as the Australian mallee fowl (*Leipoa*), or brush turkey, bury their eggs. They depend on the thermal sensitivity of their face or mouthparts to guide their efforts in controlling the temperature of the eggs during hatching. The eggs are incubated in mounds where heat is generated through the fermentation of rotting vegetation and by irradiation from the sun. For extended periods of time the male bird is busy covering and uncovering the eggs, normally keeping the temperature almost constant at 34 ± 1° C (93 ± 2° F) over the unusually long incubation period (as much as 63 days) that characterizes this family of birds.

Mammals. Detailed information is available from electrophysiological investigations of single thermosensitive nerve fibres in the skin of mammals, particularly cats and monkeys. The nose of a cat contains numerous cold and warm receptors that are highly specific in responding to thermal stimuli; they are not excited by mechanical deformation of the skin. As a rule, each thermoreceptor is connected with a single nerve fibre. By using very finely tipped thermal stimulators, investigators can locate precisely the sites of warm and cold receptors in the skin; the details of the underlying cellular structure at these spots have been studied by electron microscopy. At the site of a cold-sensitive spot in the cat's nose, a thin, myelinated (insulated) nerve fibre penetrates the dermis and divides

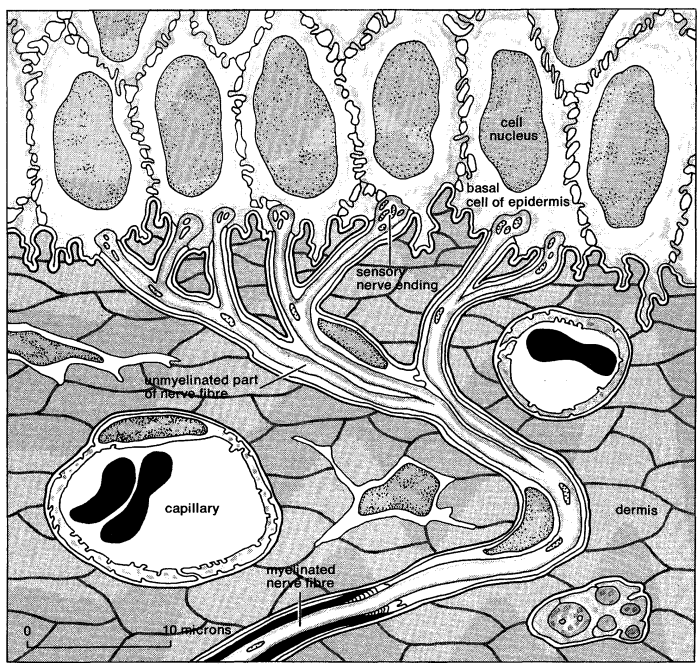

Figure 3: Cold receptor in the skin of a cat as seen with electron microscope.

into several unmyelinated branches about 70 microns beneath the skin surface (Figure 3). The tips of these branches have been shown to be the cold-sensitive nerve endings proper; they come into close contact with the basal cells of the epidermis. In most cases the nerve endings are embedded in small concavities on the lower surface of the basal cells. Warm receptors remain to be identified; they appear to be situated in a deeper layer of the skin. In monkeys and, presumably, in man, warm receptors are innervated by unmyelinated nerve fibres (diameter one micron, impulse conduction velocity of 0.5 to 1.5 metres [1.5 to five feet] per second); cold fibres are served either by unmyelinated fibres or by thin myelinated fibres (diameter two to four microns, conduction velocity three to 20 metres [ten to 66 feet] per second).

At constant skin temperatures in the normal range, cold fibres in mammals are found to be continuously active. The average maximum frequency of the static discharge is observed at 27° C (81° F), the extreme limits of the normal range of static activity being 5° and 42° C (41° and 108° F). At skin temperatures above 45° C (113° F), cold receptors again can be activated. This so-called paradoxical discharge corresponds to the similar paradoxical sensation of cold in man when a hot object is touched or the hand is put into hot water. On sudden cooling, temporary overshooting can be 30 times higher than the static frequency of eight impulses per second. Warm receptors in the cat's nose start to show their activity at skin temperatures of 30° C (86° F) and reach an average maximum of 35 impulses per second at 46° C (115° F). Above this temperature the discharge suddenly falls off.

Similar populations of cold and warm receptors have been found in monkey skin, which has an additional group of warm fibres distinguished by an average static maximum at 41° C (106° F). The transient overshooting of warm-receptor activity can be several times higher than the static maximum frequency. When cold stimuli of the same magnitude (*e.g.*, 3° C [37° F]) are rapidly applied to the warmer skin, the degree of overshooting reaches a maximum at a skin temperature of 27° C (81° F). This temperature corresponds to that which elicits maximum static discharge from the cold fibres. Overshooting on rapid warming of warm receptors follows the same general rule: the temporary maximum occurs at temperatures for which the static discharge frequency also appears at a maximum.

Distinctive properties of cold receptors are found in hibernators. European hamsters (*Cricetus cricetus*) tend to maintain body temperatures of about 5° C during hibernation. Further cooling, however, elicits arousal reactions from the animal that indicate thermoreceptive function is intact. Electrophysiological investigations have shown that myelinated cold fibres serving the hamster's nose are continuously active at very low temperatures, having a static maximum near 4° C (39° F). In contrast to these findings, myelinated cold fibres in mammals that do not hibernate are blocked at temperatures below 10° C (50° F).

Thermal information processing in the monkey brain

Relatively little is known about the processing of information from skin thermoreceptors in the central nervous system (brain and spinal cord). Responses to cooling the tongue have been recorded from single nerve cells (neurons) of the brain's thalamus in monkeys. In addition to a few brain neurons that are excited both by mechanical stimulation and cooling of the tongue, there are also numerous nerve cells in the thalamus that respond only to cooling. The latter neurons exhibit a static discharge in the temperature range (at the tongue) between 15° and 44° C (59° and 111° F), the maximum frequency being at 21° to 31° C (70° to 88° F). Rapid cooling of the tongue causes considerable transient overshooting in frequency from thalamic nerve cells over the entire range of preadapting temperatures used; by contrast, warming of the tongue results in a transient inhibition but not an increase in the rate of a discharge of any nerve elements in the brain. Thus, the activity of thalamic nerve cells activated by cooling the tongue closely reflects the behaviour of the peripheral (*e.g.*, tongue or skin) cold receptors. Even in the outer layers of the brain (cerebral cortex), nerve cells that respond specifically to cooling of the skin have been found. Other individual cortical neurons in the cat, however, receive signals not only from peripheral thermoreceptors but from mechanoreceptors and taste receptors as well.

Cats can be trained to respond behaviorally to thermal stimulation (*e.g.*, they will press a bar or lever). These experiments reveal cats to be relatively insensitive in discriminating warm and cold stimuli applied to the furred skin of the trunk or the legs, requiring temperature differ-

ences amounting to several degrees Celsius. This does not necessarily mean that cats have no finer thermal sensitivity than their grossly observable behaviour suggests. Indeed, autonomic regulatory responses, such as increased blood flow to the ear, can be elicited by mild warming of the paws, even though such warming is inadequate as a signal for training behavioral responses. In contrast to the low thermal sensitivity of their skin elsewhere in the body, cats have been found to manifest behavioral responses when the nose and upper lip are warmed or cooled by only 0.1° to 0.2° C (0.2° to 0.4° F). This corresponds to levels of thermal sensitivity of the face in human subjects and also is in accordance with electrophysiological evidence of high thermal sensitivity of the cat's nasal region.

Mammalian thermoreceptor structures, each containing elements sensitive to warm and cold, are to be found in the skin, in the deep tissues of the body, and in the hypothalamus and spinal cord. While much of the evidence of thermosensors in the central nervous system derives from experiments in neural temperature regulation within the body, in 1963 microelectrodes were used to record directly the activity of thermosensitive neurons in the frontal part of the cat hypothalamus. Many investigations made with this method show that most neural elements in the cat and rabbit hypothalamus are practically insensitive to directly applied temperature stimuli. There are, however, two smaller populations of thermosensitive neurons, one of which responds to local warming and the other to local cooling of the brain tissue.

Warm-sensitive brain neurons in cats and rabbits increase the frequency of their static impulse discharge in direct proportion to the degree that hypothalamic temperature is raised above normal. Similarly, the cold receptors there respond with an increase in impulse frequency when the temperature of the hypothalamus falls below the normal value for the animal's body. Since temperature in the deeper tissues of the body (*e.g.*, the brain) varies quite slowly, the activity of hypothalamic thermosensors seems to be almost entirely a function of the level of temperature alone and not of the rate of temperature change. By contrast, the thermoreceptors in mammalian skin are highly sensitive to rapid changes in temperature. Intervening elements in the nervous system have been identified that integrate temperature signals from the hypothalamus and from the skin. Thermosensors are also found to be localized in the midbrain of rabbits and in various parts of the spinal cord in guinea pigs and dogs. These findings are in good agreement with observations that thermoregulatory responses such as shivering or panting can be influenced by local temperature changes in the spinal region of the animal.

Signals from hypothalamic thermosensors, from deep-body thermosensors, and from those in the skin are integrated in thermoregulatory centres located mainly in the mammal and bird hypothalamus. The integrated signals provide information about the inner (core) temperature of the body and about thermal changes at the periphery (body surface). Such information serves to activate internal mechanisms that maintain body temperature within the normal range of values. When signals from warm receptors (especially from those in the hypothalamus) prevail over signals from cold sensors, such heat-loss mechanisms as sweating, panting, and widening of blood vessels (vasodilatation) in the skin act to reduce body temperature. When signals predominate from cold receptors (particularly from those in the skin), heat-conservation mechanisms are initiated. Heat production rises as muscles expend energy in shivering and through other metabolic reactions (nonshivering thermogenesis); heat loss is reduced by mechanisms that narrow the blood vessels (vasoconstriction) in the skin and that fluff out hairs or feathers to enhance thermal insulation. All these involuntary, or autonomic, regulatory changes continue even without the function of the cerebral cortex; thus, they do not require consciousness, persisting during light anesthesia or during sleep.

Sweating, panting, and shivering

In human beings, the function of thermosensors is closely involved in the highly emotional experiences of thermal comfort and discomfort. Whereas temperature sensations are mainly related to the activity of warm and cold receptors in the human skin, thermal comfort and discomfort reflect the general state of the thermoregulatory system, involving signals not only from thermoreceptors in the skin but from thermoreceptors in deep-body regions and in the hypothalamus as well. Thus, the same temperature at the skin can be experienced as comfortable or uncomfortable, depending on the thermal condition of the person's whole body. When one is overheated, an ice bag applied to the head may be perceived as pleasant; but, if someone is generally chilled just to the point of shivering, the same cold stimulus can be most unpleasant.

(H.He.)

Thiers, Adolphe

Statesman, journalist, and historian, Louis-Adolphe Thiers held office under King Louis-Philippe and was later a founder and the first president of the French Third Republic. A clever, essentially conservative, and sometimes unscrupulous politician, he was equally noted for his financial acumen. In conjunction with his stockbroker father-in-law, Alexis Dosne, he made many profitable speculations based on information he acquired through his close relations with those in power.

Early life and career

Thiers was born in Marseille on April 18, 1797, officially the son of a sea captain who married his mother on May 13 and deserted her four months later. Educated at first at the Marseille school that now bears his name, he studied law at Aix-en-Provence, where he met his lifelong friend, the historian François Mignet. In 1821 he went to

Thiers, portrait by Léon Bonnat, 1876. In the Louvre, Paris.
Archives Photographiques

Paris and became a contributor to the influential newspaper the *Constitutionnel*. In January 1830 he helped found a new opposition newspaper, the *National*, which almost openly advocated a change of dynasty should the reactionary king Charles X attempt to circumscribe public liberties. During the revolution of July 27–29, 1830, which overthrew King Charles, he took refuge in a Paris suburb and returned on the 29th to win support for Louis-Philippe, duke of Orléans. He was rewarded by being made a member of the Council of State and was elected to the Chamber as a deputy for Aix-en-Provence.

Under the Orleanist monarchy, Thiers was undersecretary of state for the treasury (1830), minister of the interior (1832, and 1834–36), and minister of trade and public works (1833–34). During those years, he was the most notable representative of the Party of Resistance (conservative moderates). He mercilessly crushed all insurrections, in particular those of the legitimists under the Duchesse de Berry in 1832 and of the Republicans in 1834. Premier and minister of foreign affairs (1836 and 1840), in his second term of office his support of the Egyptian pasha Muḥammad ʿAlī almost led to war with England because of a conflicting Near Eastern policy. Forced to resign by King Louis-Philippe's determination to avert war, Thiers nevertheless remained a leader of the resistance party.

After the Revolution of February 1848, Thiers returned to the Assembly as a representative for Seine Inferieure. Though he helped elect Prince Louis-Napoleon to the presidency of the Second Republic (1849), the two later became estranged. Exiled from 1851 to 1853, Thiers again became a deputy under the Second Empire, and was originally one of those who favoured war with Prussia in 1870. During the war crisis, however, Thiers changed his views and became an opponent of the aggressive policy that he had previously advocated. This swing stood him in good stead after the French defeat in September 1870; he thus became the wise man who had foreseen the folly of pursuing such a policy without adequate military power. He was clever enough to remain out of the national defense government set up after the fall of the Empire (September) and thus had no responsibility for the final French surrender in January 1871. In February he was elected simultaneously for 26 *départements* and on February 17 became "chief of the executive power of the French Republic." In August 1871 he became president of the republic. Thiers believed that France could be united under a conservative republic and tried to win the monarchist opposition over to this view. His first major task was to restore political order. In concert with the Germans, he ruthlessly used troops to defeat the Paris insurrection known as the Commune (March–May 1871), thus destroying for many years the strength of French Socialists and workers' movements. But even this did not win him the support of the monarchists, and in 1873 he resigned. Meanwhile, his financial skill had enabled France to pay off ahead of time the indemnity due the Germans. But his military law of 1872 failed to establish an adequate professional army and the five years' conscription period he introduced seriously depleted the labour force.

Thiers joined the republican opposition in what was now a mainly royalist Assembly. He died suddenly on September 3, 1877, at Saint-Germain-en-Laye, just outside Paris, while preparing an election manifesto.

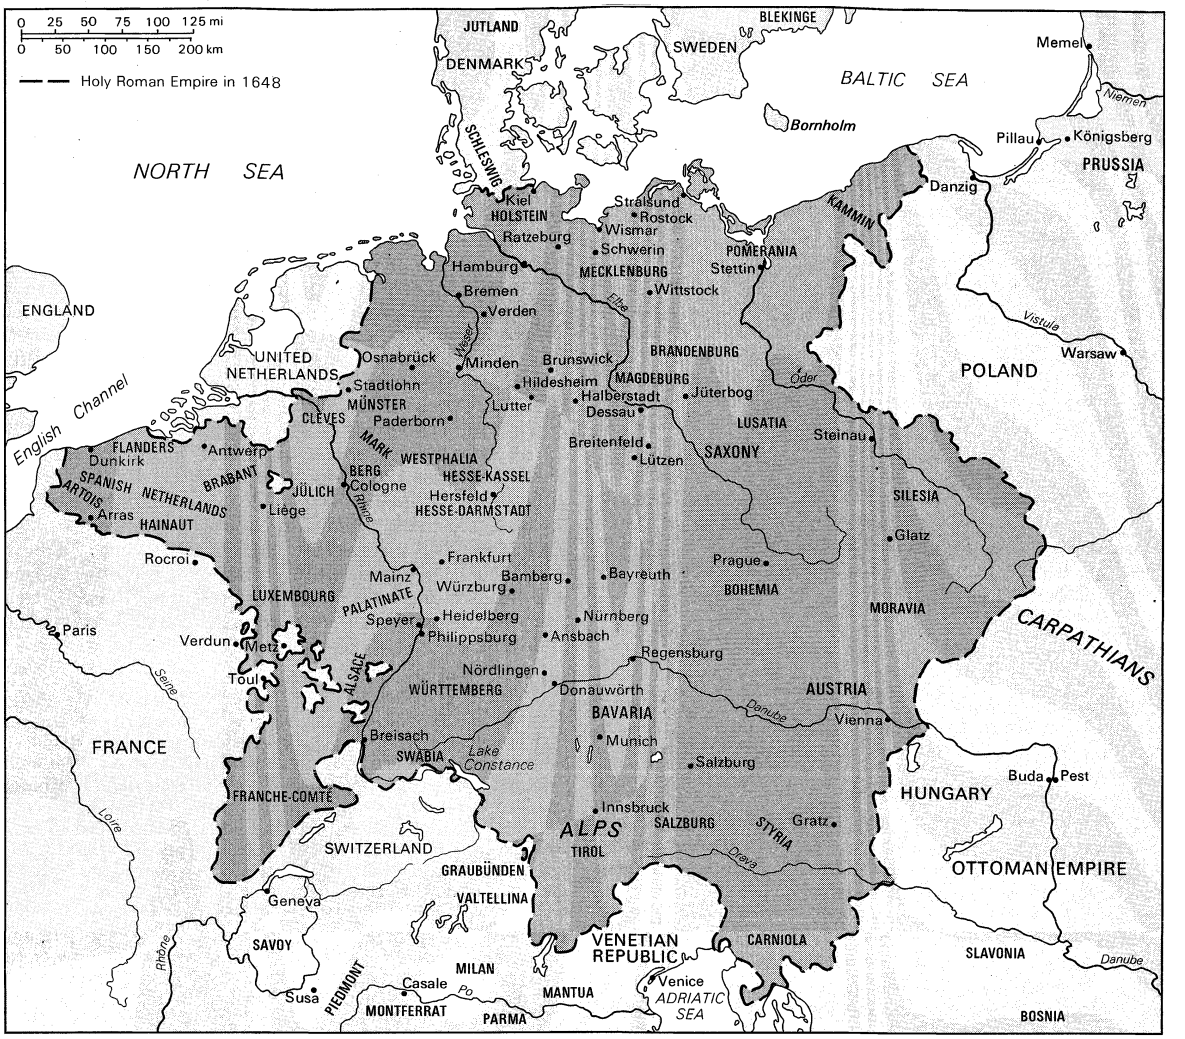
Assessment

Thiers probably achieved greater power and wealth than any French politician of his time, but his ability was not greatly appreciated by those whom he served. His *Histoire de la révolution française*, which appeared in ten volumes between 1823 and 1827, and his *Histoire du consulat et de l'empire*, published in 20 volumes between 1845 and 1862, made a notable contribution to the growth of nationalism in France. In addition, his effecting the return of Napoleon's body to France from St. Helena in 1840 fostered the Napoleonic legend. Of himself, Thiers fairly successfully promoted the image of an old, shrewd, and wise patriot, although, by those of left-wing sympathies, he was never regarded as anything but an inveterate enemy of social reform.

BIBLIOGRAPHY. HENRI MALO, *Thiers 1797–1877* (1932); and CHARLES H. POMARET, *Monsieur Thiers et son temps* (1948), are two biographies that give an overly favourable interpretation of Thiers's work. A recent and more balanced biography is ROBERT CHRISTOPHE, *Le Siècle de Monsieur Thiers* (1966). R.L. DREYFUS, *La République de M. Thiers, 1871–1873* (1930), also very favourable, provides an account of Thiers's policies during the first years of the Third Republic. The four books of HENRI GUILLEMIN on the origin of the Commune explain the policies of Thiers during the Franco-German War and the internal crisis that followed: *Cette curieuse guerre de 70* (1956); *L'Héroïque défense de Paris (1870–1871)* (1959); *La Capitulation (1871)* (1960); and *L'Avènement de M. Thiers et reflexions sur la Commune* (1971). The best studies on Thiers in English are the recent contributions of CHARLES POUTHAS and J. NERE in the *New Cambridge Modern History*, vol. 10–11 (1960–62). JOHN MAUDGRIDGE SNOWDEN ALLISON, *Thiers and the French Monarchy* (1926, reprinted 1968), remains an interesting study.

(J.Vi.)

Thirty Years' War



The Thirty Years' War is a conventional and largely misleading name for that part (1618–48) of the 50 years' struggle for the European balance of power (*c.* 1610–60) in which the Austrian Habsburgs and the German princes and cities were involved.

Interpretations

The usual picture of the Thirty Years' War, as painted by German historians and accepted uncritically by most English and American scholars, can be summarized as follows: (1) the war was one continuous struggle, fought almost exclusively on German soil, beginning with the Bohemian Revolt in 1618 and ending with the Peace of Westphalia in 1648; (2) it was the last and greatest of the Wars of Religion kindled by the German and Swiss Reformation of the 1520s, which the non-German powers, namely Denmark, Sweden, and France, together with the half-Spanish Habsburgs, exploited for political ends of their own; (3) it completely destroyed the German economy, leaving behind an impoverished near-desert that had lost one-third, one-half, or even two-thirds of its population; and (4) it dealt a mortal blow to the intellectual, moral, and artistic life of Germany.

Every one of these assertions can be challenged. First, there was not one uninterrupted war, but about a dozen wars, fought at different times, in different parts of Europe, by different belligerents, for different aims, interrupted by years of truce or peace affecting different regions.

Second, the religious differences between the German Protestants and Catholics were indissolubly bound up with constitutional and political questions. While it is impossible to assess the ratio of religious, political, constitu-

Sites associated with the Thirty Years' War.
From *Grosser Historischer Weltatlas*, vol. 3, Neuzeit, 2nd ed. (1962); Bayrischer Schulbuch—Verlag, Munich

tional, and economic considerations that determined any particular move, religious questions, more often than not, merely provided ideological and propagandist grounds for very secular war aims and peace proposals. The involvement of non-German powers was due to the geographical position of Germany in the heart of Europe and to a number of factors that would have remained even if there had been no religious conflict. The head of the Austrian Habsburgs, for instance, king of Bohemia and of Hungary and ruler of his house's ancient patrimony on the Danube, in the Alps, and on the Upper Rhine was also Holy Roman emperor, nominal sovereign over the whole *Reich*, or empire (that is, over all the other German princes); and the German princes were anxious to resist any expansion of his authority. At the same time, the emperor's Spanish Habsburg cousins, to whom he was closely bound by family ties, were nominally members of the empire insofar as they held Franche-Comté and the Netherlands (though the northern Netherlands had been in open revolt against Spain since 1572); and Spain was furthermore in dispute with France over certain Italian principalities of which the emperor was nominally overlord. The king of Denmark likewise was a member of the empire in his capacity as duke of Holstein and, eventually, as director of the Lower Saxon Circle of the empire. The Hohenzollerns of Brandenburg, electors of the empire, were vassals not only of Bohemia for certain fiefs in Silesia but also of Poland for their Duchy of Prussia. Finally, Sweden's Baltic policy led to encroachment on the Pomeranian part of the empire. These and other dynastic or territorial questions provided reasons or pretexts for German princes to call in foreign powers as well as for foreign powers to take sides in German or so-called German affairs.

Finally, the social, economic, and cultural effects have been misinterpreted. Seen in their true perspective, they will be found on a par with the results of every war.

The present article is divided into sections as follows:

Survey of political aspects
- Western Europe
- Northern Europe
- Eastern Europe
- Germany
- Great Britain

Survey of religious aspects

Events
- War of the Jülich Succession (1609–14)
- Bohemian and Palatine War (1618–23)
- Struggle for Graubünden (1620–39)
- Swedish-Polish War (1621–29)
- Danish War (1625–29) and the Edict of Restitution
- War of the Mantuan Succession (1628–31)
- Swedish War (1630–35) and the Peace of Prague
- War of Smolensk (1632–34)
- French and Swedish War (1635–48)
- Swedish-Danish War (1643–45)
- Peace of Westphalia (1648)
- Franco-Spanish War (1648–59)
- First Northern War (1655–60)

German civilization
- The population
- Economic life
- Literature and the arts

Conclusion

The first two sections allude to matters elucidated in the third section. Throughout the article the new style is used

for dating, even where English, Swedish, or Russian historians use the old.

SURVEY OF POLITICAL ASPECTS

Western Europe. The uniting aspect of this period in the history of western Europe is the struggle of the French monarchy and of the Dutch republic, or United Provinces of the Netherlands, against the two branches of the House of Habsburg: Spain and Austria.

Habsburg encirclement of France

The later wars of aggression, waged by Louis XIV of France and by Napoleon I, tend to obscure the fact that from the middle of the 16th to the middle of the 17th century France was the victim of a deliberate policy of encirclement by the Habsburg powers. In the south, possession of Roussillon gave Spain a firm foothold north of the Pyrenees. In the southeast, the Republic of Genoa was a Spanish satellite and the Duchy of Milan was Spanish territory. Genoa and Milan guaranteed a short and safe line of communication from Spain to Austria proper as well as to the Spanish possessions along the eastern borders of France, namely, Franche-Comté (contiguous with Austrian Alsace) and the Low Countries (Luxembourg, Hainaut, and Artois on the French frontier, with Flanders, Brabant, and the rest of the Netherlands in their immediate hinterland). After the successes of the Dutch rebellion, from 1572, the overland route from Genoa to Brussels was the more important because the final link of the chain around France had snapped after the death of Mary I of England (1558): the fate of the Armada in 1588 had demonstrated the insecurity of the northern sea route from Spain to the Netherlands.

The breaking of this Habsburg stranglehold was the foremost task of French statesmanship. It was first undertaken when Henry IV of France resisted the attempt by the Habsburgs, in 1609, to acquire Jülich-Cleves-Mark-Berg, as this attempt threatened to deal the deathblow to the independence of the United Provinces of the Netherlands and to lay open France's northern frontier. Henry's policy, interrupted by his assassination (1610) and by the pro-Spanish appeasement of the French regency under Marie de Médicis, was resumed by Cardinal de Richelieu, in power from 1624 until his death in 1642, and was continued by his successor, Cardinal Mazarin. France, at first too weak to wage open war against the Habsburgs, began by making treaties with powers hostile to them (or to their satellites in Germany or in eastern Europe), namely, with the United Provinces (1624), with Sweden (1631), and with Russia (1632); but the defeat of the United Provinces' ally Denmark (Peace of Lübeck, 1629) the withdrawal of Russia (Peace of Polyanov, 1634), the defeat of the Swedes (Battle of Nördlingen, 1634), and the defection of Sweden's German allies (Peace of Prague, 1635) forced Richelieu to declare open war on Spain (1635), after which Catalonia and Portugal (1640) and later Great Britain (1657) also joined the French camp. The modest French military successes were surpassed at the conference table: the Peace of Westphalia (1648) established the preponderance of France and France's allies throughout central and northern Europe; the formation of the League of the Rhine (1658) gave France a decisive voice in the affairs of the empire; and the Peace of the Pyrenees (1659) enlarged and secured France's frontiers and marked the end of Spain as a great power.

Twelve years' Truce of Antwerp

For the Dutch, the period of the Thirty Years' War forms part of their Eighty Years' War against Spain (1568–1648). The 12 years' Truce of Antwerp (April 9, 1609) can now be seen as the de facto recognition of the independence of the United Provinces; but contemporary Dutch statesmen foresaw that the Spanish crown would not easily abandon the hope of reducing the rebellious heretics and recovering its richest European province. In fact, Philip IV of Spain, whose accession in 1621 coincided with the expiry of the truce, immediately renewed the war. But whereas at the outbreak of the rebellion Spain had been the leading maritime, commercial, and colonial power, superiority in all these spheres had passed to the Netherlands. The only weakness of the maritime republic was its lack of land forces; but the States-General had no difficulty in enlisting foreign mercenaries or paying subsidies to foreign princes. Whereas the interest of Spain demanded the localization of every conflict so that resources might be concentrated against the Dutch, the interest of the Dutch was served best by extending the war so as to engage Spain's power away from their borders. Religious and constitutional affinities gave the Calvinist Dutch republicans additional zest in their support (1) of the Calvinist elector John Sigismund of Brandenburg in his struggle for Jülich; (2) of the semirepublican nobles of Bohemia in their fight against Austrian absolutism; and (3) of the generals who, from 1621, continued the Bohemian War, nominally on behalf of the Calvinist elector Frederick V of the Palatinate. But practical political considerations made the United Provinces the focal point of every anti-Habsburg coalition: the Franco-Dutch Treaty of Compiègne (June 20, 1624) was the prelude of the Treaty of The Hague (1625), which effectively brought Denmark into the war against the emperor Ferdinand II; and, after Denmark's defeat, Dutch diplomacy and subsidies aided Richelieu in enlisting Gustavus II Adolphus of Sweden as the military champion of the anti-Habsburg cause (1630–32).

From the middle of the 1630s, the French superseded the Dutch as leaders of the anti-Habsburg struggle. The conquest of Alsace and of Breisach by France's protégé Bernhard of Saxe-Weimar in 1638 and the secession of Portugal in 1640 shook Spain into preferring to come to an arrangement with the Dutch; and the latter, having smashed the Spanish Navy in the English Channel (1639) and off Pernambuco (1640), thereby putting an end to Spanish overseas expansion, now considered France and the Portuguese colonial empire greater rivals to their mercantile interests than Spain. Disregarding the alliance with France, which they had made in 1635, the Dutch on Jan. 30, 1648, signed a separate peace with Spain.

Struggle for Baltic supremacy

Northern Europe. Viewed from northern Europe, the first half of the 17th century comprises the attempts of the two Scandinavian kingdoms, Denmark and Sweden, to obtain what the diplomatic language of the time called the *dominium maris Baltici* ("lordship of the Baltic Sea"); *i.e.*, the possession of the leading Baltic ports through whose customs sheds the raw materials of the North German, Polish, and Russian hinterlands found their way into the West.

Denmark's repeated attempts to overpower Sweden failed, and the Danish outposts in the eastern Baltic were lost. King Christian IV's attempt to make himself supreme in Lower Saxony by acquiring the German bishoprics of Bremen, Verden, Minden, and Hildesheim led to the Danish War (1625–29), in which the superior generalship of his adversaries outweighed the subsidies granted to him by the Dutch and the British. The Peace of Lübeck (1629) finished Denmark as a European power of consequence.

Denmark's decline was emphasized by the simultaneous rise of Sweden. The Peace of Knäred (1613) made only transitory concessions to Christian IV of Denmark, who had attacked Sweden in 1611. Thenceforward, King Gustavus II Adolphus systematically began to close the ring of Swedish possessions around the Baltic. After preliminary gains at the expense of Muscovite Russia, whose access to the Baltic he closed (1617), he successfully attacked the Baltic provinces of Poland and of Poland's vassal, Prussia (1621–29). Besides pursuing this Baltic ambition, he may also have been aspiring to supplant his Catholic cousin, Sigismund III Vasa, on the Polish throne. Any such design, however, had to be abandoned: on the one hand the Swedish nobility objected to it; on the other, the king's Baltic policy was challenged by the advance of imperial armies along the southern shore from the west, which drew him into intervening in German affairs. The Swedish-Polish Truce of Altmark (1629) was followed by alliance with France (Treaty of Bärwalde, Jan. 23, 1631).

The alliance with France survived the death of Gustavus Adolphus and remained the sheet anchor of his successors' position until Sweden's collapse as a great power (1721). Sweden reaped the fruits of this policy; first in the Peace of Brömsebro at the end of the Swedish-Danish War of 1643–45; then in the Peace of Westphalia (1648);

and finally in the Peace of Roskilde (1658), with Denmark in the course of the First Northern War. By the end of this period Sweden had achieved dominance in the Baltic area.

Eastern Europe. The first half of the 17th century also embraces the first attempt by Poland to force Orthodox Muscovy (Russia) into the orbit of Latin Christianity as well as the first attempt on the part of the House of Romanov to enter the comity of western Europe. Poland, tied to the Habsburgs by religion and tradition, hostile to Sweden by religion and dynastic rivalry, and implacably hostile to Muscovy by history and religion, exploited the "troubles" that convulsed Russia after the death of Boris Godunov (1605). The experiment of ruling Russia through a Polish puppet, the first False Dmitry, failed in 1606 when the usurper succumbed in an outbreak of Russian nationalism and Orthodox fanaticism. But Poland came nearest to making Russia a satellite when in 1610 Sigismund III had his son, the future Wladyslaw IV of Poland, elected as tsar: the Polish dictatorship in Moscow lasted two years.

Russia's "Time of Troubles"

In 1609, the first Russo-Swedish alliance had been concluded by the tsar Vasily III Shuysky; and, despite Sweden's later aggressions, the new Romanov dynasty (from 1613) continued to regard Sweden as Russia's natural ally against Poland. England and the United Provinces acted as intermediaries at the Russo-Swedish Peace of Stolbova (1617), and 13 years later French envoys brought about Muscovy's indirect support of Gustavus Adolphus' war in Germany. Russia, however, did not want to be involved directly in Germany, and the Russo-Polish War of Smolensk (1632–34) remained a sideshow. After Gustavus Adolphus died, Swedish-Russian relations cooled, as the Swedish chancellor Axel Oxenstierna correctly assessed Russia as potentially more dangerous than Poland.

The Russo-Polish Peace of Polyanov (1634), which included Wladyslaw IV's final resignation of his claim to the Russian throne, freed Poland to resume hostilities against Sweden and, by thus tying down Swedish troops, contributed to the Swedish disaster at Nördlingen.

Germany. All these European conflicts affected Germany more often and more deeply than any of the other contestants. Germany was the only country where the Reformation had resulted in a permanent split into three religious factions—Catholic, Lutheran, and Calvinist. As these religious divisions largely marched with political frontiers, they were sustained and aggravated by dynastic rivalries, such as that between the Catholic Wittelsbachs in Munich (Bavaria) and the Calvinist Wittelsbachs in Heidelberg (the Palatinate) or that between the Calvinist Kassel branch and the Lutheran Darmstadt branch of the House of Hesse. In turn, these political and religious dissensions were partly exacerbated and partly overlaid by constitutional problems: the Holy Roman emperor, a Habsburg and a Catholic, wanted to establish monarchical absolutism in the empire; the electors, Catholics and Protestants alike, wanted to maintain what they called the "electoral preeminence" in the empire's affairs; and lastly, the other princes wanted to overthrow the ascendancy of both the emperor and the electors, so as to obtain complete freedom of action for themselves.

Dynastic rivalry

Each of the rivals found it easy and profitable to call in some foreign power. On the whole, the emperor relied on his Spanish cousins; the Protestant towns and smaller princes relied on Sweden, on France, and on the Dutch; Catholic Bavaria, with its satellites Cologne, Liège, Münster, Paderborn, and Hildesheim, usually blackmailed the emperor, while inclining to France and opposed to Spain; Lutheran Saxony disliked all foreign entanglements, but regarded the Calvinists as worse than the Catholics and generally found it most profitable to side with the emperor (since repeated endeavours to rally a neutralist "third force" never succeeded); and Protestant Brandenburg was weak and irresolute until 1640, when Frederick William, "the Great Elector," began to play off emperor, Swedes, Dutch, Poles, and French with such skill that by 1660 he had raised Brandenburg-Prussia to the rank of a great German and minor European power.

Great Britain. From the death of Queen Elizabeth I (1603) to the passing of the first Navigation Act by Cromwell's Parliament (1651), Great Britain's influence upon European affairs was negligible. The European policy of the government was vacillating between Spain, France, and the United Provinces, while Parliament and public opinion were enthusiastically anti-Spanish but unwilling to transform brave words into hard cash.

James I originally wanted to continue Elizabeth's pro-French and pro-Dutch policy, but assented to peace with Spain (1604). In 1613 he gave his daughter Elizabeth in marriage to Frederick V of the Palatinate, leader of the Protestant anti-Habsburg faction in Germany; but twice, in 1617 and in 1623, he tried to obtain a Catholic Spanish Habsburg princess for his son Charles before betrothing him, in 1624, to a Catholic French Bourbon.

James had at least not dissuaded his son-in-law from accepting the Bohemian crown (1619), but his dislike of the Czech nobility's republican sympathies and religious radicalism, combined with his desire to appease the Spaniards, prevented him from giving tangible support to Frederick during the war in Bohemia. It was only when Frederick had lost the Palatinate and when the Spanish marriage project had collapsed that a cautious parliamentary grant for the preparation of war against Spain gave expression to the English public's lively sympathy for the Protestant cause. An expedition to the Palatinate was hopelessly bungled.

Charles I, on succeeding his father, undertook the war against Spain and also associated himself with the Dutch in the Treaty of The Hague (Dec. 9, 1625) for the support of Christian of Denmark against the emperor and the Catholic League in Germany. But the naval expedition against Cádiz (1625) was a failure; and Charles failed to pay Denmark the promised £360,000 per annum, after the first installment of £46,000. Soon afterward, he squandered ships, troops, and money on the disastrous expedition of 1627 to help the Huguenot rebels of La Rochelle against his brother-in-law, Louis XIII of France. Thereafter Charles's devious foreign policy was hampered by lack of funds, which forced him to conclude peace both with France (1629) and with Spain (1630), and by lack of interest in foreign affairs on the part of his most capable adviser, Strafford. In 1636 and again in 1641, Charles offered to the Habsburgs an alliance against the Dutch in return for the restoration of the Palatinate to his nephew Charles Louis; but the Habsburgs declined this offer because Bavaria objected to it. Richelieu likewise in the same years preferred for France an understanding with Bavaria to a possible rapprochement with England.

SURVEY OF RELIGIOUS ASPECTS

Religious issues were insolubly interwoven with political and constitutional problems. For Germany the whole question stemmed from the Peace of Augsburg of 1555, a compromise between the Catholic and Lutheran Estates (members) of the empire. Neither party was satisfied, neither meant to abide by it. It fixed the religious frontiers as they had existed in 1552; *i.e.*, at the lowest ebb of Protestant fortunes. It gave the sovereign lay princes the right to change with their own religion that of their subjects; but it prohibited any Catholic bishopric or free city from adhering in future to the Lutheran creed. It expressly excluded Calvinists from the toleration granted to Lutherans. Above all, it failed to lay down any criteria by which the many doubtful points might be interpreted or to create any machinery to enforce its observance.

Peace of Augsburg

One of the many points left in suspense by the Peace of Augsburg concerned the right of the Protestant gentry in town and country under Catholic sovereigns to keep Protestant pastors and hold Protestant services. This issue played a part in the revolts of the Austrian and Bohemian nobility against their Habsburg overlords, which began in 1609 and ended with the Bohemian War in 1620. The ecclesiastical reservation that forbade the "reform" of Catholic bishoprics prevented Cologne from turning Protestant together with its archbishop, Gebhard, in 1583. Gebhard's deposition was the basis of the greatness of the House of Wittelsbach: Bavarian princes held the archbishopric of Cologne continuously from 1583 to 1761, the bishoprics of Hildesheim and of Liège almost uninterrupt-

edly throughout the same period, and the bishoprics of Paderborn and of Münster with but few more interruptions. Thus the undisputed leadership of Catholic Germany by the Wittelsbach Maximilian I of Bavaria was grounded on the pre-eminence of his house not only in the south but also in the northwest of Germany, where Jülich and Berg in the hands of his brother-in-law fortified his house.

The distribution of the religious parties in the empire during the first half of the 17th century, according, be it understood, to the sovereign's choice of religion, was approximately as follows: the whole of northern, northeastern, and central Germany, with the exception of the bishopric of Hildesheim and the abbey of Fulda, was Protestant; northwestern, western, and southeastern Germany, with the exception of the Rhenish Palatinate in the west, was Catholic, as were all the Habsburg dominions (Austria and Tirol, Bohemia-Moravia and Silesia, a portion of Swabia). Württemberg in Swabia, Ansbach and Bayreuth in Franconia, and nearly all the free cities, even those in otherwise Catholic districts, adhered to the Protestant faith. The nobility and townspeople in Bavaria and the Habsburg countries, nearly all of whom had been Protestants, had been recatholicized or expelled by about 1625.

The historian must not doubt the strength and sincerity with which the champions of the contesting factions and their humblest followers believed in the exclusive truth of their church: the emperor Ferdinand II, Maximilian of Bavaria, Tilly, and Richelieu were devout Catholics; Gustavus Adolphus, Bernhard of Weimar, the electors of Brandenburg, Saxony, and the Palatinate were unswerving Protestants; Wallenstein is perhaps the only personality of note who seems to have been entirely indifferent to religious distinctions, astrology having largely supplanted Christianity as his creed. Motives other than religious zeal, however, were the factors determining political allegiance.

The subordination of religion to politics

Pope Urban VIII and the cardinals Richelieu and Mazarin were unbending in their opposition to Catholic Spain and to the Catholic emperor. The Lutheran elector of Saxony and the Lutheran landgrave of Hesse-Darmstadt were firm adherents of the emperor so long as circumstances permitted. Lutheran Saxony and Catholic Bavaria were consistently anti-Spanish and anti-Swedish. Calvinist Hesse-Kassel was Lutheran Sweden's most reliable ally and, together with Bavaria, mostly pro-French. The struggle for the Baltic brought the Lutheran Gustavus Adolphus into conflict with Orthodox Russia, with Catholic Poland, and with Lutheran Denmark; but his fight in Germany made him the ally of Catholic France and of Orthodox Russia. Maximilian of Bavaria extended his power at the expense alike of the Lutheran cities in Swabia and in Franconia, of the Calvinist elector Palatine, and of the Habsburg emperor and did so mostly in conjunction with Lutheran Saxony and Catholic France. The bishops of Würzburg and of Bamberg were the first to abandon the Catholic interest at the peace congress of Münster. Protestant as well as Catholic princes, prelates, and cities were susceptible to French subsidies. Of none of the belligerents can it be said that religious motives were responsible for any major decision. The secret debates (1629–30) in the Swedish council about entry into the war are revealing: the security and defense of Sweden and the conquest of Germany were declared the war aims; the king was expressly warned against speaking of a war of religion since France might take umbrage.

Success of monarchy

The suppression of Protestantism by Ferdinand II in Austria and in Bohemia and by Richelieu in France was undertaken mainly on political considerations. The Protestants not only infringed the spiritual unit of the country (a tenet still held by every government) but also were the chief opponents of royal absolutism and, not without cause, were suspected of republican tendencies on Dutch and Swiss models. Their defeat therefore paved the way for that spiritual and administrative uniformity that became the hallmark of 17th- and 18th-century monarchy.

Similarly, the contest of the emperor against the Protestant princes and cities was to a large extent a contest to decide whether the empire was to be a monarchy, with the emperor at its head and the princes as his vassals, or a federation of more or less independent princes, with the emperor as its titular president. So long as Ferdinand II was willing to concede to the six electoral princes their traditional prerogatives in the government of the empire, these electors (including Lutheran Saxony and Calvinist Brandenburg) sided with him against the lesser princes. When Ferdinand in 1629 unmasked his real intentions by the Edict of Restitution, the electors, led by Catholic Bavaria, turned against him. The Peace of Westphalia brought about the triumph of the lesser princes, with whom the electors now identified themselves against any recurrence of imperial centralism.

In fact, the Peace of Westphalia proved the interdependence of the problems, religious and constitutional, political and economic, that again and again were used as interchangeable counters. The recognition of the adherents of the Reformed (Calvinist) religion as being of equal right with those of the Lutheran faith was largely a by-product of the dispute over Pomerania between Brandenburg and Sweden. The emperor sacrificed the north German bishoprics to the Protestant claimants (Sweden, Brandenburg, Saxony, Mecklenburg, and Brunswick) and Alsace and the bishoprics of Metz, Toul, and Verdun to France; and in return Sweden and France renounced their claims to Austrian territory in Silesia and in Swabia respectively and assented to the exclusion of the Austrian Protestants from the treaty's clauses on restitution and toleration. The attitude of the Catholic princes to Pope Innocent X's protest against any formal agreement with the Protestants is characteristic of the trend toward excluding denominational considerations from political decisions: the first secret intimation that the nuncio gave to the emperor and to the Catholic princes in November 1647 was answered with evasive excuses; and the formal protocol handed over on Christmas Eve did not even receive an answer from any prince, temporal or ecclesiastical. A special "anti-protest clause" in the peace treaty was signed by all parties: it declared Innocent's condemnation of the peace invalid and ineffective and thus demonstrated the complete emancipation of secular politics from ecclesiastical tutelage. The religious questions left unanswered by the Peace of Augsburg in 1555 were solved in 1648 in the modern spirit of the "reason of state."

EVENTS

Catholic League and Protestant Union

War of the Jülich Succession (1609–14). The settlement that the Peace of Augsburg had formulated for Germany was shaken in 1607–08 when Maximilian I of Bavaria annexed and recatholicized the Lutheran city of Donauwörth. Some of the German Protestant states concluded a military alliance, the Union, on May 14, 1608. The death of Duke John William of Jülich on March 25, 1609, opened a crucial question of succession over which war broke out. On July 10, 1609, a Catholic military alliance, the League, was formed.

The wealth of John William's lands—Cleves, Jülich, Mark, and Berg—and their strategic position attracted not only the powerless legitimate heirs, namely, John Sigismund of Brandenburg and Wolfgang Wilhelm of Palatinate-Neuburg but also every powerful neighbour. The Habsburgs wished to install an Austrian prince who would have placed the lands at the disposal of the Spaniards in their struggle with the Dutch and would incidentally have counteracted the predominance of Bavaria in northwestern Germany. France, the United Provinces, and England naturally objected to any strengthening of the Spaniards in that region. The assassination of Henry IV of France (May 14, 1610) prevented the war from becoming a European contest, though Spanish, Austrian, and Dutch troops repeatedly invaded the duchy in pretended support of one or the other of the heirs. The Protestant Union, which John Sigismund had joined by turning Calvinist, and the Catholic League, of which Wolfgang Wilhelm had become a member by entering the Roman Church and marrying a sister of Maximilian, brought about a compromise that excluded all foreign claims (Oct. 24, 1610) and led to the partition of the inheritance between Brandenburg and Neuburg (Treaty of Xanten, 1614).

Bohemian and Palatine War (1618–23). This war began with the insurrection, in 1618, of the Bohemian and Austrian Estates against the future emperor Ferdinand II, whose intention was to impose absolutist rule and to enforce the Catholic Counter-Reformation. The Bohemian nobles toyed with the idea of setting up a republic in order to secure the support of the Dutch but eventually, in August 1619, elected as their king the elector Frederick V of the Palatinate in the hope of obtaining the aid of the Protestant Union and Great Britain. Their expectations proved fallacious. Frederick failed to discipline the haughty Bohemian nobles or to rally the Bohemian townsmen and peasants (whom he did nothing to relieve from harsh oppression by their feudal lords) and was abandoned by his German allies as well as by his father-in-law, James I of Great Britain. Ferdinand, although in a very weak position, succeeded in buying the support of Maximilian of Bavaria and the Catholic League at a heavy price in money and land. In a campaign of a few months, the League's troops under Johann Tserclaes von Tilly crushed the Austrian Estates and broke the rule of Frederick in the Battle of the White Mountain, near Prague (Nov. 8, 1620). The conquest of Glatz (Klodzko) on Oct. 25, 1622, completed the subjugation of the lands of the Bohemian crown.

Battle of the White Mountain

In the meantime, the Spaniards from their bastions in Luxembourg and in Franche-Comté had since 1620 been overrunning the Rhenish Palatinate, where Tilly joined them in 1662, after he and Maximilian had in 1621 subdued the Upper Palatinate (north of Bavaria and west of Bohemia). Tilly also overcame the badly coordinated actions of several German princelings and generals who, in the pay of the United Provinces, Denmark, and England, still upheld Frederick's cause, notably, Ernst von Mansfeld and Christian of Brunswick. Whereas the Protestant Union had dissolved itself (May 1621), Lutheran Saxony, which had never adhered to the Union, was won over to the emperor by the offer of Lusatia. The defeat of Christian of Brunswick by Tilly at Stadtlohn (Aug. 6, 1623) left the situation as follows: the emperor was in undisputed control of his Austrian and Bohemian territories; Maximilian of Bavaria, who was created elector, had become the leading power in southern and northwestern Germany; the Spaniards were in possession of the Rhenish Palatinate; and Frederick was a landless exile, living on the bounty of the Dutch.

The Valtellina

Struggle for Graubünden (1620–39). The Valtellina, leading from the northern frontier of the Duchy of Milan through the Alps toward Tirol, opened the shortest and safest land route between Spanish Italy and the Austrian territories in Germany, whence the Spaniards could reinforce their troops in the Netherlands and in the Palatinate. It belonged to Graubünden, or the Grisons, a union of leagues in loose relations with the Swiss. Spain and Austria obviously wanted to bring the Union's lands under their own control; France and Venice naturally opposed the forging of this link, which would have completed encirclement of both of them by the Habsburg powers. The political and military issues were here poisoned by religious, personal, local, and clannish rivalries, of which Georg Jenatsch was the stormy centre. A Spanish occupation of the Valtellina (1620), reinforced by an Austrian incursion into the other territories of Graubünden (1621), provoked French and Venetian protests, which led to the nominal "deposit" of the Valtellina in the hands of the papacy (1623)—in fact a veiled means of prolonging Spanish control there. Then Richelieu ventured on the first French occupation of Graubünden (1624–26); but the internal weakness of France, where Richelieu's regime was challenged on the one hand by the pro-Spanish faction of Catholic zealots (the Parti Dévot) and on the other by the Huguenots, made it impossible to maintain this indirect attack on Spain. The Treaty of Monzón (1626) made Graubünden into a sort of Franco-Spanish protectorate, with papal troops in occupation. During the War of the Mantuan Succession, the Habsburgs again overran the country (1629–31). A final French occupation (from 1635) was ended in 1639 by a reaction of Graubünden against the French. Eventually the Peace of Milan (Sept. 3, 1639), between Spain and Graubünden, brought the country into virtually complete dependence on Spain.

Swedish-Polish War (1621–29). From 1611, Gustavus Adolphus had taken advantage of the "Time of Troubles" and its aftermath in Muscovite Russia; and by the Peace of Stolbova (1617) he had acquired Karelia and Ingria, which together constituted the land bridge between Swedish Finland and Swedish Estonia, so that the Gulf of Finland was converted into a Swedish lake. He then turned against Poland (1621). His conquest of Livonia gave him Riga, the chief Baltic port (though the Swedish nobles possessed themselves of the largest land properties in the country, to the detriment of the Swedish crown); and from the Duchy of Prussia, Poland's vassal, he took the ports of Memel and Pillau, the latter commanding the approach to Königsberg. Sweden's position in the Baltic, however, was eventually endangered by the course of the Danish War, as the imperial general Wallenstein conquered Mecklenburg (with the ports of Wismar and Rostock) and threatened moreover to conquer Pomerania; and in summer 1628 Swedish forces were sent to help the port of Stralsund, which Wallenstein was besieging. Finally, the Truce of Altmark (Sept. 25, 1629) was concluded between Sweden and Poland, largely thanks to French mediation. Livonia and the Prussian ports were left in Sweden's possession.

Danish War (1625–29) and the Edict of Restitution. Christian IV of Denmark had observed strict neutrality during the Bohemian War despite repeated Dutch attempts to enlist his help on behalf of Frederick of the Palatinate. In 1624, however, he began to contemplate offensive action. His motives were rivalry of Sweden in the Baltic regions and the wish for Danish supremacy in the estuaries of the Elbe and Weser. The king's election, in spring 1625, as director of the Lower Saxon Circle of the empire furnished him with the legal pretext for interference in Germany. The Treaty of The Hague (Dec. 9, 1625), in the negotiation of which the British statesman George Villiers, 1st duke of Buckingham, played a major part, promised British and Dutch subsidies for a military effort by Denmark on Frederick's behalf, in cooperation with the German generals who had already tried to uphold the latter's cause; and this Protestant coalition could expect the sympathy of the Habsburgs' other enemies—prince Gábor Bethlen of Transylvania, the Ottoman Turks, and also Catholic France.

Protestant coalition

The coalition's plan seems to have envisaged a fourfold advance: Christian of Brunswick was to overpower the Wittelsbach bishoprics and duchies in Westphalia and in the lower Rhineland; Christian IV of Denmark was to make himself master of Lower Saxony; Ernst von Mansfeld, generalissimo of the coalition, was to press forward into Bohemia, Silesia, and Moravia; and Bethlen was to sally forth from Hungary and join forces with Mansfeld.

On the opposite side were ranged the veteran troops of the Catholic League under Tilly, who was to deal with Christian of Brunswick and with Christian IV of Denmark, and the imperial army of Wallenstein, who was to repel Mansfeld and Bethlen.

On both sides the generals were on bad terms with one another and never effectively coordinated their efforts. But Tilly and Wallenstein had the advantage of fighting on interior lines and could therefore tackle their adversaries in turn. The coalition, on the other hand, was weakened by the faithless policy of Charles I of Great Britain, who failed to honour his financial obligations and let Buckingham embark on a foolish expedition against France in aid of the Huguenots of La Rochelle (June–November 1627). Wallenstein forced Mansfeld out of northern Germany (Battle of Dessau, April 25, 1626); and Mansfeld, though he held a strong position in Silesia, neither made full use of anti-Habsburg movements (apart from discontent in the Bohemian lands, a peasants' revolt broke out in Austria in May) nor effected a junction with Bethlen and the latter's Turkish auxiliaries. Wallenstein outmanoeuvred Bethlen, and Mansfeld died on his way to Venice (Nov. 29, 1626), whence he hoped to receive fresh subsidies. Isolated Danish troops maintained themselves

in Silesia until the autumn of 1627, when Wallenstein overwhelmed them.

Meanwhile, Tilly was favoured by the untimely death of Christian of Brunswick (June 16, 1626) and by the military incompetence of Christian IV of Denmark. The Danish Army suffered a crushing defeat in the Battle of Lutter (Aug. 27, 1626). In 1627 Tilly pursued the beaten Danes into Holstein; and Wallenstein, who joined him, continued the pursuit into Jutland. Mecklenburg, whose dukes had sided with Christian, was given by the emperor to Wallenstein, who immediately set about obtaining bases on the Baltic for an imperial navy. His attempt to add the Pomeranian port of Stralsund to his Mecklenburg ports of Wismar and Rostock led to the intervention of Gustavus Adolphus.

Wallenstein's contact with maritime affairs changed his whole outlook. His first sight of large river barges on the Oder had made him believe that they were oceangoing capital ships; but he now realized the importance of sea power and overseas trade and reassessed the political position that the emperor might take up with regard to the Hanse towns, Denmark, the Netherlands, England, and Spain. Denmark, which he wished to draw into the emperor's interest, profited by his mediation: at the Peace of Lübeck (May 22, 1629) Christian IV had only to renounce further participation in the affairs of the empire.

The defeat of the anti-Habsburg coalition raised the position of the emperor to its greatest height since Charles V's victory over the League of Schmalkalden in 1547. Edict of Restitution

Ferdinand II's Edict of Restitution (March 6, 1629), prescribing the recovery by the Catholics of all ecclesiastical lands in which Protestantism had been established since 1552, was more than an act of reparation of the damage suffered by the Catholic Church since Luther's time: it was an unambiguous assertion of the imperial prerogative in all matters pertaining to the constitutional structure of the empire. At the Electoral Diet of Regensburg (1630) the opposition, led by Lutheran Saxony (anxious to retain its threatened acquisitions) and by Catholic Bavaria (determined to counteract the emperor's aggrandizement) forced Ferdinand to dismiss Wallenstein and so to make himself defenseless at the very moment when Gustavus Adolphus had landed on German soil.

War of the Mantuan Succession (1628–31). The death of Vincenzo II Gonzaga, duke of Mantua and Montferrat, on Dec. 26, 1627, led to the first direct clash between the Habsburgs and France, albeit on a secondary theatre of war. The claims of the legitimate Gonzaga heir, Charles, duc de Nevers, whom France supported, were overridden by Ferdinand II, supreme lord of the imperial fiefs in Italy; and Spain lent military aid to Ferdinand so as to keep a French vassal away from the approaches to Milan. Richelieu, however, was soon stronger. The Huguenot rebels of La Rochelle capitulated to Louis XIII (autumn 1628); Savoyard forces, which attempted to block the French kings's way into Piedmont, were defeated at Susa (March 6, 1629); and the Peace of Susa with England (April 14), followed by the submission of the Huguenot rebels in Languedoc to the Peace of Alais (June 28), secured the French rear. The Habsburg forces withdrew from Casale in October 1630; and Richelieu, who in November triumphed over the pro-Spanish faction in France (the so-called Day of Dupes), achieved full success. By the Treaty of Cherasco (1631), the French candidate was installed in Mantua. Meanwhile, Savoy had ceded the fortress of Pinerolo to France; and Pope Urban VIII, determined opponent of the Habsburgs, annexed Urbino, another vacant imperial fief. The Austro-Spanish monopoly in Italy was broken.

Swedish War (1630–35) and the Peace of Prague. The suspension of hostilities between Sweden and Poland freed Gustavus Adolphus to intervene in Germany. After landing at Usedom (July 6, 1630), he quickly occupied the whole duchy of Pomerania and restored Wallenstein's duchy of Mecklenburg to its hereditary dukes. He concluded the Treaty of Bärwalde (Jan. 23, 1631) with France, whereby he was to receive annual subsidies of 1,000,000 livres to enable him to campaign for the restoration of the "liberty" of the German princes "oppressed" by the emperor. In these circumstances an immediate objective for Gustavus was to stop the enforcement of the Edict of Restitution on Magdeburg, which commanded a strategic crossing point on the Elbe; but his advance into central Germany was impeded by the hardly veiled hostility of the electors George William of Brandenburg and John George I of Saxony. Saxony tried at the Convent, or Conference, of Leipzig (February 1631) to establish a neutral party between the emperor and Sweden, which proved unacceptable to either. Though Gustavus stormed the Brandenburg fortress of Frankfurt an der Oder (April 13), thereby both securing his left flank against the Poles and intimidating the two electors, the delay led to the fall of Magdeburg to Tilly (May 20). Brandenburg and Saxony now yielded to the Swedish threats, especially as Tilly imprudently invaded Saxony and treated it as enemy country. Alliances with Brandenburg (June 20) and with Saxony (September 11) protected Gustavus' rear and virtually rendered the electorates Swedish satellites. The defeat of Tilly at Breitenfeld (September 17) and the conquest of Prague (November 15) by the Saxons under Hans Georg von Arnim opened southern Germany to the Swedes. Battle of Breitenfeld

The smaller German Protestant princes, such as Bernhard of Saxe-Weimar, flocked to Gustavus' standards; by April 1632 Gustavus had advanced as far as Munich, and his armies had reached Lake Constance to the south and Mainz to the west. The archbishopric of Mainz and the Rhenish Palatinate were placed under Swedish administration; the bishoprics of Würzburg and Bamberg were given to Bernhard as a Swedish fief under the name of Duchy of Franconia. The king's war aims gradually widened: his agreements with the German princes became more onerous, and the stipulations that the Treaty of Bärwalde had made for the protection of France's friends and of the Catholic religion were treated lightly. Gustavus did not aim at the imperial crown, but his secret negotiations with Wallenstein show that he thought of placing the Habsburg dominions under the rule of Swedish puppets.

The recall of Wallenstein to the leadership of the imperial army completely changed the situation: Gustavus was manoeuvred out of southern Germany and shortly afterward was killed in the Battle of Lützen (Nov. 16, 1632). While the conduct of Swedish military operations then fell to Johan Banér and subsequently Lennart Torstenson, the direction of policy was undertaken by the chancellor, Axel Oxenstierna, who, by the Treaty of Heilbronn (April 23, 1633), consolidated the Swedish alliance with the German princes, albeit without Brandenburg and Saxony. Wallenstein's victory at Steinau in Silesia (October 11) and Bernhard's capture of Regensburg (November 14) cancelled each other out, and Wallenstein's machinations to make himself the arbiter of affairs caused the emperor to have him murdered (Feb. 25, 1634); but the Swedish defeat at Nördlingen (Sept. 5–6, 1634) led to the dissolution of the League of Heilbronn and to the open defection of most German princes, led by Saxony, from the Swedish cause.

The Peace of Prague (May 30, 1635) reconciled the emperor and nearly all the German opponents of the Edict of Restitution, which it modified by making the year 1627 the criterion of rightful possession of ecclesiastical lands (instead of 1552). Thenceforth, Sweden played only a subordinate part in the war. The leading role fell to France.

War of Smolensk (1632–34). From *c.* 1628, Gustavus Adolphus and Richelieu had been trying to bring about alliances with Russia, Turkey, Transylvania, the Crimean Tatars, and the Ukrainian Cossacks, who were to engage the emperor and Poland on their eastern frontiers. Concerted action, however, proved difficult to achieve. But Moscow gave Gustavus considerable indirect aid by selling to Sweden, on a cash-and-carry basis at an artificially low price, cereals that the Swedes resold in Amsterdam at considerable profit: between 1628 and 1633 the Swedes bought Russian grain at a cost of 100,000 talers per annum and sold it at 400,000 talers per annum (the latter sum being equal in amount to the direct subsidy received annually from France). Russo-Swedish military coopera- Swedish-Russian cooperation

tion was eventually achieved, largely through the efforts of Sweden's envoy Alexander Leslie (later earl of Leven in the peerage of Scotland): the Russians invaded Poland in autumn 1632 and besieged Smolensk, while Gustavus Adolphus moved eastward and ordered his general Carl Gustav von Wrangel to prepare an offensive from his bases in Prussia.

The great scheme came to nought. The deaths of Gustavus Adolphus and of the Moscow patriarch Philaret (October 1633), who had been the two chief architects of Swedish-Russian cooperation, removed the mutual goodwill as the basis for a real alliance. Turkey, moreover, was committed in a war with Persia; the Tatars of the Crimea turned against Muscovy instead of Poland; and the revolt of the Ukrainian Cossacks against their Polish overlords was delayed. Finally, an insurrection of the peasants in central Russia forced Tsar Michael's government to conclude the Peace of Polyanov with Poland (June 14, 1634).

French and Swedish War (1635–48). The near-collapse of the Swedish system in Germany in 1634–35 forced Richelieu to abandon his cautious policy of nonintervention. He concluded offensive and defensive alliances with the United Provinces (Feb. 8, 1635) and with Sweden (Treaty of Compiègne, April 28), sent a French army to the Valtellina (March–April), and declared war on Spain (May 19). He then secured an alliance with Savoy and Parma (League of Rivoli, July 11); mediated the 20-year Truce of Stuhmsdorf between Sweden and Poland (September 12); and took the best of the German generals still serving Sweden, Bernhard of Saxe-Weimar, into French pay (October 27).

In 1636 the invasion of northern France from the Spanish Netherlands by Ottavio Piccolomini, whose capture of Corbie (August 15) threatened to expose Paris, was outweighed by a series of Swedish victories over Saxon and imperial forces, culminating in Banér's defeat of Melchior von Hatzfeldt at Wittstock (October 4), which reestablished Swedish supremacy in northern and central Germany. A careless northward movement of the imperial commander in chief, Matthias Gallas, in 1637, laid southern Germany open to the French; and Bernhard of Saxe-Weimar, having overrun Alsace, in 1638 conducted a brilliant campaign in the course of which he took the key fortresses of Rheinfelden (March 23), Freiburg (April 6), and Breisach (December 17). Before Bernhard's death, the incompetence of the French led to Piccolomini's great victory of Thionville (June 7, 1639), which, however, was to be the last success of the Austro-Spanish armies. The outbreak, in 1640, of revolution both in Catalonia and in Portugal compelled the Spaniards to limit their commitments outside the Iberian Peninsula. The capitulation of the great stronghold of Arras to the French (Aug. 9, 1640) endangered the Spanish position in the Netherlands, and a Spanish counteroffensive into Champagne ended with the French victory at Rocroi (May 19, 1643), won by the young duc d'Enghien (Prince de Condé).

In Germany the various commanders—French, Swedish, Bavarian, and imperial—waged war almost on each one's own responsibility: no coherent pattern can be found in those campaigns, which were nearly always small-scale raids with limited objectives. The Swedish victory over Saxon and imperial forces at Breitenfeld (Nov. 2, 1642) and the capture of the Little Town quarter of Prague by the Swedes (July 26, 1648) are—besides the Swedish campaign against Denmark—the most notable military events of these years. They were overshadowed by the diplomatic activity that began in 1640 and ended in 1648 with the Peace of Westphalia.

During the French and Swedish War, death had removed three great figures from the international scene: the emperor Ferdinand II on Feb. 15, 1637, leaving the succession to his son Ferdinand III; Richelieu on Dec. 4, 1642; and Louis XIII of France on May 14, 1643. Richelieu's place was taken by Cardinal Mazarin during the regency for Louis XIV.

Swedish-Danish War (1643–45). The precarious situation of the imperial cause after Breitenfeld and the Danish jealousy and fear of Sweden brought about an understanding between Ferdinand III and Christian IV; and Sweden's decision to wage a preventive war against Denmark gave the emperor a respite, since the Swedish army under Torstenson had to abandon its march on Vienna (September 1643) and to turn northward instead. In a lightning campaign (December 1643–January 1644) Torstenson conquered Schleswig-Holstein and Jutland. When an imperial army under Gallas came to the succour of the Danes, Torstenson at once marched against him, destroyed his army at Jüterbog (Nov. 23, 1644), and invaded Bohemia, where another imperial army was wiped out at Jankov (March 6, 1645). By the Peace of Brömsebro, signed on Aug. 23, 1645, Denmark ceded Jämtland and Härjedalen on the Norwegian frontier, Halland on the Kattegat, and the Baltic islands of Gotland and Ösel to Sweden.

Peace of Westphalia (1648). Treaties signed in the Westphalian towns of Münster and Osnabrück terminated both the Eighty Years' War between Spain and the United Provinces of the Netherlands (Jan. 30, 1648) and the war between France, Sweden, and the German Protestants on the one side and the emperor and the German princes on the other (October 24). The Peace of Prague (1635) between the emperor Ferdinand II and the majority of the German princes had proved abortive: it expressed too much the temporary ascendancy of the emperor, took little account of Sweden, and completely disregarded France, which at that very moment openly took up arms against Spain and the emperor. No general peace was possible without the participation of Sweden, France, and Spain; and in 1640 the parties began in earnest to prepare the summoning of a peace congress. The emperor Ferdinand III entered into secret negotiations with Sweden in Hamburg; the Imperial Diet demanded a universal congress instead of bilateral transactions. The renewal of the Franco-Swedish alliance on June 30, 1641, included the stipulation that two congresses be held simultaneously in neighbouring Westphalian towns: the Catholic envoys were to meet in Münster, the Protestant envoys, in Osnabrück.

In 1643–44 Sweden and France sent out the first invitations, and the congress began to take shape. The slow and tortuous negotiations about procedure and substance, protocol and ceremonial, the admission or rejection of envoys and mediators—all these fumblings, which went on right to the actual signing of the treaties—were mostly due not to obstruction but to inexperience. By trial and error the congress had to explore and define the methods of modern international diplomacy. The 150 representatives (about 110 Germans and 40 foreigners) lacked any precedent for their tasks, starting, as it were, from scratch every time a fresh topic turned up. They gradually developed a kind of esprit de corps, which cut across political and religious frontiers and contributed not a little to the realistic settlement, which was satisfactory to all but a few diehards.

The negotiators

Though the plenipotentiaries were bound fairly narrowly by instructions from their governments, a few figures stand out to whom the successful outcome was largely due. The imperial ambassador, Maximilian Graf von Trauttmansdorff, outshone the rest; he had been the architect of the Peace of Prague and became the main author of the Peace of Westphalia. He and his chief secretary, Isaac Volmar, were converts to the Roman faith and therefore understood the opposing positions and did their best to check the firebrands in the Catholic camp. France was brillantly represented by the duc de Longueville (Henry d'Orléans) and his duchesse (Anne Geneviève de Bourbon-Condé), but as members of the princely faction they were suspect to Mazarin. Mazarin also mistrusted France's principal actual negotiator, Claude de Mesmes, comte d'Avaux, whereas the latter's equally skillful but more ruthless colleague, Abel Servien, enjoyed the cardinal's confidence; their mutual antagonism, however, in no way impaired their efficiency as representatives of the French crown. Similar dissensions rent the Swedish mission: Johan Oxenstierna, the chancellor's son, stood for the policy of conquest sponsored by the Swedish nobility, whereas Johan Adler Salvius, a gifted and experienced

diplomat of humble birth, sided with the young queen Christina in wishing for peace at almost any price. The Spanish ambassadors, the conde de Peñaranda (Gaspar de Bracamonte) and Antonius Brun, succeeded in terminating the war with the Dutch (Jan. 30, 1648) with great sacrifice to Spanish power but without loss to Spanish honour.

The Brunswick counsellor, Jacob Lampadius, stands out as the expert in all legal problems and the Lübeck envoy, David Gloxin, as the champion of the mercantile interest. Johann Rudolf Wettstein, of Basel, was accredited only as a representative of the Swiss Protestant cantons but acted on behalf of the whole Swiss Confederation. Lastly, the two unofficial mediators must be mentioned—the papal nuncio Fabio Chigi (later Pope Alexander VII) and, especially, the Venetian diplomat Alvise Contarini: they employed their good offices for smoothing out factional divisions and keeping alive the mutual interests of the European comity of nations.

Territorial settlement. The territorial clauses of the peace treaty all favoured France, Sweden, and their allies.

Sweden obtained the largest share: Hither Pomerania (Vorpommern), with Stettin and sole control over the Oder estuary; the Mecklenburg port of Wismar; and the archbishopric (but not the city) of Bremen and the bishopric of Verden, with control over the Elbe and Weser estuaries. In addition, there was the "satisfaction" of the Swedish Army, amounting to 5,000,000 talers guaranteed collectively by the members of the empire.

French gains

France incorporated the cities and bishoprics of Metz, Toul, and Verdun in Lorraine (French protectorates since 1552) and added to them the suzerainty over the secular vassals of the three bishops. France also obtained the ill-defined feudal rights exercised by the emperor over various towns, villages, and districts in Alsace (excluding Strassburg but including the bridgehead of Breisach), and the permanent right to garrison Philippsburg, on the right bank of the Rhine south of Speyer. These gains appeared modest. The possession of Breisach and Philippsburg, however, laid all southern Germany open to French arms; and the deliberate vagueness of the clauses relating to the cessions in Lorraine and Alsace later provided the legal or casuistical pretexts for the wars of aggression waged by Louis XIV.

The only major setback that France suffered was the conclusion of the separate peace between Spain and the United Provinces. This deprived France of an ally in the rear of the Spanish Netherlands and prolonged the Franco-Spanish War by a decade.

The gains and losses of the German princes were determined by the convenience of the principal powers: France, Sweden, and Austria. These used the claims of their lesser partners as pawns mainly for adjusting differences among themselves at somebody else's expense.

Brandenburg obtained Farther Pomerania (Hinterpommern); the bishoprics of Kammin, Halberstadt, and Minden; the county of Hohnstein; and the reversion of the archibishop of Magdeburg on the death of the existing administrator, Augustus of Saxony (which occurred in 1680). Bavaria was to keep the Upper Palatinate and the electoral dignity, but the Rhenish Palatinate was restored to Frederick V's heir, Charles Louis, for whom a new electorate was created. Saxony retained what had been secured at the Peace of Prague, namely, Lusatia and Magdeburg, but the latter only for the lifetime of the present administrator. Hesse-Kassel ousted Hesse-Darmstadt from the district of Marburg and incorporated the abbey of Hersfeld and the county of Schaumburg. The Welfs of Brunswick obtained the right to have one of their princes elected as Protestant administrator of Osnabrück in alternation with a Catholic bishop. Mecklenburg was compensated for the loss of Wismar by the bishoprics of Schwerin and Ratzeburg.

Finally, the United Provinces of the Netherlands and the Swiss Confederation were released from their legal obligations toward the empire and so recognized as independent republics.

Political and religious settlement for Germany. For Germany, the Peace of Westphalia brought to a conclusion the century-old struggle between the monarchical tendencies of the emperor and the federalistic aspirations of the princes. Ferdinand II had made considerable progress in revitalizing the imperial power: without consulting the electors or princes, he had arrogated to himself the outlawry of Frederick V of the Palatinate and the transfer of the latter's electoral dignity to Maximilian of Bavaria (1623) and the deposition of the dukes of Mecklenburg (1628); on his own authority, he had interpreted, that is, in fact, rescinded, the Peace of Augsburg by the Edict of Restitution (1629), thereby superseding the legislative authority of the Imperial Diet; and by the Peace of Prague (1635), he had transformed all princely troops into contingents of an army under his supreme command and abolished the princes' traditional right to conclude alliances among themselves or with foreign powers.

The Peace of Westphalia completely reversed this trend. It confirmed the full sovereignty of the members of the empire, including their right to form alliances, restricted only by the meaningless proviso "except against the emperor and *Reich*." It bound the emperor to the decisions of the Imperial Diet in all matters concerning war and peace. The Diet, which during the past 40 years had met only three times (1608, 1613, 1640–41), increased its sphere of competence at the expense of the emperor as well as the electors; the Protestant administrators of the secularized bishoprics were admitted with full voting rights. From 1663 the Diet remained in permanent session at Regensburg.

The peace established equality of rights between Catholics, Lutherans, and Calvinists: the supreme court of the empire was to be staffed by 26 Catholics and 24 Protestants, and Protestants were admitted to the Aulic Council in Vienna. The Edict of Restitution was repealed, and 1624 was declared the "standard year" according to which territories should be deemed to be in Catholic or Protestant possession. Except in the Habsburg dominions, where toleration was not granted to non-Catholics, dissidents were allowed private worship, liberty of conscience, and the right of emigration. Religious disputes were not to be decided by majority vote of the Imperial Diet but to be solved amicably between the Corpus Evangelicorum (the Protestant states collectively) and the Corpus Catholicorum, organized under the directorate of Saxony and of Mainz respectively.

Franco-Spanish War (1648–59). The conclusion of a separate peace with the United Provinces helped Spain to continue the struggle against France; and Condé's victory over the Spaniards at Lens (Aug. 20, 1648) was offset by the outbreak of the Fronde. During these civil wars in France (1649–53), the rebel leaders, including Condé, even made treaties of their own with Spain. Success came to the French from 1655, especially after the outbreak of hostilities between Spain and England and the conclusion of Anglo-French treaties of friendship (Sept. 5, 1656) and of alliance (March 23 and May 9, 1657). Robert Blake's exploits in the Mediterranean and in the Caribbean (1655–57), followed on land with the Battle of the Dunes (June 14, 1658) and the capture of Dunkerque (June 25) and Gravelines (Aug. 24, 1658), broke Spain's resistance. In the Franco-Spanish Treaty of the Pyrenees (Nov. 7, 1659), France obtained Roussillon and northern Cerdagne (thus establishing the frontier along the line of the Pyrenees), Artois, and a number of frontier fortresses in the Netherlands and Luxembourg. Spain had ceded to France the first place among the great powers of Europe.

Treaty of the Pyrenees

First Northern War (1655–60). The last decade of the 50-year period here surveyed witnessed another conflict in northern Europe. It arose, however, from the start of the Thirteen Years' War between Russia and Poland (1654–67), which is best considered as belonging to a later historical period, characterized by the decline of Poland and by the rise of Russia and of Brandenburg-Prussia. In so far as it reaffirmed certain tendencies of the earlier period, it may be briefly summarized here.

The question of the Ukraine led to war between Russia and Poland in 1654. Charles X of Sweden took advantage of this war to attack Poland in July 1655. The elector Frederick William of Brandenburg took the Swedish side

from 1656 to 1657 but changed to the Polish in 1658. Russia began war against the Swedes in June 1656 but concluded the Truce of Valiesari in December 1658. In 1657 the emperor Ferdinand III's heir, Leopold I, allied Austria with Poland. Frederick III of Denmark attacked Sweden in June 1657.

Baltic settlement

By the Peace of Roskilde (Feb. 26, 1658), Denmark was forced to cede to Sweden not only Trondheim on the North Sea coast of Norway but also Bohuslän on the Swedish coast at the end of the Skagerrak, Skåne on the eastern side of the Sound, with adjacent Blekinge, and the island of Bornholm, thus forfeiting all hope of the "lordship of the Baltic." Denmark, however, subsequently refused to close the Baltic to Western shipping and was attacked by Sweden again in summer 1658. The Dutch, in their own commercial interests, came to Denmark's support, and the Treaty of Copenhagen (June 6, 1660) restored Bornholm and also Trondheim to Denmark, but otherwise confirmed the settlement of Roskilde.

The Peace of Oliva (May 3, 1660), between Sweden on the one hand and Poland, Austria, and Brandenburg on the other, assigned Livonia to Sweden and recognized Brandenburg's full sovereignty over ducal Prussia, both these stipulations being made at Poland's expense. The Russo-Swedish Peace of Kardis (July 1, 1661) re-established the terms of the Peace of Stolbova (1617).

France had played an active role in mediating the Baltic settlement. Habsburg Austria had gained nothing from the conflict and was meanwhile confronted by the League of the Rhine (Aug. 14, 1658), organized by Mazarin, whereby France, Sweden, the electoral archbishoprics (Mainz, Cologne, and Trier), Münster, Brunswick-Lüneburg, Palatinate-Neuburg, and Hesse-Kassel guaranteed the Peace of Westphalia against Habsburg revisionism.

GERMAN CIVILIZATION

The population. Any estimate of the movement of population of Germany between 1600 and 1650 is hampered by the absence of any census before the 18th century and the vagueness of the territory to which any statistics could be applied. All assertions of a decline of the population during the war by one-third or even more are therefore baseless guesswork. The computation of the population of "Germany" as a whole at the beginning or the end of the war would differ by about one-quarter or more according to the inclusion or exclusion (either of which can be defended on historical grounds) of certain territories, such as the Netherlands, Switzerland, Schleswig-Holstein, Brandenburg's Polish fief of Prussia, Spain's French-speaking possessions in Luxembourg and in Franche-Comté, French-speaking Lorraine, the Slav-speaking parts of Austria's possessions (Bohemia, Moravia, Carniola, Styria), and the Italian-speaking Trentino.

Such statistical surveys as were occasionally made for a small district were nearly always prompted by the wish to support some special pleading: to obtain a grant-in-aid, to reduce a tax assessment, to avoid military service or statute labour. The main sources on which historians have drawn are the reports of chroniclers and, rarely, parish registers of death—to the virtual exclusion of registers of marriage and baptisms. In view of the huge birthrate this neglect amounts to 30 to 50 percent; *i.e.*, to that one-third or one-half by which the population is said to have been reduced.

Death on the battlefield can be left out of count because the armies of the time, and consequently their losses, were very small. The Catholic League had an effective strength of about 15,000 men; Gustavus Adolphus landed in Germany with 15,000 men; Bernhard of Saxe-Weimar received French pay for 18,000 men; the strongest French army employed in Germany (in 1645) numbered 12,000; the first imperial army raised by Wallenstein in 1625 consisted of 15,000 foot and 6,000 horse.

The most serious losses were caused by epidemics, especially typhoid, the plague, and venereal diseases, spread by soldiers and refugees and intensified by lack of hygiene and the incompetence of doctors. A few chance survivals of accurate lists of victims make it certain, however, that during the worst outbreaks of the "pest" (the generic name applied to every epidemic) the mortality reached only 12 percent, and that in thickly populated towns. The average annual mortality rate seems to have been around 6 to 8 percent.

Internal migration

The most plausible explanation of the depletion of certain parts of Germany is to be found in an extensive internal migration, chiefly from the agrarian village to the industrial town and from the economically declining to the economically prosperous town (as for instance from Cologne to Frankfurt). But there was also a considerable fluctuation of refugees and evacuees from open country to the safety of the walled town: Kiel and Lübeck served as refuges for the gentry of Holstein. A typical example of this temporary dislocation of the population can be seen in five Thuringian rural districts for which accurate statistics have been computed: numbers declined during the years 1631–49 between 66 and 87 percent, and increased in the decade 1649–59 by between 78 and 125 percent. The net result of this redistribution of population was an all-around though small increase of the total population such as is characteristic of every predominantly agricultural society. Bearing in mind the elasticity of the term Germany, one can assume a population of 15,000,000–17,000,000 in 1600 and one of 16,000,000–18,000,000 in 1650, as may be inferred from the figure (fairly well attested) of 10,000,000–17,000,000 for the Empire in 1700.

Economic life. The years around 1620 saw German economic life at its lowest point. For centuries its strength, like that of Italy, had lain in the flourishing towns, where industry, banking, and trade (import and export) were concentrated. From the middle of the 16th century, the heyday of their prosperity was over. Politically, the free cities succumbed to the growing power of the territorial princes; only a few—Lübeck, Hamburg, Bremen, Danzig, Nürnberg, Augsburg, Frankfurt—maintained more than an outward semblance of independence.

Economically the Hanse towns of northern Germany were severely hit by the Muscovites' destruction of Novgorod (1570), by the Spaniards' sack of Antwerp (1585), and by Queen Elizabeth I's closing of the London Steelyard (1598); and the separation of the United Provinces from Spain gave to the Hanse's Dutch rivals a free hand to break its monopoly in the Baltic. The southern German cities, whose bankers were deeply involved in the financial transactions of both Austrian and Spanish Habsburgs, were largely ruined by the repeated bankruptcies of the Spanish crown (1557, 1575, 1596, 1607); the insolvency of the Augsburg firm of Welser in 1614 was only the most spectacular debacle of many.

Inflation

The collapse of the old order was made evident in the big inflation of the years 1619–23, which brought utter ruin to the classes dependent on savings, annuities, or fixed incomes but provided colossal gains to versatile financiers and industrialists as well as to unscrupulous speculators and profiteers. The emperor Ferdinand II, who lent his active support to a combine of ruthless racketeers, and the dukes of Brunswick-Wolfenbüttel were conspicuous among the "legal" counterfeiters. When the currency was stabilized again in 1624, a thoroughgoing transfer of capital had occurred: none of the old-established and sometimes decadent firms survived, and their place was taken by pushing upstarts. This changeover of family and business fortunes continued: the proscription of Wallenstein and his adherents in 1634 permitted the Viennese courtiers and generals to acquire for a song the richest Bohemian and Silesian estates.

In fact, the inflation of 1619–23 was the turning point. The outward sign of economic recovery was the establishment of the big clearing banks of Hamburg (1619) and Nürnberg (1621); the Hamburg Mark Banko was for two centuries the most stable international currency unit until the pound sterling superseded it.

In German agriculture, too, a regrouping of ownership and profits rather than a general decline is to be noted. The steady rise of corn prices from the mid-16th century made large-scale farming and bulk selling more profitable; and from the end of the 16th century the feudal owners of big estates practiced wholesale evictions of peasants and forced acquisition of peasant lands, thereby

depopulating the countryside and obliterating hundreds of villages. As far as can be ascertained, those villages that were wholly or partly burned down by the soldiery in the course of the war were all rebuilt and even enlarged before the end of it; and the same is true of Magdeburg, the only town of any size to be severely damaged by enemy action. The wars themselves proved a source of gain to the big landowners, who supplied victuals, grain, and livestock to the contending armies, whereas the small farmers could not compete with the lord of the manor and, moreover, endured greater hardship from marauding troops than did the townsman. Especially in those areas that suffered least from the military invasions—Prussia, Pomerania, Brandenburg, and Mecklenburg—the formerly-free farmers were reduced to virtual or legal serfdom.

Apart from the destructive effect of every war, it must be borne in mind that all the campaigns of the first half of the 17th century were of short duration and almost invariably centred around the same focal points that, by their geographical position, have been fought over again and again from time immemorial: the Alpine passes, the Rhine crossings, the bridgeheads of Regensburg on the Danube and Magdeburg on the Elbe, the plains of Leipzig and Brabant. The resilience of the people of these districts, however, has always been equal to their plight—as can be seen, for instance, at Leipzig. That city went bankrupt in 1625, was bombarded and stormed in 1631, 1632, 1633, 1637, and 1642, witnessed the major battles of Breitenfeld (1631 and 1642) and Lützen (1632) before its very gates, and was under Swedish occupation from 1642 to 1650; but in these years the annual Leipzig Fair established itself as the centre of European trade, and in 1640 the town council reported regular trade relations with Italy, Poland, England, Brabant, Scandinavia, the Ukraine, and the intermediate countries. Parts of Germany were affected by hostilities for a few weeks, others not at all. Most towns never saw an enemy within their walls.

Atrocity stories

Of all the wild exaggerations concerning the moral degeneration of the German people caused by the Thirty Years' War, that of cannibalism due to famine and starvation has a morbid appeal, which few writers have been able to withstand. The refutation of these stories is the more difficult as the original accusations were vague, the source material is buried in the files of rural magistrates' courts, and critical investigations are scattered in obscure journals. It seems that one case of cannibalism can be taken as established: it occurred among the starving garrison of Breisach during the long seige in 1638. A second case proved in court is that of a Silesian bandit tried in 1654: having killed a pregnant woman, he ate her unborn child's heart in order, as he confessed, to make himself "stronger and fiercer"—a clear example of a form of superstitious magic known to anthropologists. Every other story of cannibalism that has been investigated can be shown to be the adaptation of some classical or medieval fable, if not simply a journalistic stunt. Thus, a contributor to a popular serial in 1639 startled his readers with the rhetorical question: "Has Germany become America? Cannibals now openly walk about. . . ." The vicar of a Palatine village, asking his co-religionists abroad for donations, asserted that "food is so scarce that the dead are no longer safe in their graves." This unsubstantiated hint proved so effective that thenceforth no appeal to charity dispensed with references to body snatching and cannibalism.

Literature and the arts. The great impetus of the Renaissance and the intellectual fervour of the Reformation had exhausted themselves by 1570, just when Italy, France, England, Spain, and the Netherlands entered upon a fresh period of cultural grandeur. From the general European point of view, Germany was overshadowed and virtually ceased to count as an independent contributor in the cultural field. The picture of the years 1600–50, however, is different when studied from the narrower German angle. From the start of the 17th century onward, German scholars, scientists, musicians, writers, and poets were coming again to the fore and producing works that were to have lasting influence upon German culture.

The Baroque

The legend of the cultural exhaustion and desolation of Germany during and after the Thirty Years' War is solely due to the aesthetic standards of 19th-century historians, who despised the Baroque style and so could not appreciate the work of Baroque artists and writers. Moreover, the huge spate of German translations, chiefly of Italian, Spanish, and French scholars and scientists, prose writers, and poets, tends to be overlooked.

Italian influence was especially prominent in the German theatre of the time, in which decor, stage effects, and music were combined to produce operatic showpieces: the plays (in Latin) of the Jesuit Jakob Bidermann (1578–1639) and the Passion play of Oberammergau first performed in 1634 are spectacular examples. The composer Heinrich Schütz (1585–1672) helped to establish the fashion for Italian music in Germany with his madrigals, symphonies, and oratorios as well as the first German opera (*Dafne*, 1627) and the first German ballet (*Orpheus und Eurydice*, 1638).

German language and literature had enthusiastic though somewhat pedantic nurseries in the literary societies modelled on the Florentine Accademia della Crusca, of which the Weimar Fruchtbringende Gesellschaft (1617) was the oldest and most influential, followed by the Hamburg Teutschgesinnte Genossenschaft (1643), the Nürnberg Pegnitzorden (1644), and others. Aiming at a purification of the German language, the encouragement of writers, and an improvement of manners and morals, they listed among their members numerous leaders of society and every literary figure of note. Martin Opitz with his *Buch von der deutschen Poeterey* (1624) and Justus Georg Schottel (1612–76) with his *Teutsche Sprachkunst* (1641) standardized the theory of New High German poetics and grammar for 150 years. Opitz's own poetry is unoriginal and largely modelled on the French poets of the Pléiade; but as he tried his hand in every type of fashionable literature and was a prolific translator, his influence was considerable throughout 17th-century Germany. The mystical poems of Friedrich Spee (1591–1635), the epigrams of Friedrich von Logau (1604–55), the Latin odes of Jakob Balde (1604–68), the satirical novels of J.M. Moscherosch (1601–69), the hymns of Simon Dach (1605–59) and of Paul Gerhardt (1607–76), the occasional and patriotic poems of Georg Rudolf Weckherlin (1584–1653), the plays of Andreas Gryphius (1616–64), and the novel, *Die Adriatische Rosemund*, of Philipp von Zesen (1619–89)—these highlights of the German literature of the war years are still read. Their testimony to a flourishing literary life is further supported by the expansion of the two leading German printers and publishers, Endter in Nürnberg and Stern in Lüneburg, whose books, pamphlets, hymnals, calendars, etc., were bought by the middle and lower classes in, at least, every Protestant region of the empire.

The outstanding figure in German science is the astronomer Johannes Kepler, who discovered the laws of the planets while serving successively the emperor Rudolf II, the Estates of Upper Austria, and Wallenstein. Otto von Guericke, who as councillor and burgomaster of Magdeburg supervised the reconstruction of the city after 1631, was the inventor of the air pump and manometer. The Naturwissenschaftliche Gesellschaft, founded in Rostock in 1622, was the first learned society to devote itself primarily to the advancement of science. The English physician William Harvey chose a Frankfurt publisher to bring out his discovery of the circulation of the blood (1628).

In art and architecture, the influence of Palladio and Bernini was strong enough to Italianize all building in the south of Germany, whereas the northwest fell under Dutch influence. Maximilian of Bavaria patronized the Dutchman Peter Candid, a pupil of Giorgio Vasari, as painter and builder for his palaces in Munich and Schleissheim. All the palaces, cathedrals, and churches built in the 17th century by the Habsburg rulers and their courtiers in Vienna, Salzburg, Graz, Innsbruck, and Prague were the work of Italian designers, as were Wallenstein's palaces in Prague, Jicin, and Sagan. On the whole, however, there was little incentive for new building, since the great buildings of the prosperous first three-quarters of

the 16th century still served the need of the majority of their owners. Most private houses of the less well-to-do are artistically insignificant and have therefore failed to gain entry in the histories of architecture. A lively interest in architecture, however, is attested by the success of several textbooks for the instruction of builders and their clients, such as that by Rüdiger Kossmann of Cologne (1630, re-edited in 1644 and 1653) and three by Josef Furttenbach of Ulm (1628, 1640, and 1641).

CONCLUSION

The European struggle against the predominance of Spain is the main topic of all the hot and cold wars, diplomatic moves and alignments, religious and constitutional tensions that fill the history of the first half of the 17th century. The Thirty Years' War, so called, is merely a segment of this general upheaval. The result, in the peace treaties of Westphalia and of the Pyrenees, can be summed up as follows.

In the field of international as well as of German politics, the sovereignty and independence of the individual state was established as the principle on which, thenceforth, the European comity of nations and, in the narrower German context, the framework of the Holy Roman Empire were to be based. For Germany this structure survived, with modifications (notably in the Napoleonic period), until the foundation of the German Empire under Prussian hegemony in 1871; and for western Europe the principle was maintained into the second half of the 20th century. The medieval conception of the theoretical unity of the *respublica Christiana* with the Roman emperor and the Roman pope as its temporal and spiritual heads was formally abandoned in favour of a community of sovereign, independent states, of equal status, regardless of form of government or confession of faith, though united by a common adherence to certain fundamental principles of law and order. This was a first, tentative step toward a European community in which, however, Great Britain and Russia were not included.

Thomas, Dylan

It would seem probable that more myths have been spun about Dylan Thomas and therefore more rubbish written than about any other English-language poet since Lord Byron, a century and a half earlier. For this he was, himself, in some measure responsible. "Bewilder 'em," he said, and his earlier verse did, though it is hard now to see why. He wrote, as he put it, about birth, copulation, and death—the common concerns of man—and, although his imagery is sometimes dense, it is ultimately comprehensible. He also claimed to be "the drunkest man in the world," which he certainly was not, for he had a weak head and really preferred to drink beer. Finally, his wit was fantastic and fraught with puns and other wordplay, so that what he said was often slightly askew. A small, rather sickly man all his life, he assumed in public a Casanova-like role, which was directly contradictory to his long marriage (1936 until his death, early in his 40th year) to his Irish wife, Caitlin Macnamara, who bore him two sons and a daughter. Nevertheless, the myth of the insatiable amorist was added to the others. When he told the journalists in New York that he had come to America as part of his endless quest for naked women in wet mackintoshes, they were, of course, delighted. In fact, his American trips, on the last of which he died in a New York hospital, were made solely to earn money. Throughout his poetic career he was haunted by the thought of death, and perhaps his chief contribution to English poetry was his vision that life and death form part of a great process shared with all nature by the poet's body.

The myth of Dylan Thomas

Thomas, 1952.
Rollie McKenna

Dylan Marlais Thomas was born on October 27, 1914, in Swansea, in southwest Wales, and it was there that he spent his childhood. His father was the English teacher at Swansea grammar school, which in due course the boy attended. Dylan's mother was a small farmer's daughter, so that he had a country home he could go to when on holiday. His poem "Fern Hill" (1946) describes its joys. His mother took him as a child to chapel, which became a source of some of his imagery, although he was not a religious poet in any conventional sense. He always and correctly referred to himself as a Welsh poet, though he had no knowledge of the Welsh language. He also and incorrectly at times maintained that he was of working class origin. His family was well-educated middle class. From his earliest days the father read Shakespeare rather than children's books aloud to the boy at bedtime. Later he arranged that Dylan have elocution lessons to improve, which in this context meant to anglicize, his diction. He himself was to refer to his "cut glass" voice, and anybody who has heard him knows how perfectly he spoke English. Indeed, as a very young amateur actor, he considered taking up the stage as a profession. Those who saw him "performing" later in his life would probably agree that acting was in fact always his second profession—second to that of the poet, of course.

Education and youth

He did badly at school. Indeed, he was always intellectually lazy with regard to any subject that did not directly concern him, but when it did he was exactly the reverse. His knowledge of English poetry, for instance, was enormous, not in the theory but in the practice. He once said that he was not interested in poetry, only in poems. He had begun writing them at a very early age, and scholars have shown that the bulk of his poetic output was completed, at least in embryonic form, by the time he moved to London at the age of 21. This fact is not surprising if it is recalled that he was in youth essentially a lyric poet, and most lyrics are written by very young men.

Dylan Thomas, in Swansea with his and his father's books, was perhaps the last of the Romantic poets, heir to a tradition that stretched back through Rupert Brooke and Siegfried Sassoon, English poets of World War I, to John Keats and Percy Bysshe Shelley, in the 19th century, and beyond that to Thomas Chatterton, in the 18th. As did all of the poets of that tradition, he had to experiment with words. He was perhaps the last major poet to do so, hence the bewilderment when his early poems were first

published in the mid-1930s. Much later he was to write more "epic" work, but never in what anybody could call the classical tradition. He knew most of John Milton by heart, and at the end of his life he was preoccupied with similar themes (*e.g.*, the nature of good and evil in war, the innocent death of a child or an old man murdered by a casual bomb). Among these was an opera libretto based on the epic concept of the atomic destruction of the world, followed by the re-creation of the first man and woman and their discovery of language. This major work, however, is one of the might-have-beens of literature.

First publications

His first book, *18 Poems*, appeared in 1934, followed by *Twenty-five Poems*, two years later. London was his home for some ten years from about 1936. (He made tentative approaches to life in the capital before that, and it also took him some time to move out.) He was famous in literary circles, sociable, and very poor, with a wife and growing family to support. His attempts to make money—with the British Broadcasting Corporation and as a film scriptwriter—were not sufficiently remunerative. He managed, as far as anyone could, to avoid the war (he was excused from military service because of a lung condition), for he regarded himself in those days as a pacifist and occasionally burbled about being a Communist, though his ignorance of politics was as total as was his knowledge of English language poetry. He had, however, an instinctive aversion to the rich and smug and a sympathy for the poor and oppressed. More disastrous than his political ignorance was his total lack of any sort of business acumen. He became badly behind with his income tax returns, and what money he managed to make was snatched from him, at source, by the British Exchequer. He took to drinking more heavily and to borrowing from richer friends. Nevertheless, he continued to work, though with increased knowledge the composition of his poems became an ever slower and more painstaking business—he was nearing the end of the treasure chest compiled in his early youth—while the London or London-based atmosphere became increasingly dangerous and uncongenial both to him and to his wife. As early as 1946 he was talking of emigrating to the United States, but, without any money, how? In the following year he had what would seem to be a nervous breakdown but refused psychiatric or other medical assistance. He moved to Oxford, where he was given a cottage by A.J.P. Taylor, a distinguished historian. His trips to London, however, principally in connection with his BBC work, were gruelling, exhausting, and increasingly alcoholic.

Nervous breakdown

In 1949 Mrs. Taylor financed the purchase of a cottage, the Boat House, Laugharne, and he returned to Wales. In the following year his first American tour was arranged, and for a while it seemed as if a happy compromise had been arranged between American money and Welsh tranquillity. It was then that he wrote his "play for voices," *Under Milk Wood*, an idea with which he had been playing at least since 1945. It was presented at the Poetry Center in New York in 1953, and its final version was broadcast by the BBC in 1954. He also published his *Collected Poems* (1952), an immediate success on both sides of the Atlantic. But, because of the insistence of the Inland Revenue, he still had no money. Indeed, he had come to hate money, and what he could earn or borrow he squandered. Furthermore, he found his American tours exhausting: in Wales it was beer, in the United States and Canada it was whiskey. There were far too many people who seem to have derived pleasure from making the famous poet drunk. Despair mounted, his marriage was in peril, and at last, far from his Welsh home, he took such an overdose of hard liquor that he died, on November 9, 1953. He was on his way to California, to stay with Igor Stravinsky, to write the epic opera he had in mind.

MAJOR WORKS

POETRY: *18 Poems* (1934), including "The Force That Through the Green Fuse Drives the Flower," "Light Breaks Where No Sun Shines," "I See the Boys of Summer," and "Especially When the October Wind"; *Twenty-five Poems* (1936), including "To-day, This Insect," "Hold Hard, These Ancient Minutes in the Cuckoo's Mouth," and "Altarwise by Owl-Light"; *The Map of Love* (1939), including "We Lying by Seasand," "After the Funeral," and "Twenty-four Years"; *Deaths and Entrances* (1946), including "A Refusal To Mourn the Death, by Fire, of a Child in London," "Do Not Go Gentle into That Good Night," "Poem in October," "Ceremony After a Fire Raid," and "Ballad of the Long-legged Bait"; *In Country Sleep* (1952), including the title poem and "Over Sir John's Hill," "Lament," and "In the White Giant's Thigh"; *Collected Poems 1934–52* (1952).

SEMI-AUTOBIOGRAPHICAL PROSE: *Portrait of the Artist As a Young Dog* (1940); *Adventures in the Skin Trade* (1955).

SHORT STORIES: *A Prospect of the Sea* (1955).

DRAMA: *Under Milk Wood* (1954), a radio play for voices.

BROADCASTS: *Quite Early One Morning* (1954).

MOTION PICTURE SCRIPT: *The Doctor and the Devils* (1953), adapted from the story by Donald Taylor.

BIBLIOGRAPHY. J. ALEXANDER ROLPH, *Dylan Thomas: A Bibliography*, with a foreword by DAME EDITH SITWELL (1956), is a most scholarly work. It should be used, however, in conjunction with RALPH MAUD, *Dylan Thomas in Print: A Bibliographical History* (1970). CONSTANTINE FITZGIBBON, *The Life of Dylan Thomas* (1965), is the official biography of the poet, commissioned by his trustees and approved by his widow. This is also true of the *Selected Letters of Dylan Thomas*, ed. by FITZGIBBON (1966). Omitted from *Selected Letters* are most of the *Letters to Vernon Watkins*, ed. with an introduction by VERNON WATKINS (1957), which cast a great deal of light on Thomas' mental activities as a poet, particularly in his earlier years. *Dylan Thomas in America* (1955) is a biographical study by JOHN MALCOLM BRINNIN, who was Thomas' friend and American agent. See also Thomas' *Early Prose Writings*, ed. by WALFORD DAVIES (1971).

(C.Fi.)

Thomas Aquinas, Saint

St. Thomas Aquinas was a Christian philosopher who developed his own conclusions from Aristotelian premises, notably in the metaphysics of personality, creation, and Providence; a theologian responsible in his two masterpieces, the *Summa theologiae* and the *Summa contra gentiles*, for the classical systematization of Latin theology; and a poet who wrote some of the most gravely beautiful eucharistic hymns in the church's liturgy. Although many modern Roman Catholic theologians do not find him altogether congenial, he is recognized by the Catholic Church as its foremost Western philosopher and theologian.

Alinari—Art Reference Bureau

"Apotheosis of St. Thomas Aquinas," altarpiece by Francesco Traini, 1363. In the Sta. Caterina, Pisa.

Early years. Thomas was born in 1224/1225, at Roccasecca, near Aquino, on the road from Rome to Naples, where his parents were in possession of a modest feudal domain on a boundary constantly disputed by the emperor and the pope. His father was of Lombard origin; his mother was of the later invading Norman strain. His

people were distinguished in the service of Emperor Frederick II during the civil strife in southern Italy between the papal and imperial forces. Thomas was placed in the monastery of Monte Cassino near his home as an oblate (*i.e.*, offered as a prospective monk) when he was still a young boy; his family doubtless hoped that he would someday become abbot to their advantage. In 1239, after nine years in this sanctuary of spiritual and cultural life, young Thomas was forced to return to his family when the Emperor expelled the monks because they were too obedient to the Pope. He was then sent to the University of Naples, recently founded by the Emperor; the university provided an environment that was wide open to the scientific and philosophical works that were being translated from the Greek and the Arabic. In this setting Thomas decided to join the Friars Preachers, or Dominicans, a new religious order founded 30 years earlier, which departed from the traditional paternalistic form of government for monks to the more democratic form of the mendicant friars (*i.e.*, religious orders whose corporate as well as personal poverty made it necessary for them to beg alms) and from the monastic life of prayer and manual labour to a more active life of preaching and teaching. By this move he took a liberating step beyond the feudal world into which he was born and the monastic spirituality in which he was reared. A dramatic episode marked the full significance of his decision. His parents had him abducted on the road to Paris, where his shrewd superiors had immediately assigned him so that he would be out of the reach of his family but also so that he could pursue his studies in the most prestigious and turbulent university of the time.

Entry into the Dominican order

Studies in Paris. Thomas held out stubbornly against his family despite a year of captivity. He was finally liberated and in the autumn of 1245 went to Paris to the convent of Saint-Jacques, the great university centre of the Dominicans; there he studied under Albertus Magnus, a tremendous scholar with a wide range of intellectual interests.

Escape from the feudal world, rapid commitment to the University of Paris, and religious vocation to one of the new mendicant orders all meant a great deal in a world in which faith in the traditional institutional and conceptual structure was being attacked. The encounter between the gospel and the culture of his time formed the nerve centre of Thomas' position and directed its development. Normally, his work is presented as the integration into Christian thought of the recently discovered Aristotelian philosophy, in competition with the integration of Platonic thought effected by the Fathers of the Church during the first 12 centuries of the Christian Era. This view is essentially correct; more radically, however, it should also be asserted that Thomas' work accomplished an evangelical awakening to the need for a cultural and spiritual renewal not only in the lives of individual men but also throughout the church. Thomas must be understood in his context as a mendicant religious, influenced both by the evangelism of St. Francis of Assisi, founder of the Franciscan order, and by the devotion to scholarship of St. Dominic, founder of the Dominican order.

Study of Aristotle's works

When Thomas arrived at the University of Paris, the influx of Arabian–Aristotelian science was arousing a sharp reaction among believers; and several times (in the years 1210, 1215, 1231, and 1245) the church authorities tried to block the naturalism and rationalism that were emanating from this philosophy and, according to many ecclesiastics, seducing the younger generations. Thomas did not fear these new ideas, but, like his master Albertus Magnus (and Roger Bacon, also lecturing at Paris), he studied the works of Aristotle and eventually lectured publicly on them.

For the first time in history, Christian believers and theologians were confronted with the rigorous demands of scientific rationalism. At the same time, technical progress was requiring men to move from the rudimentary economy of an agrarian society to an urban society with production organized in trade guilds, with a market economy, and with a profound feeling of community. New generations of men and women, including clerics, were reacting against the traditional notion of contempt for the world and were striving for mastery over the forces of nature through the use of their reason. The structure of Aristotle's philosophy emphasized the primacy of the intelligence. Technology itself became a means of access to truth; mechanical arts were powers for humanizing the cosmos. Thus, the dispute over the reality of universals —*i.e.*, the question about the relation between general words such as "red" and particulars such as "this red object"—which had dominated early Scholastic philosophy, was left behind; and a coherent metaphysics of knowledge and of the world was being developed.

During the summer of 1248, Thomas left Paris with Albertus, who was to assume direction of the new faculty established by the Dominicans at the convent in Cologne. He remained there until 1252, when he returned to Paris to prepare for the degree of master of theology. After taking his bachelor's degree, he received the *licentia docendi* ("license to teach") at the beginning of 1256 and shortly afterward finished the training necessary for the title and privileges of master. Thus, in the year 1256 he began teaching theology in one of the two Dominican schools incorporated in the University of Paris.

Years at the papal Curia and return to Paris. In 1259 Thomas was appointed theological adviser and lecturer to the papal Curia, then the centre of Western humanism. He returned to Italy, where he spent two years at Anagni at the end of the reign of Alexander IV and four years at Orvieto with Urban IV. From 1265 to 1267 he taught at the convent of Santa Sabina in Rome and then, at the request of Clement IV, went to the papal Curia in Viterbo. Suddenly, in November 1268, he was sent to Paris, where he became involved in a sharp doctrinal polemic that had just been triggered off.

Opposition to the Averroists

The works of Averroës, the outstanding representative of Arabic philosophy in Spain, who was known as the great commentator and interpreter of Aristotle, were just becoming known to the Parisian masters. There seems to be no doubt about the Islāmic faith of the Cordovan philosopher; nevertheless, he asserted that the structure of religious knowledge was entirely heterogeneous to rational knowledge: two truths—one of faith, the other of reason—can, in the final analysis, be contradictory. This dualism was denied by Muslim orthodoxy and was still less acceptable to Christians. With the appearance of Siger of Brabant, however, and from 1266 on, the quality of Averroës' exegesis and the wholly rational bent of his thought began to attract disciples in the faculty of arts at the University of Paris. Thomas Aquinas rose in protest against his colleagues; nevertheless, the parties retained a mutual esteem. As soon as he returned from Italy, Thomas began to dispute with Siger, who, he claimed, was compromising not only orthodoxy but also the Christian interpretation of Aristotle. Thomas found himself wedged in between the Augustinian tradition of thought, now more emphatic than ever in its criticism of Aristotle, and the Averroists. Radical Averroism was condemned in 1270, but at the same time Thomas, who sanctioned the autonomy of reason under faith, was discredited.

In the course of this dispute, the very method of theology was called into question. According to Aquinas, reason is able to operate within faith and yet according to its own laws. The mystery of God is expressed and incarnate in human language; it is thus able to become the object of an active, conscious, and organized elaboration in which the rules and structures of rational activity are integrated in the light of faith. In the Aristotelian sense of the word, then (although not in the modern sense), theology is a "science"; it is knowledge that is rationally derived from propositions that are accepted as certain because they are revealed by God. The theologian accepts authority and faith as his starting point and then proceeds to conclusions using reason; the philosopher, on the other hand, relies solely on the natural light of reason. Thomas was the first to view theology expressly in this way or at least to present it systematically, and in doing so he raised a storm of opposition in various quarters. Even today this opposition endures, especially among religious enthusiasts for whom reason remains an intruder in the realm of mys-

tical communion, contemplation, and the sudden ecstasy of evangelical fervour.

Literary form of his works

The literary form of Thomas' works must be appreciated in the context of his methodology. He organized his teaching in the form of "questions," in which critical research is presented by pro and con arguments, according to the pedagogical system then in use in the universities. Forms varied from simple commentaries on official texts to written accounts of the public disputations, which were significant events in medieval university life. Thomas' works are divided into three categories: 1) commentaries on such works as the Old and New Testaments, the *Sentences* of Peter Lombard (the official manual of theology in the universities), and the writings of Aristotle; 2) disputed questions, accounts of his teaching as a master in the disputations; 3) two *summae* or personal syntheses, the *Summa contra gentiles* and the *Summa theologiae*, which were presented as integral introductions for the use of beginners. Numerous *opuscula* ("little works"), which have great interest because of the particular circumstances that provoked them, must also be noted.

The logic of Thomas' position regarding faith and reason required that the fundamental consistency of the realities of nature be recognized. A *physis* ("nature") has necessary laws; recognition of this fact permits the construction of a science according to a *logos* ("rational structure"). Thomas thus avoided the temptation to sacralize the forces of nature through a naïve recourse to the miraculous or the Providence of God. For him, a whole "supernatural" world that cast its shadow over things and men, in Romanesque art as in social customs, had blurred men's imaginations. Nature, discovered in its profane reality, should assume its proper religious value and lead to God by more rational ways, yet not simply as a shadow of the supernatural. This understanding is exemplified in the way that Francis of Assisi admired the birds, the plants, and the Sun.

The inclusion of Aristotle's *Physics* in university programs was not, therefore, just a matter of academic curiosity. Naturalism, however, as opposed to a sacral vision of the world, was penetrating all realms: spirituality, social customs, and political conduct. About 1270, Jean de Meun, a French poet of the new cities and Thomas' neighbour in the Rue Saint-Jacques in Paris, gave expression in his *Roman de la Rose* to the coarsest realism, not only in examining the physical universe but also in describing and judging the laws of procreation. Innumerable manuscripts of the Roman poet Ovid's *Ars amatoria* ("The Art of Loving") were in circulation; André le Chapelain, in his *De Deo amoris* ("On the God of Love") adapted a more refined version for the public. Courtly love in its more seductive forms became a more prevalent element in the culture of the 13th century.

At the same time, Roman law was undergoing a revival at the University of Bologna; this involved a rigorous analysis of the natural law and provided the jurists of Frederick II with a weapon against ecclesiastical theocracy. The traditional presentations of the role and duties of princes, in which biblical symbolism was used to outline beautiful pious images, were replaced by treatises that described experimental and rational attempts at government. Thomas had composed such a treatise—*De regimine principum* ("On the Government of Princes")—for the King of Cyprus in 1266. In the administration of justice, juridical investigations and procedures replaced fanatical recourse to ordeals and to judgments of God.

Resistance of traditional theologians

In the face of this movement, there was a fear on the part of many that the authentic values of nature would not be properly distinguished from the disorderly inclinations of mind and heart. Theologians of a traditional bent firmly resisted any form of a determinist philosophy which, they believed, would atrophy liberty, dissolve personal responsibility, destroy faith in Providence, and deny the notion of a gratuitous act of creation. Imbued with Augustine's doctrines, they asserted the necessity and power of grace for a nature torn asunder by sin. The optimism of the new theology concerning the religious value of nature scandalized them.

Although he was an Aristotelian, Thomas was certain that he could defend himself against a heterodox interpretation of "the Philosopher," as Aristotle was known. Thomas held that human liberty could be defended as a rational thesis while admitting that determinations are found in nature. In his theology of Providence, he taught a continuous creation, in which the dependence of the created on the creative wisdom guarantees the reality of the order of nature. God moves sovereignly all that he creates; but the supreme government that he exercises over the universe is conformed to the laws of a creative Providence that wills each being to act according to its proper nature. This autonomy finds its highest realization in the rational creature: man is literally self-moving in his intellectual, volitional, and physical existence. Man's freedom, far from being destroyed by his relationship to God, finds its foundation in this very relationship. "To take something away from the perfection of the creature is to abstract from the perfection of the creative power itself." This metaphysical axiom, which is also a mystical principle, is the key to St. Thomas' spirituality.

Last years at Naples. At Easter time in 1272, Thomas returned to Italy to establish a Dominican house of studies at the University of Naples. This move was undoubtedly made in answer to a request made by King Charles of Anjou, who was anxious to revive the university. After participating in a general chapter, or meeting, of the Dominicans held in Florence during Pentecost week and, having settled some family affairs, Thomas resumed his university teaching at Naples in October and continued it until the end of the following year.

Although Thomas' argument with the Averroists had for years been matched by a controversy with the Christian masters who followed the traditional Augustinian conception of man as fallen, this latter dispute now became more pronounced. In a series of university conferences in 1273, Bonaventure, a Franciscan friar and a friendly colleague of Thomas at Paris, renewed his criticism of the Aristotelian current of thought, including the teachings of Thomas. He criticized the thesis that philosophy is distinct from theology, as well as the notion of a physical nature that has determined laws; he was especially critical of the theory that the soul is bound up with the body as the two necessary principles that make up the nature of man and also reacted strongly to the Aristotelians' denial of the Platonic–Augustinian theory of knowledge based upon exemplary Ideas or Forms.

The disagreement was profound. Certainly, all Christian philosophers taught the distinction between matter and spirit. This distinction, however, could be intelligently held only if the internal relationship between matter and spirit in individual human beings was sought. It was in the process of this explanation that differences of opinion arose—not only intellectual differences between idealist and realist philosophers but also emotional differences. Some viewed the material world merely as a physical and biological reality, a stage on which the history of spiritual persons is acted out, their culture developed, and their salvation or damnation determined. This stage itself remains detached from the spiritual event, and the history of nature is only by chance the setting for the spiritual history. The history of nature follows its own path imperturbably; in this history, man is a foreigner, playing a brief role only to escape as quickly as possible from the world into the realm of pure spirit, the realm of God.

Relationship of matter and spirit for Thomas

Thomas, on the contrary, noted the inclusion of the history of nature in the history of the spirit and at the same time noted the importance of the history of spirit for the history of nature. Man is situated ontologically (*i.e.*, by his very existence) at the juncture of two universes, "like a horizon of the corporeal and of the spiritual." In man there is not only a distinction between spirit and nature but there is also an intrinsic homogeneity of the two. Aristotle furnished Thomas with the categories necessary for the expression of this concept: the soul is the "form" of the body. For Aristotle, form is that which makes a thing to be what it is; form and matter—that out of which a thing is made—are the two intrinsic causes that constitute every material thing. For Thomas, then, the body is the matter and the soul is the form of man.

The objection was raised that he was not sufficiently safeguarding the transcendence of the spirit, the doctrine that the soul survives after the death of the body.

In January 1274 Thomas was personally summoned by Gregory X to the second Council of Lyons, which was an attempt to repair the schism between the Latin and Greek churches. On his way he was stricken by illness; he stopped at the Cistercian abbey of Fossanova, where he died on March 7, 1274. In 1277 the masters of Paris, the highest theological jurisdiction in the church, condemned a series of 219 propositions; 12 of these propositions were theses of Thomas. This was the most serious condemnation possible in the Middle Ages; its repercussions were felt in the development of ideas. It produced for several centuries a certain unhealthy spiritualism that resisted the cosmic and anthropological realism of Thomas Aquinas.

Assessment. The biography of Thomas is one of extreme simplicity; it chronicles little but some modest travel during a career devoted entirely to university life: at Paris, the Roman Curia, Paris again, and Naples. It would be a mistake, however, to judge that his life was merely the quiet life of a professional teacher untouched by the social and political affairs of his day. The drama that went on in his mind and in his religious life found its causes and produced its effects in the university. In the young universities all the ingredients of a rapidly developing civilization were massed together, and to these universities the Christian Church had deliberately and authoritatively committed its doctrine and its spirit. In this environment, Thomas found the technical conditions for elaborating his work—not only the polemic occasions for turning it out but also the enveloping and penetrating spiritual milieu needed for it. It is within the homogeneous contexts supplied by this environment that it is possible today to discover the historical intelligibility of his work, just as they supplied the climate for its fruitfulness at the time of its birth.

Importance of the university environment

Thomas was canonized a saint in 1323, officially named doctor of the church in 1567, and proclaimed the protagonist of orthodoxy during the modernist crisis at the end of the 19th century. This continuous commendation, however, cannot obliterate the historical difficulties in which he was embroiled in the 13th century during a radical theological renewal—a renewal that was contested at the time and yet was brought about by the social, cultural, and religious evolution of the West. Thomas was at the heart of the doctrinal crisis that confronted Christendom when the discovery of Greek science, culture, and thought seemed about to crush it. William of Tocco, Thomas' first biographer, who had known him and was able to give evidence of the impression produced by his master's teaching, says:

> Brother Thomas raised new problems in his teaching, invented a new method, used new systems of proof. To hear him teach a new doctrine, with new arguments, one could not doubt that God, by the irradiation of this new light and by the novelty of this inspiration, gave him the power to teach, by the spoken and written word, new opinions and new knowledge.

MAJOR WORKS

THEOLOGICAL TREATISES: *Scriptum super IV libros Sententiarum* (1254–56); *De veritate* (1256–59); *Summa contra gentiles* (*c.* 1258–64; *On the Truth of the Catholic Faith*, 1955); *Summa theologiae* (1265 or 1266–73; incomplete); *De potentia Dei* (1259–68; *On the Power of God*, 1932–34); *De malo* (undated; *On Free Choice*); *De spiritualibus creaturis* (undated; *On Spiritual Creatures*, 1949); *De anima* (undated; *The Soul*, 1949); *De unione Verbi incarnati* (undated); *De virtutibus* (1269–72; *On the Virtues in General*, 1951).

BIBLICAL COMMENTARIES: *Expositio in Evangelium S. Matthaei* (1269–72); *Expositio in Job ad litteram* (1261–64); *Expositio in Evangelium Joannis* (1269–72); *Exposition in S. Pauli Apostoli epistolas* (undated; incomplete); *In psalmos Davidis expositio* (1272–73).

COMMENTARIES ON ARISTOTLE: *In octo libros Physicorum expositio* (1268–71; *Commentary on Aristotle's Physics*, 1963); *In tres libros De anima* (undated; *The Commentary of St. Thomas Aquinas on Aristotle's Treatise on the Soul*, 1946); *In librum De sensu et sensato expositio* (1270–71); *In decem libros Ethicorum expositio* (1271–72; *Commentary on the Nicomachean Ethics*, 1964); *In duodecim libros Metaphysicorum expositio* (*c.* 1272; *Commentary on the Metaphysics of Aristotle*, 1961); *In libros De caelo et mundo expositio* (1272–73); *In libros Posteriorum analyticorum expositio* (undated; probably late).

OTHER WORKS: (PHILOSOPHICAL TREATISES): *De ente et essentia* (before 1256; *On Being and Essence*, 1949); *Contra impugnantes Dei cultum et religionem* (1256; *An Apology for the Religious Orders*, 1902); *De regno* (*De regimine principum*) *ad regem Cypri* (1266; *On Kingship*, 1949); *De perfectione vitae spiritualis* (1269–70); *De unitate intellectus contra Averroistas* (1270; *The Unicity of the Intellect*, 1946); *De aeternitate mundi contra murmurantes* (1270–72); *De substantiis separatis, seu de angelorum natura* (undated; *Treatise on Separate Substances*, 1959). (HYMNS AND LITURGICAL COMPOSITIONS): "Pange, lingua, gloriosi" (1264); "Verbum supernum prodiens" (1264; "The Word of God Proceeding Forth"); office for the Feast of Corpus Christi (*c.* 1264), including the sequence "Lauda Sion Salvatorem" ("Praise, O Zion, thy Salvation").

BIBLIOGRAPHY. Thomas' first biography was that of his disciple, WILLIAM OF TOCCO, published in *Acta Sanctorum*, vol. 1, pp. 656–686 (March 1865); new ed., with other biographies, *Fontes vitae S. Thomas Aquinatis*, 6 fasc. (1912–37); and A.M. WALZ, *San Tommaso d'Aquino. Studi biografici* (1945; Eng. trans., *Saint Thomas Aquinas: A Biographical Study*, 1951).

Latin editions of the Opera omnia: Rome (17 vol., 1570), called *Piana* because they were published under Pius V; new and rev. ed., 25 vol., Parma (1852–73, reprinted 1948–50); then in Paris, Vivès ed. (34 vol., 1871–80); in progress, a critical edition, called *Leonina* because it was requested by Leo XIII (1882–). Of all his works, the *Summa theologiae* has been the most frequently re-edited. A recent, excellent edition was published by the Institute of Medieval Studies in Montreal, 5 vol. (1941–45).

English translations: The two *Summae*, by the English Dominicans (22 vol., 1911–34); selections, by THOMAS GILBY, *Philosophical Texts* (1951), and *Theological Texts* (1955); and A.C. PEGIS, *Basic Writings of St. Thomas Aquinas* (2 vol., 1945).

A bibliography was published by PIERRE MANDONNET and JEAN DESTREZ, *Bibliographie thomiste*, 2nd ed. (1960); it has been continued by the *Bulletin thomiste* since 1924. Also, V.J. BOURKE, *Thomistic Bibliography, 1920–1940*, as a supplement to vol. 21 of *The Modern Schoolman* (1945, complemented in 1948 and 1950).

Studies: ETIENNE GILSON, *Le Thomisme* (1922; Eng. trans. of the 1st ed., *The Philosophy of St. Thomas Aquinas*, 1924; rev. Eng. trans., *The Christian Philosophy of St. Thomas Aquinas*, 1956); M.D. CHENU, *Introduction à l'étude de Saint Thomas Aquin* (1950; Eng. trans., with revisions, *Toward Understanding St. Thomas*, 1964); M.C. D'ARCY, *St. Thomas Aquinas* (1953). On historical and doctrinal contexts; PIERRE MANDONNET, *Siger de Brabant et l'averroïsme latin au XIII^e siècle*, 2nd ed. (1911); ETIENNE GILSON, *L'Esprit de la Philosophie médiévale*, 2 pt. (1932; Eng. trans., *The Spirit of Medieval Philosophy*, 1936, reprinted 1965); *History of Christian Philosophy in the Middle Ages* (1955); M.D. CHENU, *La Théologie au XII^e siècle* (1957; Eng. trans., *Nature, Man and Society in the Twelfth Century*, 1968); FERNAND VAN STEENBERGHEN, *La Philosophie au XIII^e siècle* (1966).

Thomson, Sir Joseph John

Sir Joseph John Thomson, the British physicist, helped revolutionize the knowledge of atomic structure by discovering the electron, which is a fundamental unit of all matter. This discovery, at the close of the 19th century, had far-reaching consequences for 20th-century science. Moreover, under his leadership the Cavendish Laboratory at Cambridge University achieved distinction as a centre of scientific training and research.

Thomson was born on December 18, 1856, the son of a bookseller in a suburb of Manchester. When he was only 14, he entered Owens College, now the Victoria University of Manchester. He was fortunate in that, in contrast with most colleges at the time, Owens provided some courses in experimental physics. In 1876 he obtained a scholarship at Trinity College, Cambridge, where he remained for the rest of his life. After taking his B.A. degree in mathematics in 1880, the opportunity of doing experimental research drew him to the Cavendish Laboratory. He began also to develop the theory of electromagnetism. As set forth by James Clerk Maxwell, electricity

Thomson, pencil drawing by Walter Monnington, 1932. In the National Portrait Gallery, London.

and magnetism were interrelated; quantitative changes in one produced corresponding changes in the other.

Prompt recognition of Thomson's achievement by the scientific community came in 1884, with his election as a fellow of the Royal Society of London and appointment to the chair of physics at the Cavendish Laboratory. Thomson entered physics at a critical point in its history. Following the great discoveries of the 19th century in electricity, magnetism, and thermodynamics, many physicists in the 1880s were saying that their science was coming to an end like an exhausted mine. By 1900, however, only elderly conservatives held this view, and by 1914 a new physics was in existence, which raised, indeed, more questions than it could answer. The new physics was wildly exciting to those who, lucky enough to be engaged in it, saw its boundless possibilities. Probably not more than a half dozen great physicists were associated with this change. Although not everyone would have listed the same names, the majority of those qualified to judge would have included Thomson.

Discovery of the electron

Thomson's most important line of work, interrupted only for lectures at Princeton University in 1896, was that which led him, in 1897, to the conclusion that all matter, whatever its source, contains particles of the same kind that are much less massive than the atoms of which they form a part. They are now called electrons, although he originally called them corpuscles. His discovery was the result of an attempt to solve a long-standing controversy regarding the nature of cathode rays, which occur when an electric current is driven through a vessel from which most of the air or other gas has been pumped out. Nearly all German physicists of the time held that these visible rays were produced by occurrence in the ether—a weightless substance then thought to pervade all space—but that they were neither ordinary light nor the recently discovered X-rays. British and French physicists, on the other hand, believed that these rays were electrified particles. By applying an improved vacuum technique, Thomson was able to put forward a convincing argument that these rays were composed of particles. Furthermore, these rays seemed to be composed of the same particles, or corpuscles, regardless of what kind of gas carried the electric discharge or what kinds of metals were used as conductors. Thomson's conclusion that the corpuscles were present in all kinds of matter was strengthened during the next three years, when he found that corpuscles with the same properties could be produced in other ways; *e.g.*, from hot metals. Thomson may be described as "the man who split the atom" for the first time, although "chipped" might be a better word, in view of the size and number of electrons. Although some atoms contain many electrons their total mass is never so much as 1/1000 that of the atom.

By the turn of the century most of the scientific world had fully accepted Thomson's far-reaching discovery. In 1903 he had the opportunity to amplify his views on the behaviour of subatomic particles in natural phenomena when, in his Silliman Lectures at Yale, he suggested a discontinuous theory of light; his hypothesis foreshadowed Einstein's later theory of photons. In 1906 he received the Nobel Prize for Physics for his researches into the electrical conductivity of gases; in 1908 he was knighted; in 1909 he was president of the British Association for the Advancement of Science; and in 1912 he received the Order of Merit.

Work at Cavendish Laboratory

Thomson was, however, by no means a scientific recluse. During his most fruitful years as a scientist, he was administrative head of the highly successful Cavendish Laboratory. (It was there that he met Rose Elizabeth Paget, whom he married in 1890.) He not only administered the research projects but also financed two additions to the laboratory buildings primarily from students' fees, with little support from the university and colleges. Except for its share of a small government grant to the Royal Society to aid all British universities and all branches of science, the Cavendish Laboratory received no other government subsidy, nor were there contributions from charitable corporations or industry. A gift from a devoted staff member made possible the purchase of a small liquid-air machine essential for Thomson's research on positive rays, which greatly increased knowledge of the recently discovered atomic nuclei.

Thomson was, moreover, an outstanding teacher; his importance in physics depended almost as much on the work he inspired in others as on that which he did himself. The group of men he gathered around him between 1895 and 1914 came from all over the world, and after working under him, many accepted professorships abroad. Seven Nobel Prizes were awarded to those who worked under him. Thomson took his teaching duties very seriously: he lectured regularly to elementary classes in the morning and to postgraduates in the afternoon. He considered teaching to be helpful for a researcher, since it required him to reconsider basic ideas that otherwise might have been taken for granted. He never advised a man entering a new research field to begin by reading the work already done. Rather, Thomson thought it wise that he first clarify his own ideas. Then he could safely read the reports of others without having his own views influenced by assumptions that he might find difficult to throw off.

Thomson demonstrated his wide range of interests outside science by his interest in politics, current fiction, drama, university sports, and the nontechnical aspects of science. Although he was not athletic, he was an enthusiastic fan of the Cambridge cricket and rugby teams. But his greatest interest outside physics was in plants. He enjoyed long walks in the countryside, especially in hilly regions near Cambridge, where he searched for rare botanical specimens for his elaborate garden. In 1918 Thomson was made master of Trinity College. This position, in which he remained until his death, gave him the opportunity of meeting young men, most of whom were not interested in science. He enjoyed these meetings and made many new friends.

To a large extent, it was Thomson who made atomic physics a modern science. The studies of nuclear organization that continue even to this day and the further identification of elementary particles all followed his most outstanding accomplishment, his discovery of the electron in 1897. Although this new physics has continued to raise more theoretical questions than can be answered at present, from the start it rapidly gave rise to practical applications in technology and industry. Thomson's interest in science continued unabated until his death in Cambridge on August 30, 1940.

Thoreau, Henry David

Thoreau's greatness lies in the power of his principal ideas. He had only a few—that a man must follow his conscience regardless of cost, that life was too dear to be wasted in making a living, that the world of woods and streams was good, while the world of streets or crowds was bad. None could be called original. Yet his lucid, provocative writing invited everyone to read and be convinced. To many, the more man's culture has homogenized, the more cogent Thoreau's views have seemed. Their influence has been augmented by his two famous symbolic actions, both movingly described in his prose: his passing a night in jail for civil disobedience and his living for two years in a cabin at Walden Pond, not only to show that a man could be his own master but that doing so could be richly rewarding.

Thoreau, portrait by Samuel Worcester Rowse, 1854. In the Concord Free Public Library, Massachusetts.

To all appearances, he himself lived a life of bleak failure. His neighbours viewed him with familiarity verging on contempt. He had to pay to have his first book, *A Week on the Concord and Merrimack Rivers*, printed; when it sold a mere 220 copies, the publishers dumped the remaining 700 on his doorstep. His second book (he published only two during his life) was *Walden; or, Life in the Woods*; it fared less badly but still took five years to sell 2,000 copies. When after his death it was proposed that his journals be printed, the local squire, Samuel Hoar, snorted in amazement. For most of his life Thoreau responded to his neighbours with prickly independence; in fact, he called *Walden* his cockcrow to the world. Yet by the time he died he was ready to yield to the world's verdict, saying sadly, for instance, of the *Week*, "Do not suppose that I rate it too high."

Early life. Thoreau was born on July 12, 1817, in Concord, Massachusetts. Though his family moved the next year, they returned in 1823, not to move again. Even when he grew ambivalent about the village after reaching manhood, it remained his world. For he never grew ambivalent about its lovely setting of woodlands, marshes, streams, and meadows. "I think I could write a poem to be called 'Concord,' " he declared. Little distinguished his family. He was the third child of a feckless small businessman named John Thoreau and his bustling, talky wife, Cynthia Dunbar Thoreau. Such evidence as exists suggests that the family showed an interest in natural history and in books. His parents sent him to infant school, to grammar school, and then in 1828 to Concord Academy. There his playmates thought him standoffish—nicknaming him "the Judge"—but he impressed his teachers and so was permitted to prepare for college.

The curriculum was devised to ready local boys for Harvard. When he graduated from the academy, his favourite subjects were the Greek and Roman classics, natural history, and mathematics; and his favourites they stayed. At Harvard he made a good record but not an outstanding one. He found at least a few friends, attended a few clubs, and joined in a few rowdy demonstrations. Looking back later, he remarked dryly that he got little benefit from the faculty or from his fellow students, but that the library meant a good deal to him. Graduating in 1837, he searched for a teaching job and secured one in Concord at his old grammar school. No disciplinarian, he lasted two shaky weeks. Though he applied elsewhere, writing to schools as far away as Virginia and upstate New York, he came up with nothing. While applying, he worked for his father in the family pencil-making business. In June 1838 he started a small school with the help of his brother John. Despite its progressive nature, it lasted for three years, until John fell ill.

Years at Harvard

During the summer vacation of 1839, he and John took a canoe trip along the Concord and Merrimack rivers. The experience was beautiful, indeed inspiring. It confirmed him in the opinion that he ought to be not a schoolmaster but a poet of nature. That meant living in nature as well as writing about it; that also meant, as the ancient Greeks had taught him, living a life of integrity. As the 1840s opened, he took up the profession of poet. He struggled to stay in it and succeeded throughout the decade, only to falter in the 1850s.

Friendship with Emerson and the beginning of his literary career. Sheer chance made his entrance to writing easier, for he came under the benign influence of the essayist and poet Ralph Waldo Emerson, who had settled in Concord during Thoreau's sophomore year at Harvard. By the autumn of 1837, they were becoming friends. Fourteen years older than Thoreau and at the onset of his magnificent prime, Emerson sensed in him a true disciple—that is, one with so much Emersonian self-reliance that he would still be his own man. Thoreau saw in Emerson a guide, a father, and a friend. Early on, he abandoned the guide as needless and began contradicting the father. But he always esteemed the friend.

With his magnetism Emerson attracted others to his home and village. Out of their heady speculations and affirmatives came New England Transcendentalism. In retrospect it was one of the most significant literary movements of 19th-century America, with at least two authors of world stature, Thoreau and Emerson, to its credit. Essentially it combined romanticism with reform. It celebrated the individual rather than the masses, emotion rather than reason, nature rather than man. It conceded that there were two ways of knowing, through the senses and through intuition, but asserted that intuition transcended tuition. Similarly, it conceded that matter and spirit both existed. It asserted, however, that the reality of spirit transcended the reality of matter. It strove for reform yet insisted that reform begin with the individual, not the group or organization. Emerson refused to send a penny to charitable societies, convinced that they were going about reform in exactly the wrong way. Thoreau, before the anti-slavery crusade engulfed his sympathies, coolly advised the Abolitionists to free themselves before they tried to free the Negro slave.

Onset of New England Transcendentalism

In Emerson's company Thoreau's hope of becoming a poet and managing to live as one often looked not only proper but feasible. Late in 1837 he began a journal that covered thousands of pages before he scrawled the final entry two months before his death. He soon polished some of his old college essays and composed new and better ones as well. He penned some poems—a good many in fact—for several years. Captained by Emerson, the Transcendentalists started a magazine, *The Dial*; and the inaugural issue, dated July 1840, carried Thoreau's poem "Sympathy" and his scrap of essay on the Roman poet Aulus Persius Flaccus.

The Dial published more of Thoreau's poems and then, in July 1842, the first of his outdoor essays, "Natural History of Massachusetts." Though disguised as a book review, it showed that a nature writer of distinction was in the making. Then followed more lyrics, and fine ones, such as "To the Maiden in the East." There were also some translations from the Greek poets Aeschylus and Anacreon, some excerpts from Oriental scriptures (fore-

casting his interest in Oriental philosophy), and another nature essay, remarkably felicitous, "A Winter Walk." *The Dial* died with the issue of April 1844. Before it expired, however, it let Thoreau publish a richer variety of writing than any other magazine ever would.

Thoreau's one romance

By then, he had channelled his emotional life into his writing. His one romance had come in 1840, when he wanted to marry an attractive visitor to Concord named Ellen Sewall. She said yes, but her father uttered a grating no. Some of Thoreau's best poems and some highly charged prose resulted from the romance. "To the Maiden in the East," for example, is surely about Ellen. For two periods, 1841–43 and 1847–48, he stayed mostly at the Emerson house, where he found in Emerson's wife, Lidian, a sympathetic older woman he could dream of loving. Otherwise he was married to his writing.

In spite of Emerson's heady encouragement to live as a poet, Thoreau sometimes had to live as a workman. He made several reluctant attempts to find a job in the early 1840s. No one could have been more generous than Emerson in inviting Thoreau to live at his home with a minimum of duties and a maximum of freedom, and the invitation seemed to solve the problem. Yet Thoreau grew restless. His restlessness was accentuated by grief over the death in January 1842 of his brother John, who died of lockjaw after cutting his finger. Henry, too, soon suffered from lockjaw symptoms, failing to recover until the end of April. By the following May, he was staying on Staten Island as tutor in the household of Emerson's brother, William. The idea was that he could teach and write and, in the intervals, cultivate the New York literary market. The teaching and writing went indifferently, however, and the effort to conquer New York failed. "My bait will not tempt the rats," he wrote sourly. By the end of 1843 he was home again.

Move to Walden Pond. Back he went to making pencils and grinding graphite. By early 1845 he felt more restless than ever, until he decided to take up an idea of Stearns Wheeler's. Wheeler, a Harvard classmate, had once built a waterside hut, where he could loaf or read, and Thoreau had spent a short time there. In the spring he picked a spot by Walden Pond, two miles from Concord, on land Emerson owned. With Emerson's permission he chopped down some of its pines, hewed the timbers, and with the help of friends fashioned a small cabin. On July 4, his personal Independence Day, he moved in.

From the outset the move gave him profound satisfaction. It provided him with enough time to ponder what the world was really like. With his "Realometer," he said, he could now ascertain whether the world was basically good or bad, noble or mean. The move provided him with time to meet his simple wants. He could easily grow his own beans, never mind if he dined out often. And, most valuable, it provided him with time to write.

He stayed for two years. Before the first one ended, he finished the full draft of *A Week on the Concord and Merrimack Rivers* (published 1849). Before the second was over, he finished the initial draft of *Walden; or, Life in the Woods* (published 1854), which announced that the world was good. In between, he composed some lively essays, including a long one on the British writer Thomas Carlyle, and hundreds of pages of journals. His stay at Walden proved to be his most productive period.

Still, he was by no means the literary hermit that tradition has pictured him. He entertained many a guest—in fact he titled a chapter of *Walden* "Visitors"—and many a day he walked to Concord. In the summer of 1847 Emerson invited him to stay with Lidian and the children again, while Emerson himself went to Europe. Thoreau accepted. On September 6, 1847, hopeful that he had more lives to live, he left his cabin forever.

Midway in his Walden sojourn he spent his night in jail. On an evening in July 1846, he was accosted by Sam Staples, the constable and tax gatherer. Sam asked him amiably to pay his poll tax, which he had omitted paying for several years. He declined and Sam locked him up. The next morning a still unidentified lady, perhaps his aunt, Maria, paid the tax. Thoreau reluctantly emerged, did an errand, and then went huckleberrying. A single night, he decided, was enough to make his point.

Civil disobedience

His point was that he could not support a government that endorsed slavery and waged an imperialist war against Mexico. He was becoming involved; he was shifting from his first position that reform was mainly a matter for the individual. His imprisonment set Concord tongues wagging, and so he concluded that justifying his action would make an instructive lecture for the Concord Lyceum. He gave it twice, ultimately titling it "Civil Disobedience," and then his bluestocking friend Elizabeth Peabody printed it, in May 1849, in a volume she edited called *Aesthetic Papers.* Understandably, it was ignored. But by the end of the 19th century it had begun to make itself felt, and, by the middle of the 20th, it had an eager audience. To many, its message still sounds timely: there is a higher law than the civil one, and the higher law must be followed even if a penalty ensues. So does its consequence: "Under a government which imprisons any unjustly, the true place for a just man is also a prison."

Late life and works. When Thoreau left Walden, he passed the peak of his career, and his life lost much of its illumination for today. In spite of his hopefulness on leaving, he would complain by July 1852, "My life is almost altogether outward, all shell and no tender kernel." Slowly his Transcendentalism drained away. He turned naturalist and surveyor. He collected botanical specimens for himself and reptilian ones for Harvard, jotting down their descriptions in his journal. He established himself in his neighbourhood as a sound man with rod and transit. He spent more time in the family business; after his father's death he took it over entirely. He made excursions to the Maine woods, to Cape Cod, and to Canada, using the trips as raw material for three series of magazine articles: "Ktaadn [sic] and the Maine Woods," in *The Union Magazine* in 1848; "Excursion to Canada," in *Putnam's Monthly* in 1853; and "Cape Cod," in *Putnam's* in 1855.

When he became less of a Transcendentalist he became more of an activist. As the 1850s jolted along he became, above all, a dedicated Abolitionist. As much as anyone in Concord, he helped to speed fleeing slaves north on the so-called Underground Railroad. He lectured and wrote against slavery, with "Slavery in Massachusetts," a lecture delivered in 1854, as his hardest indictment. In the Abolitionist John Brown he found a father figure beside whom Emerson paled; the fiery old fanatic became his ideal. By now Thoreau was in poor health; and when Brown's raid on Harpers Ferry failed and he was hanged, Thoreau suffered a psychic shock that probably hastened his own death. He died, apparently of tuberculosis, on May 6, 1862. Yet it should be added that, according to Sam Staples' testimony, he died in peace.

MAJOR WORKS

PHILOSOPHICAL AND POLITICAL: *A Week on the Concord and Merrimack Rivers* (1849); "Resistance to Civil Government" (first published 1849, then as "Civil Disobedience" in *A Yankee in Canada* (1866); *Walden; or, Life in the Woods* (1854); "Life Without Principle," published posthumously in *The Atlantic Monthly* (1863).

TRAVEL AND NATURAL HISTORY: "Walking" (1862); *Excursions* (1863); *The Maine Woods* (1864); *Cape Cod* (1865); *A Yankee in Canada with Anti-Slavery and Reform Papers* (1866); *Early Spring in Massachusetts* (1881); *Summer* (1884); *Winter* (1888); *Autumn* (1892); *Poems of Nature* (1895).

OTHER WORKS: *Letters to Various Persons,* ed. by Ralph Waldo Emerson (1865); *Familiar Letters of Henry David Thoreau,* ed. by Frank B. Sanborn (1865, enlarged 1894); *Journal* (1906).

BIBLIOGRAPHY. FRANCIS H. ALLEN (comp.), *A Bibliography of Henry David Thoreau* (1908), the prime source up to 1908, continued by WILLIAM WHITE (comp.), *A Henry David Thoreau Bibliography, 1908–1937* (1939); and PHILIP E. BURNHAM and CARVEL COLLINS (comps.), "Contribution to a Bibliography of Thoreau, 1938–1945," *Bulletin of Bibliography,* 19:16–18, 37–39 (1946). Current bibliography appears in each issue of the quarterly *Thoreau Society Bulletin,* cumulated in *A Bibliography of the Thoreau Society Bulletin Bibliographies, 1941–1969,* ed. by WALTER HARDING (1971). The chief storehouses of Thoreau manuscripts and

other materials are the Berg Collection in the New York Public Library; the Concord, Massachusetts Public Library; the Harvard University Library; the Henry E. Huntington Library in San Marino, California; and the J. Pierpont Morgan Library in New York.

Editions and correspondence: The Writings of Henry Thoreau, 20 vol. (1906), is the standard "Walden" collection of his finished work and journal, to be replaced by the new edition being prepared by a group of Thoreau specialists. The *Collected Poems of Henry Thoreau*, ed. by CARL BODE (1943; rev. ed., 1964), is the standard collection of the poems. *The Correspondence of Henry David Thoreau*, ed. by WALTER HARDING and CARL BODE (1958), is the standard collection, containing all available letters to Thoreau as well as from him. *Consciousness in Concord*, with notes and commentary by PERRY MILLER (1958), is a small but previously missing part of the journal, edited exhaustively by Miller.

Biography and criticism: The definitive life is WALTER HARDING, *The Days of Henry Thoreau* (1965). Its still useful predecessor is HENRY S. CANBY, *Thoreau* (1939). The best general critical study is SHERMAN PAUL, *The Shores of America: Thoreau's Inward Exploration* (1958). The prime study of *Walden* alone is CHARLES R. ANDERSON, *The Magic Circle of Walden* (1968).

(Ca.B.)

Thought Processes, Theories of

In everyday language the word thinking covers several distinct psychological activities. It is sometimes a synonym for "tending to believe," especially with less than full confidence. ("I think that it will rain, but I am not sure.") At other times it denotes attentiveness ("I did it without thinking"); or it denotes whatever is in consciousness, especially if it refers to something outside the immediate environment. ("It made me think of my old grandmother.") In the sense on which psychologists have concentrated, thinking is intellectual exertion aimed at finding an answer to a question or a means of achieving a desirable practical goal.

The psychology of thought processes concerns itself with activities similar to those usually attributed to the inventor, the mathematician, or the chess player; but psychologists have not reached agreement on any definition or characterization of thinking. For some it is a matter of modifying "cognitive structures" (*i.e.*, perceptual representations of the world or parts of the world). Others view thinking as internal problem-solving behaviour, as a means of arriving at adaptive behaviour (*i.e.*, behaviour with rewarding or biologically valuable consequences) through manipulation of symbols.

Perhaps the most satisfactory provisional conception of thinking is one that applies the term to any sequence of covert symbolic responses (*i.e.*, occurrences within the human organism that can serve to represent absent events). If such a sequence is aimed at the solution of a specific problem and fulfills the criteria for reasoning, it is called directed thinking. Reasoning, of which rudimentary forms can be inferred to occur in infrahuman mammals, is a process of piecing together the results of two or more distinct previous learning experiences to produce a new pattern of behaviour. Directed thinking contrasts with other symbolic sequences that have different functions; *e.g.*, the autistic (or free-associative) thinking of the daydream or the psychoanalytic session and the simple recall (mnemonic thinking) of a chain of past events.

Directed, autistic, and mnemonic thinking

In the past, psychologists and laymen often identified thinking with conscious experiences. But as the scientific study of behaviour came to be recognized generally as the task of psychology, the limitations of introspection as a source of data have become widely apparent. It thus has become more usual to treat thought processes as intervening variables or constructs with properties that must be inferred from relations between two sets of observable events. These empirically available events are inputs (stimuli, present and past) and outputs (responses, including bodily movements and speech). For many psychologists such intervening variables are of interest as aids in dealing with and in making sense of the immensely complicated network of associations between stimulus conditions and responses, the analysis of which otherwise would be prohibitively cumbersome. Others are concerned, rather, with identifying cognitive (or mental) structures that are held to underlie a human being's observable behaviour without his necessarily being aware of them.

ELEMENTS OF THOUGHT

The prominent use of words in thinking ("silent speech") has encouraged the belief, especially among behaviourist and neobehaviourist psychologists, that to think is to string together linguistic elements subvocally. Early experiments (largely in the 1930s) by E. Jacobson and L.W. Max revealed that evidence of thinking commonly is accompanied by electrical activity in the muscles of the thinker's organs of articulation. This work later was extended with the help of more sophisticated electromyographic equipment, notably by A.N. Sokolov. It became apparent, however, that the muscular phenomena are not the actual vehicles of thinking but represent rather a means of facilitating the appropriate activities in the brain when an intellectual task is particularly exacting. The identification of thinking with speech was assailed by L.S. Vygotski and by J. Piaget, both of whom saw the origins of human reasoning in the ability of children to assemble nonverbal acts into effective and flexible combinations. These theorists insisted that thinking and speaking arise independently, although they acknowledged the profound interdependence of these functions, once they have reached fruition.

Following different approaches, a 19th-century Russian physiologist (I.M. Sechenov), the U.S. founder of the behaviourist school of psychology (J.B. Watson), and a 20th-century Swiss developmental psychologist (Piaget) all arrived at the conclusion that the activities that serve as elements of thinking are internalized or fractional versions of motor responses; that is, the elements are considered to be attenuated or curtailed variants of neuromuscular processes that, if they were not subjected to partial inhibition, would give rise to visible bodily movements.

Sensitive instruments can indeed detect faint activity in various parts of the body other than the organs of speech; *e.g.*, in a person's limbs when the movement is thought of or imagined without actually taking place. Such findings have prompted statements to the effect that we think with the whole body and not only with the brain, or that "thought is simply *behaviour*—verbal or nonverbal, covert or overt" (B.F. Skinner). The logical outcome of these and similar statements was the peripheralist view (Watson, C.L. Hull) that thinking depends on events in the musculature, feeding proprioceptive impulses back to influence subsequent events in the central nervous system, ultimately to interact with external stimuli in determining the selection of a course of overt action. There is, however, evidence that thinking is not precluded by administering drugs that suppress all muscular activity. Furthermore, it has been pointed out (*e.g.*, by K.S. Lashley) that thinking, like other more-or-less skilled activities, often proceeds so quickly that there is simply not enough time for impulses to be transmitted from the central nervous system to a peripheral organ and back again between consecutive steps. So the centralist view that thinking consists of events confined to the brain (though often accompanied by widespread activity in the rest of the body) was gaining ground in the third quarter of the 20th century. Nevertheless, each of these neural events can be regarded both as a response (to an external stimulus or to an earlier neurally mediated thought or combination of thoughts) and as a stimulus (evoking a subsequent thought or a motor response).

Thinking as a brain function

The elements of thinking are classifiable as "symbols" in accordance with the conception of the sign process ("semiotic") that has grown out of the work of some philosophers (*e.g.*, C.S. Peirce, C.K. Ogden, I.A. Richards, and C.R. Morris) and of psychologists specializing in learning (*e.g.*, C.L. Hull, N.E. Miller, O.H. Mowrer, and C.E. Osgood). The gist of this conception is that a stimulus event x can be regarded as a sign representing (or "standing for") another event y if x evokes some part, but not all, of the behaviour (external and internal) that would have been evoked by y if it had been present. When a

stimulus that qualifies as a sign results from the behaviour of an organism for which it acts as a sign, it is called a "symbol." The "stimulus-producing responses" that are said to make up thought processes (as when one thinks of something to eat) are prime examples.

This treatment, favoured by psychologists of the stimulus-response (S-R) or neo-associationist current, contrasts with that of the various cognitivist or neorationalist theories. Rather than regarding the components of thinking as derivatives of verbal or nonverbal motor acts (and thus subject to laws of learning and performance that apply to learned behaviour in general), adherents of such theories see them as unique central processes, governed by principles that are peculiar to them. These theorists attach overriding importance to the so-called structures in which "cognitive" elements are organized. Unlike the S-R theorists who feel compunction about invoking unobservable intermediaries between stimulus and response (except where there is clearly no other alternative), the cognitivists tend to see inferences, applications of rules, representations of external reality, and other ingredients of thinking at work in even the simplest forms of learned behaviour.

The Gestalt school of psychologists held the constituents of thinking to be of essentially the same nature as the perceptual patterns that the nervous system constructs out of sensory excitations. After mid-20th century, analogies with computer operations acquired great currency; in consequence, thinking frequently is described in terms of storage, retrieval, and transmission of items of information. The information in question is held to be freely translatable from one "coding" to another without impairing its functions. The physical clothing it assumes is regarded as being of minor importance. What matters in this approach is how events are combined and what other combinations might have occurred instead.

THE THOUGHT PROCESS

Laws of association: contiguity, similarity

According to the classical empiricist-associationist view, the succession of ideas or images in a train of thought is determined by the laws of association. Although additional associative laws were proposed from time to time, two invariably were recognized. The law of association by contiguity states that the sensation or idea of a particular object tends to evoke the idea of something that has often been encountered together with it. The law of association by similarity states that the sensation or idea of a particular object tends to evoke the idea of something that is similar to it. The early behaviourists, beginning with Watson, espoused essentially the same formulation but with some important modifications. The elements of the process were conceived not as conscious ideas but as fractional or incipient motor responses, each producing its proprioceptive stimulus. Association by contiguity and similarity were identified by these behaviourists with the Pavlovian principles of conditioning and generalization.

Külpe, Hull, and Selz

The Würzburg school, under the leadership of Külpe, saw the prototype of directed thinking in the "constrained-association" experiment, in which the subject has to supply a word bearing a specified relation to a stimulus word that is presented to him (*e.g.*, an opposite to an adjective, or the capital of a country). Their introspective researches led them to conclude that the emergence of the required element depends jointly on the immediately preceding element and on some kind of "determining tendency" such as *Aufgabe* ("awareness of task") or "representation of the goal." These latter factors were held to impart a direction to the thought process and to restrict its content to relevant material. Their role was analogous to that of motivational factors—"drive stimuli," "fractional anticipatory goal responses"—in the later neobehaviouristic accounts of reasoning (and of behaviour in general) produced by C.L. Hull and his followers.

Hull's theory resembled G.E. Müller's earlier "constellation theory" of constrained association. Hull held that one particular response will occur and overcome its competitors because it is associated both with the cue stimulus (which may be the immediately preceding thought process or an external event) and with the motivational condition (task, drive stimulus) and is thus evoked with more strength than are elements associated only with the one or the other. O. Selz pointed out that in many situations this kind of theory would imply the occurrence of errors as often as correct answers to questions. It thus was untenable. Selz contended that response selection depends rather on a process of "complex completion" that is set in motion by an "anticipatory schema," which includes a representation of both the cue stimulus and the relation that the element to be supplied must bear to the cue stimulus. The correct answer is associated with the schema as a whole and not with its components separately. Selz's complex completion resembles the "eduction of correlates" that C.E. Spearman saw as a primary constituent of intellectual functioning, its complement being "eduction of relations," that is, recognition of a relation when two elements are presented.

The determination of each thought element by the whole configuration of factors in the situation and by the network of relations linking them was stressed still more strongly in the 1920s and 1930s by the Gestalt psychologists on the basis of W. Köhler's experiments on "insightful" problem solving by chimpanzees, and on the basis of later experiments by M. Wertheimer and of K. Duncker on human thinking. They pointed out that the solution to a problem commonly requires an unprecedented response or pattern of responses that hardly could be attributed to simple associative reproduction of past behaviour or experiences. For them, the essence of thinking lay in sudden perceptual restructuring or reorganization, akin to the abrupt changes in appearance of an ambiguous visual figure.

Thinking as perceptual reorganization

The Gestalt theory has had a deep and far-reaching impact, especially in drawing attention to the ability of the thinker to discover creative, innovative ways of coping with situations that differ from any that have been encountered before. This theory, however, has been criticized for underestimating the contribution of prior learning and for not going beyond rudimentary attempts to classify and analyze the structures that it deems so important. Later discussions of the systems in which items of information and intellectual operations are organized have made fuller use of the resources of logic and mathematics. Merely to name them, they include the "psychologic" of Piaget, the simulation of human thinking with the help of computer programs using list-processing languages and tree structures (H.A. Simon and A. Newell), and extensions of Hull's notion of the "habit-family hierarchy" (I. Maltzman).

A further development of consequence is a growing recognition that the essential components of the thought process, the events that keep it moving in fruitful directions, are not words, images, or other symbols representing stimulus situations; rather, they are the operations that cause each of these representations to be succeeded by the next, in conformity with restrictions imposed by the problem or aim of the moment. In other words, directed thinking can reach a solution only by going through a properly ordered succession of "legitimate steps." These steps might be representations of realizable physicochemical changes, modifications of logical or mathematical formulas that are permitted by rules of inference, or legal moves in a game of chess. This conception of the train of thinking as a sequence of rigorously controlled transformations is buttressed by the theoretical arguments of Sechenov and of Piaget, the results of the Würzburg experiments, and the lessons of computer simulation.

Implicit trial and error

Early in the 20th century both E. Claparède and John Dewey suggested that directed thinking proceeds by "implicit trial-and-error." That is to say, it resembles the process whereby laboratory animals confronted with a novel problem situation try out one response after another until they sooner or later hit upon a response that leads to success. In thinking, however, the trials were said to take the form of internal responses (imagined or conceptualized courses of action, directions of symbolic search); once attained, a train of thinking that constitutes a solution often can be recognized as such without the necessity of implementation through action, followed by sampling of external consequences. This kind of theory, popular among behaviourists and neobehaviourists, was stoutly

opposed by the Gestalt school whose insight theory stressed discovery of a solution as a whole and in a flash.

The divergence between these theories appears, however, to represent a false dichotomy. The protocols of Köhler's chimpanzee experiments and of the rather similar experiments performed later under Pavlov's auspices show that insight typically is preceded by a period of groping and of misguided attempts at solution that soon are abandoned. On the other hand, even the trial-and-error behaviour of an animal in a simple selective-learning situation does not consist of a completely blind and random sampling of the behaviour of which the learner is capable. Rather, it consists of responses that very well might have succeeded if the circumstances had been slightly different.

Heuristic (probabilistic) thinking; computer simulation

A. Newell, J.C. Shaw, and H.A. Simon pointed out the indispensability in creative human thinking, as in its computer simulations, of what they call "heuristics." A large number of possibilities may have to be examined, but the search is organized heuristically in such a way that the directions most likely to lead to success are explored first. Means of ensuring that a solution will occur within a reasonable time, certainly much faster than by random hunting, include adoption of successive subgoals and working backward from the final goal (the formula to be proved, the state of affairs to be brought about).

MOTIVATIONAL ASPECTS OF THINKING

The problem to be taken up and the point at which the search for a solution will begin are customarily prescribed by the investigator for a subject participating in an experiment on thinking (or by the programmer for a computer). Thus, prevailing techniques of inquiry in the psychology of thinking have invited neglect of the motivational aspects of thinking. The conditions that determine when the person will begin to think in preference to some other activity, what he will think about, what direction his thinking will take, and when he will regard his search for a solution as successfully terminated (or abandon it as not worth pursuing further) barely are beginning to attract investigation. Although much thinking is aimed at practical ends, special motivational problems are raised by "disinterested" thinking, in which the discovery of an answer to a question is a source of satisfaction in itself.

In the views of the Gestalt school and of F.C. Bartlett, the initiation and direction of thinking are governed by recognition of a "disequilibrium" or "gap" in an intellectual structure. Similarly, Piaget's notion of "equilibration" as a process impelling advance from less equilibrated structures, fraught with uncertainty and inconsistency, toward better equilibrated structures that overcome these imperfections, was introduced to explain the child's progressive intellectual development in general. Piaget's approach may also be applicable to specific episodes of thinking. For computer specialists, the detection of a mismatch between the formula that the program so far has produced and some formula or set of requirements that define a solution is what impels continuation of the search and determines the direction it will follow.

Neobehaviourists (like psychoanalysts) have made much of secondary reward value and stimulus generalization; *i.e.*, the tendency of a stimulus pattern to become a source of satisfaction if it resembles or has frequently accompanied some form of biological gratification. The insufficiency of this kind of explanation becomes apparent, however, when the importance of novelty, surprise, complexity, incongruity, ambiguity, and uncertainty is considered. Inconsistency between beliefs, between items of incoming sensory information, or between one's belief and an item of sensory information evidently can be a source of discomfort impelling a search for resolution through reorganization of belief systems or through selective acquisition of new information.

The motivational effects of such factors have been receiving more attention since the middle of the 20th century, mainly because of the pervasive role they have been found to play in exploratory behaviour, play, and aesthetics. But their role in all forms of thinking also began to be appreciated and studied in relation to curiosity, conflict, and uncertainty. As evidence accumulates about the brain processes that underlie fluctuations in motivational state, and as psychophysiological equipment with which such fluctuations can be monitored comes in for increasing use, future advances in the theory of thinking are likely to correct the present imbalance and give due prominence to motivational questions.

BERLYNE, *Structure and Direction in Thinking* (1965), reviews experimental findings, discusses crucial problems, and attempts a synthesis that draws on S-R behaviour theory, Piaget's ideas, and modern Soviet research, among other developments.

(D.E.B.)

Thought Processes, Types of

Thought processes are inner (private or covert) activities of people that may be elicited by stimuli arising intrinsically (from within the body) or extrinsically (from the surrounding environment). While intrinsic stimulation (*e.g.*, feeling sad) may exert a major influence at a particular time, the course of thinking in general depends on stimuli from all sources. The practice of considering behaviour by specifying the instigating origin (stimulus) and the observable act (response) has led some psychologists to identify thinking as a mediating (or intervening) activity, or, in other words, as an unobservable activity that links (or mediates) observable stimuli and responses. The public, scientific study of thinking thus is concerned with investigating the properties and effects of mediation (see THOUGHT PROCESSES, THEORIES OF).

There is no sharp distinction between thinking and other aspects of covert (private, unobservable) behaviour, such as remembering or perceiving, the differences seeming to be largely those of degree. Thinking is characterized to some degree as an organizing function that produces "new" information derived from the original data of experience. In remembering, the information carried by experience is stored for later retrieval. To perceive is to interpret or give meaning to an immediate sensory stimulus. Since covert representations of experience (mediating and symbolic activities) seem to enter into all aspects of observable behaviour, psychologists search for principles that govern cognitive processes (the activities of knowing) in general.

Expressive and disciplined thinking

The spectrum or range of thinking reflects the relative intensity of intrinsic and extrinsic influences. When intrinsic processes operate strongly and are relatively free of environmental constraints, a person thinks expressively: he imagines, fantasizes, dreams, hallucinates, or has delusions. As his thinking becomes dominated by external stimuli, he tends to become more logical, directed, disciplined; the process then is identified by such terms as judging, conceptualizing, and problem solving.

Sigmund Freud recognized this distinction between expressive and disciplined function in contrasting what he called primary and secondary process thinking. Freud held that one's impulses and wishes arise from unconscious sources and determine primary process thinking, while the pursuit of exterior objects and goals determines secondary process thinking, which he associated with

planning, rational control, and continuous organization. These two aspects of thinking also can be called, respectively, autistic (determined by subjective emotional–motivational activities) and realistic (oriented toward the external environment). The terms are not mutually exclusive but rather correspond to relative degrees of influence of different conditions that enter into thinking.

In a broad sense, then, activities called thinking are internally adaptive responses to intrinsic and extrinsic stimuli; not only do they express inner impulses but they also serve to generate environmentally effective, goal-seeking behaviour.

REALISTIC THINKING

Convergent thought processes. It has been proposed that certain forms of thinking call on one's abilities to assemble and organize information. The result of such thinking satisfies a defined goal in the achievement of an effective solution to a problem. These forms are called convergent thinking and become apparent when situations arise in which one's ability to cope with a task demands resources beyond the explicit stimuli presented; *i.e.*, converges the components of one's past and present experience in organizing or directing one's response.

Experimental approaches. In studying thinking experimentally, investigators often use standardized tasks that have measurable outcomes; for example, a human subject (say, a young child) may be shown three levers—one black, the other two white. Initially, the standard task may be for the child to discover that for pulling the black lever he will receive some reward (perhaps something good to eat) but that for pulling either white lever he will get no reward at all. Orderly procedures are established under which experimental changes can be introduced to observe their effects on the thinker's performance. The results are compared with those obtained under a standard control condition without the changes.

Among the variables that can be manipulated are the amount of information available to the individual (*e.g.*, the black lever may also be illuminated); the kind or degree of incentives under which he works (*e.g.*, a larger or better tasting reward); the order or arrangement of objects (*e.g.*, black lever in the middle or on the right); the instructions provided; the subject's familiarity or degree of prior experience with the task; and the stress under which he functions, such as punishment for mistakes or the threat of failure. The thinker's personality characteristics provide another set of variables for study; for example, subjects who typically exhibit high levels of anxiety can be compared in their task performance with those who ordinarily show little anxiety; or the performance of a person who shows a compelling need to achieve success can be compared with that of a person who exhibits strong fears of failure.

Conditions that affect realistic thinking

Research results indicate that any condition that increases the complexity of a task requiring convergent thinking tends to make the solution more difficult and time-consuming. The more multiple choices (*e.g.*, ten levers instead of three) a thinker is offered, the more difficult the solution of the task is likely to be. Irrelevant items of information, such as the illumination of all levers, may complicate a problem; and as irrelevant data become more numerous or as relevant information becomes less accessible to or discoverable by the thinker, the solution becomes more difficult.

Finding a solution is helped by providing the thinker with cues, guidelines, rules, or other appropriate ways of orienting himself toward the problem (*e.g.*, he may be pointed toward the right lever). Performance is uncertain to the degree that the individual must discover these directions by his own efforts. When separate cues must be combined (*e.g.*, the colour of the lever and the presence or absence of illumination), the more suitable they are for the required relationship, the more efficient the process of solution tends to be.

Individual traits and factors. Conditions that increase the thinker's motivation, such as incentives and special instructions, tend to improve performance. A person's response to these conditions, however, depends on his personality characteristics; very anxious people typically show particularly impaired performance when the task is difficult or stressful. An important consideration is the set (or expectation) of the person; a person's tendency toward rigidity—inability to adapt readily to changing conditions of the task—is likely to have adverse effects on his performance. Instruction or special training that aids one in overcoming his prior sets fosters his ability to achieve correct solution.

Realistic thinking may be aided or hindered by the individual's strategies and cognitive or perceptual style. Such characteristics include the way a person attends to and uses sensory information; he may, for example, focus on inessentials, may fail to observe details accurately, or may be disturbed by complexities in the task stimuli. Also important to convergent thinking are the individual's abilities to analyze and to synthesize sensory information.

Realistic thinking tends to be elicited when the individual perceives no obvious or immediate path to a desired goal. It is likely to begin with his recognition of a problem—otherwise, his behaviour would simply indicate the operation of habits or the automatic production of responses. Realistic thinking continues with one's consideration of alternatives, each marked by some uncertainty or risk. He next begins processing information (including pertinent past experience) by analyzing, combining, and organizing available and potential resources for reaching his goal. In the final phase of the process he produces a response; it may be a wrong solution, a partial solution, or a correct solution. Recycling of these phases (recognition, considering alternatives, processing data, and responding) may continue in a complex way until the goal finally is reached or until the process ends in failure.

Phases of realistic thinking

The explicitness of these phases varies with the complexity of the task, as well as with the problem-solving skills of the individual. In this connection, the individual may show evidence of "learning how to learn"; that is, he may exhibit a progressive increase in skill as he encounters a series of similar problems.

Judgment. A simple form of realistic thinking that lends itself well to controlled experimentation is inferred from one's ability to discriminate discrete objects or items of information (*e.g.*, distinguishing a lion from a tiger). The outcome is a judgment, and the process may be called decision making. The availability of information, the rate at which it is presented, the set (expectancy) of the judge, and the number of alternatives available to him influence the efficiency of his judgment. Redundancy (or surplus) of information facilitates judgment; for example, the lion may be discriminated on the basis of a number of different sensory cues: he is tan or brown, he lacks stripes, he has a mane, and so on.

Within what is called the general theory of adaptation level, the decision-making response is considered to be a weighted average of various stimuli: focal (the specific sensory properties of the lion and tiger), contextual (the background in which they are observed), and residual (such intrinsic or experiential factors as memory for other brown or striped objects). Variations in one or more of these three types of stimuli shift the judge's decision in one direction or another in relation to his immediately preceding judgment.

Concept attainment. A more complex form of realistic thinking is inferred when an individual is asked to identify or use a *class* of items, as in selecting several different kinds of triangle from an array of other geometric figures. The individual may proceed to link together in his thinking a newly experienced group of objects according to one or more of their common properties. He thus may be able to give them a general name, as in first learning the meaning of the term triangle, or he may determine whether a newly given object fits a category he already knows. Physical objects are multidimensional; that is, they may vary in shape, size, colour, their location in relation to other objects, their emotional significance, or their connotative meaning. How a person identifies such dimensions, develops hypotheses (or tentative conclusions) about which of the specific dimensions define a class, arrives at the rules of class membership, and how

Linking by common properties

he tests various hypotheses all reflect his ability to grasp concepts. Successful performance in all these processes leads to his formulation of pertinent rules based on his ability to classify specific items (see CONCEPT FORMATION).

Problem solving. Still more complex forms of realistic thinking seem to occur when tasks are presented in which the goal is impossible (or very difficult) to achieve directly. In such situations, people commonly appear to pass through intermediate stages of exploring and organizing their resources; indeed, one may first need to exert himself in understanding the problem itself before he can begin to seek possible directions toward a solution. Familiar examples of problem-solving tasks include anagrams (*e.g.*, rearrange "lpepa" to spell "apple"); mathematical problems; mechanical puzzles; verbal "brain teasers" (*e.g.*, Is it legal for a man to marry his widow's sister?); and, in a more practical sense, design and construction problems. Also of interest are issues of human relations, games, and questions pertinent to economics and politics.

Trial and error. Problem-solving activity falls broadly into two categories: one emphasizes simple trial and error; the other requires some degree of insight. In trial and error, the individual proceeds mainly by exploring and manipulating elements of the problem situation in an effort to sort out possibilities and to run across steps that might carry him closer to the goal. This behaviour is most likely to be observed when the problem solver lacks advance knowledge about the character of the solution, or when no single rule seems to underlie the solution. Trial-and-error activity is not necessarily overt (as in one's observable attempts to fit together the pieces of a mechanical puzzle); it may be implicit or vicarious as well, the individual reflecting on the task and symbolically testing possibilities by thinking about them.

Solutions through insight. In striving toward insight, a person tends to exhibit a strong orientation toward understanding *principles* that might bear on the solution sought. The person actively considers what is required by the problem, noting how its elements seem to be interrelated, and seeks some rule that might lead directly to the goal. The insightful thinker is likely to centre on the problem to understand what is needed, to take the time to organize his resources, and to recentre on the problem (reinterpret the situation) in applying any principle that seems to hold promise.

Understanding, organizing, and applying principle

Direction and flexibility characterize insightful problem solving. The thinker directs or guides his steps toward solution according to some plan; he exhibits flexibility in his ability to modify or to adapt procedures as required by his plan and in altering the plan itself. Both characteristics are influenced by the thinker's attitudes and by environmental conditions. If, for example, the task is to empty a length of glass tubing of water (without breaking it) by removing wax plugs about a half-inch up the tube from each end, and the only potential tools are a few objects ordinarily found on a desk top, the usual appearance and functions of such common objects may make it difficult for the problem solver to see how they can be adapted to fit task requirements. If a paper clip is perceived as holding a sheaf of papers in the usual way, such perception would tend to interfere with the individual's ability to employ the principle that the clip's shape could be changed: straightened out for use in poking a hole in the wax.

Formal, logical processes. A special form of problem solving employs formal, systematic, logical thinking. The thinker develops a series of propositions, often as postulates; *e.g.*, the shortest distance between two points is a straight line. He builds a structure of arguments in which statements are consistent with each other in reaching some goal, such as defining the area of a triangle. This kind of logical, mathematical reasoning applies formal rules in supporting the validity of successive propositions.

Inductive and deductive thinking

Both inductive and deductive processes may be used by a problem solver. In inductive thinking one considers a number of particular or specific items of information to develop more inclusive (or general) conceptions. After aspirin was synthesized, for example, some people who swallowed the substance reported that it relieved their *particular* headaches. Through induction, the reports of these *specific* individuals were the basis for developing a more inclusive notion: aspirin may be helpful in relieving headaches in general.

Deduction is reasoning from general propositions—or hypotheses—to more specific instances or statements. Thus, after the general hypothesis about the effectiveness of aspirin had been put forward, physicians began to apply it to specific, newly encountered headache cases. The deduction was that, if aspirin is *generally* useful in managing pains in the head, it might also be helpful in easing pains elsewhere in the body. Although a person may deliberately choose to use induction or deduction, people typically shift from one to the other, depending on the exigencies of the reasoning process.

Students of problem solving almost invariably have endorsed some variety of mediation theory in their efforts to understand realistic thinking. The assumptions in that kind of theory are that implicit (internal) representations of experience are stored in and elicited from memory and are linked together during the period between the presentation of a stimulus and the implementation of a response. Those theorists who prefer to avoid the use of unobservable "entities" (*e.g.*, "mind") increasingly have been invoking the nervous system (particularly the brain) as the structure that mediates such functions.

Creative thinking. Divergent (or creative) thinking has been defined as an activity that leads to new information, or previously undiscovered solutions, rather than to a predetermined, correct solution (as in convergent thinking). Some tasks call for flexibility, originality, fluency, and inventiveness, especially for problems in which the individual must supply his own, unique solution. The "problem" might be a personal, emotional difficulty that needs resolution or expression.

Four progressive stages. A number of processes or phases have been identified as typical of creative thinking. In what logically would be the first phase (*i.e.*, preparation), the thinker assembles and explores his resources and perhaps makes preliminary decisions about their value in solving the problem at hand. Incubation represents the next period, in which he mulls over possibilities and shifts about from one to another relatively free of any rigid rational or logical preconceptions and constraints. Incubation seems to be at least partly unconscious, proceeding without the individual's full awareness. Illumination occurs when resources fall into place, and a definite decision is reached about the result or solution. Verification (refinement or polishing), the process of making relatively minor modifications in committing ideas to final form, follows. Often enough, objective standards for judging creative activity (*e.g.*, musical composition) are lacking; an important criterion is the emotional satisfaction of the creator. Although the four phases have been ordered in a logical sequence, they often vary widely and proceed in different orders from one person to the next. Many creative people attain their goals by special strategies that are not neatly describable.

Preparation, incubation, illumination, verification

The phases of preparation, incubation, illumination, and verification are characteristic of creative thinkers generally but do not guarantee that a worthwhile product will ensue. Results also depend on whether an individual has the necessary personality characteristics and abilities; in addition, the quality of creative thinking stems from the training of the creator. The artist who produces oil paintings needs to learn the brushing techniques basic to the task; the scientist who creates a new theory does so against a background of previous learning. Further, creativity intimately blends realistic (objective) and autistic (subjective) processes; the successful creator learns how to release and to express his feelings and insights.

Creative thinking is a matter of using intrinsic resources to produce tangible results. This process is markedly influenced by early experience and training. School situations, for example, that encourage individual expression and that tolerate idiosyncratic or unorthodox thinking seem to foster the development of creativity.

Artistic versus scientific creativity. While the processes of creative thinking in artistic and scientific pursuits have much in common, there are also distinctive differences. The artist places more importance on feeling and individual expression, often going to extremes to divorce himself from environmental constraints. The scientist relies more on disciplined, logical thinking to lead him in new directions. Artistic endeavour is dominantly expressive (although clearly oriented toward a goal), while scientific inventiveness is dominantly disciplined (although flexibly receptive to feelings and to imaginative experiences).

Thinking in groups. It might be supposed that greater efficiency should be achieved if several people collaborate to solve a problem than if only one individual works on it. Such results are by no means invariable.

Although groups often may increase the motivation of their members to deal with problems, there is a counterbalancing need to contend with conflicts arising among members of a group and with efforts to give it coherent direction. Problem solving is facilitated by the presence of an effective leader who not only provides direction but permits the orderly, constructive expression of a variety of opinions; much of the leader's effort may be devoted to resolving differences. Success in problem solving also depends on the distribution of ability within a group. Solutions simply may reflect the presence of an outstanding individual who might perform even better by himself.

Although groups may reach a greater number of correct solutions, or may require less time to discover an answer, their net man-hour efficiency is typically lower than that achieved by skilled individuals working alone.

Brainstorming for new solutions

A process called brainstorming has been offered as a method of facilitating the production of new solutions to problems. In brainstorming, a problem is presented to a group of people who then proceed to offer whatever they can think of, regardless of quality and with as few inhibitions as can be managed. Theoretically these unrestricted suggestions increase the probability that at least some superior solutions will emerge. Nevertheless, studies show that when individuals work alone under similar conditions, performance tends to proceed more efficiently than it does in groups.

Under special circumstances, however, a group may solve problems more effectively than does a reasonably competent individual. Group members may contribute different (and essential) resources to a solution that no individual can readily achieve alone; such pooling of information and skills can make group achievements superior in dealing with selected problems. Sometimes social demands may require group agreement on a single alternative, as in formulating national economic or military policies under democratic governments. When only one among several alternative solutions is correct, even if a group requires more time, it has a higher probability of identifying the right one than does an individual alone.

One difference between problem solving by a group and by an individual is the relative importance of covert or vicarious processes. The group depends heavily on verbal communication, while the individual, in considerable degree, attacks the problem through implicit, subjective, silent activity.

AUTISTIC THINKING

When the intensity of extrinsic (or environmental) influence is greatly reduced and intrinsic (or internal) influences dominate, thought processes tend to become autistic; these include so-called free association, fantasy (and reverie), dreaming, and pathological thinking. In such processes, thinking is especially responsive to emotional and motivational impulses. Often seeming to arise from wishes or needs, autistic thinking may represent an activity through which the individual symbolically gains gratification that the environment does not provide. For instance, one's wishes may be fulfilled only in dreaming. According to Freud, autistic thinking is especially influenced by unconscious tendencies that otherwise might find no expression.

Free association. A person freely associates by responding verbally when the usual constraints of logic, goal orientation, or controlled sequence of thinking are removed or reduced. His responses are likely to reflect aroused emotional activity or impulses; for example, during free association, ordinarily forgotten and repressed past experiences seem to be more readily remembered. What is actually produced in free association (as in other forms of autistic thinking) may not always seem to be particularly coherent or meaningful. Some theorists suggest that such responses are likely to symbolize rather than to state an impulse directly. Thus a psychoanalytic theorist might imagine that a young woman's verbal associations about being run over by a beer truck symbolically disguise a socially unacceptable wish to be seduced in some illicit romantic encounter.

One technique that is claimed to be helpful in uncovering an individual's latent or repressed tendencies is the word-association test, devised by Carl Jung, a Swiss psychiatrist. The test taker is presented with a list of words, to each of which he is supposed to respond by saying whatever he thinks of first. It is theorized that especially significant responses may be identified by such clues as the person's delay in responding, by his use of words that indicate strong emotion, or by unusual or bizarre responses. The word chair for example, prompts many people to say table; the analyst is likely to be alerted if the response is *criminal* or *blood.*

Fantasy. Fantasizing is definable as comparatively well organized sequences of thinking in which sensory imagery prevails. When a person who is otherwise awake tends to lose contact with the environment and his thinking proceeds with little or no concern for logical considerations, conditions become favourable for fantasizing. The activity may also take on a problem-solving character, especially when the thinker periodically monitors the process to evaluate the degree to which he may have progressed toward a solution. Fantasy tends to be highly egocentric, dramatic, pleasurable, and free flowing; it may range from vaguely conscious reverie to vivid, almost hallucinatory visual, auditory, or tactual daydreams.

Psychologists have tried to infer the details of such covert processes by asking people to respond to ambiguous stimuli in whatever way they wish, and by so doing to project their inner experiences. Well-known projective methods include the Rorschach Test, in which inkblots in black and white and colour are used as stimuli; and the so-called Thematic Apperception Test (TAT), in which pictures (of people, for example) are shown, about which the subject is asked to make up stories. The Rorschach Test is believed by some to provide evidence of a person's originality, of the balance he maintains between emotional and logical thinking, and of typical ways in which he perceives the environment; some psychologists assert that the TAT may yield clues to a person's motivational characteristics, his inner conflicts, and his attitudes toward other people. Others hold that those projective methods are most untrustworthy and that their use can lead to dangerously misleading conclusions (as in mistakenly committing people to psychiatric hospitals).

Rorschach and other projective tests

Certain marginal states of consciousness seem especially favourable for autistic thinking. An example is the drowsy (hypnagogic) period experienced just before falling asleep; at such times, images and apparently random thinking may well up and "float" freely. Similar (hypnopompic) experiences that emerge on awakening also have been reported. Roughly equivalent activities may occur even when one seems fully awake, but when autistic processes hover between full fantasy and conscious orientation to the environment.

Drugs may induce a variety of alterations in thinking; there may be heightened sensitivity to sensory stimuli and responsiveness to inner states through enhanced imagery and unusual ideational activity. Dosed with some drugs, people seem completely to withdraw from the environment and may show evidence of hallucinatory and delusional experiences (see HALLUCINOGEN).

Dreaming. Autistic thinking during sleep is called dreaming. Reduction in external stimulation while one is asleep permits intrinsic activities to exert a strong influence on thought processes. Some psychoanalytic theo-

Freud's theories of dreams

rists interpret dreaming as a mechanism for maintaining sleep and fulfilling wishes. Freud held that impulses may be expressed in disguised form when one dreams, particularly if their frank expression would be in conflict with the dreamer's moral and social standards. Freud wrote that the original wish that prompts dreaming corresponds to the dream's latent content. Such latent content is to be inferred from the dream as it is directly experienced (the manifest content). The meaning of any dream, according to Freud, lies in its latent content; to the extent that the latent wish is unacceptable to or threatens the dreamer, he is said to employ mechanisms of symbolic imagery, condensation, displacement, and secondary elaboration to disguise it. Condensation refers to the combining of elements; by itself, a knife may suggest a hostile weapon, but dreamed of in combination with other eating utensils it appears innocuous. In displacement the dreamer shifts an impulse from one object to another; he may dream of slicing a melon (manifest) rather than an enemy (latent). Secondary elaboration is the process of imposing structure to increase the coherence and logic of the dream.

Other theorists suggest that in many instances dreams do not hold the latent or hidden significance that Freud assigned them. These critics indicate that dreams may simply be the result of random remembering or of imagery that wells up during sleep. In such dreaming, the sequence of dream elements would represent little more than transient associations (see DREAMS).

Physiological studies of dreaming

In their efforts to study dreaming in terms of more objective evidence, some investigators record electrical activity generated by the brains of sleeping people. People are most likely to say they have been dreaming if they are awakened during a period of so-called rapid eye movement, at which times distinctive changes in brain activity are observable. When people are chronically wakened whenever such signs of dreaming appear, they tend to develop symptoms of psychological disturbance (*e.g.*, hallucinatory activity) during daylight hours. When later permitted to sleep without interruption, they give evidence of dreaming intensively, as if to compensate for previous deprivation. It would appear that dreaming may meet some fundamental physiological need.

Although dreaming largely seems to express intrinsic activity, it can be influenced by external stimuli and is likely to include experiences that symbolize such stimuli. A light tap on the foot of a sleeper, for example, might prompt him to dream of buying a new pair of shoes (see also SLEEP).

Pathological thinking. One popular system for classifying disturbances in personality is based on general patterns or categories of activity called behaviour disorder, neurosis, and psychosis.

Behaviour disorders. Individuals who are judged to show difficulty in self-control, in ability to withstand stress, or who hold unorthodox moral and social standards are likely to be labelled as exhibiting behaviour disorders. The thinking of such people appears to be essentially "normal" in that they show efficient awareness of the environment. Behaviour disorder is displayed mainly in antisocial acts, stemming from what many observers consider to be the individual's deviant evaluation of what is "right" or "wrong," or of what is socially acceptable.

Neurosis. According to some theories, persons classified as neurotic are thought to suffer deep-lying conflicts, controlled in varying degrees by repression. Their tensions are held to produce feelings of anxiety and guilt and to lead to emotion-laden thinking (or worrying). Such theories also posit the operation of so-called ego-defense mechanisms, or activities believed to allow the individual to keep his distressing, repressed impulses from his own awareness. Thus his reasoning may be altered, as in dreaming. Defense mechanisms include rationalization, which justifies actions on a false basis, as when a soldier who enjoys killing feels he does so through patriotism; projection, which attributes to others one's own impulses, as when a hater feels hated; denial, or refusal to admit unacceptable or embarrassing aspects of experience; reaction formation, in which one acts contrary to his repressed impulses, as when he drowns his lecherous tendencies in excessive piety; and rigidity, or excessively careful, fixed thinking (see also PSYCHONEUROSES).

Psychosis. When one's thinking seems grossly disturbed over an appreciable period, he is usually classified by psychiatrists as psychotic. Severe personality disorders of this sort may result from environmental stress, bodily disease, chemical or toxic factors, or any number of experiential influences (*e.g.*, combat experiences, loss of loved ones). The relation between thinking and environmental constraints seems grossly distorted in some forms of psychosis; the effect may be disorientation in time, in space, or in personal identity. In significant degree, the psychotic's emotional and cognitive processes appear to the observer to be independent of what is happening in the surrounding environment.

Bizarre symptoms of psychosis

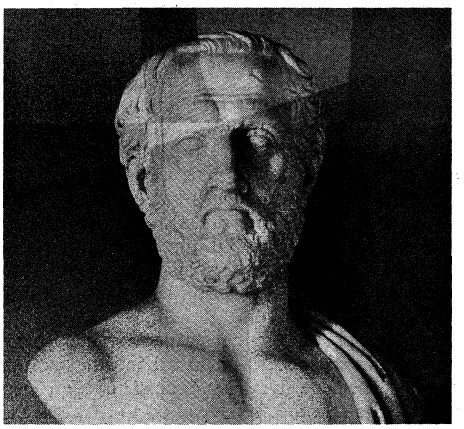
Some ideational symptoms observed among psychotics are bizarre hallucinatory activities such as those reflected in vivid visual or auditory experiences (*e.g.*, hearing "voices") perceived by the individual as coming from the environment; delusions, ostensibly false beliefs that dominate thinking, such as notions of being persecuted or of having a special identity or a mission (as of being appointed to destroy the world); stereotyped, repetitive ideation or actions, such as the incessant recurrence of silly, emotionless "laughter" or detailed rituals resembling peculiar kinds of calisthenics.

Psychotic persons also may show signs of amnesia, inability to understand what others are saying, failures of attention, disorganization of thinking as expressed in meaningless or incoherent speaking or writing. Among psychotics who are likely to be identified as schizophrenics, speech tends to become odd, fragmented, and difficult to follow rationally; their idiosyncratic use of words is common, along with apparently meaningless phrases and sometimes disregard for sentence structure. Instances of what some claim to be "second sight," divine inspiration, possession by spirits, or extreme detachment from ordinary concerns all are likely, in psychiatric settings, to be interpreted as temporary psychotic episodes.

Thought processes cover a remarkably wide range of types; many are poorly understood or may not even be known to professional psychologists. It seems clear, however, that any kind of thinking mediates between intrinsic (bodily) activities and extrinsic (external) sources of stimulation, each type of thought process representing a resultant of autistic and environmental influences.

BIBLIOGRAPHY. General background for the psychoanalytic view of thinking is provided by SIGMUND FREUD, *A General Introduction to Psychoanalysis*, ed. by J. RIVIERE (1938); D. RAPAPORT, "Toward a Theory of Thinking," in *Organization and Pathology of Thought*, pp. 689–730 (1951); and C.S. HALL and G. LINDZEY, "Freud's Psychoanalytic Theory," in *Theories of Personality*, pp. 29–75 (1957). Several general textbooks cover a variety of thought processes. W.E. VINACKE, *The Psychology of Thinking* (1952), discusses such topics as logic, concept formation, problem solving, imagination, creative thinking, and attitudes; a 2nd edition (in press), pays special attention to mediation theory, information theory, and motivational influences on thinking. D.M. JOHNSON, *The Psychology of Thought and Judgment* (1955), deals with problem solving and the experimental study of decisions and judgment. F.C. BARTLETT, *Thinking* (1958), gives interesting examples of thought as a "gap-filled" and steplike process, with attention to "adventurous" thinking. A systematic treatment, based on modern behaviourist ("neo-associationist") conceptions is D.E. BERLYNE, *Structure and Direction in Thinking* (1965). Historically important formulations of insightful processes are K. DUNCKER, *Zur Psychologie des Produktiven Denkens* (1935; Eng. trans., *On Problem-Solving*, 1945); and MAX WERTHEIMER, *Productive Thinking*, ed. by *Michael Wertheimer* (1959). A wide variety of authors discuss special topics in E. HARMS (ed.), *Fundamentals of Psychology: The Psychology of Thinking* (1961). A thorough review of problem solving by groups is H.H. KELLEY and J.W. THIBAUT, "Group Problem Solving," in G. LINDZEY and E. ARONSON (eds.), *The Handbook of Social Psychology*, 2nd ed., vol. 4 (1969). E.J. MURRAY, *Sleep, Dreams, and Arousal* (1965), is a good source for experimental work; and C.T. TART (ed.), *Altered States of Consciousness* (1969), presents chapters on imagery, the effects of drugs, meditation, and other unusual forms of thinking.

(W.E.V.)



Thucydides

Thucydides, the greatest of Greek historians, was perhaps the first person to apply a highly refined intellect to a large-scale examination of the nature of political power and the way in which state policies are made. His *History of the Peloponnesian War*, though incomplete, is a military, political, but most important, a psychological account of the war between Athens and Sparta that lasted from 431 to 404 BC, and of the inevitable moral attrition brought about by the war. His influence on all subsequent historians has been incalculable. All that is certainly known (perhaps all that ancient scholars knew) of his life is what he reveals about himself in the course of his narrative. He

Life

was an Athenian, old enough when the war began to estimate its importance and judge that it was likely to be a long one and to write an account of it, observing and making notes from its beginning. He was probably born, therefore, not later than 460—perhaps a few years earlier since his detailed narrative begins, just before 431, with the events which provoked the war. He was certainly over 30 when he was elected *stratēgos*, a military magistrate of great importance, in 424. Hence, he belongs to the generation younger than that of the Greek historian Herodotus. His father's name was Olorus, which is not known as an Athenian name; Olorus was probably of Thracian descent on his mother's side. Thucydides was related in some way to the great Athenian statesman and general Miltiades, who had married the daughter of a Thracian prince of this name. He himself had property in Thrace, including mining rights in the gold mines opposite the island of Thasos, and was, he tells us, a man of influence there.

Thucydides, detail of a Roman bust after a Greek original. In Holkham Hall, Norfolk, England.

He was in Athens when the great pestilence of 430–429 raged; he caught the disease himself and saw others suffer. Later, in 424, he was elected one of the ten *stratēgoi* of the year, and, because of his connections, was given command of the fleet in the Thraceward region, based at Thasos. He failed to prevent the capture of the important city of Amphipolis by the Spartan general Brasidas, who launched a sudden attack in the middle of winter. Because of this blunder, Thucydides was recalled, tried, and sentenced to exile. This, he says later, gave him greater opportunity for undistracted study for his *History* and for travel and wider contacts, especially on the Peloponnesian side—Sparta and its allies. He lived through the war, and his exile of 20 years ended only with the fall of Athens and the peace of 404. The time and manner of his death are uncertain, but that he died shortly after 404 is probable, and that he died by violence in the troubled times following the peace may well be true, for the *History* stops abruptly long before its appointed end. His tomb and a monument to his memory were still to be seen in Athens in the 2nd century AD.

Scope and plan of the "History." The *History*, which is divided into eight books, probably not by Thucydides' design, stops in the middle of the events of the autumn of 411 BC, more than six and a half years before the end of the war. This much at least is known: that three historians, Cratippus, a younger contemporary; Xenophon, who lived a generation later; and Theopompus, who lived in the last third of the 4th century, all began their histories of Greece where Thucydides left off. Xenophon, one might say, began the next paragraph nearly as abruptly as Thucydides ended his. So it is certain that Thucydides' work was well-known soon after publication and that no more was ever published other than the eight books that have survived; it may reasonably be inferred from the silence of the available sources that no separate section of the work was published in his lifetime. It may also be inferred that parts of the *History*, and the last book in particular, are defective, in the sense that he would have written at greater length had he known more and that he was trying still to learn more—*e.g.*, of internal Athenian politics in the years of "uneasy truce." His existing narrative is in parts barely understandable without some imaginative guesswork.

It may be assumed, then, that there are three fairly definable stages in his work: first, the "notes" he made of events as they occurred; secondly, the arrangement and rewriting of these notes into a consecutive narrative, as a "chronicle," but by no means in the final form that Thucydides intended; thirdly, the final, elaborated narrative —of the preliminaries of the war (Book i), of the "Ten Years' War," and of the Athenian expedition to conquer Sicily. Thucydides supplemented his "note" stage throughout the project; even the most elaborated parts of the *History* may have been added right up to the time of his death—certainly many additions were made after the war was over.

Stages of Thucydides' work

All this is significant because Thucydides was writing what few others have attempted—a strictly contemporary history of events that he lived through and that succeeded each other almost throughout his adult life. He endeavoured to do more than merely record events, in some of which he took an active part, and in all of which he was a direct or indirect spectator; he attempted to write the final history for later generations and, as far as a man can and as no other man has, he succeeded. It is obvious that he did not rush his work; the last of the complete narrative (stage three, above) took him to the autumn of 413, eight and a half years before the end of the war, the last of stage two, to six and a half years before. During these last years he was observing, inquiring, writing his notes, adding to or modifying what he had already written; at no time before the end, during all the 27 years of the war, did he know what that end would be nor, therefore, what would be the length and the final shape of his own *History*. It is evident that he did not long survive the war since he did not leave any connected account, even at stage two, of the last six years. But in what he lived to complete, he wrote a definitive history.

Character studies. Besides the political causes of the war, Thucydides was interested in and emphasized the conflict between two types of character: the ever-active, innovating, revolutionary, disturbing Athenians and the slower-moving, more cautious Peloponnesians, especially the Spartans, "not excited by success nor despairing in misfortune," but quietly self-confident. Thucydides was not really concerned with individuals but rather with the actions, sufferings, and the characters of states ("the Athenians," "the Syracusans," etc.); but he did understand the significance of personalities. Besides depicting by their words and deeds the characters of some who influenced events, such as Cleon, the harsh demagogue of Athens; Hermocrates, the would-be moderate leader in Syracuse; the brave Nicostratus; and the incompetent Alcidas, he goes out of his way to give a clear picture of the characters and influence of four men: Themistocles (in a digression, the Athenian hero of the Second Persian War), Pericles, Brasidas, and Alcibiades. All four of them were of the active, revolutionary type. Pericles of Athens was indeed unique for Thucydides in that he combined caution and moderation in action and great stability of character with a daring imagination and intellect; he was a leader of the new age. During the war each of them

Portraits of Themistocles, Pericles, Brasidas, and Alcibiades

—Pericles and Alcibiades in Athens, Brasidas in Sparta —was in conflict with a conservative, quietist opposition within his own country. The conflict between the revolutionary and the conservative also extended between the generally daring Athenian state and the generally cautious Peloponnesians. It is a great loss that Thucydides did not live to write the story of the last years of the war, when Lysander, the other great revolutionary Spartan, played a larger part than any other single man in the defeat of Athens. This defeat was, in one aspect, the defeat of intellectual brilliance and daring by "stolidity" and stability of character (this last the quality most lacking in Alcibiades, the most brilliant Athenian of the second half of the war); but it was largely brought about by Brasidas and Lysander, the two Spartans who rivalled the Athenians in daring and intellect.

Study of the war's technical aspects. Thucydides was also interested in the technical aspect of the war. The most important problems in the war, besides protecting food supplies during land fighting, centred around the difficulties and possibilities of war between an all-powerful land force (Sparta and its allies) and an all-powerful naval force (Athens). Thucydides also studied the details of siege warfare; the difficulties of the heavily armed combat in mountain country and of fighting against the fierce but unruly barbarians of the north; an army trying to force a landing from ships against troops on shore; the one great night battle, at Syracuse; the skill and the daring manoeuvres of the Athenian sailors and the way these manoeuvres were overcome by the Syracusans; the unexpected recovery of the Athenian fleet after the Sicilian disaster—in all these aspects of the war he took a keen professional interest.

In Thucydides' introductory pages on the early history of Greece he lays much stress on the development of sea trading and naval power and on the accumulation of capital resources: they help to explain the great war between a land power and a sea power.

Style and historical aims. Thucydides was himself an intellectual of the Athenian kind; markedly individualist, his style shows a man brought up in the company of Sophocles and Euripides, the playwrights, and the philosophers Anaxagoras, Socrates, and the contemporary Sophists. His writing is condensed and direct, almost austere in places, and is meant to be read rather than delivered orally. He explains in a scientific and impartial manner the intricacies and complexities of the events he observed. Only in his speeches does he sometimes fall short of the lucidity of the narrative prose; his fondness for abstract expressions and the obscurity of his rhetorical antithesis often make the passages difficult to understand.

In a prefatory note near the beginning of the *History*, Thucydides speaks a little of the nature of his task and of his aims. It was difficult, he says, to arrive at the truth of the speeches made—whether he heard them himself or received a report from others—and of the actions of the war. For the latter, even if he himself observed a particular battle, he made as thorough an enquiry as he could—for he realized that eyewitnesses, either from faulty memory or from bias, were not always reliable.

Use of speeches

He wrote the speeches out of his own words, appropriate to the occasion, keeping as closely as possible to the general sense of what had actually been said. He could never have omitted them, for it is through the speeches that he explains the motives and ambitions of the leading men and states; and this, the study of the human mind in time of war, is one of his principal aims. (The omission of speeches from the last book is a great loss and is caused, no doubt, by the difficulty he had in getting information about Athens at this period.) They are reported as though directly quoted but are Thucydides' own words and are written in his own unique style, partly because he could not pretend that they were exact reports and partly because long passages in indirect speech would be scarcely tolerable and no more "authentic." He avoided, he says, all "storytelling" (this is a criticism of Herodotus), and his work might be the less attractive in consequence;

> but I have written not for immediate applause but for posterity, and I shall be content if the future student of these events, or of other similar events which are likely in human nature to occur in after ages, finds my narrative of them useful.

This is all that he expressly tells of his aim and methods. Moreover, in the course of his narrative (except for the pestilence of 430 and his command in 424) he never gives his authority for a statement. He does not say which of the speeches he actually heard, which of the other campaigns he took part in, what places he visited, or what persons he consulted. Thucydides insisted in doing all the work himself; and he provides, for the parts he completed, only the finished structure, not the plans or the consultations.

Authority of his work

His authority is hardly equalled by that of any other historian. He kept to a strict chronological scheme, and where it can be accurately tested by the eclipses that he mentions, it fits closely. There are also a fair number of contemporary documents recorded on stone, most of which confirm his account both in general and in detail. There is the silent testimony of the three historians who began where he left off, not attempting, in spite of much independence of opinion, to revise what he had already done, not even the last book, which he clearly did not complete. Another historian, Philistus, a Syracusan who was a boy during the Athenian siege of his city, had little to alter or to add to Thucydides' account in his own *History of Sicily*. Above all, there are the contemporary political comedies of Aristophanes—a man about 15 years younger than Thucydides with as different a temper and writing purpose as could be—which remarkably reinforce the reliability of the historian's dark picture of Athens at war. The modern historian of this war is in much the same position as the ancient: he cannot do much more than translate, abridge, or enlarge upon Thucydides.

For Thucydides kept rigidly to his theme: the history of a war—that is, a story of battles and sieges, of alliances hastily made and soon broken, and, most important, of the behaviour of peoples as the war dragged on and on, of the inevitable "corrosion of the human spirit." He vividly narrates exciting episodes and carefully describes tactics on land and sea. He gives a picture, direct in speeches, indirect in the narrative, of the ambitious imperialism of Athens—controlled ambition in Pericles, reckless in Alcibiades, debased in Cleon—ever confident that nothing was impossible for them, resilient after the worst disaster. He shows also the opposing picture of the slow steadiness of Sparta, sometimes so successful, at other times so accommodating to the enemy. His record of Pericles' speech on those killed in the first year of the war is the most glowing account of Athens and Athenian democracy that any leading citizen could hope to hear. It is followed (in, of course, due chronological order) by a minutely accurate account of the symptoms of the pestilence ("so that it may be recognized by medical men if it recurs") and a moving description of the demoralizing despair that overtook men after so much suffering and such heavy losses—probably more than a quarter of the population, most of it crowded within the walls of the city, died.

Equally moving is the account of the last battles in the great harbour of Syracuse and of the Athenian retreat. In one of his best-known passages he analyzes by a most careful choice of words, almost creating the language as he writes, the moral and political effects of civil strife within a state in time of war. By a different method, in speeches, he portrays the hard fate of the town of Plataea due to the long-embittered envy and cruelty of Thebes and the faithlessness of Sparta, and the harsh brutality of Cleon when he proposed to execute all the men of the Aegean island city of Mytilene. Occasionally, he is forced into personal comment, as on the pathetic fate of the virtuous and much-liked Athenian Nicias.

He had strong feelings, both as a man and as a citizen of Athens. He was filled with a passion for the truth as he saw it, which not only kept him free from vulgar partiality against the enemy but served him as a historian in the

accurate narrative of events—accurate in their detail and order and also in their relative importance. He does not, for example, exaggerate the significance of the campaign he himself commanded, nor does he offer a self-defense for his failure. Characteristically, he mentions his exile not as an event of the war but in his "second preface"—after the peace of 421—to explain his opportunities of wider contacts.

Subsequent fame. The story of his later fame is a curious one. It has been mentioned above that in the two generations after his death three historians began their work where he had left off; but apart from this silent tribute and late stories of his great influence on the orator Demosthenes, Thucydides is nowhere referred to in surviving 4th-century literature, not even in Aristotle, who, in his *Constitution of Athens*, describes the revolution in Athens in 411 and diverges in many ways from Thucydides' account. It was not until the end of the 4th century that the philosopher Theophrastus coupled Thucydides with Herodotus as a founder of the writing of history. Little is known of what the scholars of Alexandria and Pergamum did for his book; but copies of it were being made in considerable numbers in Egypt, and so, doubtless, elsewhere, from the 1st to the 5th centuries AD. By the 1st century BC, as is clear from the writings of Cicero and Dionysius (who vainly disputed his pre-eminence), Thucydides was established as the great historian, and since that time his fame has been secure wherever he has been known.

Commentaries: That of T. ARNOLD, 4th ed., 3 vol. (1857), is still worth consulting; important for the interpretation of language are J.M. STAHL's edition (in Latin, 1882–88); and that of J. CLASSEN, rev. by J. STEUP (1900–22); for books i-ii only, A. CROISET (1886). See also A.W. GOMME, *Historical Commentary*, 3 vol. (1945–56).

English translation: That of THOMAS HOBBES (1629), is well worth reading. Modern translations include an accurate and vigorous translation by R. CRAWLEY (1874; in Everyman's Library, 1910, and reprinted in "Great Books of the Western World," vol. 6, 1952); and a lively one by REX WARNER (1954).

Studies and special aspects: J.B. BURY, *The Ancient Greek Historians*, ch. 3–4 (1909, reprinted 1958), old, but still valuable and useful; SIR F.E. ADCOCK, *Thucydides and His History* (1963), quite brief but with some novel theories; J.H. FINLEY, *Thucydides*, 2nd ed. (1942, reprinted 1963), a suave, bland account by probably the most eminent American student of Thucydides; JACQUELINE DE ROMILLY, *Thucydide et l'impérialisme athénien* (1947; Eng. trans., *Thucydides and Athenian Imperialism*, 1963), a profound and searching analysis, not narrowly concerned with imperialism; C.N. COCHRANE, *Thucydides and the Science of History* (1929, reprinted 1965), detects a profound influence on Thucydides by the Hippocratic school of scientific medicine of his time —particularly in regard to such things as "cause" and "symptom."

(A.W.Ge.)

Thunderstorms

A thunderstorm is a short-lived storm produced by clouds of great vertical extent and always accompanied by lightning and thunder. A thunderstorm often produces strong, gusty winds, heavy rain, and sometimes hail. Almost invariably, thunderstorms are associated with cumulonimbus clouds, dense rain clouds with exceptional vertical development that look like mountains or huge towers. In an advanced stage, their summits have a smooth, fibrous appearance and sometimes resemble a huge anvil (Figure 1). The base of a cumulonimbus cloud is usually dark because it has great depth. Sometimes, particularly in the mountainous areas of the western United States, water drops from a thunderstorm are small, and they evaporate before reaching the ground as precipitation (*q.v.*).

Within a cumulonimbus cloud there are strong updrafts that carry cloud particles and raindrops to the cold upper parts of the clouds. The interaction of water and ice particles causes the separation of electrical charge. In general, positive charge is concentrated in the upper regions of the cloud and negative charges near the central regions. When the accumulated electric charge becomes sufficiently large, a lightning (*q.v.*) discharge occurs. The massive surge of current in the lightning channel causes tremendous heating and sudden expansion of the air, and the resultant shock wave becomes the sound wave known as thunder.

Thunderstorms generally occur in warm, moist air. Although all of them have certain common features, in some ways they differ greatly. Some storms may be less than three kilometres (1.9 miles) in diameter, last less than half an hour, deposit no rainfall at the ground, and exhibit only one lightning flash. In other cases, lines of thunderstorms hundreds of miles long can sweep across the country causing torrential rain and hail, extremely strong winds, and tornadoes. When this happens, the storms pose great hazards to man, animals, crops, and property.

The damage to property and crops by hail in the United States is estimated to average about $200,000,000 a year. In northern Italy, southwestern U.S.S.R., Argentina, and many other countries, hail does tremendous damage to fruit orchards, vineyards, and grain fields. Lightning kills, maims, and burns every year. According to figures published by the U.S. Forest Service, lightning-caused forest fires destroy more than 500,000 acres per year in the United States.

The tornado, spawned by thunderstorms, is the most violent of atmospheric phenomena. On the average, tornadoes, whirlwinds, and waterspouts (*q.v.*) kill about 250 people each year and do tens of millions of dollars in damage.

Clearly, severe thunderstorms sometimes cause great destruction and misery, but they also do a great deal of good. In most regions of the world, rainfall during the growing season is supplied by thunderstorms. If heavy showers did not occur over the corn and wheat fields of the United States, Canada, and the Ukraine, there would be catastrophic shortages of food.

Society would benefit greatly if thunderstorms could be more accurately predicted, more precisely observed and tracked, and if they could be artificially controlled. If rainfall intensities and winds could be reduced, if lightning and hail could be suppressed, and if tornadoes could be eliminated, man would reap the benefits without suffering the disasters. Atmospheric scientists in the second half of the 20th century were actively working toward these difficult but not impossible goals.

CAUSES OF THUNDERSTORMS

Instability and convection

Thunderstorms occur when the atmosphere has a property termed instability. In essence, when a weather system is unstable, a small displacement leads to a larger one. When the atmosphere is unstable, a volume of air having an upward displacement for any reason will continue moving upward at an accelerating rate. If a sufficiently large mass of air begins rising, the result will be the formation of an updraft. If the air is moist as well as unstable, a cloud will form; and further growth can lead to precipitation and lightning.

The earth's atmosphere becomes unstable when the temperature decreases rapidly with height, this change coming about most often as a result of solar heating of the earth's surface and of the air in the lowest layers of the atmosphere. Some of the heat is transported upward by means of molecular motion and small-scale turbulent eddies of air. If the incoming energy exceeds that being transported upward, the temperatures in the lowest layers rise, causing the temperature lapse rate, the rate of temperature decrease with height, to continue increasing. When the lapse rate exceeds certain specific values depending on the humidity properties of the air, the atmosphere becomes unstable. If upward air motion is initiated by a mountain ridge, for example, a rising convection current is set in motion. The ascending stream of air will be warmer and more buoyant than the surrounding air. Heat and moisture are carried upward. Countercurrents transport cooler

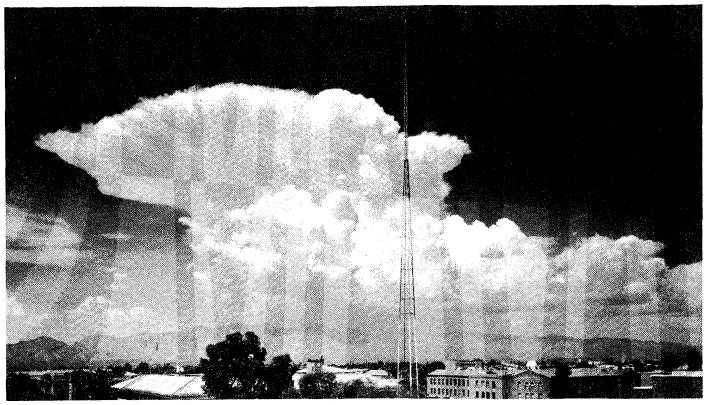

Figure 1: Cumulonimbus cloud with anvil, a classic thunderstorm
Louis J. Battan

and drier air downward. For the reasons just cited, the puffy clouds that start as cumulus and may become cumulonimbus are called convective clouds.

Such clouds may be initiated in a variety of ways. Some early studies often indicated that convective clouds and thunderstorms were started as a result of excessive warming of certain surface areas. The temperature differences were attributed to differences in the colour and hence the absorption properties of various soils and rocks. Sometimes thermals may be traced to such hot spots, but evidence indicates that most thunderstorms are set off as a result of organized lifting of the air.

As noted previously, mountain ridges are important in generating thunderstorms. Not only do they serve as a barrier that forces the air to rise, but also they become what are sometimes called high-level heat sources. Solar heating of the high terrain causes the air close to them to be warmer than the air at the same altitudes over the adjacent valleys. Because the warm air is less dense, it rises through the surrounding cooler and heavier air. The importance of this effect is shown by the fact that, even in mountainous areas, most thunderstorms occur during the afternoon and early evening hours when it is warmest.

Weather fronts

Thunderstorms are often initiated when a cold front advances toward moist, unstable air (see WINDS AND STORMS), which is forced to rise over the frontal surface. Sometimes lines of thunderstorms occur above and nearly parallel to a cold frontal surface. More often, particularly over the central United States, long lines or zones of thunderstorms develop in the warm air many tens of miles, sometimes several hundred miles, ahead of the cold front. The tendency of these so-called prefrontal squall lines to be more or less parallel to the front has suggested that they have been initiated by a dynamic mechanism related to the front.

In the tropics, weather fronts of the kinds so commonly noted at higher latitudes are almost never observed. Air masses of contrasting temperature do not come into contact, as is the case at the polar front, when air from the polar regions encounters air from the tropics. Nevertheless, the regions of maximum thunderstorm frequency occur in equatorial and tropical regions (Figure 2). These storms are triggered by air rising as a result of converging wind systems. When the northeast trade winds meet the southeast trades, the air at the zone of confrontation must rise. Because it is both moist and unstable, showers and thunderstorms are produced in abundance.

A variety of disturbances in the low-altitude wind field may lead to convergence and ascending air. Such disturbances occur often in equatorial areas and at higher latitudes as well and lead to cumulonimbus clouds and thunderstorms.

TYPES OF THUNDERSTORMS

At one time it was common to classify thunderstorms according to where they occurred; for example, as airmass, frontal, or orographic (mountain-related) thunderstorms. During the 1960s, it was found more meaningful to classify them according to the chief characteristics of the storms themselves; the characteristics depend largely on the properties of the environment in which a given thunderstorm develops.

Isolated thunderstorms, especially those that occur under atmospheric conditions such that the wind velocity does not change markedly with height, are sometimes called

By courtesy of the World Meteorological Organization

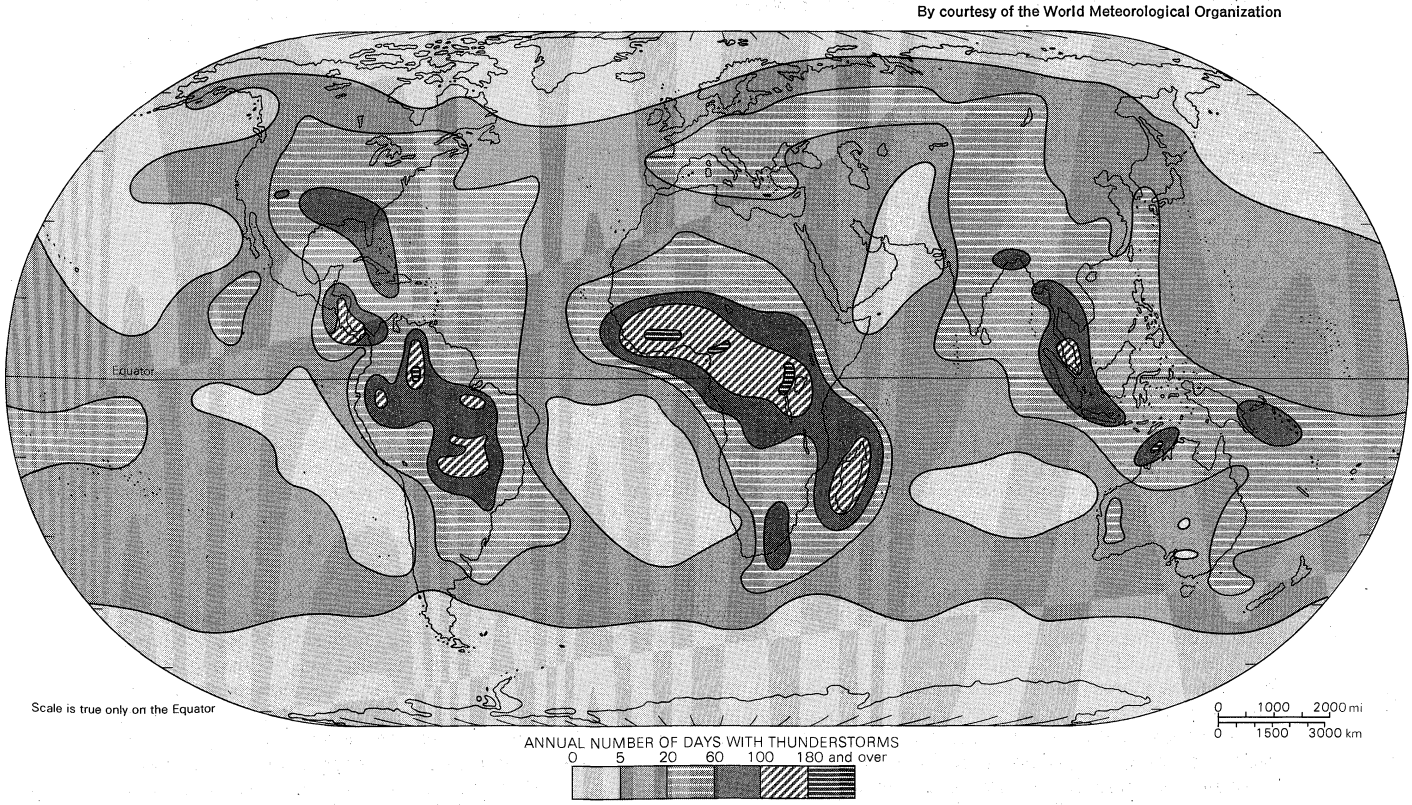

Figure 2: World patterns of thunderstorm frequency.

air-mass, or local, thunderstorms. They are mostly vertical in structure, relatively short-lived, and usually do not produce violent weather at the ground level. Extensive flight measurements indicate that such thunderstorms are composed of one or more individual cells, each of which passes through a definable life cycle. Early in the growth of the cloud, air motions are mostly upward not as a steady, uniform stream but as one that is composed of a series of rising eddies. The precipitation particles grow as the cloud grows; when the accumulated water and ice becomes excessive, a downdraft is started. At maturity a local storm may be composed of intense updrafts and downdrafts side by side (Figure 3). In its later stages the

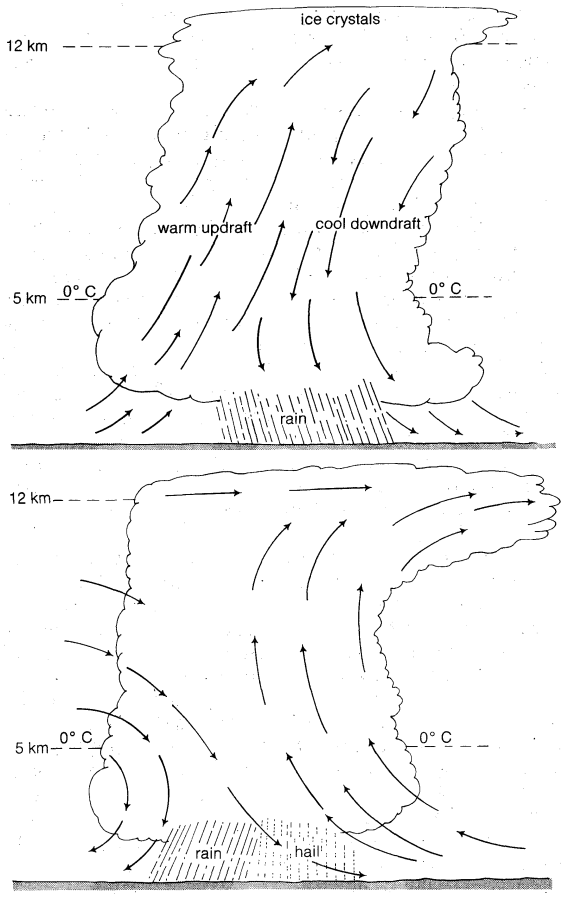

Figure 3: *Thunderstorm models.*
(Top) Mature stage of an isolated thunderstorm cell.
(Bottom) Cross section through a hail-producing organized thunderstorm.

updraft spreads throughout the cell and diminishes in intensity as the precipitation falls out.

Organized storms

Violent weather at the ground level usually results from a type of thunderstorm that is sometimes called an organized storm. Over the central United States, it commonly occurs when the winds in the middle layer of the atmosphere are from the southwesterly quadrant and are strong. Although there is still considerable debate about the structure of such storms, many authorities are convinced that in such thunderstorms the updraft is tilted from the vertical. Such storms may have a duration of many hours, remaining in a constant state of regeneration because moist, unstable air is drawn into the lower part of the cloud. Long swaths of hail can be produced by these storms; strong, gusty winds are common; and tornadoes sometimes are generated.

ENERGY OF THUNDERSTORMS

The energy to drive thunderstorms is supplied by a variety of sources, but most of it comes from the heat released when water vapour condenses to form cloud droplets. For every gram of water condensed, about 600 calories of heat are made available. When the water freezes in the upper parts of the cloud, another 80 calories of heat per gram of water are released. This energy goes to increase the temperature of the updraft and, in part, is converted to kinetic energy of upward and downward air movement. If the quantity of water that is condensed in and then precipitated from a cloud is known, then the total energy of a thunderstorm can be calculated. In an average thunderstorm, the energy emitted amounts to about 10^7 kilowatt-hours, which is equivalent to a 20-kiloton atomic bomb. A large, severe thunderstorm might be 10 to 100 times more energetic.

PHYSICAL CHARACTERISTICS OF THUNDERSTORMS

An individual thunderstorm cell may be perhaps 3 km (less than 2 mi) in diameter, may extend to an altitude of 8 to 10 km (26,000–33,000 ft), and may last less than 30 minutes. A larger local thunderstorm would be composed of many cells in varying stages in their life history. Such a storm can be tens of kilometers in diameter, its summit may extend to altitudes exceeding 18 km (59,000 ft), and its duration may be many hours.

When referring to the diameter of a thunderstorm, it is necessary to specify what is being measured. The quantities cited above refer to the diameter of the cloud at middle altitudes, the distance observed by an airplane flying through the cloud at an altitude of perhaps 5 km (16,000 ft). In such a penetration, the aircraft might encounter several updrafts and downdrafts. The most extensive measurements of thunderstorm properties by means of airplanes were made by the Thunderstorm Project conducted in 1946 and 1947 by the U.S. Weather Bureau in collaboration with the U.S. Navy and Army Air Forces.

Updrafts and downdrafts. Although updrafts and downdrafts encountered in Ohio and Florida thunderstorms sometimes had diameters exceeding 4 km (13,000 ft), most often they were between about 500 and 2,500 m at the altitudes between 3 km and 8 km (10,000–26,000 ft). At flight levels near 1,500 m (5,000 ft) the drafts tended to have a greater diameter and be weaker than at greater heights in the clouds.

Updraft speeds measured by the Thunderstorm Project ranged to a maximum of 26 metres per second (m/sec) (85 ft/sec) but usually were less than half that much. They increased with height and averaged 5.0, 7.3, and 8.4 m/sec (16.4, 24.0, and 27.6 ft/sec) at altitudes of 1.5 (5,000 ft), 4.5 (15,000 ft), and 7.6 km (25,000 ft), respectively. At the same altitudes, downdraft speeds were 4.6, 6.1, and 7.3 m/sec (15.1, 20.0, and 24.0 ft/sec), respectively. At greater altitudes, higher updraft speeds have been measured by aircraft and radar and have been inferred on theoretical grounds. Updrafts exceeding 20 m/sec (65 ft/sec) are not considered unusual in the upper parts of large thunderstorms. Airplanes flying through them at altitudes about 10 km (33,000 ft) have measured updrafts exceeding 30 m/sec (100 ft/sec). The strongest updrafts have been observed in severe organized thunderstorms, which often are many tens of kilometres in diameter. Lines or zones of such storms sometimes extend for many hundreds of miles.

Vertical extent of thunderstorms. The heights of thunderstorms have been measured by radar and by aircraft flying over their tops. They commonly extend to altitudes over 11 km (36,000 ft) and sometimes to over 20 km (66,000 ft). On very unstable days when the atmosphere is moist, the upper limit of the thunderstorm cloud is determined by the depth of the troposphere, that part of the atmosphere lying below the stratosphere. On such occasions the rising updraft air would be warmer than its environment until it penetrates through the base of the stratosphere. Since this layer is characterized by air temperatures that are nearly constant or may increase with height, it has great stability. The momentum of an updraft would carry it into the stratosphere, but after a short penetration the rising air would be cooler and heavier than the surrounding air. The resulting downward force would stop further upward motion.

The base of the stratosphere varies with latitude and season of the year. In general, it ranges from about 10 to 20 km (33,000 to 66,000 ft) with the higher found in the

summer at lower latitudes. When the rising cloud air encounters the stable stratosphere, it spreads outward and forms the anvil cloud so characteristic of thunderstorms. If winds are light, the anvil may extend in all directions around the cloud. Most of the winds at the anvil altitudes carry cloud material downwind.

Thunderstorm tops do not usually reach the stratosphere. More often their vertical extent is determined by a stable layer in the troposphere. For a number of reasons, layers may be formed where the temperature is constant or increases with height. Sometimes the air temperature decreases only slowly with height. Regions where the temperature decreases slowly or increases with height are stable layers, and a rising volume of air encountering them often cannot penetrate them. As a result the stable layer determines the maximum vertical extent of the cloud and the altitude where the cloud spreads out to form the anvil.

Turbulence. An airplane flying through a thunderstorm is commonly carried upward and downward by the drafts in the storm. In addition, it often is buffeted from side to side and up and down. This motion is called turbulence, which is caused by large changes in air motions over distances comparable to the dimensions of the airplane. Turbulence not only contributes to crew and passenger discomfort but also subjects the aircraft to undesirable stresses. In severe turbulence, structural damage may result, most likely when the turbulence stresses are augmented by forces caused by airplane manoeuvres. For example, if the pilot tries to maintain altitude for an airplane in a very strong downdraft that contains so-called sharp-edge gusts that produce turbulence, he will impose additional forces on the wings, adding to those imposed by the gusty air. In the limiting case, a wing may collapse.

Turbulence may be expressed in various units. Commonly, the g unit, equal to the acceleration of gravity of the earth, is used. A gust of 1 g will cause severe aircraft turbulence. In the upper part of violent thunderstorms, vertical accelerations of about 3 g have been reported.

Movement of thunderstorms. The motion of a thunderstorm is determined largely by the average wind velocity in the layer of the atmosphere in which the storm develops. The average speed of 120 thunderstorms observed in Florida and Ohio was 20 kilometres per hour (12.4 miles per hour), but some storms moved much faster. In extreme circumstances thunderstorms may move at 65 to 80 km/hr (40 to 50 mph).

When considering the movement of a thunderstorm, the dynamic character of it must be taken into account. Most storms are in a constant state of change, with new cells developing while old ones dissipate. When wind speeds are light, an individual cell may move very little, less than 2 km (1.2 mi), during its lifetime; but new cells forming downwind may give the illusion of rapid cloud motion. This type of behaviour is often observed in mountainous areas. The first storms of the day generally form over the ridges. As the day progresses, new clouds develop near the existing ones but closer to the valleys. An observer who sees the nearest edge of the clouds getting closer may readily assume that the original clouds are moving over the valley.

Although new cloud developments generally occur downwind of an existing storm, this is not necessarily the case. Sometimes they grow on the flanks and, as a result, visual observations may lead to the notion that there is little relation between the winds and thunderstorm motion. As would be expected, this view is most likely to arise when wind speeds are low.

WEATHER UNDER THUNDERSTORMS

Wind velocities and temperature

The air in a thunderstorm downdraft descends from altitudes where the temperature is lower than at the ground. Moreover, the downdraft is maintained at a cooler temperature than its environment by the evaporation of water and ice particles. The sinking air is not only heavier than the surrounding air, but its so-called horizontal momentum also differs from that of the surrounding air. If the descending air originated at an altitude of 10 km (6.2 mi), for example, it would reach the ground with a horizontal velocity that somewhat resembles the wind velocity at its level of origin. When the air strikes the ground, it usually moves outward ahead of the storm at a higher speed than the speed of the storm itself.

In extreme circumstances, the outrushing, cool air may reach velocities of 100 kilometres per hour (62 miles per hour) or more and do extensive damage to property and vegetation. This severe wind most often occurs when organized lines of severe thunderstorms form in an environment where the middle level winds are very strong. When serious wind damage is produced by such a storm, the victims may suspect that it was caused by a tornado. Of course, if a funnel cloud is observed, then the nature of a storm would be obvious. If a funnel cloud is not observed, the character of the damage can be revealing. Tornadoes blow debris in a tight circular pattern, whereas the outflowing air from a thunderstorm pushes it mostly in one direction.

An observer on the ground watching a thunderstorm approach can feel the gusty, cool air before the thunderstorm passes overhead. The outspreading, downdraft air forms a pool some 500 to 2,000 m (1,600 to 6,600 ft) deep. Often there is a very distinct boundary between the cool air and the warm, humid air in which the storm formed in the first place. The passage of such a boundary is easily recognized as wind speeds increase and the air temperature suddenly drops. Over a five-minute period, a cooling of 10° F (more than 5° C) is not unusual, and cooling that is twice as great is not unknown.

Precipitation from storms

By the time the cool air begins spreading over the ground, rain usually is reaching the surface. Sometimes all the raindrops evaporate while falling, and the result is a dry thunderstorm. At the other extreme, thunderstorms can produce the most torrential downpours imaginable. Under a cumulonimbus cloud, impending rain usually can be predicted when the cloud base darkens, indicating a deep layer of cloud obscuring the rays from the sun. Often, but not usually, a flash of lightning occurs and the rain follows several minutes later. There is still disagreement about the interpretation of this sequence of events. Once the rain starts, it builds up rapidly, commonly reaching its maximum intensity between five to ten minutes after the start. In small Ohio thunderstorms, the maximum five-minute rate was 122 millimetres (about 4.8 inches) per hour but most often was less than one-tenth of this amount. The average thunderstorm yielded 2×10^8 kg (220,000 short tons) of rain, but some large storms gave ten times more. Large organized storms can produce 10^{10} to 10^{12} kg of rain.

The following table lists certain extreme rainfall quantities in various parts of the world. They represent measurements at a single point.

Some Extreme Rainfall Rates*

date	place	duration	amount (inches)	amount (cm)	average rate (mm/hr)
April 5, 1926	Opids Camp, Calif.	1 min	0.65	1.65	990
Sept. 30, 1925	Haughton Grove, Jamaica	3 min	1.6	4.07	814
Nov. 29, 1911	Porto Bello, Panama	5 min	2.5	6.37	765
May 12, 1916	Plumb Point, Jamaica	15 min	8.0	20.3	812
June 22, 1947	Holt, Mo.	42 min	12.0	30.5	436
July 14–15, 1947	Baguio, P.I.	24 hr	46.0	117.0	487

*Probably from thunderstorms, but not documented.

As the duration of the rainfall increased, the average rates decreased but were extreme in every case shown. Such rapid accumulations of water invariably cause flooding; greater damage is, of course, associated with longer durations and greater quantities.

OCCURRENCE OF THUNDERSTORMS

Thunderstorms are most likely to occur in a moist, unstable atmosphere. Air masses having these properties are commonly formed over equatorial and tropical areas. When a body of air moves over low-latitude oceans, it is

humidified by evaporation from the underlying water surface. Heat is transferred from the warm ocean water to the air. In addition, the nearly direct rays from the sun warm the moist, lowest layers of the atmosphere. As a consequence of these processes, moist, tropical air masses develop suitable properties for thunderstorm formation.

Disturbances in the wind field caused by pressure perturbations or changes in topography leading to an upward displacement of the air initiate the development of thunderstorms. All the conditions necessary for their occurrence are most often met over the land areas in the equatorial zone between ten degrees north and south latitudes

Frequency of storms

where the average number of days with thunderstorms exceeds 100 per year. In certain places in equatorial Africa and South America, there are more than 180 thunderstorm days in an average year (Figure 2).

At higher latitudes, the frequency of thunderstorms depends on the character of the topography and the frequency of invasions of moist, tropical air. Since this happens most often in the spring and summer, the Northern Hemisphere experiences most of its thunderstorms between May and September, whereas thunderstorm maximums are found some six months later in the Southern Hemisphere.

Over the large continental area of North America, thunderstorms occasionally occur, even in the winter, in the states along the coast of the Gulf of Mexico. As summer approaches, moist, tropical air gradually extends to higher latitudes and thunderstorms do likewise. By July and August they occur on the average on more than six days per month over the flatlands of central Canada.

During midsummer, areas of high thunderstorm frequency are centred over the Florida peninsula and northern New Mexico where 18 to 20 thunderstorm days per month are experienced. The frequent thunderstorms in the New Mexico-Colorado area are initiated as warm, humid air is forced to rise on the east slope of the Rocky Mountains. On a yearly basis there are about 90 thunderstorm days in central Florida.

Thunderstorms constitute a common feature of the summer monsoons (*q.v.*) in many parts of the world, particularly over southern Asia. As the continent is warmed by solar radiation, an ocean-to-land air current is established. Moist, unstable air from the Indian Ocean is carried inland and is forced to rise up the steep slopes of the Himalayas. As a result, showers and thunderstorms are produced in great abundance. Record high rainfalls occur. The annual average precipitation at Cherrapunji, India, is about 11.6 m (457 in.) per year with about 10 m falling during the period from May to September.

In cold regions, poleward of about 60° latitude, thunderstorms are scarce or nonexistent because of the cold air near the ground and the stable atmospheric conditions. There also are few thunderstorms over those parts of the earth dominated by semipermanent high-pressure centres. See CYCLONES AND ANTICYCLONES. In these regions, which correspond to the great deserts of the world, the air generally descends. This causes a drying of the air and a stabilization of the atmosphere; as a result, thunderstorm development is inhibited.

OBSERVATIONS OF THUNDERSTORMS

Most of the existing data on thunderstorms have been accumulated by weather observers. Unfortunately, by visual observations, it is difficult and often impossible to obtain quantitative information about the characteristics of the clouds that produce the thunder. When widespread thunderstorms occur, the sky commonly is overcast with many intermingled layers of clouds of various types. Cloud summits are frequently obscured.

Advances in aviation, and in particular the development of airplanes of high structural integrity, have made it possible to fly through thunderstorms to measure their internal properties. High-flying airplanes have yielded accurate data on the vertical extent of thunderstorms.

Radar observation of storms

The development of radar during World War II contributed a great deal to the store of knowledge about thunderstorms. Most of the available statistics on thunderstorm dimensions and movements have been obtained by means of radar. Conventional radar sets measure the location and reflectivity of water and ice particle concentrations. By noting changes in the intensity, size, or position of radar echoes, it has been possible to infer the nature of the motions in the thunderstorms.

By courtesy of the National Severe Storms Laboratory, ESSA

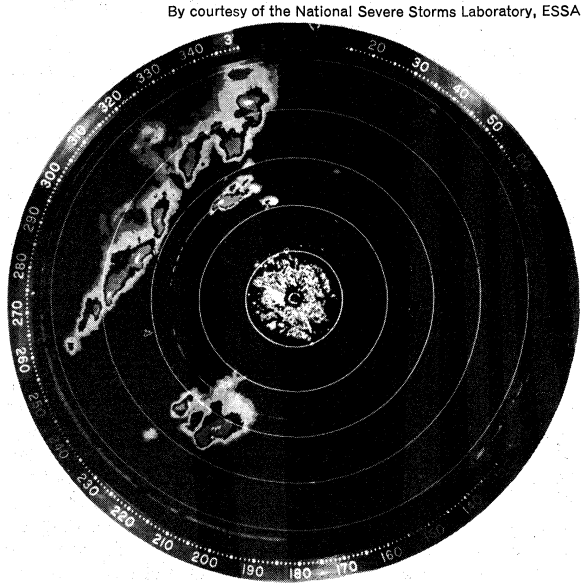

Figure 4: Radarscope with concentric rings spaced at intervals of 20 nautical miles. A line of thunderstorms is oriented northeast–southwest. Another large isolated storm is located southwest of the centre. The varying shades of gray show the varying intensity of the radar echo.

Networks of radar sets are employed by the civil and military weather services in several countries to detect and track thunderstorms. All commercial airliners are now equipped with radar to allow the pilots to observe thunderstorms and take evasive action and thereby reduce flight hazards and increase passenger comfort.

Since about 1960, atmospheric scientists have begun to use pulsed-Doppler radar sets. Such equipment not only can make the same observations as were made by earlier radars but can measure the instantaneous fields of motion of the precipitation particles. In certain circumstances, this information can be used to measure the speeds of updrafts and downdrafts. Furthermore, it is sometimes possible to infer the size of the precipitation particles.

Weather satellites photograph cloud patterns and telemeter the pictures back to earth (see WEATHER FORECASTING). Radiometers on board the satellites supply information on the temperatures of the clouds (*q.v.*) that are observed. On the basis of appearance and temperature, it is possible to infer when a cloud is a cumulonimbus and, hence, probably a thunderstorm source. At the present time, satellite data are revealing patterns of convective cloud and thunderstorm development on a scale never seen before. The information has been particularly valuable over the vast, low-latitude oceanic areas that were never adequately observed in the past. It is anticipated that, in time, satellite data coupled with radar and aircraft data will lead to more realistic models of thunderstorms than exist today.

Thutmose III

Perhaps the greatest of the pharaohs of ancient Egypt, Thutmose III is generally regarded as the architect of the Egyptian empire. His reign marked the beginning of the greatest epoch in the country's history. But the first 21 years of his reign must have been filled with frustration and disappointment.

Thutmose III was the son of Thutmose II, a son of Thutmose I; his mother was one of the King's minor wives or concubines, named Isis. Thutmose II married his half sister Hatshepsut and was crowned the fourth king of Egypt's 18th dynasty. Before his untimely death (1504 BC) Thutmose II made some show of arms against the Palestinian Bedouin and crushed a rebellion in Nubia with severity. Since there was no prince with a better claim to the throne, the boy was crowned king on the early death of his father; he was about ten at the time and was betrothed to the heiress, his half sister Neferure. Nefe-rure's mother, Hatshepsut, the daughter of Thutmose I and wife and sister of Thutmose II, acted as regent. In the second year of his reign this strong-minded and ambitious woman herself assumed the attributes, dress, and insignia of a king and to all intents and purposes reigned in his stead. As one of her courtiers says, "she directed the affairs of the whole land according to her wishes." Still, Thutmose was given an education befitting his royal station. He was taught all military skills, especially archery, which he demonstrated in public display, and horsemanship, in which he showed considerable prowess. He was later to boast that none among his followers could equal him in physical strength and in marksmanship.

Thutmose's minority

Hirmer Fotoarchiv, Munchen

Thutmose III smiting the Asiatics, limestone relief from the Temple of Amon at Karnak, 1490–36 BC.

As he grew up, Thutmose may even have been entrusted with command of the army on campaign in Nubia; whether he also fought in Palestine is doubtful. His grandfather Thutmose I had penetrated into northern Syria; Thutmose II, though far from a weakling, had not followed this success, and Hatshepsut, as a woman, may have been unwilling to send an army into the field. Thus, through inaction, Egyptian influence in Syria and Palestine had declined. The sons and grandsons of the Syrian princes who had surrendered to Thutmose I no longer sent tribute, and the king of Mitanni, a powerful Mesopotamian kingdom with its capital beyond the Euphrates, was able to extend his control westward to the Mediterranean.

In the 22nd year of Thutmose's reign, a formidable coalition was formed against Egypt, led by the king of Kadesh in northern Syria, and no doubt supported by the Mitanni. At this moment of crisis Hatshepsut died. Her death was opportune; whether her nephew was responsible is a matter of surmise only, but later in his reign, he decreed that her name be obliterated on all her monuments, her statues smashed, and her figure erased from reliefs.

First Syrian campaign

After a few months' preparation the King was ready to march at the head of his army. The first campaign is recorded in some detail on the walls of the temple he built at Karnak in Thebes that depict the march to Gaza and thence to Yahmai south of the Carmel Range, the Council of War, and the King's bold decision to surprise the enemy encamped at Megiddo, northeast of Carmel and about 18 miles southeast of the modern city of Haifa. Thutmose's approach was by the route least expected, a narrow defile over the mountain. It was successful. The enemy was defeated and Megiddo was taken after a siege of eight months. In subsequent campaigns, which are less fully described in the annals, ports on the Phoenician coast were converted into Egyptian supply bases, and Kadesh and other cities in al-Biqāʿ (Beka) Valley were taken.

In the 33rd year of Thutmose's reign, the time was at last ripe for his most audacious move, an attack on the kingdom of Mitanni itself, which had grown stronger since the day when Thutmose I had taken its army by surprise. Thutmose planned the campaign well; pontoon boats were transported across Syria on oxcarts for the crossing of the Euphrates River. The ensuing encounter, which must have taken place on the eastern bank, is not described by the annalist; it resulted in the precipitate flight of the Mitannian king and the capture of thirty members of his harem and some hundreds of his soldiers. Triumphantly, Thutmose set up his commemorative inscription by the river's edge, next to that of his grandfather Thutmose I. It was his farthest point of advance. On the homeward journey he also hunted elephant in the land of Niy, in the Orontes Valley, and on his return he celebrated a great triumph at Thebes and dedicated prisoners and booty to the temple of the state god Amon.

In later campaigns (there were 17 in all), Thutmose III was content to consolidate what he had won and to lay the foundations of an imperial organization of his Asian possessions. Native rulers, members of local ruling dynasties, were henceforward set to govern their own territories as vassals of Egypt and were bound by solemn oath to keep the peace, render annual tribute, and obey the Egyptian representative in the region, the "overseer of foreign lands." Their sons were sent as hostages to Egypt and educated at court, so that in due course they might return to rule their inheritance, Egyptianized in outlook and sympathies. Fortresses were built, and Egyptian garrisons were stationed at key points along the coast and in the highlands.

To the south, Thutmose extended the limits of Egyptian domination over Nubia as far as Napata, near the Gebel Barkal, where he built a temple to Amon. He thoroughly subdued the turbulent Nubian tribes and employed many of them in the gold mines, which from his reign on became the basis of Egyptian wealth in foreign exchange with the princess of western Asia. For the last 12 years of his reign, he was content to enjoy the fruits of his victories. The tribute of Syria and Palestine and of the Sudan poured into his treasury; the annals list huge quantities of timber and metal ores, cattle, and grain delivered by the conquered. Minoan Crete and Cyprus, Babylonia, Assyria, and the Hittites sent gifts. The tombs of high officials of the reign are decorated with scenes depicting the reception of foreign envoys coming from places as far away as the Aegean and the Greek mainland to lay their rich and exotic gifts at the feet of the pharaoh. The prestige of Egypt had never been so high.

The new prosperity is reflected in the remarkable pro-

Architectural endeavours

gram of building undertaken by the King's architects. The Temple of Amon at Karnak in particular was enlarged and enriched by many new buildings and a number of obelisks. Two of the splendid granite obelisks that he erected there are now in Istanbul and Rome; of the two, now known as Cleopatra's Needles, with which he adorned the temple of the sun-god at Heliopolis, one is in New York's Central Park, and the other on the Thames embankment in London. During his reign art and craftsmanship received new impetus from his patronage. The exotic birds, beasts, and plants that he brought back from his campaigns in Asia are depicted on the walls of his Festival Hall at Karnak; among the gifts sent him from abroad were a live bear, an elephant, a giraffe, and "birds that give birth every day"—probably domestic hens, which were rare in the Near East at that time.

During the last year of his life, feeling his strength failing, Thutmose appointed his son Amenhotep II, the son of his second wife, Hatshepsut's daughter Meryetre, as co-regent. When he died, in 1450 BC, he was laid to rest in a remote corner of the Valley of the Tombs of the Kings in western Thebes. Along with many other royal burials, this tomb was later looted by robbers and the mummy of the pharaoh was one of those discovered in 1889, in a hiding place where the priest-kings of the 21st dynasty had hidden them for safety. Of the rich furniture that must originally have been placed in the tomb, only a few fragments were found. His mortuary temple, which was built on a terrace at Dayr al-Baḥrī beside that of Hatshepsut, was discovered in 1962.

Nearby, the burial place of three members of his harem was found; judging by their names, they were Syrian princesses, and though of minor rank their jewelry and equipment were extremely lavish.

Of all the kings of ancient Egypt, Thutmose III is perhaps the one who, for the modern historian, most nearly comes to life. His records, though couched in the boastful and extravagant terms thought befitting a pharaoh's exploits, leave little doubt not only of his ability as a soldier and a statesman, but also of his abilities as an athlete and a hunter of lion, wild cattle, and elephant. From his mummy it is known that he was a small man, not above five feet three inches in height. His statues show a resolute face with a large, high-bridged nose and pleasantly smiling mouth.

His fame lived after him. His name, inscribed on countless amulets, was thought to bring power and protection to the wearers. A popular hymn celebrating his triumphs became a model for later paeans of victory; in it the god Amon-Re says:

> I set thy glory and the fear of thee in all lands, and the terror of thee as far as the four supports of the sky. . . . the rulers of all foreign countries are gathered together within thy grasp. I stretch out my hands to bind them for thee.

BIBLIOGRAPHY. There is no separate life of Thutmose III. His career and achievements are described in some detail in general histories such as J.H. BREASTED, *A History of Egypt from the Earliest Times to the Persian Conquest* (1905, reprinted many times); and, more recently, A.H. GARDINER, *Egypt of the Pharaohs* (1961). The newly revised edition of *The Cambridge Ancient History*, vol. 2, pt. 1 (1971), contains chapters by WILLIAM C. HAYES on the early part of the 18th dynasty; and by MARGARET S. DROWER on the Egyptian Challenge and Egypt in Asia. The bibliographies to these chapters are very full. The text of Thutmose's annals and other inscriptions may be found in J.H. BREASTED (ed.), *Ancient Records of Egypt*, vol. 2 (1906). For a better translation of the more important texts, see J.B. PRITCHARD, *Ancient Near Eastern Texts Illustrating the Old Testament*, 3rd ed. (1966); the fullest commentary on the Asian campaigns is that of H.W. HELCK in *Die Beziehungen Ägyptens zu Vorderasien im 3. und 2. Jahrtausend v. Chr.* (1962). Statues of the king, some of which may be portraits, are illustrated by C. ALDRED in *New Kingdom Art in Ancient Egypt During the Eighteenth Dynasty, 1590 to 1315 B.C.* (1951), no. 25, 35–37, 39.

(M.S.D.)

Thysanoptera

Members of the order Thysanoptera, among the smallest of the winged insects, are abundant in the tropical and temperate regions of the world. The approximately 5,000 species that have been described so far are also known as thrips. Thrips have an economic importance, for some species transmit plant viruses, and by their feeding reduce seed production, disfigure flowers and fruits, and damage plant leaves. In warm areas a number of them cause plant galls and leaf rolls. On the other hand, a few species prey on destructive mites and scale insects, and a number may aid in the pollination of flowers and, indirectly, in the formation of leaf mold.

General features

Most thrips are 1.5 to 3 millimetres in size, with the smallest being about 0.6 millimetres and the largest about 15 millimetres. Because of their minute size they can enter the smallest flowers or tiniest cracks in stems and bark. Their wings, when present, are narrow and fringed, hence the name Thysanoptera (Latin, "fringed wings"). Despite their Lilliputian size, thrips are often elaborately ornamented with hexagonal designs, spines, or body flanges. The bristles (setae) of some are expanded at the tips or elongated, or the body wall may be expanded into prongs or forks. The larvae of thrips tend toward bright colours (red, orange, or yellow); the adults range from whitish to browns or black. Adults have extensible bladders on the tarsi of the legs, as suggested by the common name bladder feet.

Natural history. *Life cycle.* The development of thrips takes place in the egg, in two larval stages, during which all the immature feeding occurs, and in one, two, or three pupal stages in which no feeding has ever been observed.

Although the changes that occur in pupae of Thysanoptera resemble those that occur in insects that undergo complete metamorphosis, thrips are said to undergo only simple metamorphosis.

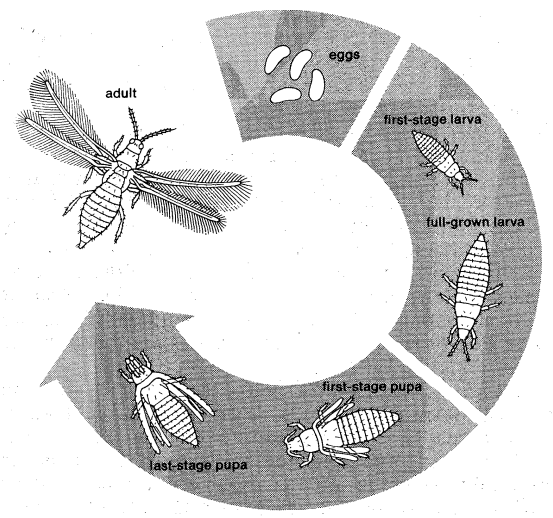

Figure 1: Life cycle of pear thrips.

The primary method of reproduction among thrips is by bisexual union. The males frequently are shorter lived than females, and mating often takes place early in the life span, when the adults first appear. Reproduction by unfertilized eggs (parthenogenesis) has been known to occur occasionally.

Egg laying

Thrips in the suborder Terebrantia always lay eggs, as do most thrips in the more advanced suborder Tubulifera. Hatching of eggs within the female (ovoviparity), occurs in some highly evolved members of the Tubulifera. Eggs are elongated, oval to kidney shaped, faintly to distinctly sculptured, and, as is the case in other minute insects, are proportionately large, often occupying two or three abdominal segments of the female before laying. Ordinarily, eggs of the Terebrantia are inserted into living plant tissue in a slit prepared by the sawlike ovipositor of the female. By contrast, eggs of the Tubulifera, whose females have no ovipositor, are pushed under bark, in or between flowers and leaf sheaths, or are glued onto leaf or bark surfaces. Eggs take from three to 16 days to hatch according to the species and conditions.

Although similar in overall form to the adult, the larvae of thrips are weaker and simpler in structure. The long anal bristles characteristic of larvae may hold droplets of excreted liquid that are deposited on leaf surfaces. The presence of dark coloured spots of excreta adjacent to light coloured feeding zones are some typical signs of thrips damage.

Larval stages

The first stage is short (a few days); the second may last up to many months when estivation or hibernation occurs. In the Terebrantia the second stage larva transforms into a prepupa, whereas in the Tubulifera an abbreviated form, the primipupa, is part of the sequence of development and is followed by the prepupal form. The prepupal stage is of short duration (a few hours to several days) and gives rise to the final pupal stage, of short or long duration, that eventually produces the adult. Pupation takes place in the ground in earthen cells (in the case of many advanced Terebrantia), in cocoons (in many primitive Terebrantia), or on a host plant (in many advanced Terebrantia and the Tubulifera). Some thrips, for example, the pear thrips, have only one generation per year; others such as the onion thrips may have several generations each growing season.

Ecology. In regions having winter cold, thrips hibernate as adults or immature forms in detritus, hollow stems, or in the ground. Those that perish with the cold are replaced each year by spring migrants from warmer areas. In the tropics many thrips exhibit seasonal fluctuations, being more active in the wet than in the dry seasons. Some thrips are sensitive to relative humidity. Larvae are generally found in shady locations, on the underside of leaves or branches. Adults occasionally occur on the upper side of leaves in bright light. Most thrips rest tightly against leaf veins or in crevices. They are primarily active during the daylight hours.

Thrips are preyed upon by many insects (including other thrips), mites, birds, salamanders, and lizards. Heavy rains, winds, and dust are, however, probably as destructive to thrips as are predators.

Form and function. *The larva.* In the larvae, the compound eyes are composed of a few facets, simple eyes (ocelli) are absent, antennal segments are fewer than in the adult, the middle portion of the body (thorax) is simple, the lower part of the leg (tarsus) is always one segmented (although also occasionally so in some adults), and the wings and genitalia are not developed. Larval bristles (setae) often differ in form, number, and arrangement from adult setae. Occasionally additional processes such as spines, combs, and plates are found on larvae.

The adult. The head of a thrips is slightly skewed with the mouth cone directed posteriorly. Generally the antennae, basically nine-segmented but frequently reduced by fusion, project forward in front of the eyes. Of the mouthparts only the single left mandible is developed and the maxillae are modified into piercing stylets. Both the maxillae and the labium bear segmented sensory projections (palps).

The middle portion of the body (thorax) bears the legs. The first part of the thorax (prothorax) of thrips bears the fore legs, the inner parts (coxae) of which may exhibit ridges that when rubbed with spurs from the lower parts (femurs) supposedly emit sound. The remainder of the thorax (pterothorax) bears the wings as well as the mid and hind legs. The wings are usually fairly simple and straplike. At rest they are laid over the abdomen but never folded. Typically the wings have long posterior fringes with shorter fringes occurring on the leading edge of the wings.

The abdomen is elongated and generally flattened dorso-ventrally, especially in the Tubulifera. There are ten distinctive segments with a rudiment of the 11th. The first and eighth abdominal segments bear breathing holes (spiracles). Often in the Tubulifera, several setae on the back are S-shaped and hook into the wing fringes to hold the wings at rest. In the Terebrantia the terminal segment is rounded in the males and split ventrally up to the eighth segment in the females. In the Tubulifera the terminal segment is tubelike.

The male genital organs are composed of paired appendages and an unpaired copulatory organ (aedeagus), all of which retract into the abdomen. The paired testes and accessory glands with their ducts occur in the posterior half of the abdomen. The female of the Terebrantia usually has an ovipositor composed of two pairs of sawlike blades. These are absent in the Tubulifera. There are eight egg sacs (ovarioles) and spherical, often pigmented, seminal receptacle for storage of sperm acquired during mating.

Evolution, paleontology, and classification. The Thysanoptera are part of the Psocoptera or Corrodentia-Hemiptera phyletic line of insects. Their origin may have been correlated with the development of the left mandible as an efficient chisel for piercing pollen granules. Possibly during the period when ancestral types were pollen feeders early thrips proliferated into a distinct order, which has since become diverse. Because of their small size, the development of fringe wings seemingly was favoured to overcome disproportionate drag on the uplift of the wings.

The earliest fossil, *Permothrips longipennis*, seems closest to the family Aeolothripidae, the most generalized and perhaps ancestral type. All extant families are known from fossils embedded in amber. The most advanced groups are the families Thripidae and Phlaeothripidae. The terebrantian families mostly retain their habit of feeding on vascular plants and pollen. Many members of the single extant tubiferan family Phlaeothripidae have adjusted to feeding in moldy debris.

Distinguishing taxonomic features. Although no particular structure is absolutely indicative of a taxonomic level, many features are useful in separating the major groups of Thysanoptera. The form of the antennae and its appendages, the shape and structure of the forewing, abdominal characters including form of the ovipositor in females, and glandular and setal location are important characters for determining the familial relationships. At the generic and species level antennal details, mouthparts, and body sculpturing are useful taxonomic characters, along with colour and bristle arrangement.

Annotated classification. The classification presented here is based on that of H. Priesner (1957, 1960).

ORDER THYSANOPTERA

Insects averaging about 2 mm; unique in that the right mandible is atrophied, resulting in an asymmetrical mouthcone; wings, when present, bear long fringes. Extensible bladders on the tarsi of the adults.

Suborder Terebrantia

The 10th and last abdominal segment, rarely tubelike, always split ventrally, major anal setae arising from subapical region, never from separate platelets; with sawlike ovipositor in female; wings usually with fine hairs (micotrichia) and at least 1 longitudinal vein; larvae with intermediate antennal segments bearing rings and microsetae; pupae with antennal sheaths either extended forward of head or lying over head; eggs without polar thickenings. 2 fossil families, Permothripidae and an undetermined family are, respectively, from Permian and Jurassic periods. Present families include the following.

Family Aeolothripidae

Oligocene (Baltic amber) to present. Worldwide. Antennae 9-segmented; ovipositor may be upturned or straight; forewings broad and rounded at tips, surface with microtrichia and several longitudinal and cross veins; antennal sensors on intermediate segments in form of linear or circular disks.

Family Merothripidae

Oligocene (Baltic amber) to present. Worldwide. Antennae 8- or 9-segmented; ovipositor downturned, often weakly developed; forewings narrow, surface smooth; antennal sensors on intermediate segments disclike.

Family Heterothripidae

Cretaceous (Cedar Lake amber) to present. Western Hemisphere and India. Antennae nine-segmented; ovipositor downturned; forewings narrow, surface with microtrichia; antennal sensors on intermediate segments as flat discs or protruding peglike cones.

Family Thripidae

Oligocene (Baltic amber) to present. Worldwide. Antennae 6- to 9-segmented; ovipositor downturned, rarely weakly

developed; forewings narrow, with microtrichia; antennal sensors on intermediate segments as simple or forked sense cones.

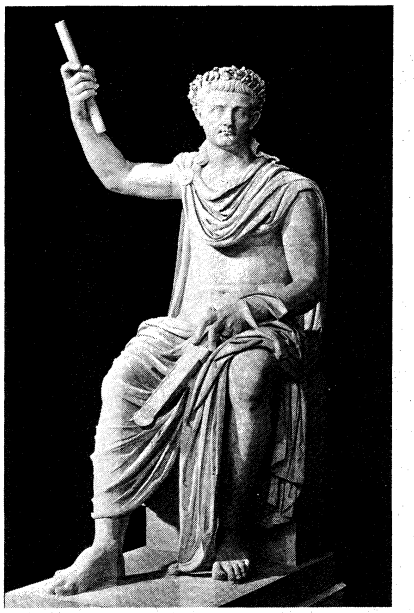
Suborder Tubulifera

The 10th abdominal segment tubelike, never split, major anal setae arising from separate plates adjacent to the tube; females without ovipositor; wings without longitudinal veins or fringe; larvae with antennal segments smooth not ringed; pupae with antennal sheaths hornlike or curved around (not over) head; eggs often with a tubercule on anterior pole.

Family Phlaeothripidae

This is the only family currently assigned to the suborder. Representatives occur throughout the world are known from Oligocene (Baltic amber) to the present.

Critical appraisal. The subordinal disposition of the thrips is well established, but the ranking of family groups as given above is disputed by some who would raise the families to superfamily rank. The order was earlier (1838) designated the Physapoda by H. Burmeister, given in allusion to the swollen tarsi, the so-called bladder feet.



BIBLIOGRAPHY. The literature on Thysanoptera is widely scattered throughout numerous entomological journals with occasional summaries given in monographs or lists. The monographs are predominantly faunal studies, though they often include regional revisions of some of the taxa. Only a few complete generic revisions have been published. Some of the latest, though not necessarily recent, faunal monographs are: S.F. BAILEY, "The Thrips of California, Part 1: Suborder Terebrantia," *Bull. Calif. Insect Surv.*, vol. 4, no. 5, pp. 143–220 (1957); H.E. COTT, *Systematics of the Suborder Tubulifera (Thysanoptera) in California* (1956); L.J. STANNARD, "The Thrips, or Thysanoptera, of Illinois," *Bull. Ill. Nat. Hist. Surv.*, vol. 29, no. 4, pp. 215–552 (1968); G.D. MORISON, "Thysanoptera of the London Area," *Lond. Nat.*, reprint no. 59 (1947–49). Two comprehensive catalogues and annotated synopses are C.F. JACOT-GUILLARMOD, "Catalogue of the Thysanoptera of the World (Part 1)," *Ann. Cape Provincial Museums (Nat. Hist.)* (1970); and L.J. STANNARD, *The Phylogeny and Classification of the North American Genera of the Suborder Tubulifera (Thysanoptera)* (1957). Proposals for the classification of the thrips that have received general acceptance are those by H. PRIESNER, "Zur Vergleichender Morphologie des Endothorax der Thysanoptera," *Zool. Anz.*, vol. 159, no. 7–8, pp. 159–167 (1957), and "Das System der Tubulifera (Thysanoptera)," *Anz. öst. Akad. Wiss.*, 13:283–296 (1960). Morphological treatments of the Thysanoptera are found in R.G. DAVIES, "Observations on the Morphology of the Head and Mouthparts in the Thysanoptera," *Proc. R. Ent. Soc. Lond.* (A), vol. 33, no. 7–9, pp. 97–106 (1958); and P. PESSON, "Ordre des Thysanoptera," in P. GRASSE, *Traité de zoologie*, vol. 10, no. 2, pp. 1805–1869 (1951). A source of ecological information on thrips is that by L. CEDERHOLM, *Ecological Studies on Thysanoptera* (1963).

(L.J.S.)

Tiberius

Tiberius, Rome's second emperor, whose reign was initially marked by wise and beneficent measure, ended his life as a tyrannical recluse. Yet he left behind him institutions that helped to ensure the survival of the empire. Tiberius Claudius Nero Caesar Augustus was a man of puzzlingly conflicting qualities. He had the training and talent to be a great administrator and a victorious general. Rome—the state, not the city—flourished under Tiberius. The rebellious borders were subdued, the treasury grew fat, and the provinces were prosperous and well governed. The city itself was less fortunate. By the time Tiberius became emperor he was 56 years old. He had lost every person he ever loved, and he had himself experienced insults, threats, and exile. Tiberius, or those who spoke in his name and employed his power, brought to the city of Rome an accelerating reign of insecurity and terror that threatened almost every major figure and destroyed many of them.

Background and youth. Tiberius was born on November 16, 42 BC. His father, also named Tiberius Claudius Nero, a high priest and a magistrate, was a former fleet captain for Julius Caesar. His mother, the beautiful Livia Drusilla, was her husband's cousin and may have been only 13 years old when Tiberius was born. (Many dates during that era of civil strife cannot be accurately determined.) In the civil wars following the assassination of Julius Caesar, the elder Tiberius gave his allegiance to Mark Antony, Caesar's protégé. When Augustus, Caesar's grandnephew and heir, fell out with Antony and defeated him in the ensuing power struggle, the elder Tiberius and his family became fugitives. They fled first to Sicily and then to Greece, but by the time Tiberius was three years old an amnesty was granted and the family was able to return to Rome.

Tiberius, sculpture by an unknown artist. In the Vatican Museum.
Alinari

In 39 BC Augustus had the power, if not yet the title, of emperor. Attracted by the beauty of Livia, who was at that time pregnant with a second son, Augustus divorced his own wife, who was also pregnant, and, forcing the elder Tiberius to give up Livia, married her. The infant Tiberius remained with his father, and, when the younger brother, Drusus, was born a few months later, he was sent to join them.

Life with Augustus

At the death of his father, Tiberius was nine years old and, with Drusus, he went to live with Livia and the Emperor. The two boys and the Emperor's daughter, Julia, between them in age, studied together, played together, and took part in the obligatory ceremonials of temple dedication and celebration of victories. They were joined by their cousin Marcellus, the son of Augustus' sister, Octavia.

In the absence of a clear law designating Augustus' successor as emperor, all three boys were trained accordingly. They were instructed in rhetoric, literature, diplomacy, and military skills, and soon they also began taking a ceremonial role in the affairs of state. As oldest, Tiberius was the first to do so.

In the triumph following Augustus' victory over Cleopatra and Antony at Actium, the 13-year-old Tiberius rode the right-hand horse of Augustus' chariot in the procession. Though not a striking figure, he conducted himself well.

Serious by nature, he had become a shy youth, though he was sometimes called sullen. His rhetoric teacher, Theodorus the Gadarene called him "mud, kneaded with blood." His great talent was application. With the best teachers in the empire at his disposal and, above all, as a participant in the life of the palace, the centre of the civilized Western world, he learned rapidly. By the age of 14, Tiberius was used to dining with client kings of the empire, to conducting religious services over the heads of powerful men five times his age, and even to seeing his own face and form in marble statues.

Years in the shadow of Augustus. He was not handsome. As a teen-ager he was tall and broad-shouldered, but his complexion was bad. His nose had a pronounced hook, but that was typically Roman: his beautiful moth-

er, Livia, had the same nose. His manner was disconcerting. He had a slow, methodical way of speaking that seemed intended to conceal his meaning rather than make it plain. But he was diligent. He may not have known he would be emperor, but he cannot have doubted that he would be at least a general at a rather early age and thereafter he would be a high official in the government of Rome. In 27 BC, when Tiberius was 15 years old, Augustus took him and Marcellus to Gaul to inspect outposts. They experienced no fighting, but they learned a great deal about how to rule the marches, keep fortifications intact, and keep garrisons alert. When they returned, Augustus gave Marcellus his daughter Julia as wife.

Marriage to Vipsania

Then Tiberius himself married. Love matches were infrequent in imperial Rome, but Tiberius' marriage to Vipsania Agrippina was one. She was the daughter of Marcus Agrippa, Augustus' son-in-law and lieutenant. During Tiberius' long life, there are hardly a dozen years when he could have been said to be happy: the years of his marriage to Vipsania. Besides his love for his wife and for his brother Drusus, now growing into manhood, he was occupied with important work. His first military command at the age of 22, resulting in the recovery of standards of some Roman legions that had been lost decades before in Parthia, brought him great acclaim. As a reward he asked for another active command and was given the assignment of pacifying the turbulent province of Pannonia on the eastern shore of the Adriatic Sea.

Tiberius not only conquered the enemy but so distinguished himself by his care for his men that he found himself popular and even loved. His fellow officers gave him the affectionate nickname of "Biberius Caldius Mero," which was a Latin play on his own name signifying "drinker of wine with no water added." When he returned to Rome, he was awarded a triumph.

But Tiberius' happy years were coming to an end. His beloved brother, Drusus, broke his leg in falling from a horse while campaigning in Germany. Tiberius was at Ticinum, on the Po River, south of what is now Milan, 400 miles away. Riding day and night to be with his brother, he arrived just in time to see Drusus die. Tiberius escorted the body back to Rome, walking in front of it on foot all the way.

Shortly after the death of Drusus, he had to give up his wife, Vipsania, the other person he loved. Augustus' daughter Julia had become a widow for the second time. Her first husband, Marcellus, had died, and the emperor had married her to Agrippa (who, as Vipsania's father, was Tiberius' father-in-law). When Agrippa died in 12 BC, Augustus wanted her suitably married at once and chose Tiberius as her third husband. Tiberius had no more choice than his father had had when Augustus decided to marry Livia. Tiberius was as obedient as his father. He divorced Vipsania and married Julia.

Marriage to Julia

Tiberius' new wife has come down in history with a reputation for adultery and licentiousness. It is not certain how much of the reputation she deserved. Roman historians often dealt in gossip and had axes to grind, inventing scandal when there was none; but in Julia's case they had good reason for their opinion.

When Julia married Tiberius, he was 30. She was 27, twice a widow, the mother of five children (not all surviving). She was pretty, light-minded, and liked the society of men. She did not get along with her mother-in-law (who was also her stepmother), Livia, and after the first few months she did not get along with Tiberius. It is certain that she committed adultery, and this presented Tiberius with an immense problem, not only personal but political. A law of Augustus himself required a husband to denounce a wife who committed adultery. But Julia was the Emperor's beloved child, and, as Augustus knew nothing of her vices, to denounce her would be to wound him greatly, and that was dangerous.

With no good course of action to follow, Tiberius fled the dilemma. He asked for and received fighting commands away from Rome. When once in Rome between battles, he chanced to see Vipsania at the home of a friend. She had, at Augustus' orders, been remarried to a senator. Tiberius was so overcome with sorrow that he followed her through the streets, weeping. Augustus heard of it and ordered Tiberius never to see her again.

Although Augustus heaped honours on Tiberius, they did not compensate for Julia's behaviour. In 6 BC Tiberius was granted the powers of a tribune (one of the highest Roman offices) and shortly thereafter went into a self-imposed exile on the island of Rhodes, leaving Julia to frolic in Rome.

Tiberius was now 36 years old and at the pinnacle of his power. He was capable of ruling an empire, conducting a great war, or governing a province of barbarians. In Rhodes he had nothing to do. From this point on, all of his ability and strength appear to begin to turn inward, into strange and unpleasant behaviour. From this point begins the story of Tiberius the monster. It is impossible to know whether the picture of an evil, sadistic, ultimately all-powerful old man that began to take shape then is justified. The histories of Tiberius' reign—written either by flatterers, like his old war comrade Velleius Paterculus, or by enemies—are not wholly trustworthy.

Exile in Rhodes

Yet there can be no question that a change took place in Tiberius at this time. The loving husband and brother, the keen student, and the victorious general all began to disappear. What emerged was a man who seemed interested only in his own satisfactions and the increasingly perverse ways to find them. On Rhodes Tiberius became a recluse —unassuming and amiable at first, resentful and angry later on.

Though Tiberius had left Rome for Rhodes of his own free will, daring the Emperor's wrath, he could not return without Augustus' permission. Augustus withheld that permission for the better part of a decade. Tiberius has no history during those years, for he had nothing to do. He walked and talked with his astrologer, Thrasyllus, and with other guests, servants, and clients of his estate. He read Greek poetry, Egyptian pornography, histories of warfare, and treatises on science. He bathed, and dined, and grew older.

In Rome Julia caroused with many lovers; Seneca says she practiced "every shamelessness in the arms of the first passerby." At last Livia secured proofs of Julia's many adulteries and took them to Augustus, who was shocked and then furious. Under his own law she should have been executed, but he did not have the heart for that; instead, he exiled her for life to the tiny island of Pandateria. But even then Tiberius was not recalled. There were three young men whom the Emperor appeared to favour as heirs, all sons of Julia. One of them, Postumus, reportedly no more than a boor, fell into disfavour with Augustus and was sent into exile with his mother. The other two, Lucius and Gaius, were clearly candidates to succeed. But in 2 BC Lucius died, in Massilia (Marseilles), and the Emperor relented. He called Tiberius back to Rome.

By AD 4 he was in possession of all his honours again, and in that year Gaius was killed in a war in Lycia. Tiberius had become the second man in Rome. Augustus did not like him, but he adopted him as his son. "Poor Rome, doomed to be chewed by those slow-moving jaws," Augustus complained; but he had no choice. He was growing old. Tiberius was the least objectionable successor left.

Tiberius became proud and powerful. His statues had been torn down and defaced while he was in Rhodes. Now they were rebuilt. He was given command of an army to quell Arminius, who had destroyed three Roman legions in Germany in AD 9; he succeeded wholly. He was succeeding at everything now, and in AD 14, on August 19, Augustus died.

Tiberius, now supreme, played politics with the Senate and did not allow it to name him emperor for almost a month, but on September 17 he succeeded to the principate. He was 56 years old.

Reign as emperor. The opening years of Tiberius' reign seem almost a model of wise and temperate rule. They were not without displays of force and violence, of a kind calculated to secure his power. The one remaining possible contender for the throne, Postumus, was mur-

dered, probably at Tiberius' orders. The only real threat to his power, the Roman Senate, was intimidated by the concentration of the Praetorian Guard, normally dispersed all over Italy, within marching distance of Rome.

Apart from acts such as these, Tiberius' laws and policies were both patient and far-seeing. He did not attempt great new conquests. He did not move armies about or change governors of provinces without reason. He stopped the waste of the imperial treasury, so that when he died he left behind 20 times the wealth he had inherited, and the power of Rome was never more secure. He strengthened the Roman navy. He abandoned the practice of providing gladiatorial games. He forbade some of the more outlandish forms of respect to his office, such as naming a month of the calendar after him, as had been done for Julius Caesar and Augustus. He ruled so well that the German historian Theodor Mommsen, for instance, calls him "the ablest of all the sovereigns the empire ever had."

There were, to be sure, occasional wars and acts of savage repression. Tiberius' legions put down a provincial rebellion with considerable bloodshed. In Rome itself, on the pretext that four Jews had conspired to steal a woman's treasure, Tiberius exiled the entire Jewish community of the city. Four thousand of the strongest men were impressed into the army and sent to Sardinia to die of malaria and neglect; the remaining 6,000 persons were banished.

The most ominous and least defensible aspect of Tiberius' first years as emperor was the growth of the practice called "delation." Most crimes committed by well-to-do citizens were, under Roman law, punished in part by heavy fines and confiscations. These fines contributed in large part to the growth of the imperial treasury, but the money did not all go to the fiscus. Because there were no paid prosecutors, any citizen could act as a volunteer prosecutor and, if the person he accused was convicted, collect a share of the confiscated property. These volunteers, called *delatores*, made a profitable career of seeking out or inventing crime. Many of the prosecutions were based on rumour or falsified evidence, and there were few Romans who were so honoured or so powerful that they did not need to fear the attack of the *delatores* on any suspicion, or on none at all.

Death of Drusus

In AD 23 Tiberius' son died. Young Drusus, named after the favourite brother who had died in Germany, had not been loved by his father and seems not to have earned much love. Devoted to blood sports of all kinds, he loved watching executions and gladiatorial displays, and spent his leisure time in hunting wild game. He does not appear to have possessed a great deal of intelligence. Nevertheless, his death saddened Tiberius. From then on he spared less and less thought to the work of empire. More and more he delegated his authority in the actual running of affairs over to the man he had entrusted with the important command of the Praetorian Guard, Sejanus. Before long it was Sejanus who ruled Rome, and Tiberius was emperor only in name.

Ironically, the death of Drusus, the event that brought Sejanus to power, may have been Sejanus' own doing. Apparently Sejanus seduced the wife of the younger Drusus, Livilla, and induced her to become his accomplice in murdering her husband. The evidence is not absolute and has been questioned by many historians, but, when it eventually appeared, it was not questioned by Tiberius. In AD 27, at the age of 67, Tiberius left Rome to visit some of the southern parts of Italy. En route he paused to go to the island of Capri. His intention appears to have been only to stay for a time, but he never returned to Rome.

Life on Capri

It is the remaining decade or so of Tiberius' life that has given rise to the legend of Tiberius the monster. It seems probable, to begin with, that Tiberius, never handsome, had become repulsively ugly at about the time of his removal to Capri. First his skin broke out in blotches, and then his complexion became covered with pus-filled eruptions, exuding a bad smell and causing a good deal of pain. He built himself a dozen great villas ringing Capri, with prisons, underground dungeons, torture chambers, and places of execution. He filled his villas with treasure and art objects of every kind and with the enormous retinue appropriate to a Caesar: servants, guards, entertainers, philosophers, astrologers, musicians, and seekers after favour. If the near-contemporary historians are to be believed, his favorite entertainments were cruel and obscene; but the historians' venom ascribes to him every imaginable vice. Even under the most favourable interpretation, he killed ferociously and almost at random. It is probable that by then his mind was disordered.

He had not, however, lost touch with the real world. He came to realize just how strong he had made Sejanus and how weak he had left himself. In AD 31 he had allowed himself to be elected consul of Rome for a fifth time and had chosen as his co-consul Sejanus. He gave Sejanus permission to marry Livilla, the widow of Tiberius' son, Drusus. Now Sejanus not only had the substance of power but its forms as well. Golden statues were erected to him. His birthday was declared a holiday. Animals were sacrificed in his honour.

Execution of Sejanus

But Tiberius had come to fear and mistrust him. With the aid of Macro, Sejanus' successor as commander of the Praetorians, Tiberius smuggled a letter to the Senate denouncing Sejanus and calling for his execution. The Senate was shocked and taken aback by the swift change, but it complied instantly. Perhaps moved by the justice of Tiberius' charges or by the strength of the Praetorian Guard, it condemned Sejanus to death. Sejanus woke that morning the most powerful man in the Western world, but by nightfall he was dead and his body lay, covered with spittle, by the Tiber.

Apparently Tiberius now reached a peak of denunciation and torture and execution that lasted for the remaining six years of his life. In the course of this reign of terror his *delatores* and torturers found evidence for him of the murder of his son, Drusus, by Livilla and Sejanus. Many great Roman names were implicated, falsely or not, and while that inquisition lasted no one on Capri was safe. A casual guest arriving to see Tiberius was mistaken for a suspect and went to the torturers.

Tiberius' chief remaining concern for the empire was who would rule it when he was gone. There were few living successors with any real claim, and Tiberius settled, as Augustus had done before him, on the least offensive of an undesirable lot. His choice was Gaius Caesar, still a young boy and known by the nickname the Roman legions had given him when he was a camp mascot, Caligula, or Little Boots. Caligula, a great-grandson of Augustus through Julia and her daughter, had a claim to the throne as good as any. If his morals and habits were less attractive, Tiberius did not seem to mind. "I am nursing a viper in Rome's bosom," Tiberius observed, and named Caligula his adopted son and successor.

On March 15, AD 37, Tiberius took part in a ceremonial game that required him to throw a javelin. He wrenched his shoulder, took to his bed, became very ill, and lapsed into a coma.

His physicians, who had not been allowed to examine him for nearly half a century, now studied his emaciated body and declared that he would die within the day. The successor, Caligula, was sent for. The Praetorian Guard declared their support for the new emperor. The news of the succession was proclaimed to the world. Then Tiberius recovered consciousness, sat up, and asked for something to eat. Caligula fled in terror. The notables of Rome, hasty to declare their fidelity to the new Caesar, were thrown into confusion. Only the Praetorian commander, Macro, kept his head. The next day, March 16, he hurried to Tiberius' bed, caught up a heap of blankets, and smothered Tiberius with them.

As an infant Tiberius had been a fugitive and then a pawn in large affairs. As a grown man he had been a popular and victorious general and then an exile. He came to supreme power already growing old. When he died he left the Roman Empire prosperous and stable, and the institution of the principate was so strong that for long it was able to survive the madness and excesses of his successors. Without him the later history of Rome might have been less colourful, lacking a Caligula or a Nero, but probably it would also have been far shorter.

Tiber River

One of the great historic rivers of Europe and the second-longest Italian river after the Po, the Tiber (Italian Tevere) flows through a countryside rich in traces of ancient Etruscan civilization and in associations with classical Roman times. It is on the banks of the Tiber that the city of Rome stands. The river is 252 miles (405 kilometres) long, and its waters rise at a height of 4,590 feet (1,400 metres) above sea level on the slope of Monte Fumaiolo, a major summit of the Appennino Tosco-Emiliano. Twisting in a generally southerly direction through a series of scenic defiles and broad valleys, the Tiber enters the Tyrrhenian Sea of the Mediterranean near Ostia Antica. Some ancient writers allege that it was known originally as Albula—a reference to the whiteness of its waters—but it was renamed Tiberis after Tiberinus, a king of Alba Longa (an area centred on Lago Albano, south of Rome) who was drowned in it (for related information, see ROME).

The naming of the river

The course of the river. From its source, the Tiber plunges precipitously to the south, widening as it swings southeast into the broad alluvial basin of the Val Tiberina. Bearing south-southwest at Ponte San Giovanni, it is joined from the left by the Chiascio and its tributary the Topino and also, from the right, by the Nestore. At Todi it bends west toward Orvieto, south of where it is joined by another right-bank tributary, the Paglia. It then flows in a south-southeasterly direction to its junction (near Orte) with the Nera, its most important tributary, which runs in from the left. Below the confluence, it skirts the picturesque foothills of the Monti Sabini, then turns south-southwest at Passo Corese, to be joined, again from the left, by the Aniene near the sprawling city of Rome. Below Rome, the Tiber branches out into a delta, the main channel being the Fiumara, with the Fiumicino functioning as a distributary branch on the north side.

Climate and hydrology. The hydrological regime of the Upper Tiber is influenced by the Mediterranean type of climate, which produces an irregular flow, dependent largely on snow and rainfall, with a spring maximum. Conversely, the lower course of the Tiber is so augmented by the waters of the Nera and the Aniene, whose combined catchment and springwater may amount to over 650,000,000 cubic yards (500,000,000 cubic metres), that the river remains navigable at Rome even during prolonged summer droughts. Though little rainfall derives from the brief storms that, in November and December, break over the mountains of the lower basin, floods occasioned by the river's absorption of underground water may last for several days. Descending from valley to valley at a comparatively gentle rate—between five and six feet per mile in the stretch of its course lying between the confluence of the Chiascio and the Nera, one or two feet per mile between the Nera and the Fara in Sabina, and one and a half feet per mile between the Fara in Sabina and Rome—the Tiber meanders in great loops and curves over its floodplain.

Historical associations. Although the Romans made some effort to control its lower course, their ignorance of hydraulic principles prevented the development of adequate protection against floods. It is only in modern times that the Tiber has flowed through Rome between high stone embankments. Though the river varies in depth between seven and 20 feet, there is some evidence that navigation upstream to the Val Tiberina was significant for the grain trade as long ago as the 5th century BC. Later, the shipment of building stone and also of timber became important. In its zenith, classical Rome was supplied with vegetables grown in the gardens of riverside villas.

The importance of the Lower Tiber was first recognized in the 3rd century BC, when Ostia was made a naval base during the Punic Wars. It later became a commercial centre for the import of Mediterranean wheat, oil, and wine. Successive attempts to maintain Ostia, on the Fiumara, and the port of the emperors Claudius and Trajan, on the Fiumicino, were defeated by the processes of silting and by the deposition of sandbars at the river mouths. In later centuries, several popes tried to improve navigation on the Lower Tiber, and ports were built at Rome in 1692, 1703, and 1744. Navigation and trade upon the Lower Tiber flourished again between the late 18th and mid-19th centuries, when further dredging took place on the lower course.

Silting problems

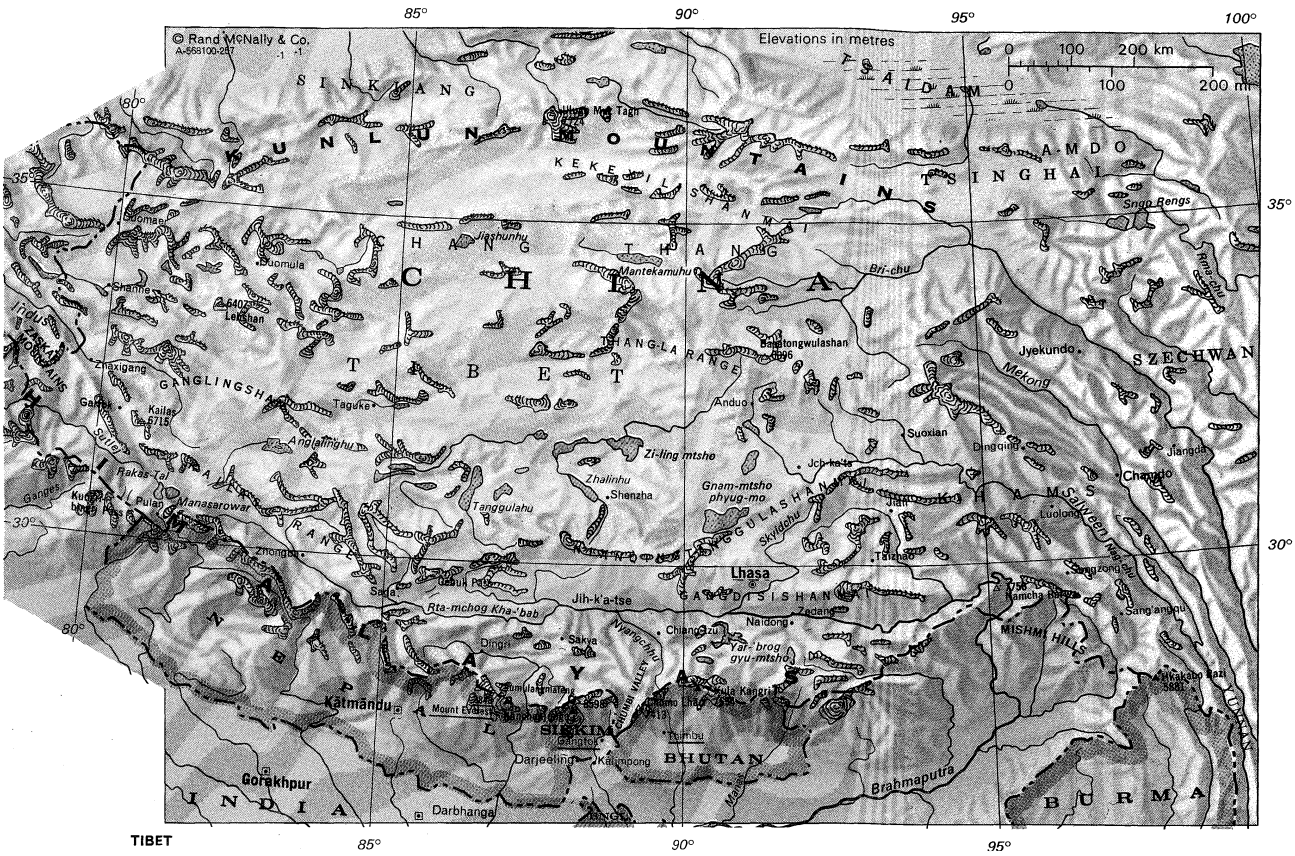
Silting has, nevertheless, continued with such persistence that, by the 1970s, the Tiber was only navigable at Rome itself. The Tiber Delta, meanwhile, has advanced about two miles seaward since Roman times. Whatever the problems occasioned by the seemingly inexorable processes of nature, the contemporary Tiber continues to contribute much to the beauty of the landscapes through which it passes.

HOUSTON, *The Western Mediterranean World*, pp. 408–410, 547–555 (1964), a geographical description of the landscapes of the western Mediterranean, with a broad survey of the Tiber Valley; JOEL LE GALL, *Le Tibre, fleuve de Rome dans l'antiquité* (1953), an authoritative French study of the Tiber, its role in prehistory and classical terms, its hydrology, modifications made by man, and its commercial significance.

(J.Ho.)

Tibet

Tibet, an autonomous region (*tzu-chih-ch'ü*) of China since 1965, is often referred to as "the roof of the world." It occupies about 471,700 square miles (1,221,700 square kilometres) of the plateaus and mountains of Central Asia, including the world's highest known peak, Mt. Everest. It is bordered by the Chinese provinces of Szechwan to the east, Yunnan to the southeast, Tsinghai to the northeast, the Chinese autonomous region of Sinkiang to the northwest, the state of Jammu and Kashmir to the West, and India, Nepal, Sikkim, Bhutan, and Burma to the south. The population was estimated at 1,500,000 before annexation by China in 1951; the 1971 estimate was 1,300,000. Lhasa is the capital city.



The Tibetan name for the region is Bod. The name Tibet is derived from the Mongolian Thubet, the Chinese Tufan, the Tai Thibet, and the Arabic Tubbat.

Before the 1950s Tibet was a unique entity that sought isolation from the rest of the world. It comprised a cultural and religious whole, marked by the Tibetan language and Tibetan Buddhism. Little effort was made to facilitate communication with other countries, and economic development in Western terms was minimal. Under Chinese administration, Tibet remains veiled from the outside world. Tibetans in exile speak of destruction of the Tibetan way of life, while the Chinese have announced some industrial development of the area. Because of the lack of information since the mid-1950s, much of the material in this article deals with Tibet before the Chinese occupation. For history see TIBET, HISTORY OF. For religion see BUDDHISM; and BUDDHISM, HISTORY OF. For the capital city, see LHASA. For related physical features, see BRAHMAPUTRA RIVER; EVEREST, MOUNT; GANGES RIVER; HIMALAYAN MOUNTAIN RANGES; HUANG HO (RIVER); INDUS RIVER; KUNLUN MOUNTAINS; MEKONG RIVER; and YANGTZE RIVER.

(T.W.D.S.)

THE LANDSCAPE

The natural landscape. *Relief features.* Tibet is on a high plateau surrounded by mountain masses. The rela-

tively level northern part of the plateau is called the Byang-thang (Ch'iang-t'ang), or Northern Plain, which extends more than 800 miles from west to east at an average elevation of 15,000 feet. The Byang-thang is dotted with brackish lakes, remnants of the Tethys Sea, which covered Asia Minor during the Eocene Epoch from 54,000,000 to 38,000,000 years ago. There are, however, no river systems there. Approximately at longitude 92° E, the Byang-thang begins to descend in elevation. The mountain ranges in eastern Tibet transverse from north to south creating meridional barriers to travel and communication. In central and western Tibet, the ranges run from northwest to southeast with deep or shallow valleys forming innumerable furrows.

The rugged terrain

The Byang-thang Plateau is bordered on the north by the Kunlun Mountains extending from longitude 77° to 93° E, with the highest peak, Ulugh Muz Tagh (Ulugh Muz Mountain), reaching 25,338 feet (7,723 metres). North of the Kunlun range lies the Tsaidam Basin, averaging 9,000 feet and bordered in turn by the Astin Tagh and Nan Shan (mountains). The western and southern border of the Plateau of Tibet is formed by the Himalayan mass that stretches from Nanga Parbat (26,660 feet [8,126 metres]) in the northwest to Namcha Barwa (25,446 feet [7,756 metres]) in the southeast. The highest peak is Mt. Everest, which rises to 29,028 feet (8,848 metres) on the Tibet–Nepal border.

North of Lake Manasarowar and stretching eastwardly is the Trans-Himalaya, or Kailas Range, with clusters of peaks, several exceeding 20,000 feet. The Trans-Himalayas are separated from the Himalayas by the Brahmaputra River, which flows across southern Tibet from longitude 82° to about 95° E then cuts south through the mountains to India. (T.V.W.)

Drainage and soils. Tibet is a prime source of water supply for Central Asia. The Indus River, known in Tibet as the Seng-ge Kha-'bab ("out of the lion's mouth"), has its source in western Tibet near Mt. Kailas, a mountain sacred to Buddhists and Hindus; it then flows eastward across Kashmir to Pakistan. Three other rivers also begin in the west. The Glang-chen Kha-'bab ("out of the elephant's mouth") flows south to become the Sutlej in western India; the Rma-bya Kha-'bab ("out of the peacock's mouth") becomes the sacred Ganges; and the Rta-mchog Kha-'bab ("out of the horse's mouth") flows east and, after joining the Skid Chu (Happy River) south of Lhasa, forms the Brahmaputra.

The Salween River has its source in central Tibet as the Dngul Chu River, which flows through eastern Tibet and then enters Burma. The Mekong River begins in northern Tibet as two rivers—the Ngom Chu and the Rdza Chu—which flow through eastern Tibet, merge at Chamudo (Ch'ang-tu), and enter Laos and Thailand. The 'Bri Chu River rises in the northeast and is the source of the Yangtze River, and the Huang Ho, or Yellow River, of China first obtains its waters from the Rma Chu, which also rises in northeastern Tibet.

Among the country's lakes, the largest are Manasarowar, in the west, which is sacred to both Buddhists and Hindus, and the Zi-ling mtsho and Gnam-mtsho phyug-mo (Na-mu Hu), the Yar-'brog gyu-mtsho, or Yar-'brog, and the Mtsho Skya-rengs and Sngo-rengs in central Tibet.

Soils are alluvial and are often composed of sand that is blown by the wind to form a layer above gravels and shingles. Colour varies from light brown to gray, according to the humus content, which is generally poor.

Climate. Although Tibetans refer to their country as Gangs-ljongs or Kha-ba-can (Land of Snows), the climate is generally dry, and most of Tibet receives only 18 inches of rain and snow annually. The Himalayas act as a barrier to the monsoon (rain-bearing) winds from the south, and precipitation decreases from south to north. The perpetual snow line lies at about 16,000 feet in the Himalayas but rises to about 20,000 feet in the northern mountains. Humidity is low, and fog is practically nonexistent.

Temperature ranges

Temperatures in the higher altitudes are cold, but the lower valleys and the southeast are mild and pleasant. Seasonal variation is minimal, and the greatest temperature differences occur during a 24-hour period. Lhasa, which lies at an elevation of 11,830 feet (3,606 metres), has a maximum daily temperature of 45° F (7° C) and a minimum of 18° F (−18° C). The bitterly cold tem-

peratures of the early morning and night are aggravated by the gale winds that blow throughout most of the year. Because of the cool dry air, grain can be safely stored for 50 to 60 years, dried raw meat and butter can be preserved for over one year, and epidemics are rare.

Vegetation and animal life. The windswept Byang-thang is devoid of trees and larger forms of vegetation. Its arid climate supports little except grasses. The varied plant life of Tibet is found in the river valleys and in the lower, wetter regions of the south and southeast. Plant life includes weeping and Alpine willows; white and black poplars; junipers; spreading yews; pines, firs, spruces, teak, rhododendrons, oaks, birches, elms; bamboo, sugarcane; babul trees; thorn trees; azaleas; tea bushes; *gro-ba* (a small white tree that grows mainly in hilly regions); *'om-bu* (a bushlike tree with red flowers that grows near water); *khres-pa* (a strong durable forest tree used to make bowls and food containers); *glang-ma* (a large willow tree used for basketry); and *rtsi-shing* (the seeds of which are used for making varnish). Fruit-bearing trees include the peach, walnut, apple, pear, apricot, banana, crabapple, and wild rose. Nettles, rhubarb, mushrooms, sweet potatoes, and certain roots are used for food, as are the leaves of the *lca-wa, khumag,* and *sre-ral,* all of which grow in the low, wet regions.

Both wild and domestic flowers flourish in Tibet. Among the wild flowers are the blue poppy, lotus, wild pansy, oleander, orchid, *tsi-tog* (a light pink flower that grows at high altitudes), *shang-dril* (a bell-shaped flower, either white, yellow, or maroon, that also grows at high altitudes), and *ogchu* (a red flower that grows in sandy regions). Domestic flowers include the rose, hollyhock, marigold, petunia, sweet pea, hydrangea, pansy, nasturtium, iris, tiger lily, dahlia, poppy, chrysanthemum, sunflower, carnation, gladiolus, and magnolia.

Forest animals

Animal life in the forest regions includes tiger, leopard, bear, wild boar, wild goat, stone marten (a kind of cat), langur (a slender, long-tailed monkey), lynx, porcupine, jackal, wild buffalo, weasel, *pha-ra* (a small member of the jackal family), and *gsa'* (a spotted cat that is smaller than a leopard).

In the high grasslands and dry bush areas, there are brown bears, deer, wild and big-horned sheep, mountain antelope, musk deer, wild asses, wild yaks, foxes, wolves, marmots, rabbits, rats, snakes, scorpions, lizards, and *dre-tse* (members of the wolf family). Water life includes various types of fish such as trout and catfish, frog, crab, otter, and turtle.

Undisturbed by aircraft or hunters, the bird reigns supreme in the Tibetan sky. Among the many kinds to be seen are the vulture, eagle, jungle fowl, ptarmigan, pheasant, cuckoo, dove, owl, spotted tinamou, mynah, robin, hawk, raven, crow, hoopoe, sparrow, lark, and nightingale. Other kinds include the gull, crane, sheldrake, cinnamon teal, *sing-bya* (a tiny, owllike bird), *khra* (a crow-sized, hawklike bird), *bya-long* (a blind bird about the size of a duck), and *skya-ka* (a black and white, crow-sized bird). The *rmos-'debs*—a small, gray bird that inhabits agricultural regions—gives a call that signals the opening of the planting season.

Traditional regions. Tibet is traditionally divided into three regions, or *Chol-kha-gsum* (*Chol-kha* means "region"; *gsum* means "three"). The Dbus-Gtsang region stretches from Mng'a-ris skor-gsum at the border of Jammu and Kashmir to Sog-la skya-bo near the town of Sog. The Khams, or Mdo-stod, region consists of the territory between Sog-la skya-bo and the upper bend of the Huang Ho (Yellow River; Tibetan Rma-chu), now located in Tsinghai Province. The A-mdo, or Mdo-smad, region reaches from the Huang Ho to Mchod-rten dkarpo in Kansu Province, China. Tibetans say that the best religion comes from Dbus-Gtsang, the best men from Khams, and the best horses from A-mdo.

The landscape under human settlement. Within the three *Chol-kha-gsum,* approximately 30 percent of the area is uninhabitable, 18 percent is roamed by nomads, 25 percent is occupied by semi-nomads, 22 percent is held by agriculturalists, and 5 percent is claimed by trappers in the forest belt.

Rural settlement patterns

Nomads, from November to March, occupy semipermanent base camps. Located between 14,000 and 17,000 feet above sea level, these camps are no more than about half a mile apart and are composed of large yak-hair tents. Between April and October, when the men take their animals in search of pasturage, they carry smaller, portable tents. The semi-nomads live between 12,000 and 14,000 feet above sea level in villages of about 150 families. The single- or two-story houses are built of stone and brick. Water mills, trees, and thornbushes are typical features of the villages, which are surrounded by small fields. The semi-nomads become nomadic between April and October. The villages of the agriculturalists are similar to those of the semi-nomads. They are located, however, at elevations of 8,000 to 12,000 feet in river valleys. The southern forest dwellers occupy wooden houses, with stone foundations and slate roofs, that are grouped into villages. Hunting and forestry are supplemented by agriculture; cultivation is carried out on narrow terraces.

The largest urban settlement was Lhasa, with an estimated population of 70,000 in the 1950s. Other cities include Jih-k'a-tse (Zhikatse) (population 20,000) and Chiang-tzu (Gyangtse) (10,000).

PEOPLE AND POPULATION

Language. The Tibetan and Burmese languages are related, although they are mutually unintelligible in their modern forms. Spoken Tibetan has developed a pattern of regional dialects and subdialects, which can be mutually understood. The dialect of Lhasa is used as a lingua franca. There are two social levels of speech—*zhe-sa* (honorific) and *phal-skad* (ordinary); their use depends upon the relative social status between the speaker and the listener. Chinese has been imposed on the Tibetans since the 1960s.

Tibetan is written in a script derived from that of Indian Gupta in about AD 600. It has a syllabary of 30 consonants and five vowels; six additional symbols are used in writing Sanskrit words. The script itself has four variations—*dbu-can* (primarily for Buddhist textbooks), *dbu-med* and *'Khyug-yig* (for general use), and *'bru-tsha* (for decorative writing).

Religion. Bon is considered to be the first known religion in Tibet, although there is some argument as to the time of its establishment. It is a form of shamanism, encompassing a belief in gods, demons, and ancestral spirits who are responsive to priests, or shamans. With the rise of Buddhism, Bon adopted certain Buddhist rituals and concepts; the Buddhists also adopted certain features of Bon, so that the two religions have many points of resemblance.

Tibetan Buddhism

Although Chinese Buddhism was introduced in ancient times, the mainstream of Buddhist teachings came to Tibet from India. The first Buddhist scripture may have arrived in the 3rd century AD, but active promulgation did not begin until the 8th century. In later centuries, numerous Buddhist sects were formed, including the Dge-lugs-pa sect, which emphasizes monastic discipline; in the 17th century this sect, known also as the "Yellow Hats," gained political supremacy.

In recent times the overwhelming majority of Tibetans have traditionally been Buddhists. Before the Chinese occupation, prayer flags flew from every home and adorned the mountain slopes. Monasteries were established throughout the country, and the Dalai Lama (the spiritual head of Tibetan Buddhism) was the supreme political head of the nation. A small minority, however, were adherents of either Islām, Hinduism, Bon, or Christianity. The Chinese have attempted to eliminate the influence of religion in Tibetan life. The Dalai Lama was forced into exile in 1959, temples were closed, religious artifacts and scriptures were destroyed, and prayer flags were taken down.

Population groups. The majority of Tibetans have the same ethnic origin, have traditionally practiced the same religion, and speak the same language. The population is, however, divided into social and economic strata.

The basic economic groups have been the nomads (*'brog-pa*), semi-nomads (*sa-ma-'brog*), agricultural-

ists (*zhing-pa*), and forest dwellers (*rong-pa*). There are also traders (*tshong-pa*), craftsmen (*lag-shes-pa*), government officials (*gzhung-zhabs*), monks (*grwa-pa*), and nuns (*a-ne*). In Lhasa there was a special group of outcastes (*ro-rgyab-pa*) who earned their living by begging and by disposing of corpses. These groupings did not, however, constitute rigid castes; monks, for example, could be government officials, and nomads or agriculturalists could be traders.

The Tibetan nobility

Social divisions existed between the nobility and the peasantry. Membership in the nobility is based on heredity. Of the more than 175 noble families in Tibet, six were descended from the families of the Dalai Lamas, and a few were descended from early kings and rulers. The remainder were families descended from those who had been ennobled for service to the government of the Dalai Lama. The overwhelming majority of the population were members of the peasantry.

THE ECONOMY

Although Tibet is rich in mineral resources, its economy has remained underdeveloped. Because of the difficult terrain and severe climate, agricultural development remained on a subsistence level. Trade was minimal, minerals were unexploited, and forestry was hampered by lack of transportation. Since the Chinese occupation, roads have been constructed, apparently more for military than for economic purposes. (T.W.D.S.)

The extent and distribution of resources. *Mineral resources.* A scientific investigation of western Tibet was conducted by Swami Pranavananda, an Indian who made surveys in the 1930s and 1940s in the Mt. Kailas and Lake Manasarowar districts. He discovered extensive goldfields in the district of Sankora; radium, iron, titanium, and emery on the eastern shores of Manasarowar and at nearby Rakas Tal; lead near Gebuk on the Ma-chüan Ho; arsenic and serpentine (a green mineral composed of a hydrous magnesium silicate) near Kungri-bingri Pass; and large deposits of borax on the shore of Tseti Tsho (Lake Tseti).

Following the occupation of Tibet, the geological section of the Chinese Academy of Science dispatched investigation teams who reported the existence of oil shale, asphalt, iron, manganese, magnesium, copper, lead, zinc, molybdenum (a metallic element that resembles chromium and tungsten), antimony, salt, soda, borax, Glauber's salt (the crystalline decahydrate of sodium sulfate, used in dyeing and as a laxative), sulfur, alum, mica, barite (barium sulfate, a white, yellow, or colourless mineral), graphite, talc, gypsum, jade, and china clay. A belt of iron deposits was located on the western bank of the Mekong River stretching for almost 25 miles south of Chamudo. Graphite was obtained from Ningtsin, and coal was reported plentiful around Chamudo. Iron deposits containing ore in concentrated seams of high quality and extractable depth were also found in the T'ang-ku-la Shan-mo on the border of Tibet and the province of Tsinghai. Three rich crystal deposits were found in the glaciers of the Sane Range. Oil-bearing formations, a reserve of oil shales, and coal were unearthed, as well as lead, zinc, and manganese.

Biological resources. The most valuable woodland is the Khams district, though extensive forest-clad mountains are also found in the Sutlej River Valley in the west and in the Chumbi Valley in the south. The Spo-smad area in Khams is estimated to contain 17,300 square miles (44,800 square kilometres) of virgin forests. In the late 1950s, 30 kinds of trees including those of comparatively high economic value, such as varnish trees, spruce, and fir were discovered. Conifers averaging 90 feet high and some as high as 200 feet with a girth of five feet were reported, and the estimated total of forest timber resources in that part of Tibet alone was placed at more than 3,510,000,000 cubic feet.

Power resources. The swift-flowing rivers and mountain streams have enormous hydroelectric power potential. Especially promising are the Brahmaputra, Skyid, and Nyang rivers. The coal deposits and forests represent possible sources of thermal-power production. (T.V.W.)

Sources of income. *Agriculture and forestry.* The staple crops are barley, wheat, and pulses; other important crops include millet, buckwheat, *rgya-bra* (a grain similar to buckwheat), beans, hemp, and mustard. Butter from the yak (large, long-haired ox) or the *mdzo-mo* (a crossbreed of the yak and the cow) is the main dairy product. The diet is supplemented by a variety of garden vegetables including radishes, turnips, carrots, potatoes, peas, parsley, lettuce, tomatoes, and cabbage. Garlic, onions, mint, celery, cauliflower, pumpkins, squash, and eggplant are also grown. Some rice is raised in the southeast. The only imported foods are tea, sugar, and rice.

Agricultural problems

Agriculture is on a subsistence level and is limited by climate and elevation. During periods of bad harvest, the food kept in storehouses is adequate to meet the country's needs. Most cultivation is carried out in the river valleys and in the southeast. Most farmers keep domestic animals such as yaks, horses, mules, donkeys, and goats, and meat is obtained from cows, sheep, pigs, and chickens.

Because of the inaccessibility of Tibet's forests, forestry is largely undeveloped. The forest dwellers, however, derive their main source of income from the production of such wood products as planks, beams, wooden printing blocks, and kitchen utensils. Tibetans do not usually fish.

Mining. Traditional beliefs that mining would diminish the natural strength of the land and that the deities, being disturbed, would bring harm to men and animals discouraged the general exploitation of mineral resources. Some gold was mined in the west by placer techniques. It was reported that iron and coal mines were in production in the Nag-chu-kha region in the late 1950s.

Handicraft industries

Industry. Before the 1950s, Tibet had no modern industries. There were, however, small handicraft centres that were owned either individually or collectively and that produced scroll paintings, metal images, wooden block prints, and religious images. For these crafts, the *lag-shes-pa*, or craftsmen, had to be well versed in literature and mathematics. There were also carpet weavers, tanners, potters, goldsmiths and silversmiths, carpenters, tailors, and incense-stick makers—all of whom learned their trade through apprenticeship. Because the government rewarded outstanding artists and craftsmen with official titles, estates, and money, the arts and crafts of Tibet were well preserved.

In 1952 an ironwork and woodwork factory was opened in Lhasa; this was followed by the establishment of an automobile repair shop in 1957 and of a tannery in 1958.

Energy. Under the Chinese government, the small hydroelectric power station at Lhasa was repaired and reinforced with three generators. A new thermal station was installed in Jih-k'a-tse. Hydrographic stations in Lhasa and various parts of the country were established to determine the hydroelectric potential of the Brahmaputra, Skyid, and Nyang rivers.

Financial services. There were no banks before 1951. Small loans to be paid with interest could be obtained from local merchants, and the Tibetan government loaned public funds at interest as a means of collecting revenue. The Chinese have established branches of The People's Bank of China in Lhasa, Jih-k'a-tse, Chiang-tzu, Chamudo, and Gartok (Ka-erh). They have also extended agricultural and commercial credit and introduced Chinese currency.

Foreign trade. Tibet's major exports included wool, yak tail, musk, bear bile, deer horn, salt, borax, mica, sheep, medicinal herbs, and the skins of yak, fox, sheep, marmot, and lynx. Woollen cloth, felt, blankets, rugs, incense, dried fish, mules, and ponies were some of the minor export items.

Tibet imported tea, porcelain, brocades, and silks from China. India was the source of textiles, sugar, rice, tobacco, medicines, fuels, and dried nuts. Rice and dried fruit were imported from Nepal and Bhutan.

Management of the economy. Under the Tibetan government, the economy operated under a free enterprise system dependent upon supply and demand. Currency was allowed to float on the market for foreign exchange purposes.

The major government expenditure, 29 percent of the

Government expenditures

budget, was spent on religion and education. Monasteries were given land, grain, and butter for consumption by the monks and nuns, for use in exchange for labour, and for prayer gatherings. About 27 percent of the budget was allocated to defense, 22 percent to development, 10 percent for health services, 4 percent for maintenance of the government, and 8 percent for emergency and miscellaneous requirements.

Government tax revenues were mainly paid in the form of goods. Agriculturalists and nomads paid with services or in kind, and businessmen paid with the goods they handled. Taxes were collected by district administrators and by travelling tax collectors. (T.W.D.S.)

Transport and communications. *Roads.* Before 1951, travelling in Tibet was done either on foot or on the backs of animals. Coracles (small boats made of wicker and hides) were used to cross the larger rivers. The Tibetan government obstructed the development of modern transportation to make access to the country difficult for outsiders. For trading, the Tibetans relied on the centuries-old caravan routes leading to Lhasa, of which the most important were from Tsinghai (via Nag-chu-kha) and Szechwan (via Chamudo), India (via Kalimpong and Sna-gdong [Ya-tung]); Nepal (via Skyid-grong and Nya-lam rdzong); and Kashmir (via Leh and Gartok).

Under the Communist Chinese, a network of motor roads was constructed, notably the Tsinghai and Szechwan highways. Many secondary roads were under construction.

Air transport. The first air communication between Tibet and Peking, China was inaugurated in 1956. The airport is located north of Lhasa. There is unscheduled service with Cheng-chou, China, via Yü-shu, Tsinghai Province. Military airfields have been constructed at Chamudo, Jih-k'a-tse, Dingri (Ting-jih), and Gartok.

Railways. There were no railways in Tibet before the Chinese occupation. After making an aerial survey, the Chinese carried out a land survey for a railroad from Tsinghai to Tibet. The proposed railway was to be 807 miles long, with Hsi-ning, Tsinghai Province, and Jih-k'a-tse, Tibet, as terminals. It would pass through complicated geological and topographical regions, and its average altitude would be more than 12,000 feet.

Postal and telegraph service. The first telegraph line was strung between Kalimpong and Gyangtse by the British in 1904. In the 1920s another line connecting Gyangtse with Lhasa was erected, this being the only telegraph system in use until the Chinese took over in 1951. Some 50 postal and telecommunication stations in Tibet, including mobile units, serve remote border areas and geological, hydrological, and construction teams. (T.V.W.)

ADMINISTRATION AND SOCIAL CONDITIONS

The theocratic system of government

Government structure. *The Tibetan government.* Tibet had a theocratic government of which the Dalai Lama was the supreme religious and temporal head. He was chosen for life, in accordance with religious traditions and ceremonies, as a reincarnation of his predecessor. When he was unable to assume his position because of his youth, a regent was chosen from among the highest ranking monks by the National Assembly. The regent had full ruling powers, which he exercised until the Dalai Lama attained his majority between the ages of 16 and 18.

Next in line to the regent or the Dalai Lama were two prime ministers, one a monk and one a layman. Beneath them was the four-member Bka'-shag (Council of Ministers). In the late 1950s the collective function of the Bka'-shag was altered by the assignment of separate portfolios to each member. There were four ministries of home affairs, foreign affairs, defense, and economic affairs.

Parallel to the secular Bka'-shag was the Department of Religious Affairs (Yig-tsang), which was headed by a lord chamberlain (*spyi-skyabs mkhan-po*). The department was composed of four monks who held the title of secretary general; the entire departmental staff was also composed of monks. They dealt with the internal affairs of the monasteries and cases involving monks. The lord chamberlain was also the head of the Department of Forestry and of the Dalai Lama's personal affairs.

Four laymen, known as *rtsis-dpon,* headed the Finance Department and the Revenue Department. They were also in charge of all lay governmental personnel. A council of the four secretaries general and the four finance secretaries (the *drung-rtse*) met with the Bka'-shag on important political issues. The members of this council were also permanent spokesmen of the National Assembly.

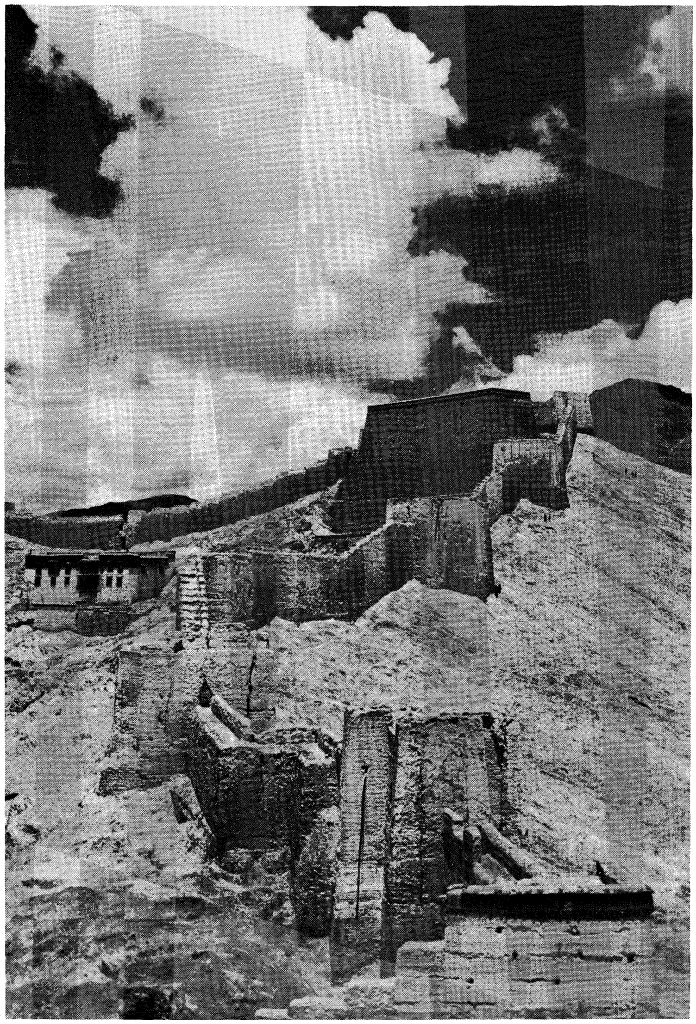
There were two assemblies. The National Assembly was composed of about 350 members, all government officials: the abbots and former abbots of the Se-ra, 'Bras-spungs, and Dga'-ldan monasteries; representatives of previous regencies; and representatives of the people. A smaller assembly known as the Rag-sdus rgyas-pa was composed of approximately 60 key members of the National Assembly, who represented governmental departments. The agendas of the assemblies were drafted by the Bka'-shag and the *drung-rtse.* When decisions were made, they were forwarded to the Dalai Lama, who could either accept or reject them.

The 105 districts (*rdzong*) and approximately 70 subdistricts (*gzhis-sdod*) were headed separately by eight governors (*spyi-skyabs*). In certain border regions and vassal territories, administrative offices were hereditary; governors and district officials were otherwise appointed.

All lay officials were appointed by the Bka'-shag and the Dalai Lama. Monk officials were selected by the Department of Religious Affairs and the Dalai Lama.

Contact between villages and the central government was maintained by a liaison official, or *rgan-po,* appointed by each village. Groups of villages appointed a liaison official known as a *gtso-drag.* Nomads had little contact with the government and were ruled by hereditary leaders.

The Chinese government. Since 1965, Tibet has been administered as an autonomous region (*tzu-chih-ch'ü*) of China. It is ruled by a revolutionary committee, which is headed by the local party chief and the military commander of Tibet. The region is divided into the municipality (*shih*) of Lhasa and five special districts (*chuan-ch'ü*), which are subdivided into 70 counties (*hsien*).



The judicial system has remained largely the same in structure. The army consists of more than 300,000 regular Chinese troops under a Chinese military commander, who is stationed at Lhasa. There are military cantonments in major towns along the borders with India, Nepal, and Bhutan. Tibetans have been forcibly recruited into regular, security, and militia regiments. (T.W.D.S.)

The social sector. *Education.* There were a few secular schools in Tibet before the Chinese occupation. The monasteries were the main seats of learning, and some of the larger ones were similar in operation to theological universities. The doors of the monasteries were open to all, and no age limit or educational qualifications were set for admittance. The monks pursued a prescribed curriculum in Buddhist literature and, upon completion, became fully ordained. The intelligent ones could pursue an additional course of study in advanced philosophical works, usually requiring six to seven years to finish. If the candidate successfully passed the final examinations, he was given the coveted title of *dge-bshes.* A *dge-bshes* was respected for his education and was qualified to serve as a monk official in the government or on the administrative board of the monasteries.

Monastic education

Not all of the enrolled monks intended to acquire a serious education, and some came for vocational training as calligraphers, printers, painters, and craftsmen. A large number specialized in performing rituals for the sick. It was considered an honour to send at least one son to become a monk, and this was often done when the boy was only seven or eight years old. (T.V.W.)

Health and welfare services. Under the health program of the Tibetan government, medical advice and medicine were provided free to expectant mothers. In addition to free vaccinations, sacred pendants known as

Massive walls of stone bricks and mud built in Chiang-tzu (Gyantse), Tibet, to defend the city from Mongol attacks.
Fosco Maraini—Monkmeyer

rims-srungs were distributed annually to prevent epidemics. The construction and maintenance of proper drainage systems, wells, and canals—and security facilities to guard against pollution of water sources—were undertaken through the health program. Care of the kinless aged and handicapped persons was also undertaken. The Chinese have built modern hospitals, improved the drainage system, and placed mobile health units at key locations. (T.W.D.S.)

Housing. The finest dwellings were those of the nobility. These were built of stone around a rectangular courtyard, on three sides of which were stables and storehouses. On the fourth side, opposite the gate, was the mansion itself, usually three stories high. The family quarters and chapel were located on the third floor, where the rooms, unlike the dark and ill-ventilated rooms below, may have had glass windows and doors. The walls and ceiling were painted with iconographic pictures and auspicious designs.

The peasants lived in one- or two-story buildings. The roof was flat and made of clay like the earthen floor. Windows were plentiful, but glass was rare and the windows were covered by waxed paper or other translucent material, which was protected by strong wooden shutters. The houses of the village peasants were, as a rule, solid and substantial, with walls of stone or sun-dried bricks, though occasionally of clods of earth. Flat roofs of beaten earth were common throughout the Tibetan highland, but, in the Chumbi Valley and other rainy districts, the roofs were gently sloped. Where pine trees grew, the roofs were constructed of pine shingles, kept in position by heavy stones. The nomadic pastoralists dwelled in tents of yak hair, rectangular in shape and ranging from 12 to 50 feet in length. An aperture of about two feet in width along the middle of the roof lets out smoke. (T.V.W.)

Social conditions. Under the Tibetan government there were no wages in the sense of monetary remuneration. Government officials and those who gave service to the government were paid in land. Monk officials received payments of barley, tea, butter, and cloth. District officials received a minimal payment. Labourers received food or clothing in payment for their services.

The social importance of land

The ownership of land was an indication of social status. Large estates were held by government officials and the hereditary nobility, while only a few peasants owned small plots of land. Most Tibetans were either tenant farmers or hired agricultural labourers.

CULTURAL LIFE

The arts. Tibet is most renowned for its religious scroll paintings (*thang-ka*), metal images, and wooden block prints. There are three categories of images—representing the peaceful, moderate, and angry deities—and three schools of painting—the *Sman-thang, Gong-dkar Mkhan-bris,* and *Kar-ma sgar-bris*—which are differentiated by colour tones and depicted facial expressions.

The rich and ancient culture is based on religion. The *Gar* and the *'cham* are stylistic dances performed by monks; they re-enact the behaviour, attitudes, and gestures of the deities. Ancient legendary tales, historic events, classical solo songs, and musical debates are elaborately staged in the open air in the form of operas, operettas, and dramas. The folk songs and dances of local regions abound with colour, joy, and simplicity: the *bro* of the Khams region, the *sgor-gzhas* of the *dbus-gtsang* peasants, and the Kadra of the A-mdo area are spectacles that are performed in groups; on festive occasions they continue for several days. These cheerful performances tell of the people's loves and celebrate their faith in their religion, the beauty of their country, and the brave deeds of their ancestors.

Customs. Traditional marriage ceremonies involve consultations with both a lama and an astrologer in order to predict the compatibility of a couple. The signing of a marriage contract is followed by an official ceremony at the home of the bridegroom. Appearance in a temple or before a civil authority is not required. After a couple is officially wedded, prayer flags are hoisted from the bride's side of the family upon the rooftop of the bridegroom's house to symbolize the equality of the bride in her new home. Although polygamy and polyandry were practiced on a limited scale, monogamy was the predominant form of marriage.

Tibetan marriage practices

When a death occurs, the family members make charitable contributions in the hope of ensuring a better reincarnation for the deceased. In the case of the death of an important religious figure, his corpse is preserved in a tomb. Otherwise, tradition calls for the corpse to be fed to the vultures, as a symbol of charity. The customs of burial and cremation exist but are seldom practiced.

A white scarf (*kha-btags*) is offered during greetings, visits to shrines, marriage and death ceremonies, and other occasions. This beautiful and unique tradition was derived from the ancient custom of offering clothes to adorn the statues of deities. Gradually, it became extended into a form of greeting, and the white scarf offering, symbolizing purity, became customary. Another unique tradition is the hoisting of prayer flags on rooftops, tents, hilltops, and almost anywhere a Tibetan can be found. These flags signify fortune and good luck.

Food and drink. The staple Tibetan food is barley flour (*rtsam-pa*), which is consumed daily. Other major foods include wheat flour, yak meat, mutton, and pork. Dairy products such as butter, milk, and cheese are also popular. The people in the higher altitudes generally consume more meat than those of the lower regions, where a variety of vegetables are available. Rice is generally restricted in consumption to the well-to-do families, southern border farmers, and monks.

Two beverages—tea and barley beer (*chang*)—are particularly noteworthy. Brick tea from China and local

Tibetan tea leaves are boiled in soda water. The tea is then strained and poured into a churn, and salt and butter are added before the mixture is churned. The resulting tea is light reddish white and has a thick buttery surface. *Chang*, which is mildly intoxicating, is thick and white and has a sweet and pungent taste.

Festivals. Festivals are both national and local in character. The many local celebrations are varied; national festivals, though fewer, are marked with a spirit of unity and lavishness.

The first day of the first month of the Tibetan calendar (February or March of the Gregorian calendar) is marked by New Year celebrations all over Tibet. Monasteries, temples, *stūpas* (outdoor shrines), and home chapels are visited at dawn, and offerings are made before statues and relics of deities and saints. A special fried cookie known as *kha-zas* is prepared in every home. Either a real or an artificial head of a horned sheep adorns the offerings. A colourful container filled with barley flour and wheat grain and another container of *chang* are presented to all visitors, who take a pinch of the contents and make an offering to the deities by throwing it in the air.

Religious celebrations

The New Year celebrations are almost immediately followed by the Smom-lam ("prayer") festival, which begins three days after the New Year and is celebrated for 15 days. The festival marks the victory of Buddha over his six religious opponents through debates and the performance of miracles. During this festival, special prayers are offered daily. Prayers, fasting, and charitable donations mark *sa-ga zla-ba*, the celebration of the anniversary of Buddha's birth, enlightenment, and death—three events that all occurred on the 15th day of the fourth month of the Tibetan calendar.

The death of Tsong-kha-pa Blo-bzang grags-pa, founder of the Dge-lugs-pa sect, is celebrated on the 25th day of the tenth month by the burning of butter lamps on the roofs and windowsills of every house. This festival is known as *lnga-mchod*. The *dgu-gtor* festival, or festival of the banishment of evil spirits, takes place on the 29th day of the last month of the Tibetan year. At night a bowl of flour soup and a bunch of burning straws are taken into every room of every house, and the evil spirits are called out. Outside, on a distant path, the bowl of soup and the burning straws are thrown and left to burn.

Superstitions. Superstition is prominent in Tibet. A traveller who encounters either a funeral procession, the source of running water, or a passerby carrying a pitcher of water is considered to have good fortune awaiting him. If a vulture or an owl perches on a rooftop, it is believed that death or misfortune will soon befall the household. If snow falls during a marriage procession, it is believed that the newlyweds will face many misfortunes or difficulties. A snowfall during a funeral, however, symbolizes an impediment to death in the family for a long period of time. (T.W.D.S.)

BIBLIOGRAPHY. The most knowledgeable Western sources on the political and social affairs of Tibet are SIR CHARLES BELL, *Tibet: Past and Present* (1924); and HUGH E. RICHARDSON, *A Short History of Tibet* (1962). CHANDRA DAS, *Journey to Lhasa and Central Tibet* (1902); and TSEPON W.D. SHAKABPA, *The Sacred Relics in Tibet* (1951), focus on the religious influence in Tibet. Books that give firsthand experience of turmoil in Tibet since the Chinese invasion are DALAI LAMA (the fourteenth), *My Land and My People* (1962); NGAWANG THUTOB, *Tibet Today* (1966); and KUNSANG PALJOR, *Tibet, the Undying Flame* (1970). The OFFICE OF H.H. THE DALAI LAMA, *Tibetans in Exile* (1969), is an official report of the work done, from 1959 to 1969, for the rehabilitation of Tibetan refugees in India. TURRELL V. WYLIE, *The Geography of Tibet According to the 'dZam-gling-rGyas-bShad* (1962), is an authoritative geography of Tibet.

(T.W.D.S./T.V.W.)

Tibet, History of

According to legend the Tibetan people originated from the union of a monkey and a female demon. The Chinese T'ang annals (10th century) place the Tibetans' origin among the nomadic, pastoral Ch'iang tribes recorded about 200 BC as inhabiting the great steppe northwest of China. That region, where diverse racial elements met and mingled for centuries, may be accepted as the original homeland of the Tibetans; but, until at least the 7th century AD, they continued to mix, by conquest or alliance, with other peoples. From that heritage two strains in particular stand out—the brachycephalic, or round-headed, peoples and the dolichocephalic, or longheaded, peoples. The former, which predominate in the cultivated valleys, may have derived from the Yellow River basin and be akin to the early Chinese and Burmese; the latter, found mainly among the nomads of the north and in the noble families of Lhasa, seem to have affinities with the Turkic peoples, whose primitive wandering grounds were farther to the north. In addition, there are Dardic and Indian strains in the west, and, along the eastern Himalayan border, there are connections with a complex of tribal peoples known to the Tibetans as Mon. A common language and a single faith diffused a common culture that blended the several elements into a population consciously and recognizably Tibetan.

Impact of Tibet on Asian history

From the 7th to the 9th century, the Tibetan kingdom was a power to be reckoned with in Central Asia. When that kingdom disintegrated, Tibetans figured there from the 10th to the 13th century only casually as traders and raiders. The patronage of Tibetan Buddhism by the Mongol Yüan dynasty of China made it a potential spiritual focus for the disunited tribes of Mongolia. This religious significance became of practical importance only in the 18th century, when the Dzungars, who professed Tibetan Buddhism, threatened the authority of the Ch'ing dynasty throughout Mongolia. In the 19th century, Tibet was a buffer between Russian imperial expansion and India's frontier defense policy. Today, with Sinkiang, Tibet forms part of China's bastion—or salient—between its Indian and Soviet neighbours.

Historiographic sources. Contemporary sources for the early period (600–900 AD) consist of fragmentary annals, chronicles, and administrative documents, mostly from the cave library at Tun-huang. Some edicts inscribed on stone pillars also survive, and the Chinese T'ang annals provide invaluable evidence. Thereafter, there is little until the flowering of Buddhism in the 13th century, when monk-scholars began to compose religious histories (*chos-'byung*) and royal genealogies (*rgyal-rabs*). Whatever was known of earlier history tended to be overlaid with hagiography. Buddhist literature (there is virtually no other) also produced biographies of holy men that often contain historical matter. There are also local histories, lists of monasteries, guidebooks to sacred places, and a few secular family histories. Only a fraction of this material was ever accessible to foreign scholars; and the Tibetans, until their exodus to India in 1959, knew nothing of Western critical methods. Today, though the rich monastery libraries of Tibet have been lost, new material is sometimes found in the possession of refugees or in little-known monasteries in Nepal, Bhutan, and Ladākh, and from Mongolia.

EARLY HISTORY TO THE 9TH CENTURY

The Tibetan kingdom. A 9th-century chronicle traces the rulers of Tibet through some 36 generations from a semidivine figure Nyag-khri btsan-po, or 'O-lde spu-rgyal, beyond whom extends a shadowy lineage of deities. Later, Buddhist chroniclers piously sought the first ancestor in India, either among the legendary Pāṇḍavas or in the family of the Buddha. Though both periods are incredibly remote, it is not impossible that some adventurous warrior later crossed the Himalayas and won acceptance as leader of a Tibetan clan. The T'ang annals offer another, plausibly dated, theory that in AD 414 a fugitive prince of the Turkic, Southern Liang dynasty in north Szechwan made himself ruler of some Tibetan tribes.

Credible history begins late in the 6th century, when three discontented vassals of one of the princes among whom Tibet was then divided conspired to support the neighbouring lord of Yar-lung, whose title was Spu-rgyal btsan-po. *Btsan-po* ("mighty") became the designation of all kings of Tibet; *rgyal* means "king"; and *spu*, the meaning of which is uncertain, may refer to a sacral quality of

the princes of Yar-lung as divine manifestations (*lha-'phrul*) that might have inspired the conspirators' choice of a figurehead. Their dynamic championship led not only to the defeat of their old master but also to the rapid transformation of the new one, Gnam-ri slon-btsan, from a princeling in a small valley into the ruler of a vigorously expanding military empire.

Slon-brtsan's reign

Gnam-ri slon-btsan (*c.* 570–*c.* AD 619) imposed his authority over several Ch'iang tribes on the Chinese border and became known to the Sui dynasty (581–618) as the commander of 100,000 warriors. But it was his son, Slon-brtsan-sgam-po (*c.* 608–650), who brought Tibet forcibly to the notice of T'ai Tsung (reigned 626–649), founder of the T'ang dynasty. Slon-brtsan-sgam-po is traditionally believed to have been 82 years old when he died, but the earliest evidence suggests that he was quite young in AD 632, when he shook off ministerial tutelage and led an army against China. To pacify him, T'ang T'ai Tsung granted him a princess as his bride. She and a Nepalese princess whom Slon-brtsan had previously married, as well as a Tibetan lady, are credited with introducing Buddhism into Tibet, though later writers believe Buddhism was implanted several generations earlier. Slon-brtsan-sgam-po is famed as the first *chos-rgyal* ("religious king") and for his all-important influence on Tibetan culture, the introduction of writing for which he borrowed a script from India, enabling the texts of the new religion to be translated. He extended his empire over Nepal, western Tibet, the T'u-yü-hun, and other tribes on China's border; and he invaded north India.

For 50 years after Slon-brtsan-sgam-po's death a regency was imposed by his great minister, Mgar Stong-brtsan yul-bzung (died 667), and his able and aggressive sons. Peace with China was broken in 670, and for two centuries Tibetan armies in Ch'ing-hai and Sikang kept the frontier in a state of war. In alliance with the western Turks, the Tibetans challenged Chinese control of the trade routes through Central Asia.

In 698 the Mgar regency was broken by King 'Dus-srong (676–704), but the militaristic spirit went unchanged. There were calm periods, as in 710, when another marriage alliance was concluded between a Chinese princess and 'Dus-slon's young successor, Khri-lde-gtsug-brtsan (704–754). But the next reign, that of Khri-slon-lde-brtsan (755–797), marked the peak of Tibetan military success, including the exaction of tribute from China and capture of its capital, Ch'ang-an, in 763. Tibetans were also in contact with the Arab conquerors of Iran and penetrated into northern India.

Establishment of Buddhism in Tibet

But it was as the second religious king and champion of Buddhism that Khri-slon-lde-brtsan was immortalized by posterity. Buddhism, hitherto confined mostly to the royal household, had suffered proscription during the King's minority; but in 763 when he was 21, he invited Buddhist teachers from India and China to Tibet, and *c.* 779 he established the great temple of Bsam-yas, where Tibetans were trained as monks.

Buddhism did not at once become the national religion. Bitter differences between masters of Chinese and Indian doctrines were publicly debated and resolved, perhaps for political reasons, in favour of the Indian school. Internally, Buddhism foreshadowed the end of "Spu-rgyal's Tibet." The kings did not fully appreciate that its spiritual authority endangered their own supernatural prestige or that its philosophy was irreconcilable with belief in personal survival. They tried to combine old and new, patronizing Buddhist foundations but retaining their claims as divine manifestations and the rite of tumulus burial.

When a Buddhist monk could be appointed chief minister with precedence over all laymen, ecclesiastical influence was certain to become a factor in the rivalry between noble families. Increasing dissension caused a setback to Buddhism even before the death of Khri-slon-lde-brtsan. It recovered *c.* 805 with the accession of Khri-lde-slon-brtsan (died 815) and reached its climax under his successor, Ral-pa-can, whose blind devotion left the administration to a monk-minister. Military activity did not slacken, and a treaty with China in AD 821 acknowledged frontiers favourable to Tibet. But *c.* 836, hostile nobles, after removing the monk-minister, assassinated the King and enthroned his brother Glang-dar-ma. Reputed to have persecuted Buddhism almost to extinction, he was killed in 842 by an avenging monk.

Buddhist tradition records a contested succession involving a posthumous son by one queen, who is regarded as continuing the royal line, and the adopted son of another queen. But there are many inconsistencies, and contemporary Chinese histories indicate that Glang-dar-ma left no son and that Tibetan unity and strength were destroyed by rivalry between generals commanding the frontier armies. Early in the 9th century a scion of the old royal family migrated to western Tibet and founded successor kingdoms there, and by 889 Tibet was a mere congeries of separate lordships.

Culture of early Tibet. The rugged, warlike society—in which, however, women held an honoured place—centred around clan loyalty to chiefs who were bound by oath to the king. While preserving nomadic habits, Tibetans by the 6th century were also cultivating barley around stone-built, flat-roofed dwellings.

Buddhism competed for a foothold with earlier magical and animist rites (generally known as Bon), many of which—excluding blood sacrifices—were incorporated in later religious practice.

As attested in the Chinese annals, the Tibetans soon applied the new writing to translating not only Sanskrit religious texts but also to native chronicles, aphoristic poetry, and other works and to administrative purposes. Edicts were inscribed on impressive stone pillars, and surviving manuscripts show that the empire was based on sound organization.

The arts of early Tibet

In the arts Tibetans excelled at goldwork and silverwork and in fine armour. Their massive, boldly proportioned architecture, evident in the remains of early castles, was adapted to Buddhist temples in a characteristically Tibetan style; but the decorative arts probably owed much to Nepalese influence and to Chinese painting; as, for example, in the cave temples of Tun-huang. Contact with China brought paper, silk, jade, porcelain, and tea.

DISUNITY, 9TH TO 14TH CENTURY

With the disintegration of the kingdom, Tibetan generals and chieftains on the eastern border established themselves in separate territories. Some supported religious communities; others invited as leader a member of the old royal family. The acknowledged successors of the religious kings prospered in their migration to the west and maintained contact with Indian Buddhist universities through Tibetan scholars, notably the famous translator Rin-chen bzang-po (died 1055). In central Tibet, nobles and royal collaterals held on in their rival estates; but there, whether through persecution or apathy, Buddhism, which had probably not penetrated deeply into society, suffered an eclipse. As calm and prosperity returned, Buddhism trickled back, first from the east *c.* 978 and later, with greater force, from the west. A missionary journey by the renowned Indian pandit Atīśa in 1042 rekindled the faith through central Tibet, and from then onward Buddhism increasingly spread its influence over every aspect of Tibetan life.

Inspired by Atīśa and by other pandits whom they visited in India, Tibetan religious men formed small communities and expounded different aspects of doctrine. Atīśa's own teaching became the basis of the austere Bka'-gdams-pa sect. The Tibetan scholar Dkon-mchog rgyal-po established the monastery of Sa-skya (1073), and a series of lamas (Tibetan priests) founded several monasteries of what is generally called the Bka'-brgyud-pa sect.

Hermits such as Mi-la ras-pa (1040-1123) shunned material things; but the systematized sects became prosperous through the support of local lords, often kinsmen of the founding lama, and, except for the Bka'-gdams-pa, each developed its own system of keeping the hierarchical succession within a noble family. In some sects, particularly the Karma-pa and 'Bri-gung-pa, the principle of succession through reincarnation was evolved. Al-

though lamas of different schools studied amicably together, their supporters inevitably indulged in worldly competition. This tendency was intensified by the intervention of a new Asian power, the Mongols.

Relations with the Mongols

Timely submission by the Tibetans in 1207 averted invasion by the world-conquering Genghis Khan; but their failure to pay tribute to the Mongols after Genghis Khan's death resulted in punitive raids, and in 1247 a religious leader, the Sa-skya lama, was summoned to Mongolia, where he did homage and was appointed the Mongols' viceroy for Tibet. His nephew 'Phags-pa, who succeeded him, won great influence with Kublai Khan, the Mongol conqueror of China and founder in 1279 of the Yüan dynasty, with whom the relationship of Tibet to China was stated as a personal bond between the lama as priest and the emperor as patron (*yon-mchod*).

A series of Sa-skya lamas, living at the Chinese court, thus became rulers of Tibet on behalf of the Mongols. Administration was left to selected Tibetan officers, but the Mongols prescribed a reorganization of the many small estates into 13 myriarchies (administrative districts each comprising, theoretically, 10,000 families), nominally under their viceroy. The ideal was a single authority; but other monasteries, especially 'Bri-gung and Phag-mo-gru of the Bka'-brgyud-pa sect, whose supporters controlled several myriarchies, actively contested Sa-skya's supremacy, which was further weakened by domestic dissension.

The collapse of the Yüan dynasty in 1368 also brought down Sa-skya after 80 years of power. Indeed, already in 1358 a dynamic rival, Byang-chub rgyal-mtshan of Phag-mo-gru, who was dedicated to the elimination of Mongol influence and the restoration of the Tibetan ethos, had displaced the Sa-skya hierarch as effective master of Tibet. Consequently, when the native Chinese Ming dynasty evicted the Mongols, Tibet had regained its actual independence; for over 100 years the Phag-mo-gru-pa line continued to govern in its own right.

Some of the Ming emperors courted Tibetan lamas, but external support was no longer a factor in Tibetan politics; the changes of regime that occurred in 1481 and 1565 were purely internal matters. Indeed, the Chinese often seemed unaware of where real power in Tibet actually lay.

A proliferation of scholars, preachers, mystics, hermits, and eccentrics, as well as monastic administrators and warriors, accompanied the revival of Buddhism. Literary activity was intense. Sanskrit works were translated with the help of visiting Indian pandits; the earliest codifiers, classifiers, biographers, and historians appeared. In an outburst of monastic building, the characteristic Tibetan style acquired greater extent, mass, and dignity. Chinese workmen were imported for decorative work, such as tiled roofs and gilded ornaments. Temple walls were covered with fine frescoes; huge carved and painted wooden pillars were hung with silk and with painted banners (*thang-ka*). Chapels abounded in images, great and small, of gold, gilded copper, or painted and gilded clay; some were decorated with stucco scenes in high relief; in others the remains of deceased lamas were enshrined in silver or gilded stupas. Under Nepalese influence, images were cast and ritual vessels and musical instruments made in a style blending exuberant power and sophisticated craftsmanship; wood-carvers produced beautiful shrines and book covers, and from India came palm-leaf books, ancient images, and bell-metal stupas of all sizes.

Foreign influence on the arts

Many monks visited China, and the emperors lavished offerings of jewels, gold seals, jade, porcelain, and brocades on high lamas and their monasteries. Chinese inspiration, as well as Indian and Nepalese, shows in the style of painting and in decorative motifs, but specifically Mongolian influences, apart from administrative organization, seem confined to details of dress and ornament.

Although the earlier Bon continued in places, Buddhism, with its impressive externals and patronage, now became the popular religion. Some of the new prosperity may have filtered down to the common people; at least there is no hint of popular discontent.

TIBET, 14TH–19TH CENTURY

The Dge-lugs-pa (Yellow Hat) order. For 70 peaceful years Byang-chub rgyal-mtshan (died 1364) and his two successors ruled a domain wider than that of the Sa-skya-pa. Thereafter, although the Phag-mo-gru Gong-ma (as the ruler was called) remained nominally supreme, violent dissension erupted again; and in 1481 power was seized by the lay princes of Rin-spungs, ministers of the Gong-ma and patrons of the increasingly influential Karma-pa sect. Already a new political factor had appeared in the Dge-lugs-pa sect. Its founder was a saintly scholar, Blo-bzang grags-pa (died 1419), known, from his birthplace near Koko Nor, as Tsong-kha-pa. After studying with leading teachers of the day, he formulated his own doctrine, emphasizing the moral and philosophical ideas of Atīśa rather than the magic and mysticism of Sa-skya—though he did not discard the latter entirely. In 1409 he founded his own monastery at Dga'-ldan, devoted to the restoration of strict monastic discipline.

Although many monks lived truly religious lives, prosperity and political involvement inevitably undermined monastic behaviour, and Tsong-kha-pa's disciplinary reform appealed to people weary of rivalry and strife between wealthy monasteries. Tsong-kha-pa probably did not imagine that his disciples would form a new sect and join in that rivalry, but, after his death, devoted and ambitious followers built around his teaching and prestige what became the Dge-lugs-pa, or Yellow Hat, order, which was gradually drawn into the political arena.

The Dge-lugs-pa, who early adopted the practice of hierarchical succession through reincarnation, gradually built a number of monasteries. Although they won influence by mediating between more powerful sects, they met irreconcilable dislike from the Karma-pa, the allies of the Rin-spungs princes and their successors, the Gtsang kings, who displaced them in 1565.

In 1578 the Dge-lugs-pa, repressed in their homeland, took a step destined to bring foreign interference once more into Tibetan affairs. The older orders had failed to pursue their missionary opportunities in Mongolia after the fall of the Yüan dynasty. Now, the third Dge-lugs-pa hierarch, Bsod-nams-rgya-mtsho, was invited to visit the powerful Tümed Mongol leader Altan Khan, with whom he revived the patron–priest relationship that had existed between Kublai Khan and 'Phags-pa. From this time dates the title of Dalai ("Oceanwide") Lama, conferred by Altan and applied retrospectively to the two previous hierarchs. The holder is regarded as the embodiment of a spiritual emanation of the *bodhisattva* Spyan-ras-gzigs (pr Chenrezi)—Avalokiteśvara. The succession is maintained by the discovery of a child, born soon after the death of a Dalai Lama, into whom the spirit of the deceased is believed to have entered. Until 1642 the Dalai Lamas were principal abbots of the Dge-lugs-pa, and in that year acquired temporal and spiritual rule of Tibet. With Altan's help virtually all the Mongols became Dge-lugs-pa adherents, and on Bsod-nams-rgya-mtsho's death they acquired a proprietary interest in the order and some claims on Tibet itself when the fourth Dalai Lama was conveniently discovered in the Tümed royal family.

To support their protégé the Mongols sent armed bands into Tibet, bringing a new dimension into sectarian enmity. Their opponents were the Red Hat Lama, head of a Karma-pa subsect, and his patron the Gtsang king. The lama's personal title has misled some Western writers into thinking that the Yellow Hats were opposed by all the older sects, inaccurately lumped together as Red Hats.

That phase of rivalry ended inconclusively with the early death of the fourth Dalai Lama and the decline of Tümed Mongol authority in Mongolia. The next came when Gushi Khan, leader of the Khoshotd tribe, which had displaced the Tümed, appeared as champion of the Dge-lugs-pa. In 1640 he answered an appeal from Bsod-nams chos-'phel, the energetic minister of the fifth Dalai Lama, Ngag-dbang-rgya-mtsho and invaded Tibet, where after fierce fighting he defeated the Gtsang king and his Karma-pa supporters.

The unification of Tibet. Once more the priest found a patron. In 1642, with exemplary devotion, Gushi en-

throned the Dalai Lama as ruler of Tibet, appointing Bsod-nams chos-'phel as minister for administrative affairs and himself taking the title of king and the role of military protector. These three forceful personalities methodically and efficiently consolidated the religious and temporal authority of the Dge-lugs-pa. Lhasa, long the spiritual heart of Tibet, now became the political capital as well. Gushi's troops enforced the Dalai Lama's rule from K'ang-ting in the east to the Ladākh border. Dge-lugs-pa supremacy was imposed on all other orders, with special severity, but without savagery, toward the Karma-pa. A reorganized district administration, largely under nominees of the Dalai Lama, reduced the power of the lay nobility.

The grandeur and prestige of the regime were enhanced by reviving ceremonies attributed to the religious kings, by enlarging the nearby monasteries of 'Bras-spungs, Se-ra, and Dga'-ldan, and by building the superb Potala palace, completed by another great figure, Sangs-rgyas rgya-mtsho (1679–1705), who succeeded as minister regent just before the death of his patron the Dalai Lama. By then a soundly based and unified government had been established over a wider extent than any for eight centuries.

Relations with the Manchus

The installation of the fifth Dalai Lama at Lhasa (1642) and the Manchu Ch'ing dynasty in China (1644) were almost synchronous. The two had previously been in communication, and Gushi had had earlier relations with the Manchus. In 1653 the Dalai Lama, having been invited by the emperor, visited the Chinese court as an independent ruler.

Good relations with Tibet were important to the Manchus because of the Dalai Lama's prestige among the Mongols, from whom a new threat was taking shape in the ambitions of the powerful Dzungars of western Mongolia. During the fifth Dalai Lama's lifetime, Tibetan influence was generally favourable to Chinese interests.

Elsewhere, Lhasa's expanding authority brought disagreements with Bhutan, which held its own against Tibetan incursions in 1646 and 1657, and with Ladākh, where a campaign ended in 1684 in Tibetan withdrawal to an accepted frontier when the Ladākhī king appealed for help to the Muslim governor of Kashmir.

In 1707, Capuchin fathers from Nepal reached Lhasa. Jesuit missionaries had found their way briefly to western Tibet (1624–41) and Shigatse (1628–30), and two Jesuits from China passed through Lhasa itself in 1661. The Capuchin mission continued with a few interruptions until 1745, and from 1716 to 1721 a famous Jesuit scholar, Ippolito Desideri, was also at Lhasa.

Tibet under Chinese overlordship. The Dalai Lama's death in 1682 and the discovery of his five-year-old reincarnation in 1688 were concealed by Sangs-rgyas rgya-mtsho, who was intent on continuing the administration without disturbance. He informed the Chinese only in 1696. Emperor K'ang-hsi (reigned 1662–1722), already suspicious because of Tibetan collusion with the hostile Dzungar leader, Dga'-ldan, was incensed at the deception. In 1703 he discovered an ally in Tibet and an antagonist to Sangs-rgyas rgya-mtsho when Lha-bzang Khan, fourth successor of Gushi, sought to assert rights as king that had atrophied under his immediate predecessors.

The behaviour of the sixth Dalai Lama, Tshangs-dbyangs-rgya-mtsho, who preferred poetry and libertine amusements to religion, gave Lha-bzang his opportunity. In 1705, with the Emperor's approval, he attacked and killed Sangs-rgyas rgya-mtsho, deposed Tshangs-dbyangs-rgya-mtsho as a spurious reincarnation, and dispatched him toward China, on which journey he died. Lha-bzang then installed, as rightful incarnation, a mature lama. The Tibetans angrily rejected him and soon recognized in east Tibet the infant reincarnation of Tshangs-dbyangs-rgya-mtsho.

In 1717 the Dzungars, nominally Dge-lugs-pa supporters, took advantage of Tibetan discontents to intervene in a sudden raid, ostensibly to avenge the Dalai Lama and Sangs-rgyas rgya-mtsho. They defeated and killed Lha-bzang and, seizing power at Lhasa, behaved with outrageous rapacity.

Fear of hostile Mongol domination of Tibet compelled the Emperor to send troops against the Dzungars. After an initial reverse, his armies drove them out in 1720 and were welcomed at Lhasa as deliverers, all the more because they brought with them the new Dalai Lama, Bskal-bzang-rgya-mtsho, of whom the Emperor had skillfully secured possession. Then and for the next 200 years there was no fighting between Tibetans and Chinese; but after evicting the Dzungars the Emperor decided to safeguard Chinese interests by appointing representatives—generally known as Ambans—at Lhasa, with a small garrison in support.

The Tibetans, interpreting this as another patron and priest relationship, accepted the situation, which, for the most part, left them to manage their own affairs. It was only in recurring crises that Chinese participation became, briefly, energetic. The first occasion was a civil war in Tibet from 1727 to 1728, when, by a change of Imperial policy, Chinese troops had been withdrawn. Fear of renewed Dzungar interference necessitated another expedition to restore order. The Chinese wisely supported an able lay nobleman, Pho-lha Bsod-nams sttobs-rgyas, who, for 30 years until his death in 1747, governed Tibet peacefully, in virtual independence but with due respect for Chinese suzerainty.

Pho-lha's son and successor rashly conspired with the Dzungars, and in 1750 he was assassinated as a preventive measure by the Ambans. They, too, were immediately killed by infuriated Tibetans; but order was quickly restored by the Dalai Lama, and a small Chinese expedition found nothing to do.

The Gurkha invasion

The third crisis was the invasion of Tibet in 1792 by the militant Gurkhas, who had ruled Nepal since 1768. They were driven out and pursued into Nepal itself by the Manchu general, Fu-k'ang-an.

That led to nominally stricter Chinese control over Tibet; but, as Manchu energy declined, the Tibetans became increasingly independent, though still recognizing the formal suzerainty of the Emperor, behind which it sometimes suited them to shelter. At no time did the Ambans have administrative power, and after 1792, when Tibet was involved in wars with Ladākh (1842) and Nepal (1858), the Chinese were unable to help or protect them.

Administration and culture under the Manchus. No Dalai Lama until the 13th approached the personal authority of the "Great Fifth." The seventh incarnation was overshadowed by Pho-lha; the eighth was diffident and retiring. But after the Pho-lha family's regime, Dge-lugs-pa churchmen resumed power and held on to it through a series of monk regents for about 145 years. Some check on them existed in the Paṇchen Lamas of Bkra-shis lhun-po, the second-ranking line of incarnations, whom the Chinese since 1727 had built up to counterbalance the authority of Lhasa.

The original austerity of Tsong-kha-pa's order was diluted by power, wealth, and numbers. There were, of course, disciplinarians and saints and many scholars also. The older sects, free from political responsibilities, were often renowned for piety and discipline and produced scholars and mystics with wide-ranging religious views.

Chinese contacts affected Tibetan culture less than might be expected. They helped to shape the administrative machinery, army, and mail service, which were based on existing institutions and run by Tibetans. Chinese customs influenced dress, food, and manners; china and chopsticks were widely used by the upper classes.

The arts of painting, wood carving, and casting figures continued on traditional lines, with much technical skill but few signs of innovation. An important effect of Manchu supremacy was the exclusion of foreigners after 1792. That ended the hopes of Christian missionaries and the diplomatic visits from British India, which had been started in 1774. Tibet was now closed, and mutual ignorance enshrouded future exchanges with its British neighbours in India.

TIBET IN THE 20TH CENTURY

In the mid-19th century the Tibetans repeatedly rebuffed overtures from the British, who at first saw Tibet as a

trade route to China and later as countenancing Russian advances that might endanger India. Eventually, in 1903, after failure to get China to control its unruly vassal, a political mission led by Col. Francis Younghusband with strong military support was dispatched from India to secure understandings on frontier and trade relations. Tibetan resistance was overcome by force, the Dalai Lama fled to China, and the rough wooing ended in a treaty at Lhasa in 1904 between Britain and Tibet without Chinese adherence.

In 1906 the Chinese by skillful diplomacy achieved a treaty with Britain, without Tibetan participation, which recognized their suzerainty over Tibet, although that suzerainty was clearly ineffective and had not been acknowledged in the Lhasa treaty. Success emboldened the Chinese to seek direct control of Tibet by using force against the Tibetans for the first time in ten centuries. In 1910 the Dalai Lama again was forced to flee, this time to India.

Declaration of Tibetan independence. That dying burst by the Manchu dynasty converted Tibetan indifference into enmity; and, after the Chinese Revolution in 1911, they expelled all Chinese from Tibet, declared their independence of the new republic, and looked to Britain for support. The British government, doubting Tibet's ability to maintain complete independence, persuaded the Chinese to join in a tripartite conference aimed at a settlement that might guarantee Tibetan autonomy under nominal Chinese suzerainty. Though a convention was initialled by the three representatives, the Chinese, ostensibly dissatisfied on the frontier issue, withdrew before final signature. Thereupon the British and Tibetans jointly declared the convention between themselves binding, denying the Chinese all advantages under it unless they also signed.

Expulsion of the Chinese

The effects of this agreement were differently interpreted by the several parties. The Chinese denied its validity; but Tibet functioned in practice as an independent government until 1951 and defended its frontier against China in occasional fighting as late as 1931. A British representative at Gyantse conducted friendly, if distant, communications with Lhasa. But the Chinese, though continuing to claim Tibet as their territory, were allowed no presence there in any capacity from 1913 until 1935.

In 1935 the Tibetans, weakened by the death of the resolute 13th Dalai Lama, admitted a Chinese "condolence mission." Once at Lhasa, it established a small office and sought to arrange the return, under Chinese protection, of the sixth Panchen Lama, who had left Tibet in 1923 after disagreements with the Dalai Lama. The British government sent Sir Basil Gould, political officer in Sikkim, to observe that development, which contravened their agreements with Tibet. After his departure in 1937, a small, temporary British mission remained at Lhasa. In 1947 it was taken over by the new government of India, together with its predecessor's rights and responsibilities toward Tibet.

The independent regime of the Tibetan government continued unchanged. The sixth Panchen Lama died in China. The 14th Dalai Lama was discovered in 1939. In World War II Tibet preserved its neutrality in spite of pressure from China and its allies to use the country as a supply route. In 1947 an attempted coup by a former regent, suspected of Chinese sympathies, was frustrated. In 1949, in view of Communist successes in China, the Tibetans evicted the Chinese mission from Lhasa.

The Chinese conquest. But the Communists were not to be diverted. In 1949 the "liberation" of Tibet was heralded, and in October 1950 they launched an invasion of east Tibet. The poorly equipped Tibetan troops were overwhelmed. An appeal by the Dalai Lama to the United Nations was denied, and expected support from India and Britain was not forthcoming. A Tibetan delegation summoned to China in 1951 had to sign a treaty dictated by the conquerors. It professed to guarantee Tibetan autonomy and religion but also allowed the establishment at Lhasa of Chinese civil and military headquarters. Unremitting pressure was exerted to bring Tibetan society and government into line with those of Communist China. The unique authority of the Dalai Lama was undermined by dividing Tibet into three regions.

Chinese occupation

To soften the loss of independence, the Tibetans were offered some modern benefits, such as hospitals, new agricultural methods, schools (under Chinese supervision), and rudimentary local industries. But the greater progress was in making roads and bridges, an innovation for the Tibetans, who had no wheeled vehicles, and a necessity for the extension of Chinese control.

Smoldering resentment at the strain on the country's resources from the influx of Chinese soldiery and civilians was inflamed in 1956 by reports of savage fighting and oppression in districts east of the upper Yangtze, outside the administration of Lhasa but bound to it by race, language, and religion. Refugees from the fighting in the east carried guerrilla warfare against the Chinese into central Tibet, creating tensions that exploded in a popular rising at Lhasa in March 1959. The Dalai Lama, most of his ministers, and many followers escaped across the Himalayas; and after days of fighting and bloodshed the rising was fiercely suppressed.

The Tibetan government was replaced by a military dictatorship intent on imposing the pattern of China. It immediately demolished the framework of Tibetan society and the influence of church and nobility by confiscating all private property. The country was reorganized into peasant associations in preparation for collectivization and communes. To give an appearance of Tibetanness, the new Panchen Lama, a creature of the Chinese, was appointed chairman of an interim administration, and a few of the countless Buddhist temples were maintained as showplaces. The rest were abandoned, and the monks fled, were imprisoned, or reverted to lay life. Strict regimentation, monopoly of agricultural production, prevention of travel by Tibetans, severe punishments, and forced labour for suspected opponents were aggravated in 1961 and 1962 by near famine resulting from the upheaval. More refugees fled to India, guerrilla activities continued, and the Panchen Lama, rapidy disillusioned, was dismissed and disgraced in 1964.

Relations with India

The events of 1959 intensified disagreements with India, which had given asylum to the Dalai Lama, and, in 1962, Chinese forces proved the efficiency of the new communications by invading northeast Assam.

In 1966 and 1967 the Chinese position was shaken by Red Guard excesses and internecine fighting when the Cultural Revolution reached Lhasa. Military control was restored by 1969; and in 1971, although resistance was officially admitted and former collaborators of any status had disappeared, a new local government committee, containing 14 Chinese and three Tibetan nonentities, was announced. Between 1963 and 1971 no foreign visitor was allowed to enter Tibet, and only a few Nepalese traders remain. There has since been a trickle of information to indicate that the Chinese have destroyed all overt traces of Tibetan religion and submerged the old culture and religion, now openly preserved only by some 70,000 Tibetan refugees in India, Nepal, Bhutan, and Sikkim.

Tides

Sea-level oscillations of approximately daily, or diurnal, and twice daily, or semidiurnal, period are a worldwide phenomenon observed at continental coasts and islands. According to Newton, this motion is caused by the difference of the gravitational attraction between celestial bodies and the centrifugal acceleration of their rotation. These differences of accelerations are called tide-generating accelerations, and the motion itself is called tides.

Because these tide-generating accelerations act on the particles in the atmosphere and in the Earth as well as on the water masses of the ocean, there are atmospheric tides, Earth tides, and ocean tides. Tidal oscillations are periodic because they are related to the motion of the Earth, the Sun, and the Moon. The tides on the Earth are not influenced by other celestial bodies. It is customary in the English language to refer sometimes to certain phenomena that do not arise from tide-generating forces as tides, for instance meteorological tides and tsunamis (*i.e.*, great sea waves produced by submarine earthquakes or volcanic eruptions).

For centuries efforts have been directed toward understanding the physics and hydrodynamics of the tides in the sea. Amplitudes of tidal oscillations are largest there; atmospheric and Earth tides are less significant. At most coastal or island locations the interval between successive high waters is about 12 hours and 25 minutes, which is half the time of the Moon's apparent revolution around the Earth. In some areas, such as the China Sea, the interval is approximately 24 hours. The first are called semidiurnal tides, the second diurnal tides. If there is a prevailing semidiurnal tide, the difference between the high-water time and the time the Moon crosses the meridian of the location is approximately constant, and this difference is known as the high-water interval for the particular location.

In addition to semidiurnal and diurnal tides, there are also long-period tides. Periods of 14 days to 19 years exist as a result of the motion of the Sun, Moon, and Earth. A fourth group of tides, not of direct astronomic origin, consists of the shallow-water tides that result from the interaction of the semidiurnal and diurnal and other tides.

The difference in sea level between successive high water and low water, called the range of tide, may vary from day to day in a certain place; within a fortnight it reaches a maximum value, known as spring tide, and a minimum value, known as neap tide. In the open sea distances of high- and low-water level from undisturbed sea level are more or less equal to one another. The vertical tidal motion of the sea level is combined with components of horizontal motion. The water particles moved by harmonic tidal currents oscillate on an ellipse within one tidal period. The times between maximum and minimum currents are about six hours and 12 minutes. In shallow waters, especially in tidal rivers, the incoming tidal current, called the flood current, passes upstream with increasing maximum current and decreasing duration. The maximum velocity of the seaward-directed current or ebb current becomes progressively less going up the river and flows for an increasingly larger time. If the tide is entering a very shallow river the wave as a whole does not proceed as fast as the water particles do, according to the tidal currents. The result is a wall-like wave, called a bore, or a mascaret, which travels up the river.

In some areas—*e.g.*, the Mediterranean and the Baltic—the tidal range for both diurnal and semidiurnal tides is quite small. In other areas the range increases, and in the Bay of Fundy it reaches more than 15 metres (50 feet). Most of tidal sea-level records originate from the coasts of the continents and from islands. Available measurements taken in the open sea are insufficient to permit understanding of the tidal processes in that region, which constitutes the greater part of the surface of the world's oceans. For this reason, theoretical tidal studies are of great importance; they lead to a physical understanding of tidal processes in the sea. This article treats the causes of tides and tidal currents, and their prediction by means of hydrodynamic–numerical (HN) models: For other motions of the sea, see WATER WAVES and OCEAN CURRENTS; and for the general interaction of these motions and their world character, see OCEANS AND SEAS. See also ESTUARIES and LAKES AND LAKE SYSTEMS for further information on these water bodies, which are also affected by the tides.

THE CAUSES OF TIDES

Tide-generating forces

The gravitational attraction of two bodies such as the Earth and the Moon is proportional to the product of their masses and inversely proportional to the square of the distance between their centres. Their gravitational attraction tends to force them to approach one another, but this is inhibited by the centrifugal force of rotation around their joint centre of gravity. If it is assumed that the mass of each body is concentrated in its centre, then the two forces balance each other. There is an important difference between these two forces, gravitational attraction and the centrifugal force of rotation. The first depends on distance and consequently varies for different particles on the Earth; the second is constant for all points of the Earth. If a single water particle of the ocean is considered, there is no balance; the gravitational attraction of the Moon may be different from the centrifugal force of rotation.

These differences are the tide-generating forces. In the same way, tide-generating forces are caused by the gravitational attraction of the Sun; they are determined by the motions of the Sun, the Earth and the Moon, the distance, the mass, and the volume. The tide-generating forces are vectors (*i.e.*, they are physical quantities that have magnitude and direction). One component is directed to the centre of the Earth and coincides in direction with the gravitational force of the Earth itself, altering this only in a very small amount (the ratio is 1:9,000,000). The other components are situated on a tangential plane at the sea surface and drive the water masses in the direction of the Moon and Sun, respectively.

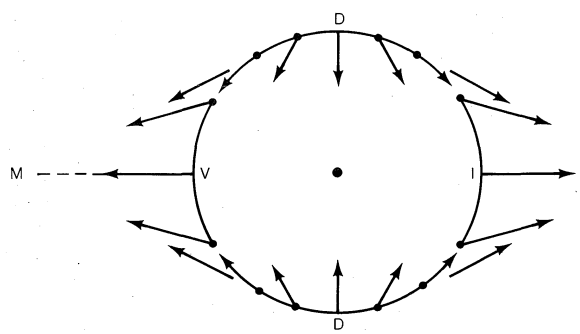

Figure 1: Tide-generating forces (see text).

Figure 1 shows the distribution of the tide-generating forces on the Earth. The lengths of the arrows are proportional to the magnitudes of the forces. M is the direction of the Moon; the water masses tend to build a deviation toward the Moon (Point V), as well as in the opposite direction (Point I). At point D there is a lowering of the sea level. A deformation of the sea level is similarly caused by the tide-generating forces of the Sun. The tide potential V of the Moon at the sea surface based on the relationship of the distance between and positions of the Earth and Moon is expressed as follows:

$$V = 26{,}206\left[\left(\frac{c}{r}\right)^3\left(\cos 2\,\delta + \frac{1}{3}\right) + 0.002598\left(\frac{c}{r}\right)^4(5\cos 3\,\delta + 3\cos\delta)\right]\frac{\text{cm}^2}{\text{sec}^2},$$

in which c is the average distance of the Moon and r the distance between the centre of the Moon and the centre of the Earth, δ is the angle between the line joining the centres of the Moon and the Earth and the line from the centre of the Earth to the point on the Earth's surface that is being considered. A similar equation is valid for the tide potential of the Sun.

The equilibrium tide

The differential quotients of the tide potential yield the tide-generating acceleration. The dimension of the potential V is centimetres squared per second squared. If V is divided by the acceleration of gravity (which has the dimension centimetres per second squared) a term remains, $\bar{\xi}$, which has the dimension centimetres. The surfaces of equal acceleration of gravity are disturbed by this value $\bar{\xi}$. Figure 1 indicates a maximum elevation at points V and I and a maximum depression at point D. This shape of the sea surface would occur in an ocean covering the whole Earth, if the Earth were completely rigid and the tide potential remained constant. This type of tide, called equilibrium tide, is fictitious but accurately represents tide-generating forces at the surface of and within the Earth. In such a case the slope of the surface of the sea would be balanced by the tide-generating acceleration, and there would be no tidal currents.

In investigating the dynamics of the tides, the tide-generating acceleration may be replaced by the acceleration caused by the slope of the equilibrium tide.

The maximum elevation of the equilibrium tide of the Moon is 35.6 centimetres (14.0 inches), and the greatest depression would be 17.8 centimetres (7.0 inches). The natural tidal range in the sea is quite different from these values of the equilibrium tide, and accordingly the conclusion that there are no tidal currents in the sea is completely unrealistic.

TIDAL ANALYSIS

Tidal harmonics. The tide potential of the Moon and the Sun are functions of the following variables: the Earth's speed of rotation, γ; the mean motion of the Moon, σ; the mean motion of the Sun, η; the speed of revolution of the Moon's nodes, N; the mean motion of the Moon at its closest approach—the lunar perigee, ω; and the time. These speeds are incommensurable (*i.e.*, they are not divisible, in whole numbers, by each other), and they may serve as independent variables in representing the tide potential by means of a Fourier series (a mathematical series of terms consisting of the trigonometric functions, sine and cosine), each term in which is called a tide or a tidal constituent; the most important are given in Table 1.

Table 1: Tidal Constituents

name	symbol	speed (° per hour)	coefficient	speed
Diurnal species				
Lunisolar	K_1	15.041	0.265	γ
Larger lunar	O_1	13.943	0.189	$\gamma - 2\sigma$
Larger solar	P_1	14.959	0.088	$\gamma - 2\eta$
Semidiurnal species				
Principal lunar	M_2	28.984	0.454	$2\gamma - \sigma$
Principal solar	S_2	30.000	0.211	2γ
Larger lunar elliptic	N_2	28.440	0.088	$2\gamma - 3\sigma + \omega$
Lunisolar	K_2	30.082	0.058	2γ

The coefficient is proportional to the equilibrium amplitude within the given species and indicates the magnitude of a constituent.

Besides the diurnal and semidiurnal constituents there are long- and short-period constituents. Tidal oscillations of high frequency may be important in shallow-water areas.

Tidal constituents. As long as tidal motions are linear (*i.e.*, no interaction occurs between different constituents), the constituents of the Fourier series may be investigated separately. Table 1 shows that the principal lunar (M_2) tide is the predominant one. The nature of the tide potential gives rise to a similar development of the observed sea level into harmonic series (a series of terms whose reciprocals form an arithmetic progression, 1, ½, ⅓, . . . 1/n). The frequencies are taken from the tide potential, and, for a given place, measurements of the sea level within a time interval are used to determine amplitudes and phases by various mathematical methods. After amplitudes and phases are known, the measurements may be reproduced. Furthermore, it becomes possible to synthesize the tide for any time, past, present, or future. This harmonic method may be used to predict tides and the components of tidal currents, but only for places for which sufficient long-term records of sea-level elevations are available. Harmonic-tide predictions are fairly good for deepwater ports; in shallow-water areas, especially in tidal estuaries, special corrections are needed in order to get precise results, or non-harmonic methods must be applied.

Tide-predicting machines

Special machines have been developed to synthesize tidal constituents and especially to determine high- and low-water height and time. The first to design such a tide-predicting machine was a Scottish physicist, Lord Kelvin, in 1872. In 1930, H. Rauschelbach constructed a machine containing 62 tidal constituents. Such analogue machines have been replaced by digital computers, which are much faster. Predicted high- and low-water time and water heights for important ports all over the world are published in tide tables prepared by hydrographic offices in the different countries.

In a similar way it is possible to predict tidal currents, but normally no such predictions are available.

Tidal measurements. Along the coastlines of continents and islands a large number of tide gauges are in permanent operation. The harmonic analyses of these sea-level records are collected and published by the International Hydrographic Bureau (IHB) in Monaco. Measurements of tidal currents are available for only a few places. The same is true of sea-level observations in the open sea. Recently developed instruments provide the first measurements of the vertical tidal components in the deep sea.

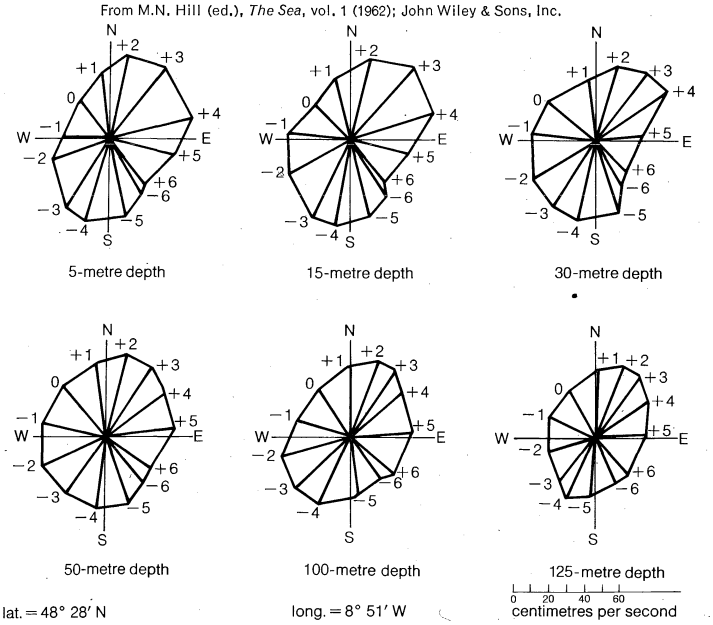

Figure 2: Observed tidal currents at the entrance to the English Channel, and their variation with water depth. Positive and negative values shown indicate the number of hours after and prior to the Moon's transit of Greenwich.

The tidal harmonics for Immingham, in the North Sea, and Do Son, in the South China Sea, are given in Table 2.

In the North Sea the tides are semidiurnal; in the South China Sea they are diurnal. Considering tidal currents, the amplitude and phase may vary from the surface to the bottom. Figure 2 represents tidal currents as a function of time for different depths, as revealed by records made west of the entrance to the English Channel.

The elements of tidal current ellipses, including the amounts, direction, and time of maximum velocity, may be shown on maps. The large axes of the tidal current ellipses in Figure 3 are proportional to the maximum speed of the tidal current, and their orientation coincides with the direction of the maximum tidal current in the North Sea. Small axes refer to the minimum speed of the tidal currents. Full lines indicate the time of max-

imum speed of tidal currents referred to Moon's transit in Greenwich. Maps of this type provide an idea of the geographical distribution of the tidal currents in the sea. The time of the occurrence of high water and the

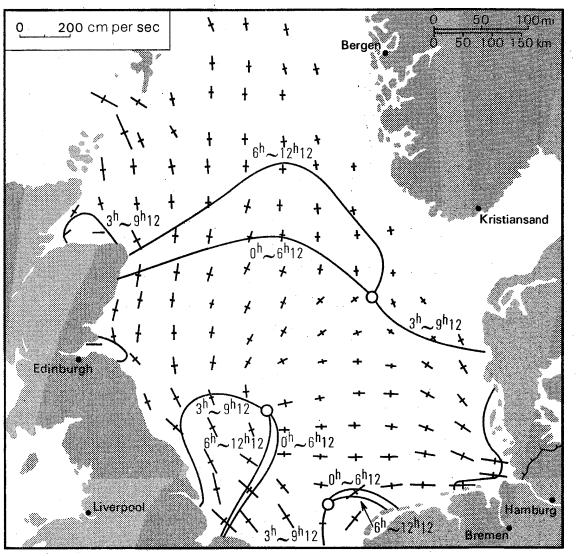

Figure 3: Major and minor axes of tidal current ellipses in the North Sea (see text).

tidal range and their geographical distribution are also of interest. But because tidal sea-level records originate primarily from harbours and other coastal locations and because no measurements from the open sea are available, it is difficult to draw maps containing cotidal and corange lines (along a cotidal line the time of high water is constant, and along a corange line the tidal range is constant). In several cases such lines in the open sea have been constructed by means of an interpolation of coastal values. If no measurements are available, then the distribution of cotidal lines in the open sea remains uncertain. Corange lines have not been drawn. In order to overcome these difficulties, theoretical methods have been used. One powerful available tool developed by Walter Hansen since 1939 is the hydrodynamic–numerical method, which will be considered later.

TIDAL DYNAMICS AND PREDICTION

Tides and tidal currents are best explained by the mathematical–physical laws that govern the tidal motion in the sea. These laws are expressed as hydrodynamical differential equations, a system that consists of the equations of motion and the continuity equation. The equations of motion express the several forces that produce tidal accelerations. The continuity equation expresses the fact that the volume of any body of water must remain constant despite its motion. The density of the seawater is assumed to be constant.

Conditions required for tidal prediction

Under certain conditions the hydrodynamic equations make it possible to determine the tides and tidal currents in an estuary, in a sea, or even in the world ocean. These conditions are: (1) the tide-generating accelerations are given quantitatively as functions of time and space; (2) the distribution of the depth and the shape of the coastline of the sea are considered to be known; (3) boundary conditions must be defined, especially those which relate to the coastline: no flow normal (perpendicular) to the coast.

Condition (1) is fulfilled because the tide potential is known very precisely. Condition (2) is normally met by existing pilot charts. With respect to condition (3), there are two types of boundaries. The first is represented by a coastline, and the condition is: no water transport into or out of the land; consequently, the normal component of the tidal current must be zero. The world ocean is an example of a sea totally surrounded by land. The advantage of this coastal boundary condition is that the tides are uniquely determined without using any tidal measurements. The second type is the open boundary. If the sea level is prescribed along a line around the open sea, then the tides within the area bounded by this line are uniquely determined. In natural seas both of these boundary conditions normally occur. The second condition can be applied in cases of neighbouring seas.

Tidal prediction using analytical methods. In the past, mathematicians and physicists developed analytical solutions of the hydrodynamic equations, partly in Cartesian, partly in spherical coordinates. For this purpose it was necessary to simplify the equations, especially with regard to the depth and the shape of the water body considered. In recent years tides in oceans bounded by meridians have been investigated by two English oceanographers, Joseph Proudman and Arthur Doodson, but it has not been possible to reproduce the natural tide quantitatively by means of these analytical solutions.

A very simple solution is obtained by assuming the tidal currents to be zero. In this case the tide-generating accelerations are balanced by the shape of the sea surface, and the equilibrium tide is reproduced. There is no real possibility of reproducing natural tides in such a simple way.

There exists a large number of solutions concerned with tides in areas of very simple geometry. Amplitudes and phases depend on the ratio of the frequency of the tide-generating acceleration to the eigenfrequency (characteristic frequency) of the basin. The amplitudes increase if this ratio approaches one. Friction inhibits the unlimited increase of the amplitude if frequencies are equal to each other. The eigenfrequencies depend on the geometry of the basin.

A tide-generating constituent in a narrow canal that is closed on both ends causes simple harmonic oscillations to occur. These tides are called independent tides. In a canal closed on one side and open on the other, tidal oscillations may be caused by co-oscillation with the water masses beyond the open end of the canal. These tides are called co-oscillating tides. In many adjacent and marginal seas the co-oscillating tide is much more important than the independent tide.

The distinction between completely and partly closed seas is important in the view of tide reproduction. In the case of completely closed basin, tides and tidal currents can be determined quantitatively without using any measurements. In a sea with partly open boundaries, such as the North Sea or the Gulf of St. Lawrence, it is necessary to prescribe the sea level as a function of time on or along the open boundary. Completely closed seas, then, are well suited to checking the results derived from hydrodynamic equations against measurements from the sea under consideration.

Although the world ocean fits these conditions, it is too complicated to use in such an analytical investigation. There are no other completely closed seas on Earth, and the tides of lakes, such as Lake Baikal, are small. Other seas that are almost completely closed have, like lakes, only very small tides: the Black Sea, Baltic Sea, and even the Mediterranean Sea are examples.

Therefore, in order to check hydrodynamic theories, it is necessary to restrict the investigations to seas with boundaries that are not too open. The tides within such an area should be appreciable. Although a full check of the quality of hydrodynamic theories is not possible in such cases, because the solution of these equations is influenced by the prescribed sea level, the computed tides

in the interior of the area may be compared with the measurements in corresponding locations, and in this way the quality of the solution may be tested.

Finite difference method

Tidal prediction using hydrodynamic–numerical methods. *Tides in natural seas of small width.* Solutions of the hydrodynamic equations, taking into account arbitrary depth and coastline distribution, are developed as follows: time is eliminated by assuming that the sea level is a pure harmonic function of time. The derivatives in space direction are then replaced by finite differences. Finally, a system of linear equations remains to be solved. The tides in canal-like seas have been investigated using this difference method in one dimension. As a boundary condition, the tidal currents are assumed to be zero at the closed end, and the amplitude and phase are prescribed at the open end. The numerical computation is a simple one, and no mathematical difficulties appear. The Austrian oceanographer Albert Defant and others have applied these or similar methods to several canal-like adjacent areas, among them the Adriatic Sea, the Red Sea, and the Persian Gulf. Figure 4 represents Defant's results for the Red Sea. The quality of the reproduction of the tidal measurements is remarkable; furthermore, these investigations yield an understanding of tidal processes in elongated canals. The way in which the resulting amplitudes and phases are related to the geometry of canal-like seas is clear.

From M.N. Hill (ed.), *The Sea*, vol. 1 (1962); John Wiley & Sons, Inc.

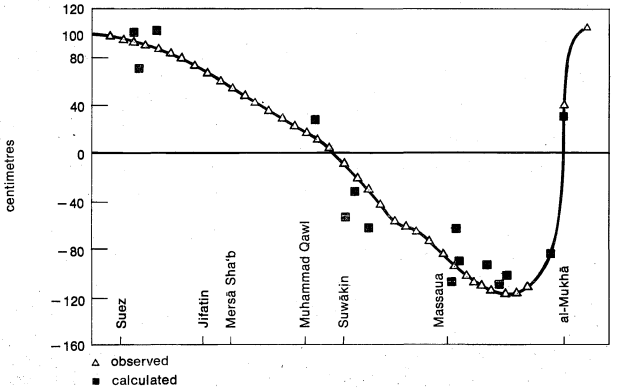

Figure 4: Range of observed and calculated values of the M_2 tidal constituent in the Red Sea.

Defant also considered the North Sea, and even the Atlantic, as an elongated canal in order to apply the one-dimensional method, but it was not possible to reproduce the measurements quantitatively. Numerical methods for solving tidal problems in two dimensions were developed. First, the boundary value method was performed, the time dependency again assumed to be harmonic. After eliminating the components of tidal currents, for the sea-level variation there remains a partial differential equation of the second order and of elliptic type. This differential equation is replaced by a system of linear equations that relate sea level to the points of a grid placed upon the sea under investigation. The tide is determined if the sea level is defined by the grid points on the boundary. It is also possible to transfer the hydrodynamical equation, after introducing a time factor, into a system of linear equations without eliminating the components of the tidal currents.

Boundary value method

In water that is not too shallow this boundary value method yields a sufficient reproduction of measured tides. There are, however, a number of disadvantages. Different tidal constituents must be computed separately. The resulting sea level is a pure harmonic function of time. Because the equations are linear, no nonlinear interaction can be taken into account. Especially in shallow-water areas, such as tidal estuaries, tides and tidal currents may differ strongly from a harmonic function of time. Furthermore, it is impossible to investigate the interaction between different tidal constituents and among tides, surges, and gradient currents.

General prediction of tides. Attempts to design more general numerical methods, as a continuation of the boundary value method but avoiding its disadvantages, have been made since 1945. These efforts resulted in the hydrodynamic–numerical methods (abbreviated HN methods), which also may be called initial boundary value methods.

The method is fairly general and is applicable to all kinds of processes of motion in the deep ocean and in shallow waters. Nonlinearity and nonharmonic time dependency can be taken into account, and the method yields not only tidal motion but any motion in the sea turbulence.

The hydrodynamic–numerical (HN) model in a simple quadratic area is derived as follows. The sea under consideration is first covered by a grid. The sea level ζ is indicated by + points, the west–east component u by • points, and the south–north component v of the tidal currents are determined at x points. The hydrodynamic differential equations are replaced by difference equations, the variables ζ, u and v, the tide-generating acceleration X, the depth H, and the friction R being indicated by the grid point to which they belong. The grid distance is 1 and the time step τ, a bar indicating averaged values. The equations of the HN model in this case are as follows:

$$\zeta_2' = \zeta_1 - \frac{\tau}{l}H_2u_2 + \frac{\tau}{l}H_4v_{4_1}u_2' = u_2(1 - R_{2\tau}) + f\tau\bar{v}_2 - q\frac{\tau}{l}(\zeta_3 - \zeta_1) - \tau X_{2_1}$$

$$\zeta_3 = \zeta_3 + \frac{\tau}{l}H_2u_2 + \frac{\tau}{l}H_5v_{5_1}u_4' = u_4(1 - R_{7\tau}) + f\tau\bar{v}_7 - q\frac{\tau}{l}(\zeta_8 - \zeta_6) - \tau X_{7_1}$$

$$\zeta_6 = \zeta_6 - \frac{\tau}{l}H_7u_7 - \frac{\tau}{l}H_4v_{4_1}v_4' = v_4(1 - R_{4\tau}) - f\tau\bar{u}_4 - q\frac{\tau}{l}(\zeta_1 - \zeta_6) - \tau X_{4_1}$$

$$\zeta_8 = \zeta_8 + \frac{\tau}{l}H_7u_7 - \frac{\tau}{l}H_5v_{5_1}v_5' = v_5(1 - R_{5\tau}) - f\tau\bar{u}_5 - q\frac{\tau}{l}(\zeta_3 - \zeta_8) - \tau X_5.$$

The variables ζ, u, v on the right-hand side of the equations are assumed to be known, ζ', u', v' are uniquely determined by these equations τ seconds later. In this iteration process, the sea level ζ and the components of tidal currents u and v are computed step by step. The advantages of such models are: (1) very general nonlinear and even random processes may be taken into account, (2) no restrictions are placed on the geometry and depth of the basin under consideration, and (3) the large amount of numerical work is performed by electronic computers.

Prediction of tides in the North Sea, Atlantic, and the world ocean. Computers are not initially available for computation work with hydrodynamic–numerical models, and it was not possible to start investigations with the world ocean. Tidal estuaries, adjacent, and marginal seas were therefore treated first.

As an example, the tide in the North Sea has been computed by means of a hydrodynamic–numerical model. In this area tides along the coast and tidal currents in the open sea are fairly well known, and a comparison between computed and measured values is possible.

Tides in the North Sea

Figure 5 shows the corange and cotidal lines of the principal lunar (M_2) tide of the North Sea, obtained by hydrodynamic–numerical-model computation. The correlation of observed and computed sea levels is excellent.

The influence of the depth distribution and the rotation of the Earth is indicated in the results of two HN models that accounted for these assumptions. Figure 6 shows the cotidal and corange lines of the tide in the North Sea with a constant depth of 80 metres (260 feet); Figure 7, the cotidal and corange lines with the depth constant (80 metres = mean depth of the North Sea), but the Coriolis acceleration (that due to rotation of the Earth) assumed to be zero, hence the effect of the rotation of the Earth is neglected. The results show that the high tidal range along the British coast is not caused by the rotation of the Earth as had been assumed in earlier investigations. HN models make it clear that the depth of the North Sea is predominantly responsible for observed distribution of the range.

Corange and cotidal lines that are drawn for the tides in a rectangular basin of constant depth, which, as a very rough first approximation, represents the North Sea reveal amplitudes and phases of the principal lunar (M_2) tide that are quite different from the tides discussed immediately above. This demonstrates in a distinctive way

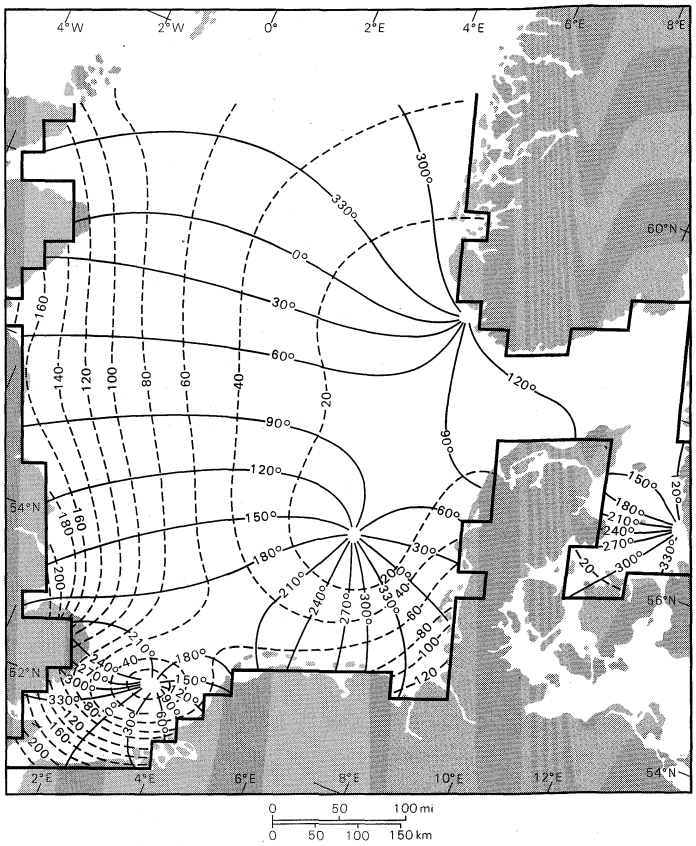

Figure 5: Cotidal and corange lines in North Sea according to HN computation. Measured range and time of high water in coastal locations. Zero time equal to Moon's transit in Greenwich. Amplitudes in centimetres.

the important influence of the coastal configuration, and that it is not possible to reproduce the tides in natural seas by investigating basins of simple geometry.

Before considering the world ocean, it is useful to examine tidal prediction in a body of water of intermediate size like the Atlantic Ocean. Figure 8 shows the computed sea level at the time of the Moon's transit in Greenwich and three hours six minutes later, compared with the measured sea level along the coasts of the Atlantic Ocean. Again, the hydrodynamic–numerical method can be considered successful.

Tides in the world ocean

Figure 9 represents the world ocean including amphidromic points of the principal lunar (M_2) tide delivered by a 6° model. Amphidromic points, characterized by zero tidal range, are points at which the sea level remains unchanged by the tides. Dashed lines are referred to zero sea level at the time of the Moon's transit in Greenwich, and full lines correspond to zero sea level at three hours six minutes after the time of the Moon's transit in Greenwich. Because the hydrodynamic–numerical model does not require any tidal measurement, the results are independent of sea-level records. On the other hand the grid size of 6° in this model is relatively large, and, consequently, not all the fine structure of the ocean's depth and coast is sufficiently accounted for. For example, the shelf configuration may drop through the grid system because of the wide spacing. The response of the shallow-water areas on tides is important for the distribution of tidal amplitudes and phases. The grid distance should be about 50 kilometres (30 miles); it is more than 600 kilometres (400 miles) in this model.

Accuracy of hydrodynamic–numerical methods. Using hydrodynamic–numerical models it is possible to perform tidal predictions of sea level and tidal currents for an entire sea with only one computation. At the open boundary, the tidal constituents given in Table 1 (at least M_2, S_2, N_2, K_2, K_1, O_1, P_1) are prescribed by their amplitudes and phases. By means of these constituents the tides on the boundary are predicted. The model determines tides and tidal currents as a function of time at all grid points in the interior of the basin. This prediction method has been tried for several areas and Figure 10 shows the model computation compared with tidal prediction for selected points around the North Sea; similar results have been obtained for the Gulf of St. Lawrence and for Kuwait in the Persian Gulf. Tidal currents are predicted by the same computation. Because only measurements on the boundary are needed, hydrodynamic–numerical model tidal prediction provides a maximum of information with a minimum of measurements.

Effect of shallow water. In shallow-water areas the nonlinear terms in the hydrodynamical equations become increasingly important. Different tidal constituents, such as M_2 and S_2, cannot be treated separately, and the sea level is no longer a simple harmonic function of time. For tidal currents in the harmonic case, a water particle returns to its original location within a tidal period, thus describing a tidal ellipse. But in the nonlinear case the water masses do not return to their origin within one tidal period. Consequently, a periodic process on the open boundary of the sea results in a nonperiodic motion like a permanent transport in the interior of the sea under consideration. Figure 11 shows such a residual transport in the North Sea caused by the principal lunar (M_2) tide prescribed on the open boundaries as a simple harmonic function of time. Tides and surges also must be investigated within one process; separate treatment delivers only a first approximation. Little is known about the interaction of tides and the strong permanent currents in the world ocean, such as Gulf Stream, Kuroshio, and the equatorial countercurrent and undercurrent.

Residual currents

Tidal currents. Tidal current measurements show the variation of velocity as a function of depth (see Figure 2). Attempts have been made to determine the tidal current as a function of depth. In estuaries and in narrow straits with alternating tidal currents, it was found that the true velocity is approximated by the formula:

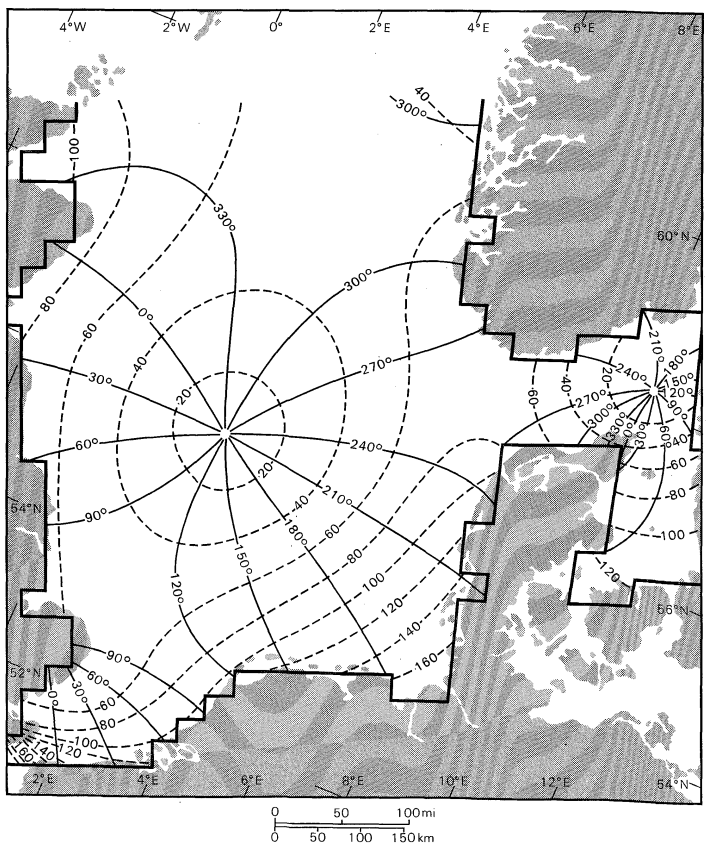

Figure 6: Tides in a North Sea basin of constant depth (80 metres), with the Earth's rotation taken into account. Solid lines are cotidal lines referred to Moon's transit in Greenwich. Dashed lines are amplitudes in centimetres.

$U = U_{ob}\left(\frac{Z}{H}\right)^{\alpha}$, in which U_{ob} is the surface velocity, Z is depth, H the total depth, and α is a coefficient that varies from $\frac{1}{5}$ to $\frac{1}{7}$.

If the water in the sea is stratified, there are layers each with its own density, which may oscillate at their interfaces. Amplitudes may become remarkable and can be expected to be on the order of tens of metres. This type of motion is called internal waves; the oscillations are irregular, but there are periods of a day or of half a day. Hydrodynamic–numerical models are designed for stratified water masses, but not enough measurements are available for comparing computations and measurements.

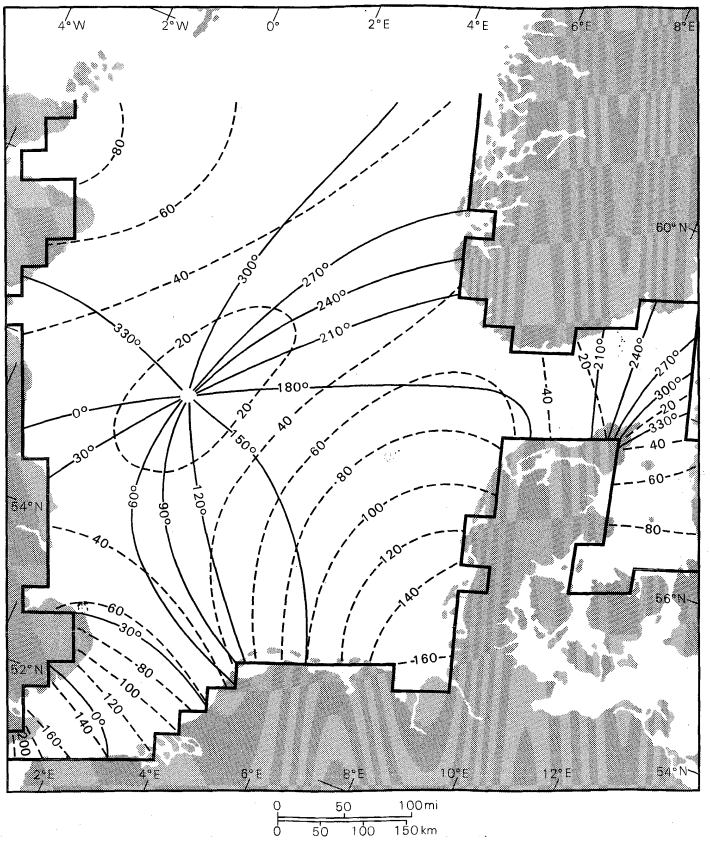

Figure 7: Tides in a North Sea basin of constant depth (80 metres) without taking into account the Earth's rotation. Solid lines, cotidal lines, refer to Moon's transit in Greenwich. Dashed lines are amplitudes in centimetres.

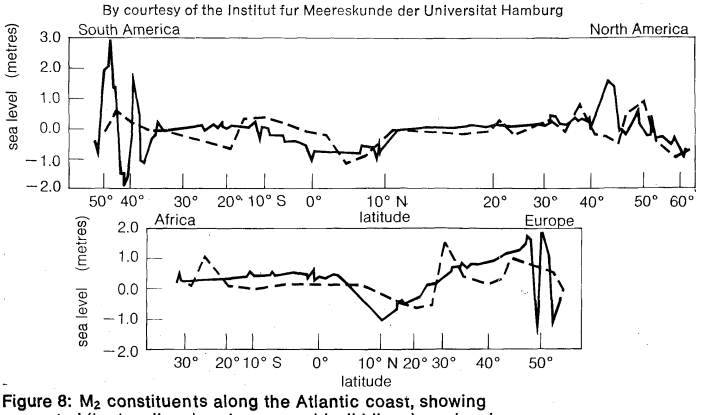

Figure 8: M_2 constituents along the Atlantic coast, showing computed (broken lines) and measured (solid lines) sea level.

Practical aspects. The knowledge of tides and tidal currents may serve important purposes. Navigators approaching a coast and steaming into a river need information on the depth in these areas; moreover, it is advantageous for a ship to sail in the direction of the tidal current flow. Coastal-engineering work is also intensively concerned with tides. The regulation of a tidal estuary, the damming of a tidal river, or the construction of a harbour are problems that require knowledge of tides and tidal currents; such work may change the natural condition to such a degree that unwanted effects arise. As an example, the damming of a tidal river may cause flood current of very short duration and high velocity and, consequently, an ebb current of long duration and low velocity. A river in a sand-bed channel allows transport of such bottom material landward during each tidal period, but if the ebb current is extremely small, this material will not return to the sea within the same tidal period. The result is that the depth of such a tidal river decreases within a short time, and ultimately the river cannot be used as a waterway for ships. Information on the behaviour of the tides in a river that will result from artificial construction is therefore of great practical value, and hydrodynamic–numerical

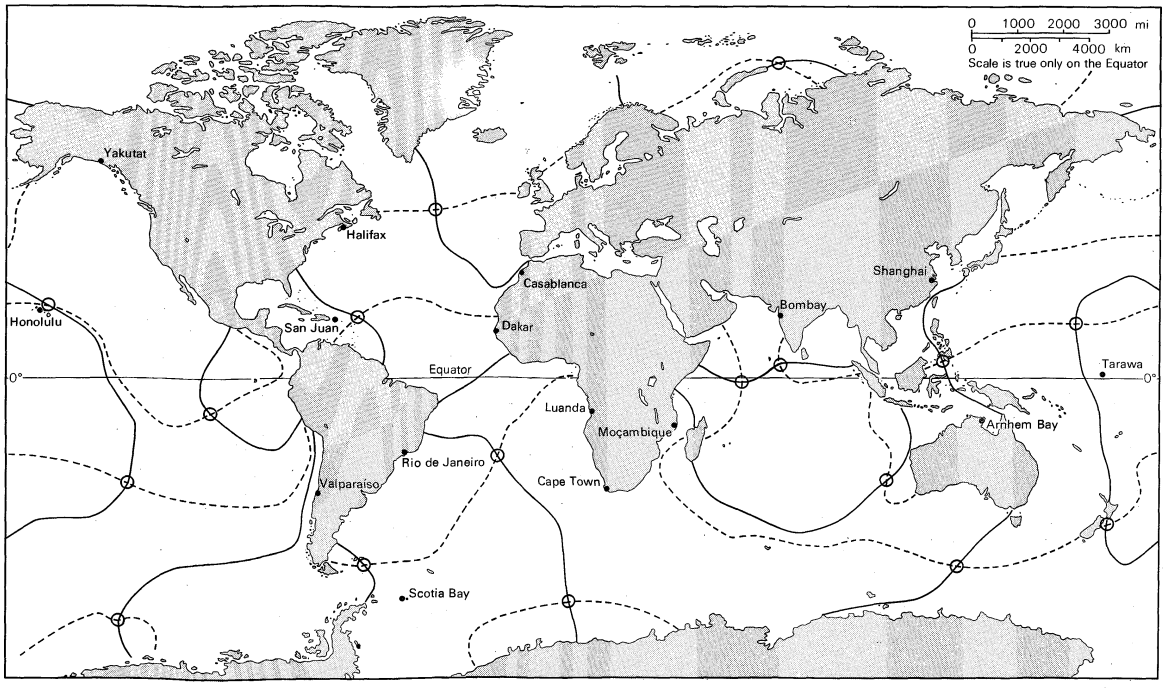

Figure 9: Amphidromic points of the M_2-tide in the world ocean (see text).

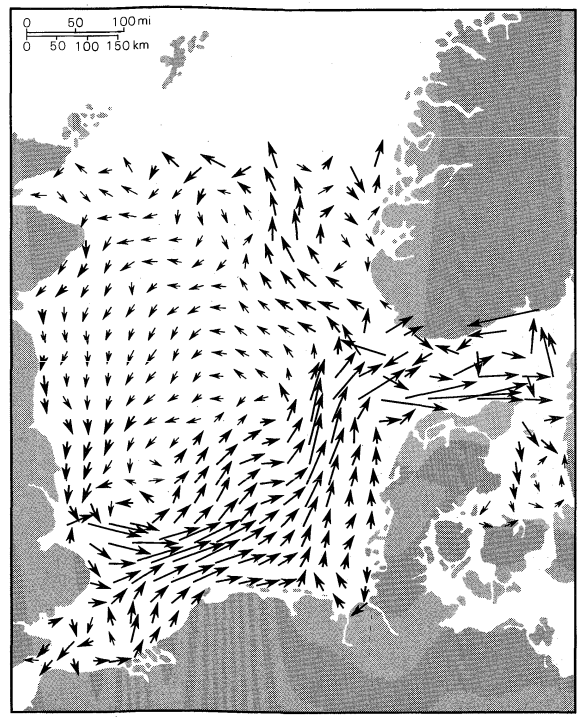

Figure 11: Residual current caused by the M_2 tide on the boundaries of the North Sea.

models may be useful in such cases. Other practical aspects of tide information are related to efforts to convert the energy of tides into electric energy, and the problems that arise from the pollution of water in coastal areas and in the open sea. It has been pointed out that tides in shallow water cause a permanent transport, and polluted water masses may be transported by tides without any support by other currents. Similarly, tidal motion may be important for fishery, especially in cases of stratified water masses.

Complicating factors. Ocean currents and sea-level variations not caused by tide-generating accelerations are observed in the ocean. Among these are storm tides, tsunamis, surface waves, gradient currents, and others; each of these phenomena may be periodic or nonperiodic.

Meteorological effects are caused by several forces. The wind stress on the sea surface and the air-pressure gradients act on water masses from the surface to the bottom. Radiation and backradiation, evaporation, and precipitation influence temperature and salinity of the seawater; the density of the water is a function of the last two conditions. Horizontal-density gradients are responsible for gradient currents. In the ocean, the meteorological effects are in near correlation with the large ocean currents, such as the Gulf Stream, Kuroshio Current, and others. The current systems as a first approximation are considered to be constant. In adjacent and marginal seas, storms may from time to time cause storm tides involving sea-level elevations of up to several metres. Under normal conditions the wind velocity decreases after several hours. Such an elevation of sea level is neither a permanent nor a periodic one, but it may be a complicated function of time, especially in areas where the storm surge interacts with the tides. In shallow-water areas this interaction is expected to be nonlinear. Tides and storm surges in several areas have been successfully reproduced by means of hydrodynamic–numerical models. Hitherto it has been assumed that the mass of the ocean water is constant. A considerable amount of frozen water is stored in polar areas, however, and given proper variation of the climate of the Earth, this amount of ice and the elevation of sea level will change. Another potential cause of sea-level change is the vertical motion of the land.

Changes in climate and length of day

The amplitudes of the tides depend to some extent on water depth; climatic changes may therefore cause changes in tidal amplitudes. It was previously pointed out that the tidal potential can be represented by a Fourier series. The assumption is that the motion of the Sun, the Earth, and the Moon as a celestial system is unchanged. According to some theories of the Moon's development,

the distance between the Moon and the Earth has changed. Under such conditions the tidal potential also has changed.

The ocean tides have been determined by assuming a completely rigid Earth, which means that the surface of the Earth is unchanged. But according to measurements it may be assumed that the elasticity of the Earth is comparable to the elasticity of steel, which is the reason there are bodily, or Earth, tides as well as water tides. Measurements indicate that the ratio of ocean tides to Earth tides plus ocean tides is about 0.7. There are other factors influencing Earth tides and ocean tides. It has been discovered that the length of a day has increased by one to two seconds within the last 120,000 years. This decrease in the Earth's rotation is partly explained by the friction of tidal currents. The friction term in the hydrodynamical equation is inverse to the depth. Therefore, much tidal energy is dissipated in shallow-water areas such as the Siberian Shelf, Bering Sea, Irish Sea, and the Patagonian Shelf.

TIDES IN THE ATMOSPHERE AND SOLID EARTH

Atmospheric tides. Like the water, the atmosphere is under the influence of the tide-generating acceleration, and air tides are to be expected. In the layers of air near the surface, pressure oscillations of the principal lunar (M_2) as well as principal solar (S_2) frequencies have been determined for a number of places. Because of the lesser density of the air, the tides in the atmosphere are much smaller than those in the ocean. Analysis yields larger amplitudes for S_2 than for M_2 atmospheric tides, which is explained by the fact that daily heating and cooling is responsible for these oscillations. Because the frequency is precisely the same as the frequency of the tidal-generating oscillation, it is not possible to separate the effects. The M_2 amplitude of atmospheric tides is of the order of magnitude of 0.06 millimetre (0.002 inch) mercury.

Atmospheric oscillations

In the ionosphere there are different layers that oscillate with lunar or solar frequencies; the amplitudes may be of the order of several hundred metres.

Earth tides. The tidal potential also acts on the solid body of the Earth, the lithosphere. Whereas it is possible in the case of ocean tides to assume that the depth of the ocean is small compared with its horizontal dimensions, the density variation and other properties of the lithosphere make the determination of bodily tides more difficult than determination of ocean tides.

Knowledge of the precise nature of the solid body of the Earth as a whole is limited, but it is known to be influenced by the tide-generating acceleration in two different ways. First, these accelerations act on the particles of the solid body of the Earth, which behaves as an elastic body, so that tides are developed within it. In addition, the tides of the ocean, especially the water masses transported by tidal currents, cause a periodic loading and unloading, a process that results in indirect tides. If the solid body of the Earth were completely rigid, no bodily tides would occur, and, at least in principle, the tide-generating forces could be measured; in this case they would be in agreement with the equilibrium tide. Measurements indicate that the theoretical values are not reached and that the elasticity is comparable to the elasticity of a steel sphere the same size as the Earth.

Tide-generating accelerations are a space-wide phenomenon acting on the particles of celestial bodies. If there are oceans on other planets, it is possible, in principle, to determine the tides in such oceans, and, if all the astronomical parameters are known, the bodily tides of the planets also can be calculated. (W.Hn.)

ASTRONOMICAL TIDES

Tidal effects on the planets and other bodies in the solar system, like those on the Earth, are caused by differences in the pull of gravity exerted by one body on various parts of another. The gravity difference can cause an elongation through stress if the subject body is deformable; if it is not, the stress set up may cause some adjustment of the distribution of material. In extreme cases, tidal force caused by an external gravity difference may be greater than the internal gravity of a body combined with any cohesive forces that may be present in it. In such cases the body will be disrupted by the tidal force, and it will break up. In the solar system, the most interesting tidal effects are found in the Earth–Moon system, in the Mars satellites, and in the rings of Saturn. Tides also influence stars, star clusters, and galaxies.

A tidally produced elongation of an astronomical body may be permanent or temporary, according to the nature of the material of which it is composed. Also, in the absence of drag (tidal friction), the elongation may be in the direction of the gravity difference (equilibrium tide), or, when the body is rapidly rotating, the tidal bulge may be carried forward around it by an amount that depends on the physical conditions.

Just as the Moon raises tides on the Earth, the Earth, with its far greater mass, raises tides on the Moon. Moreover, because the surfaces of stars are gaseous, the individual stars of many close pairs in binary star systems (two stars that revolve around a common centre of gravity) are elongated by tidal forces and often show evidence of streams of gas passing between the two stars.

Effect of the Earth on the Moon

Lunar tides. Tides raised on the Moon by the Earth are much simpler to depict than those raised on the Earth by the Moon. Because there is no surface water on the Moon, it is only necessary to consider the tides in the solid material; that is, the bodily tides. Solar tides can be neglected for the Moon. The solar tide-raising potential is about the same for both Earth and Moon, but tide-raising potential does not need to be taken into account when considering lunar tides because since the Earth is much closer to the Moon, the solar tide is overwhelmed by the Earth's tidal effect on the Moon. On the average, the solar tide-raising potential on the Moon is only 1.5 percent of the Earth's and is never greater than 3 percent.

The long-term effect of tidal friction on the Moon has been to slow its rate of rotation until it is synchronous with its period of revolution around the Earth. (The same effect on the Earth is increasing the average length of the day by about two milliseconds per year.) The Moon rotates once each month and completes one revolution of the Earth in approximately the same time. For this reason, the same face of the Moon is always turned toward the Earth. Because the Moon's orbit around the Earth is irregular, it alternately approaches and recedes from the Earth. While rotating at constant speed, which is so slow that tidal friction is very small, the Moon moves forward fastest in its orbit at the point where it is closest to the Earth (perigee) and slowest at the point at which it is farthest away (apogee). Because of these variations in the Moon's rate of revolution around the Earth and because of the inclination of the Moon's axis of rotation, small areas near the Moon's edge appear and disappear from time to time. As a result of this oscillatory phenomenon, which is called libration, slightly more than half of the Moon's surface is seen as it revolves. At the same time relative distances between the Earth and individual areas on the Moon's surface are altered. Thus, tidal forces on the Moon due to the Earth are greatest at perigee and least at apogee. Moreover, because the amount of change in these forces varies with the libration position, they may differ considerably from one time to another at the same place on the lunar surface.

Evidence suggests that two types of phenomena on the Moon are tidally related. Temporary changes in the appearance of small areas occasionally have been noted. The sighting of glows of light, colour changes, and obscuration of detail in such areas have been reported since the late 18th century, and similar observations were made even before the invention of the telescope. These lunar transient events seem to occur unpredictably, but statistically they are observed more frequently at perigee, when the overall tidal effect of the Earth on the Moon is greatest.

In 1970 the discovery of seismic signals, which measure interior disturbances in the Moon, heightened interest in lunar tides. One type of signal, called type A, occurred at each perigee and was found to originate at very nearly the

same place each time. Because it was extremely unlikely that meteorites would fall precisely at each perigee in the same place, it was concluded that the disturbances that caused the A-type signals were moonquakes, triggered by extreme tidal conditions. A second group, type B, were believed to be tidally related because they were found to occur sometimes at perigee and also at apogee.

The relative frequencies of the two types are so similar that it now appears certain that the lunar events are related to moonquakes of a kind similar to those with which the seismic signals were associated; the glows and obscurations may represent the appearance of small quantities of gas and dust, tidally released through cracks in the Moon's surface. This idea is supported also by the small amounts of gases that have been detected on the Moon.

The Roche limit. Although a tidal force on a planet or satellite in the solar system is essentially disruptive, it amounts to only a small fraction of that body's own gravitational forces. If, however, such forces are sufficiently large, they may overcome the combined effect of internal gravity and the cohesive forces that hold a body together. The body will then begin to break up.

If a natural satellite (a moon) moves closer to its planet through time, the effect of the planet's tide-generating force increases rapidly, and the spherical shape of the satellite becomes distorted. If the satellite is sufficiently deformable, it will become more and more elongated. Finally, if it comes close enough to the planet, the satellite will break up completely.

A French scientist, Édouard Roche, calculated the shape that a small satellite would assume if it were free to adapt itself to tidal stresses under conditions similar to those just described. Roche also determined how close such a satellite could approach its planet without breaking up. In order to change its shape freely the satellite would have to be a fluid, composed either of a gas or a liquid. Although this situation is quite artificial, it can be used as a first approach to find the absolute limits in some real examples.

He found that the limiting figure, or shape, of such a liquid or gaseous satellite is a prolate spheroid—a nearly egg-shaped body in which the longest axis is slightly more than twice the length of either of the shorter ones. The satellite is least likely to break up when it moves with its long axis pointing directly toward the centre of the planet. Roche also proved that when the satellite and the planet have the same density, the satellite will break up, in the absence of any internal cohesive forces, at a distance of 2.44 times the planet's radius, or 1.44 times the radius above the planet's surface. In other words, for a planet and satellite of the same density, the satellite cannot exist permanently inside a sphere drawn around the planet at 2.44 times its radius, or 1.44 times the radius above its surface. The limiting distances, or Roche limit, in any such situation depends on the relative densities of the planet and satellite as well as the planet's radius; it would be nearer to the planet for higher planetary density and farther away for a satellite that is denser than its planet.

Although the Moon is well outside the Roche limit of the Earth, many small artificial satellites have been put into orbits much closer, and some of them have lasted for several years. Eventually, though, the satellites lose energy through atmospheric drag and spiral toward the Earth. If, however, the parts of the satellite were not rigid and rigidly held together by rivets, screws, and the like, the satellite's internal gravity would not be sufficient to prevent the parts from gradually separating. The case of a nose cone and a space vehicle, or of two space vehicles travelling together, perhaps illustrates the point. Unless the units are physically joined by a clamping device, continual small adjustments in speed must be made to keep them together, or else they will slowly drift apart.

The rings of Saturn

Saturn possesses ten satellites, all of which orbit outside the Roche limit. In addition, the planet also has around it a remarkable series of broad flat rings, the nature of which remained a puzzle for some 200 years following their discovery in the 17th century. The rings are inclined to Saturn's orbital plane and also to the orbital plane of the Earth (the ecliptic). Most of the time the rings appear as concentric ovals that change in shape; occasionally, they disappear from view. Because this happens whenever the Sun or the Earth passes through the plane of the rings, it indicates that the material of the rings is confined very closely to a plane.

Because the whole system of rings is inside the equal-density Roche limit, the existence of the rings can be directly attributed to tidal forces. This was recognized by Roche in 1848 and was explained in mathematical terms in 1859 by the Scottish physicist James Clerk Maxwell. Saturn has such an extremely low density that a piece of it would float in water. If, on the other hand, the ring material is solid, it must be heavier than the material of which Saturn is composed, and the actual Roche limit must be beyond the rings. It appears that the rings are indeed composed of small, separate, rocklike particles revolving in free orbits and held together by internal cohesion only. The particles probably collide occasionally and thus erode very slowly into smaller and smaller particles. Even if such a flat system as Saturn's rings could exist temporarily as a single continuous sheet, it would be unstable, and the tidal force of the planet would break it up.

The Mars satellites

Mars has two satellites, Deimos and Phobos. Deimos is relatively far removed from the planet, but the orbit of Phobos is close to Mars, at a mean distance of 2.75 Martian radii. The density of Mars is known to be 3.97; if the densities of Phobos and Mars are in about the same proportion as those of the Moon and the Earth, the Roche limit will be about 2.86 times the planet's radius. Thus, Phobos revolves at just about the limit of stability.

In 1970 the image of the little satellite was recorded by chance by a spacecraft circling Mars. The spacecraft, which was engaged in photographing the planet itself, was more distant than Phobos from the planet. Silhouetted against the body of the planet, Phobos was seen to be elliptical. It measures 14 miles (23 kilometres) in diameter along the orbital and 11 miles (18 kilometres) in the perpendicular direction. Eventually, it may be broken up by the tidal action of Mars.

Tides in stars and galaxies. Tidal disturbances are present in many binary star systems. Observations show that stars in such systems are usually ellipsoidal rather than spherical in shape. The amount of distortion can be measured in terms of the ellipticity of the star; in general, the shorter the period of rotation of one star about the other, the greater the ellipticity. Because the period, in turn, depends on the size of the orbit and because the square of the period is proportional to the cube of the mean distance between the stars, the ellipticity depends strongly on the distance. This effect is at least partly tidal, though in some binary star systems—particularly those containing very hot (young) stars—another factor, rapid rotation, may also be active. In such cases, the two possible causes of ellipticity would reinforce each other.

In many binary systems, spectral measurements show that streams of gas pass from one star to the other. The best known systems with gas streams of this kind are Beta Lyrae (the second brightest star in the constellation Lyra, the Lyre) and W Ursa Majoris (the variable, W, in the constellation of Ursa Major, the Great Bear). In Beta Lyrae, only one star can be seen; the other is too faint. Nevertheless, the gas streams that have been detected (as bright mission lines in the spectrum) are flowing from the bright, early type star to the fainter, which is believed, therefore, to be the more massive. In addition to showing tidal distortion, the bright star also rotates rapidly, and this increases the instability of the system.

Disintegration of star clusters

The stars in a cluster are in continuous motion and interact gravitationally with one another. Close chance encounter between the stars in a cluster, however, may change any star's motion sufficiently for it to escape from the group. The differential rotation of a galaxy and its tidal action on the cluster both act to separate the innermost and outermost parts of the cluster; in time, the less massive stars are lost, and the cluster progressively disintegrates. For the Pleiades, the time needed for disintegration is about 10^9 years; for a looser group, or stellar

association, the so-called O-B class (hot and bright) of stars, very much less time is needed.

Some external galaxies occur in pairs or groups. When the pairs are quite close in the sky, it is sometimes found that jets and streams of bright material extend from one to the other. The inference in these cases is that the pairs are actually close in space and are interacting tidally. In spiral galaxies with companions, radio observations of neutral hydrogen have shown some asymmetries that are also believed to be due to tidal distortions. One such example is known as M101 (NGC 5457). Similar but rather smaller asymmetries have been found by radio measurement of the hydrogen gas in the galaxy called the Andromeda Nebula and its nearby companions; others are believed to exist in the Milky Way, which has as close companions the Magellanic Clouds. On the other hand, bright galaxies without close companions are apparently undistorted at radio wavelengths. A recent optical study of bright galaxies revealed that about 20 percent have close companions and exhibit distorted optical features.

Tien Shan (Mountains)

The Tien Shan, a Chinese name meaning "Celestial Mountains," forms one of the great mountain systems of Central Asia. Situated in the U.S.S.R. and China, it stretches for about 1,800 miles (3,000 kilometres) from west-southwest to east-northeast. It is about 300 miles wide in places at its eastern and western extremities but narrows to about 220 miles in width at the centre.

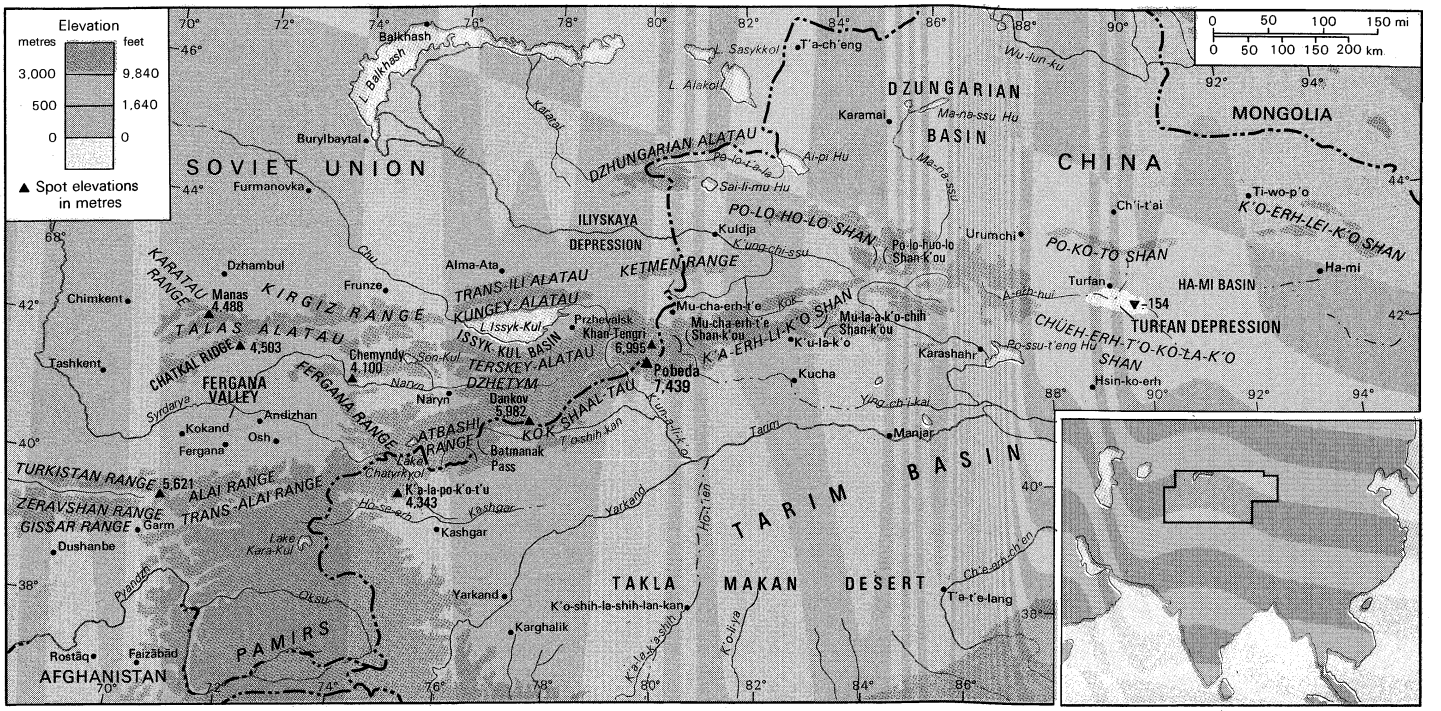
The Tien Shan are bounded to the north by the Dzhungarian and southern Kazakhstan plains and to the southeast by the Tarim Basin; to the southwest, the Gissar-Alai Mountains form part of the Tien Shan, making the Alai (Alayskaya), Surkhandarya (Surkhobskaya), and Gissar (Gissarskaya) valleys the boundaries of the system with the Pamir mountain ranges. The Tien Shan Range also includes the Chu-Ili Mountains (Chu-Iliyskiye Gory) and the Karatau Range (Khrebet), which extend far to the northwest into the Kazakhstan lowlands. Within these limits the total area of the Tien Shan is about 386,000 square miles (1,000,000 square kilometres).

The highest peaks

The highest peaks are a central cluster of mountains forming a knot, from which ridges extend along the boundary between China and the Soviet Union; these peaks are the Pobeda Peak (Pik Pobedy, or Victory Peak), which is 24,406 feet (7,439 metres) high, and the Khan-Tengri Peak, which is 22,949 feet (6,995 metres) high. (For an associated physical feature, see ISSYK-KUL, LAKE.)

The natural environment. *Physiography.* The relief is characterized by a combination of mountain ranges and intervening valleys and basins, trending generally from east to west. The deepest depression in the eastern Tien Shan is the Turfan Depression, within which is the lowest point in Central Asia—505 feet (154 metres) below sea level. Thus, the differences in elevation in the Tien Shan are extreme, exceeding four and a half miles. The eastern extension of the Turfan Depression is the Ha-mi Basin; both basins are bounded on the north by the Po-ko-to Shan, with elevations of up to 17,864 feet (5,445 metres), and by the eastern extremity of the Tien Shan, the K'o-erh-lei-k'o Shan, which reaches heights up to 16,158 feet (4,925 metres).

The ranges are of the Alpine type, with steep slopes; glaciers occur along their crests. The basins are bounded on the south by the low rising Chiao-lo Shan. West of the Turfan Depression is one of the greatest mountain knots of the eastern Tien Shan: the O-ha-pu-t'e Shan, which reaches elevations of up to 18,208 feet (5,550 metres). The ridge has considerable glacial development, as well as numerous forms of relief indicating ancient glaciation.



The Ili Depression

West of 84° east, the eastern Tien Shan ridges fork, trending in southwestern and northwestern directions, and enclose the vast Ili Depression (Iliyskaya Vpadina), which gradually widens and loses height as it proceeds westward. It is bounded on the north by the Po-lo-ho-lo Shan, which has glaciers in the eastern part and is characterized by steeply sloping ridges. This range also gradually descends westward, where, at a height of 6,801 feet (2,073 metres), lies the great undrained lake of Sai-li-mu Hu. The Ili Depression is bounded on the south by the highest mountains in the eastern Tien Shan—the K'a-erh-li-k'o Shan, reaching heights up to 22,346 feet (6,811 metres), and the isolated Ketmen Range (Khrebet Ketmen), which rises to an elevation of 11,936 feet (3,638 metres) in the central part of the depression.

The northern extremity of the Soviet part of the Tien Shan forms the Dzhungarian Alatau Range (14,645 feet [4,464 metres]), which is subject to considerable glacial action. To the south, the Trans-Ili Alatau Range rises abruptly above the Ili Depression to a height of 16,315 feet (4,973 metres). The successive transition of climatic zones, determined by altitude, from arid and dry steppe at lower levels to glacial at the summit is evident on the northern slopes of this range. The Kirgiz (Kirgizsky) and Talas (Talassky) Alatau ranges, rising above 13,000 feet and located farther west, also belong to the outer chain of the northern Tien Shan. There is a great difference in elevation between these outer mountain ridges and the plains at their base. Streams, therefore, usually plunge down the mountainsides through deep gorges and, as they flow out onto the plains, form vast fan-shaped deposits of silt and mud. On the fertile land thus formed are located many oases and population centres, including the cities of Alma-Ata and Frunze in the Kazakh and the Kirgiz Soviet Socialist republics (*q.q.v.*). The Kungey-Alatau and Terskey-Alatau ranges also belong to the northern Tien Shan. They rise to a height of 17,100 feet and border the vast Issyk-Kul Basin, the centre of which is filled by Lake Issyk-Kul.

The Aksay River (T'o-shih-kan Ho in Chinese) Basin and most of the Naryn River Basin are situated within the inner Tien Shan. This region is characterized by the alternation of comparatively short mountain ranges and valleys, both extending east and west. The predominant elevations of the mountains vary from about 10,000 to 15,000 feet, while the elevations of the depressions that separate them vary from between about 6,000 to 10,500 feet. The most important ranges are Borkoldoy (16,565 feet [5,049 metres]), Dzhetym (16,178 feet [4,931 metres]), Atbashi (15,702 feet [4,786 metres]), and the Kok Shaal-Tau Range, in which Dankov Peak reaches a height of 19,626 feet (5,982 metres).

The elevation of the mountains increases in the Sarydzhaz River (called K'un-a-li-k'o Ho in Chinese) Basin area in the central Tien Shan, lying to the east of the Akshiyrak Range. The ranges gradually converge, forming the high-altitude mountain knot already mentioned,

The Tien Shan.

which includes the Khan-Tengri crests and Pobeda (Victory) Peak.

The Fergana Range

In contrast to most of the Tien Shan ranges, which run approximately east–west, the Fergana Range (Fergansky Khrebet), separating the inner region from the western and southern Tien Shan, extends from southeast to northwest. Its maximum elevation is 15,354 feet (4,680 metres). The southwestern slopes display a variety of climatic zones in the course of their gradual descent.

The western Tien Shan ranges lie north of the Fergana Valley (Ferganskaya Dolina). Several short but high and steep ranges running southwest–northeast here meet the southern sides of ranges running westward and northwestward. The highest peak is the Chatkal Ridge (14,773 feet, or 4,503 metres), and the predominant elevations vary from about 7,500 to 10,500 feet.

The southern Tien Shan ranges (including Turkistan, Zeravshan, and Alai, among others) border the Fergana Valley on the south and extend chiefly east and west. The maximum elevation is 18,441 feet (5,621 metres), with several peaks above 15,000 feet. To the south, the Tien Shan meets the Pamirs. Foothills approach the northern slopes of the ranges; there are oases on the plains below the mountains.

Largest glacial areas

Glaciers. The total area of the Tien Shan glaciers exceeds 3,800 square miles, of which more than four-fifths is in the Soviet Union. Largest among the several glacier areas are the Khan-Tengri-Pobeda region and the O-hapu-t'e Shan. There are also many glaciers in the Kok Shaal-Tau Range, the Akshiyrak Range, the Trans-Ili Alatau Range, and the southern Tien Shan. The largest glacier in the Tien Shan is Inylchek Glacier (Lednik), which is approximately 37 miles long; it descends from the western slopes of the Khan-Tengri massif and branches into numerous tributaries. Other large glaciers in this area include North (Severny) Inylchek (24 miles) and Mu-cha-erh-t'e Shan-k'ou (21 miles). The length of the largest Tien Shan glaciers elsewhere is usually between six and 12 miles; the most usual size is that of the relatively small valley glaciers, from about one and a half to three miles long.

The glaciers are usually fed by snowfall upon the glaciers themselves or by snow avalanches from the surrounding slopes. Glacial action in the Tien Shan is apparently decreasing; most glaciers are either receding or standing still. During recent decades, however, large glaciers in the inner Tien Shan region have made short-term advances. The glaciers of Tien Shan feed many large rivers, including the Naryn, Sarydzhaz, Ili, and Zeravshan.

Rivers and lakes. The rivers of the Tien Shan flow into major inland depressions, such as the Azalskaya and Tarim. The largest rivers are the Ili and Chu in the northern Tien Shan, Narym in inner Tien Shan, Sarydzhaz in central Tien Shan, and Zeravshan in southern Tien Shan. Their maximum flows occur at the end of spring and in summer. Freshets sometimes cause catastrophic flows of mud and stone. Much water is diverted for irrigation. Hydroelectric power plants are being constructed on the Narym, the largest river of the Tien Shan.

The largest lake is the undrained Issyk-Kul, situated at 5,279 feet (1,609 metres). The lake, which has an area of 2,425 square miles, is saline and does not freeze in the winter; it is used for navigation and is a popular resort and tourist attraction. Po-ssu-t'eng Hu (533 square miles in area) is situated in the eastern Tien Shan.

Geology. The mountains of Tien Shan are composed in the main of crystalline and sedimentary rocks of the Paleozoic Era (from 570,000,000 to 225,000,000 years ago). The intermontane basins are filled with sediments from the Mesozoic (225,000,000 to 65,000,000 years ago) and Cenozoic (65,000,000 years ago to the present) eras. These sediments were chiefly formed by erosive river action. Granite-like rocks crop out over much of the area in the north and east of the Tien Shan.

The north and east portions of the region underwent folding during the mountain-building period that occurred during the Early Paleozoic Era; it has been uplifted dry land since, and its original sedimentary cover has been almost completely obliterated by erosion. The southern and western parts of the Tien Shan, however, consist principally of sedimentary metamorphosed (structurally changed by heat and pressure) rock and, to a lesser degree, of intrusive and volcanic rock. These regions experienced folding during the Late Paleozoic Era.

A new stage of development began in the middle of the Tertiary Period (about 26,000,000 years ago) and has continued to the present time. It has been characterized by sudden movements of the Earth's crust. Loose fragments of rock have slid into the valleys and formed accumulations; those in the Fergana Valley are almost five miles thick. Shallow lakes were formed in many valleys and later evaporated, leaving behind salty deposits.

Subsequently, glaciers deposited boulder moraines (accumulations of earth and stones) in the mountains, while gravel and loess (wind-borne deposits) strata accumulated in the valleys. Zones of deep faulting occur, usually along the boundaries between the ridges and the valleys. Large-scale horizontal movements have occurred along the great Talas Fergana fault, which traverses nearly the entire Tien Shan system along the northeastern slopes of the Fergana Range and its northwestern extension. The deep faults are associated with catastrophic earthquakes that occurred at Verny (1887), at Kashgar (1902), in the northern Tien Shan chains (1911), and at Chatkal (1946), and Khait (1948).

Climate. The position of Tien Shan in the centre of Eurasia governs its sharply continental climate, characterized by great extremes of temperature in summer and winter. The characteristic aridity of the region is manifest in the surrounding deserts and dry regions. The area absorbs much solar heat, and there are about 2,500 hours of sun each year. The climate becomes progressively cooler and more humid as the elevation of the mountains increases. Permafrost (perennially frozen subsoil) is extensive above 9,000 feet. The prevalent air masses are transported over the Tien Shan by moisture-bearing westerly winds from the Atlantic Ocean. Most of the precipitation falls on the windward western and northwestern slopes at altitudes of between about 7,500 and 9,000 feet; it varies from between about 28 and 31 inches at one extreme and 59 and 79 inches at the other. To the east and in the interior regions of the Tien Shan, the total precipitation decreases to between eight and 12 inches, and it amounts to less than four inches in places. Maximum precipitation falls on the southern Tien Shan in March and April, and the summer is dry. In western and northern Tien Shan most of the rain falls during the warm period of the year, with a maximum in April or May. Most of the rain in the inner and eastern Tien Shan regions falls during the summer months. Many mountain valleys here are used as winter pastures because of the small amount of snow that falls in wintertime.

Precipitation

Temperatures vary in the Tien Shan, mostly depending on height. Summer is hot in the foothills: the mean temperature in July in Fergana Valley may reach 81° F (27° C); in the Ili Depression it may reach 73° F (23° C); and up to 93° F (34° C) to the east, in the Turfan Depression, where the climate is even more continental. The temperature in July at a height of about 10,500 feet in inner Tien Shan drops to 41° F (5° C), and frost is possible throughout summer. The mean temperature in January in Fergana Valley is 25° F (−4° C); in the Ili Depression it is 14° F (−10° C); and it drops to −9° F (−23° C) in the Alpine regions of inner Tien Shan, while in places (in particular, Aksay Valley) temperatures of −58° F (−50° C) have been recorded.

Plant and animal life. The characteristics of the living world of the Tien Shan are largely determined by the region's distinct zones of elevation, which provide a diverse distribution of soils and vegetation. In the foothills and plains at the base of the mountains semidesert and desert areas have usually developed; these zones continue to heights of between 5,250 and 5,800 feet. In the Tien Shan they are characterized by ephemeral vegetation growths that die out at the beginning of summer; xerophyte (adapted to a scant supply of water) grasses, wormwood, and the desert shrub ephedra are generally distributed. The most common landscape in the Tien Shan is steppe, which occurs at elevations of between about 3,500 and 11,000 feet.

The forests of the Tien Shan alternate with steppes and meadows. They are principally on the northern slopes and extend to an elevation of 9,000 to 9,800 feet. On the lower slopes of the outer ranges the forests are principally deciduous, consisting of maple and aspen, with extensive admixtures of wild fruit trees (apples and apricots). Vast areas of the southwestern slopes of the Fergana Range are occupied by very ancient nut-bearing forests. Stands of pistachio, walnut, and juniper are found up to 7,500 feet on the shaded slopes of several western and southern Tien Shan ranges. North and east of the Fergana Valley, coniferous forests predominate. At the upper boundary they are often replaced by sparse juniper forests. The water meadow forests in the river valley bottoms, in which aspen, birch, poplar, and various brushwoods ordinarily grow, lie far outside the forest zone. The forest glades and areas adjacent to the upper tree line are usually covered with meadow vegetation. Sub-Alpine meadows of mixed grasses and cereals extend up to almost 10,000 feet on the moist northern slopes but on southern slopes are usually replaced by mountain steppes. There are short-grass Alpine meadows up to 11,500 feet. In the inner and eastern Tien Shan regions, at elevations between 11,500 and 12,000 feet and sometimes higher, the level areas and gentle slopes are "cold deserts," with sparse and short vegetation. Mosses and lichens are found in the areas of the glacial zone that are free of snow and ice.

Animals in the Tien Shan include the wolf, fox, and ermine. There are also many typical Central Asian species, inhabiting chiefly the high mountains; these include snow leopard, mountain goat, Manchurian roe, and mountain sheep. The forest–meadow–steppe zone is inhabited by bear, wild boar, badger, field vole, members of the jerboa family (nocturnal jumping rodents), and members of the Ochotonidae family (short-eared mammals related to the rabbits). The many birds include the mountain partridge, pigeon, Alpine chough, crow, mountain wagtail, redstart, Himalayan snow cock, and other species. The lower zones—desert and semi-arid regions—are visited by animals from the neighbouring plains, such as antelope, gazelles, Tolai hares, and gray hamsters. Lizards and snakes are also found. (Y.Y.R.)

Animal life

The human imprint. *The inhabitants.* Several million people live in the Tien Shan. The Fergana Valley is the most densely populated, with more than 500 persons per square mile in places. Most of the Tien Shan is occupied by the Kirgiz and Uighur ethnic groups. Tadzhiks, Uzbeks, Kazakhs, and Mongolians reside along the periphery of the region. Substantial Russian and Ukrainian populations have been established in the Soviet part of the Tien Shan in recent decades; Chinese populations live in the eastern Tien Shan. Irrigated agriculture has developed in the valleys and on the mountain slopes, and livestock herding is practiced in the mountains.

After the Russian Revolution of 1917, the nomadic Kirgiz and Kazakhs adopted a settled way of life. Their principal occupation is the herding of livestock; in the summer herds of horses, sheep, and cattle are driven to the mountain pastures. Where conditions permit, agriculture is developed. The Uighurs live principally by irrigated agriculture, supplemented by handicraft production. Except for the Mongolians, the other peoples of the Tien Shan also engage in agriculture. (S.I.B.)

Exploration. The Russian Geographical Society played a major role in the scientific exploration of the Tien Shan. From 1856 to 1857 the Russian geographer P.P. Semyonov-Tyan-Shansky gave the first scientific description of many regions of northern and inner Tien Shan, while the expeditions of another Russian geographer, G.Y. Grum-Grzhimaylo, in the 1880s, contributed greatly to the exploration of the eastern Tien Shan. The peak of Khan-Tengri was ascended for the first time in 1931 by a Soviet expedition led by M.T. Pogrebetsky. Pobeda Peak, the highest point, was conquered in 1956 by another Soviet expedition led by V.M. Abalakov.

Prospects for the future. Industry has been developing rapidly in the Soviet part of the Tien Shan; this development has been accompanied by a corresponding increase in the urban population in the valleys, which increased from 20 percent of the total population in 1942 to 40 percent in 1970. Further economic growth depends on the expansion of the area of irrigated lands; on hydroelectrical development, on the extraction of mineral deposits (which include copper-molybdenum and lead zinc ores in the western Tien Shan and antimony-mercury in the southern Tien Shan), and on the development of the exceptional recreational and touristic potential of parts of the region, especially for mountain climbing.

(Y.Y.R.)

Tientsin

Tientsin (Wade–Giles romanization T'ien-ching, Pinyin romanization Tian-jing or Tian-jin), the third largest city of the People's Republic of China after Peking and Shanghai, is located in eastern Hopeh Province at the northeastern extremity of the North China Plain. It lies about 60 miles southeast of Peking and about 35 miles inland from the Gulf of Chihli (Po Hai) of the Yellow Sea. The Tientsin Municipality covers an area of about 1,500 square miles (4,000 square kilometres), and the municipality contains a total population of about 4,300,000. Tientsin (meaning literally Heavenly Ford) has been an important transport and trading centre since the Yüan dynasty (1279–1368). It is China's second largest manufacturing centre after Shanghai, and the leading port in North China.

Tientsin was famous as a cosmopolitan centre long before the arrival of the European trading community in the 19th century. Its maritime orientation and its role as the commercial gateway to Peking fostered the growth of an ethnically diverse population that was commercially innovative and culturally distinctive. The city is noted for its woven handicraft products, terra-cotta figurines, and extensive seafood cuisine.

History. The marshy, poorly drained area surrounding contemporary Tientsin was sparsely populated until the Sung dynasty (960–1126), when the settlement of Chiu-san-han-k'ou was built on the west bank of the Hai Ho (Hai River). The original settlement was later joined by the larger town of Chih-ku, built on high ground at the confluence of the Tzu-ya and Hai rivers. Chih-ku grew rapidly as a port and commercial centre, and it became the chief storage, transfer, and distribution point for grain and other foodstuffs from central and South China.

Origins of the city

In recognition of the importance of Chih-ku (then called Hai-chin) as a shipping centre, the Yüan (Mongol) government (1279–1368) established offices for the regulation of navigation and customs and expanded the town's warehouse and harbour facilities. The city also became a major salt producer when salterns were constructed along the Hai Ho.

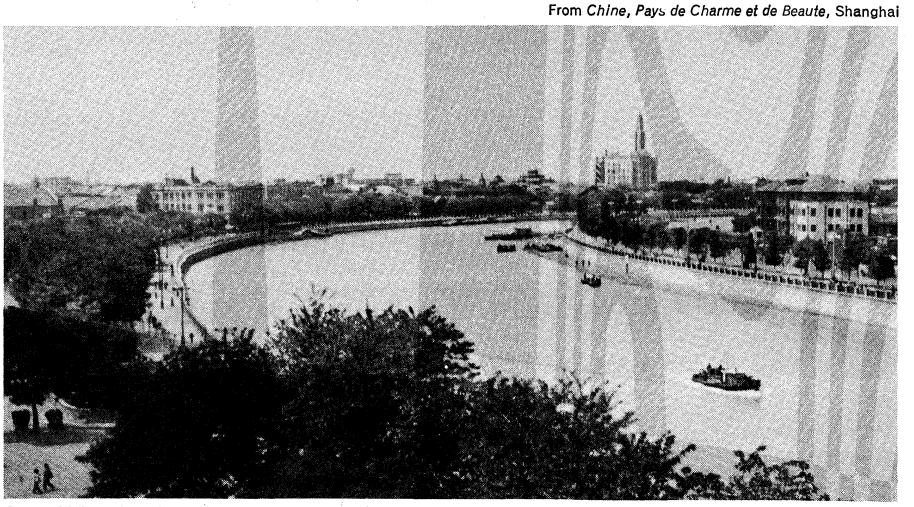
The development of modern Tientsin began during the Ming dynasty (1368–1644), when the national capital was shifted from Nanking to Peking. In 1368 the settlement became a garrison town and was named T'ien-chin-wei (Defense of the Heavenly Ford). A large military base was built and a rectangular wall constructed in 1425. The town prospered as it became the main gateway to Peking, and its population was swelled by immigrants from Shantung, Kiangsu, and Fukien provinces.

By the beginning of the Ch'ing (Manchu) dynasty (1644–1911), Tientsin had become the leading economic centre of North China because of its location at the northern terminus of the Grand Canal (Yün Ho). As better inland waterway connections were established, there was a steady increase in the city's volume of trade. Members of the first Dutch diplomatic mission to China in the mid-17th century commented favourably on the well-constructed 25-foot-high wall surrounding the city and noted the many temples and the large commercial and marketing area.

The period of foreign control

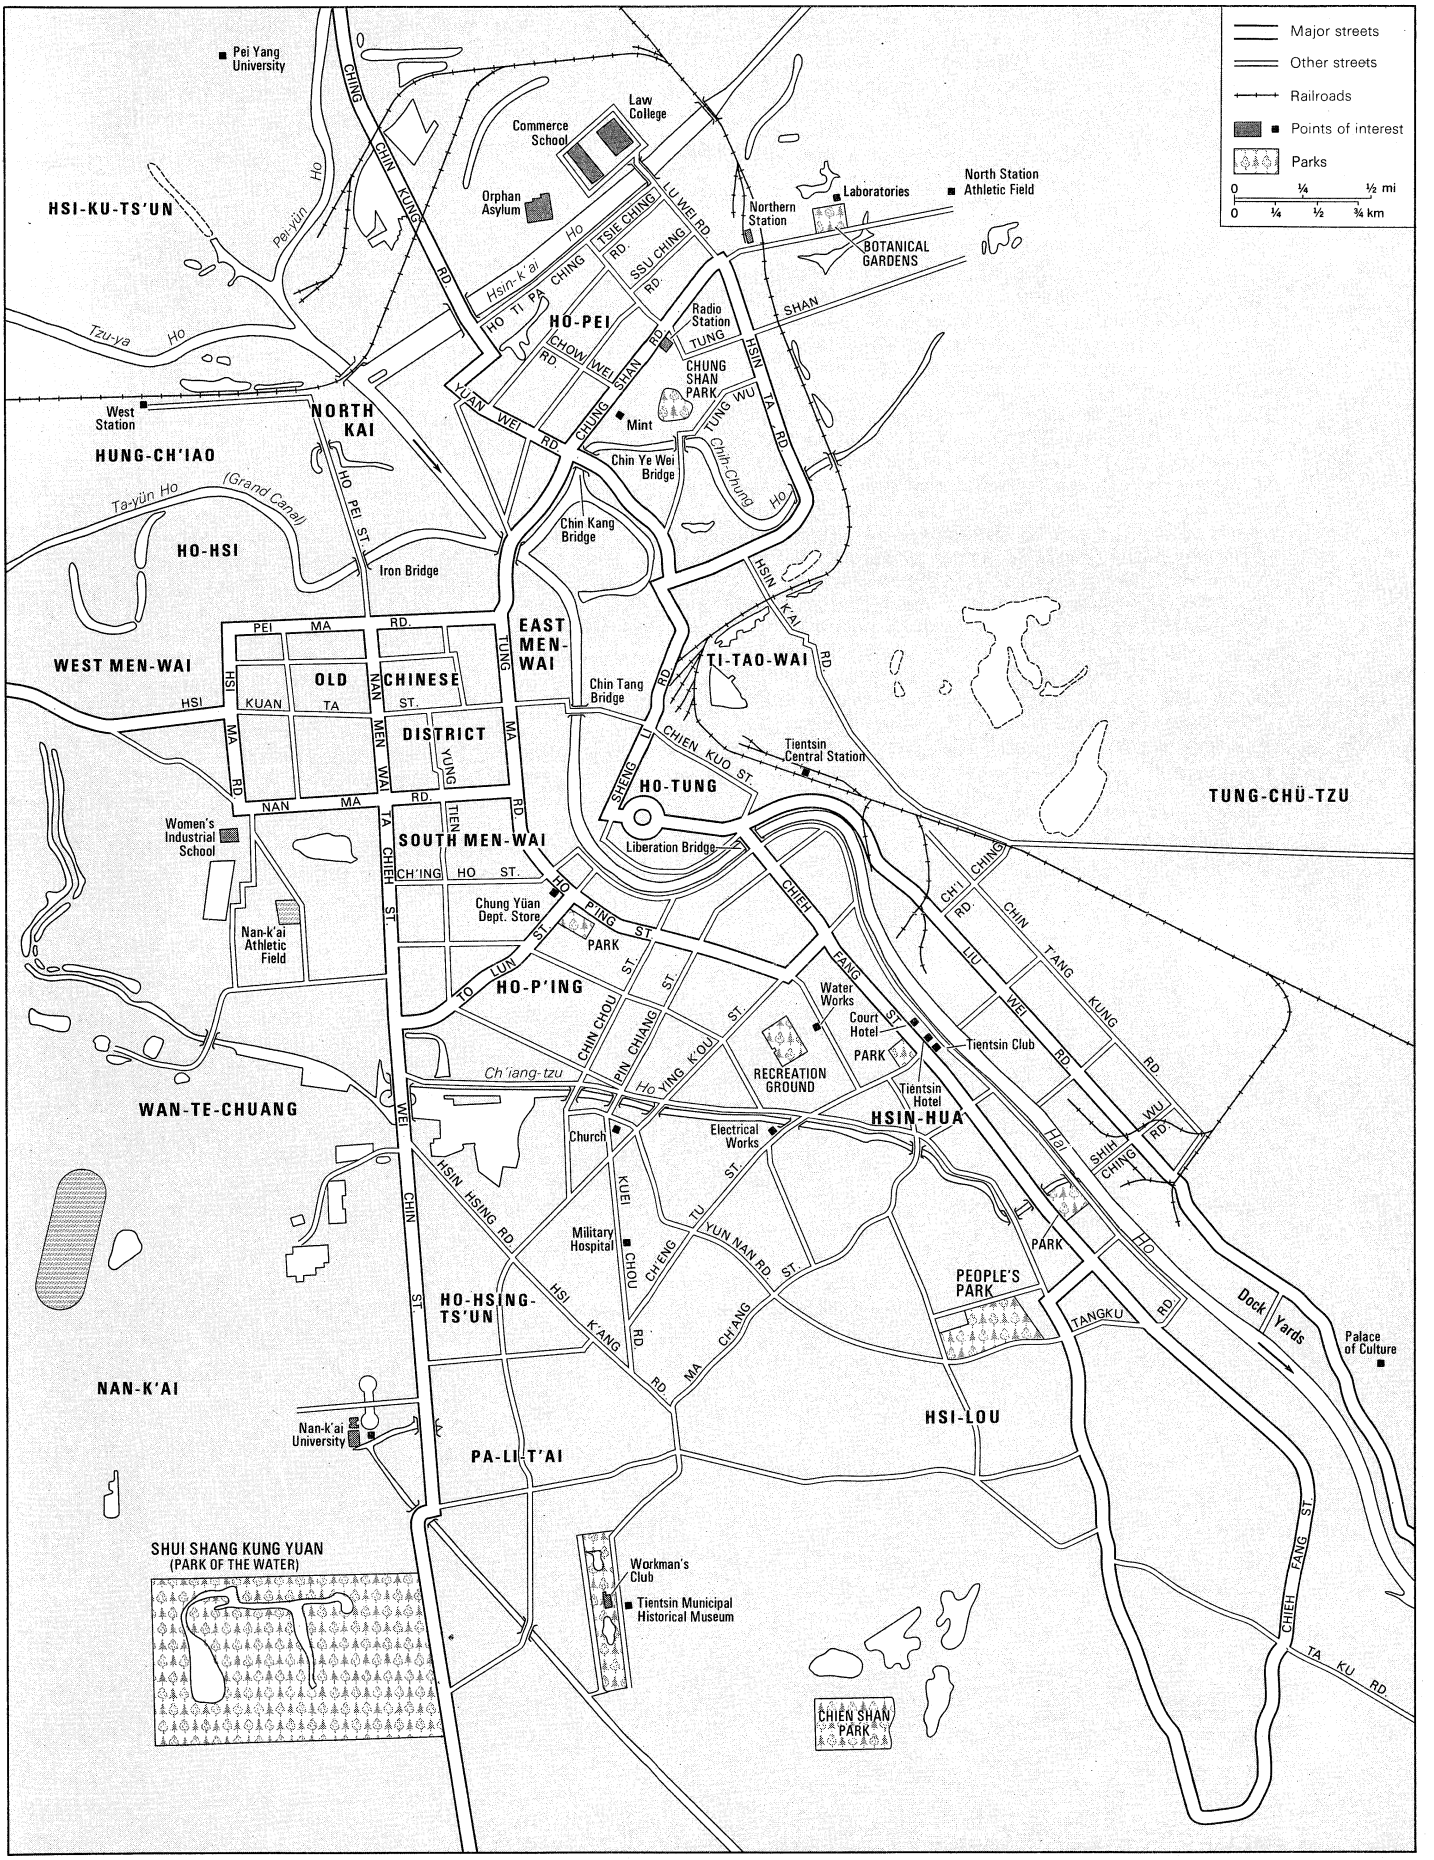
Economic prosperity declined temporarily during the mid-19th century when the European nations trading with China unremittingly pressed their demands for commercial and diplomatic privileges. The Treaty of Tientsin, which ended the second Anglo-French War (1856–58) against China, was signed by the British, French, and Chinese in 1858. Among its provisions, it authorized the establishment of British and French concessions in Tientsin. Between 1895 and 1902 concessions were given to Japan, Germany, Russia, Austria-Hungary, Italy, and Belgium. Hostilities were resumed in Tientsin in 1860, and the city was shelled by the British and French; the Convention of Peking then declared Tientsin an open trading port. Ten years later, a violent expression of Chinese anti-foreign feeling erupted in the city when the French Catholic orphanage and cathedral were attacked. In 1900 renewed anti-foreign demonstrations led to the shelling and occupation of the city by Allied (Western) forces and the destruction of the old city wall.

By the end of the 19th century, Tientsin had grown to more than 200,000 people, with about half the population residing within the old Chinese city. Living conditions for the Chinese were in sharp contrast to those in the spacious, well-tended European quarters that were distributed to the southeast and along the riverbanks.



Tientsin became an important ocean shipping centre by 1900. The Huang Ho (Yellow River) shifted its course, and the Grand Canal became silted up in the early 1850s, thereby restricting inland waterway traffic through the city, and shipping operations were shifted eastward along the banks of the Hai Ho. Facilities were also built at Ta-ku and T'ang-ku at the mouth of the Hai Ho.

The Chinese Republic period



Under the Republic of China (1911–49), Tientsin became a special municipality (*shih*) under the direct administration of the National government. In 1935 the Japanese attempted to extend their control over North China by establishing an autonomous area in eastern Hopeh Province, which was to be administered by Japanese military authorities in Tientsin. One year later, the Japanese presented demands to the Chinese authorities that were designed to weaken Chinese control over the area. With the opening of the Sino-Japanese War (1937–45), Tientsin was occupied by the Japanese, and in 1939 the Japanese blockaded the British and French concessions in response to anti-Japanese demonstrations.

During the Communist Revolution (1945–49), Tientsin remained under Nationalist control until mid-January 1949, when the city was captured by the Communists. Since then, Tientsin's growth as a trading and manu-

Central Tientsin, with the Hai Ho in the foreground.

The city of Tientsin.

facturing centre has been responsive to internal development needs. Despite its proximity to Peking, the city retains a distinctive character, attributable to its functional and utilitarian origins.

The contemporary city. *The city site.* Central Tientsin is located at the point where the Yung-ting, Ta-ch'ing, Tzu-ya, Nan-yün, and Pei-yün rivers converge before merging into the Hai Ho, which then flows eastward into the Gulf of Chihli. The city stands at an elevation of less than 15 feet above sea level on a level alluvial plain. Some low-lying areas east of the city are only about six feet above sea level, and about 80 percent of the built-up area is below 12 feet.

The area of the Tientsin Municipality encompasses approximately 1,500 square miles (4,000 square kilometres), while the city and immediate suburbs cover approximately 675 square miles (1,750 square kilometres). The municipality borders on the Tientsin Special District (T'ien-ching Chuan-ch'ü) on the north and west, the Ts'ang-chou Special District (Ts'ang-chou Chuan-ch'ü) on the south, and the Gulf of Chihli on the east. Between 1955 and 1967 Tientsin was a subprovince-level city, which served as the capital of Hopeh Province. Its jurisdiction extended over the built-up urban core and eastward along the Hai Ho to include the port at T'ang-ku. At that time, Tientsin city was administratively separate from the Tientsin Special District, which had its seat at Yang-liu-ch'ing, southwest of central Tientsin.

In 1967 Tientsin Municipality was made a first-order, province-level administrative unit, and the area under its immediate control was expanded to include counties (*hsien*) formerly under the special district. The city simultaneously became the special district seat but lost its position as provincial capital. It was estimated in the early 1970s that 13 wards (*ch'u*) were included within greater Tientsin, which was administratively responsible to the central government in Peking. It was not clear, however, how many rural or suburban counties (*hsien*) were administratively tied to the municipality.

The environment. Despite Tientsin's proximity to the sea, it has a distinctly continental climate with sharp daily and seasonal temperature fluctuations. It is subject to the full effects of the cool, dry Siberian high-pressure system during the winter (October to April), while in the summer (May to September), the high pressure system over the North Pacific Ocean brings hot and rainy weather. Winter precipitation is minimal, and the air is dry, with relative humidity averaging 50 percent. In summer, moist, rain-bearing southerly winds prevail, and the average relative humidity exceeds 70 percent. The average annual temperature is 56° F (13° C), with a January average of 39° F (4° C) and a July average of 84° F (29° C). Severe winter storms are common, but typhoons seldom occur. Both the Hai Ho and the port of T'ang-ku freeze over for approximately 80 days during the winter. Ice appears at the beginning of December and usually thaws by the end of February.

Flood-control measures

The Hai Ho was long subject to frequent flooding. As the main outlet for the rivers of the North China Plain, it frequently became heavily silted during the spring and summer months; during the winter season its water level was often too low for navigation. Extensive water conservation began in 1897. The river was straightened to facilitate tidal action and to shorten the distance to the sea. Locks were constructed to regulate the flow of water from the river into its many canals, the river and the sand bars at its mouth were dredged, and silt-laden water was diverted into settling basins.

Since 1949 multipurpose flood-control, irrigation, and navigation improvements have been in progress over an area of some 15,200 square miles. Construction of the Kuang-ting Reservoir on the Yung-ting Ho near Peking has helped alleviate flood damage within metropolitan Tientsin. New diversion channels have also been built to control the floodwaters of the Ta-ch'ing and Tzu-ya rivers to the southwest.

The marshy lakes and floodplains around Tientsin abound with numerous varieties of reeds, bulrushes, and shrubs, such as tamarisk. Closer to the seashore, Russian thistle, glasswort, and artemisia (herbs and shrubs with strong-smelling foliage) can be found. Freshwater fish (including silver and golden carp) are raised in the ponds and marshy depressions.

The city plan. The urban core of Tientsin extends for about seven miles from east to west and about nine miles from north to south. Ho-p'ing, the central district, is located on the west bank of the Hai Ho, just below the large bend of the Hai Ho. It is the main commercial and financial centre, and its two main streets of Ho P'ing Lu (Ho P'ing Road) and Chieh Fang Lu have several large department stores, restaurants, and hotels.

The central district

The old Chinese district is situated immediately to the northwest of Ho P'ing Lu. It is bounded by the four wide boulevards of Tung, Hsi, Pei and Nan Ma Lu that follow the course of the old rectangular wall. The street pattern in the old town is winding and irregular, in contrast to the more regular gridded pattern in the foreign-developed zones to the south and west. The district is subdivided into four smaller sections, each of which in traditional times had special marketing and commercial functions.

North and west of the old Chinese town and continuing across the Nan-yün Ho is the mixed residential and industrial Hung-ch'iao district. It extends to the confluence of the Tzu-ya Ho, Pei-yün Ho, and Hai Ho. The northern outskirts contain workers' housing developments, and the area is famous for its domestic handicrafts.

The newer western and southern districts of Hsin-hua, Ho-hsi, and Nan-k'ai were built on what (until it was drained) was marshy, low-lying land. Hsin-hua, at the bend of the Hai Ho well south of the central district, is the main trading, shipping, and administrative area. It has extensive shipping facilities and is the site of the customs office, the central post office, the harbour bureau, and the central police headquarters. Residential sections have been built in the southern part of this district. Ho-hsi and Nan-k'ai districts in the west and southwest are given primarily to residential and recreational use, and Nan-k'ai is also a major university centre.

The eastern districts of Ho-pei and Ho-tung, east of the Hai Ho, centre on industry and transport. Ho-pei has a few technical and vocational educational institutions in addition to its residential quarters, while Ho-tung is mainly industrial.

Transportation. Tientsin is North China's leading transport centre. The Ching-p'u railway runs south from Tientsin to Shanghai via Chi-nan, Shantung Province, and Süchow, Kiangsu Province. The Ching-shan railway runs north from Peking through Tientsin and Shan-hai-kuan on the Hopeh–Liaoning border to Mukden (Shen-yang), Liaoning Province. The lines are served in Tientsin by three railway stations, classification yards, and extensive maintenance and repair facilities.

Railway services

Heavily traversed inland waterways radiate to the south and southwest along the Grand Canal and Tzu-ya and Ta-ch'ing rivers; they connect the city with Pao-ting, Ts'ang-chou, and Heng-shui in southern Hopeh Province. The Ching-t'ang highway from Peking through Tientsin to T'ang-ku is the main all-weather freight road to the sea. Other main roads extend southward along the Ching-p'u railway into Shantung Province, westward to Shansi Province, and northward to Ch'in-huang-tao, northeastern Hopeh, and the Northeast (formerly Manchuria).

Intra-urban transport has expanded since 1949. About 120 miles of trolley, electric-trolleybus, and motorbus routes connect the city's railway stations and extend to the suburbs of Pei-ts'ang in the north, Hui-tui in the east, and Li-ch'u-chuang in the south.

Tientsin is the main collection point and transshipment centre in North China for goods manufactured for export and is the chief port of entry for heavy machinery and other capital-intensive imports. About one-fourth of China's total foreign trade by value is handled through Tientsin's outport and fishing port of T'ang-ku, which was enlarged and modernized in the early 1950s.

The population. The total population of the Tientsin Municipality was estimated in 1970 at about 4,300,000. The majority lives in the central city, where densities are

probably in the range of 15,000 to 75,000 persons per square mile. Statistical information is not available on the suburban population or the population in rural areas that extend to the municipal borders.

Before 1949 most people were engaged in commercial or service occupations. Since then the occupational structure of the city has changed, and about half the population is employed by industry and only about 17 percent in commerce. An additional 7 percent are involved in construction, 8 percent in transport and communications, 7 percent in administration, and 10 percent in education, public health, and social welfare.

Ethnic minorities compose about 3 percent of the population, the largest groups being Tungans, Koreans, Manchus, and Uighurs. Most of them live in the central city in areas that have special historical associations. The largest single community of Tungans is in the northern suburb of T'ien-mu-ts'un.

Housing and architecture. The provision of housing for Tientsin's work force has been a major concern of the municipal authorities. The emphasis since 1949 has been on suburban development, although residential areas in the central city have also been rehabilitated. Before World War II many of the suburban residential areas were built on marshy, poorly drained land subject to flooding, and sanitary conditions were especially bad. Most of the new complexes have been constructed near industrial zones on the outskirts of the city.

Many of the large commercial and administrative buildings in the central city were built by foreign concessionaires. They are typical of European and Japanese colonial architecture of the 1920s and 1930s, with buildings of contrasting architectural styles juxtaposed helter-skelter, without any plan. Some of the public buildings dating from the 1950s were built in imitation of the Soviet monolithic style, and housing complexes are usually standard two- or three-story rectangular blocks. The best known is a commercial structure, the Ch'un-yeh-ch'ang building in the heart of the central business district.

Economic life. Since 1949 heavy industry has been developed and the existing industrial base consolidated for greater productivity. Major activities are the production of heavy machinery, chemicals, and iron and steel and shipbuilding and repair. The Tientsin Heavy Machine-building plant employs about 5,000 workers and is one of China's largest manufacturers of mining equipment. Other products include machinery for textile mills and agriculture, machine tools, electrical equipment, bicycles, tractors, elevators, precision instruments, trucks, and watches.

The chemical complex at Ta-ku, T'ang-ku, and also at Han-ku (north of T'ang-ku on the rail line to T'ang-shan) produces agricultural fertilizers and pesticides, pharmaceuticals, chemicals and petrochemical products, plastics, artificial fibres, dyestuffs, and paints. The Yung-li alkali products plant at T'ang-ku accounts for 40 percent of China's total output of purified soda, some of which is exported to Japan.

Tientsin's light industries

Textiles are the chief light industry. Other such products include processed foods, hides, rubber goods, and paper. Tientsin's industry is largely under the jurisdiction of the municipality, with about 40 percent of production subject to local price setting, planning, and raw-material allocation.

Financial services include branches of the People's Bank of China, the Joint State-Private Bank, the Agricultural Bank of China, and The People's Insurance Company of China. Retail and wholesale trade is managed by commerce bureaus that are responsible to municipal and provincial authorities. Pricing and personnel matters are managed locally, while the distribution of commodities, long-range planning, and high-level financial management are handled by provincial-level bureaus.

The Municipal Revolutionary Committee

Political and government institutions. The Tientsin Municipal Revolutionary Committee is the city's chief administrative body. It was established in 1967 during the political disruption of the Great Proletarian Cultural Revolution (1966–69). Prior to 1967 responsibility for the management of the city's affairs was shared by a number of bureaus under both party and governmental control. Since then, it is difficult to gauge the level of administrative autonomy that the committee—composed of representatives of the army and the mass revolutionary organizations (representing peasants, workers, and students) and of former Communist Party officials—can exercise relative to the Hopeh provincial government and the central government in Peking.

Until 1967, and perhaps currently, the Tientsin Municipal Planning Commission played a key role in managing industry and commerce. It controlled the supply and distribution of industrial raw materials, set production levels, allocated funds for capital investments, determined manpower needs, supervised product research and development, and coordinated transportation and public utility use.

Public utilities. Major public works projects since 1949 have helped alleviate chronic flood damage and have improved the city's water supply and sewage disposal systems. Marshy, low-lying lands have been drained and converted to agricultural and recreational use, new roads have been constructed, and streetlights have been installed.

The city's water supply

The supply of fresh water has always been a problem because of the city's location near the sea at low elevation. Several freshwater reservoirs have been built in the southwestern and northeastern suburbs. Swampy lowlands to the southwest have been drained; one of the most extensive was converted into the large recreational area of the Shui-shang Kung-yüan (Park on the Water).

Thermal electric power plants (fuelled with coal) are capable of generating more than 100,000 kilowatts of electricity, and the city is connected by a power grid with Peking and T'ang-shan, Hopeh.

Health and safety. Tientsin has more than 40 Western-style and Chinese hospitals, with separate facilities for children, workers, and members of ethnic minorities. Factories and recreational and convalescent centres also provide health care services through their associated clinics.

Tientsin was one of the first cities to establish women's committees to assist working women in household maintenance and child care and to disseminate public health information. Since the program began in 1962 as an outgrowth of the urban commune movement, more than 1,500 committees with some 28,000 housewives have been operating.

Education. By 1960 about one-sixth of Tientsin's population was enrolled in educational institutions. This figure was undoubtedly smaller in the 1970s as a result of the drastic educational reforms of the 1960s. Emphasis is now on practice as well as theory, and students are expected to participate in productive activities while undergoing formal courses of study. The general universities of Nan-k'ai, Hopeh, and Tientsin are located in a new university quarter in Nan-k'ai, on the southwestern periphery of the city. Other higher educational institutions include the Polytechnic Institute, the Central Conservatory of art and music, a medical school, and a teacher training school. Work–study schools attached to factories supplement formal educational programs.

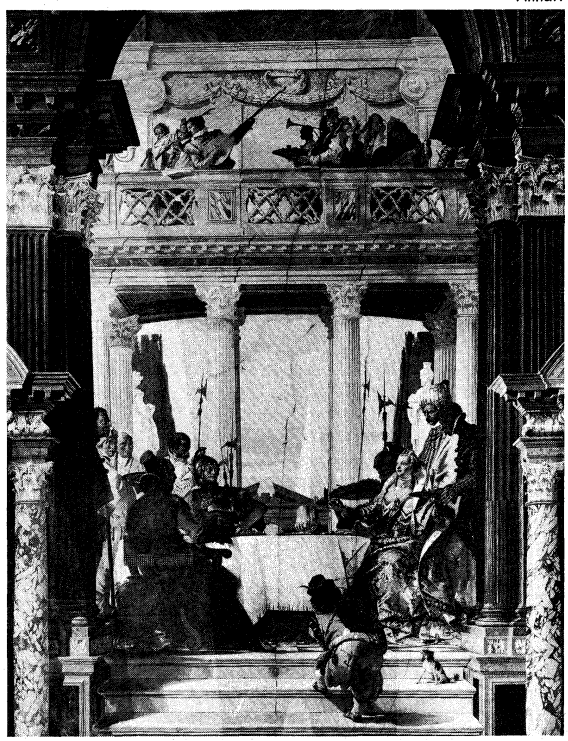
Cultural life. The city has several museums and a major library. The Museum of Fine Arts is noted for its collection of Yüan, Ming, and Ch'ing dynasty paintings, while the Tientsin Municipal Historical Museum and the Tientsin People's Science Hall have more contemporary displays. The Tientsin Municipal Library, with 840,000 volumes, is the city's largest library.

Special exhibits are held at the Palace of Exhibitions and the National Minorities Cultural Palace, and the People's Festival Hall is used for operas, plays, and concerts. The largest movie house is the Peace Cinema. There is also an astronomical observatory.

As in other large Chinese cities, billboards, the cinema, telephone directories, newspapers, and magazines are the main advertising media. The chief newspaper is the *T'ien-ching jih-pao* ("Tientsin Daily"). There is also a television station. Radio and television broadcasts are in Mandarin.

Recreational facilities

There are more than 30 parks and recreation centres. Victory Park and the Children's Park are in the centre of the city, and the Hsi-ku, Nan-k'ai, People's, Chien-shan, and Shui-shang parks are in the suburbs. Recreational clubs have also been built for industrial workers, and there are four stadiums.



BIBLIOGRAPHY. Although there are no recent works dealing specifically with Tientsin, AUDREY G. DONNITHORNE, *China's Economic System* (1967); BARRY M. RICHMAN, *Industrial Society in Communist China* (1969); and JOHN WILSON LEWIS (ed.), *The City in Communist China* (1971), refer to the organization and management of the city's industry, trade, and financial institutions. *Nagel's Encyclopedia-Guide to China* (1968) gives a brief description of the city.

(B.Bo.)

Tiepolo, Giovanni Battista

After a long period in the 19th century in which his reputation was in eclipse, Giovanni Battista Tiepolo has come to be recognized as the greatest painter of 18th-century Italy. His huge decorative works formed a perfect complement to the Rococo churches and palaces of his time. Described by one of his contemporaries as being "all spirit and fire," he worked with astonishing verve, and his output of ceilings, murals, easel compositions and portraits, sketches, and etchings is so huge as to invite the suspicion of superficiality. Yet there is an underlying melancholy in all his best works that give them a profundity rarely found in other art of his time. Critics now rank him with the great painters of all ages.

Alinari

"Story of Anthony and Cleopatra," fresco by G.B. Tiepolo. In the Palazzo Labia, Venice.

Giovanni Battista, or Giambattista, Tiepolo was born in Venice on March 5, 1696; his father, who had been engaged in the shipping business, died the following year, leaving his wife and five children in comfortable circumstances. His mother entrusted Giambattista to Gregorio Lazzarini, a painter of decorative, academic taste, who taught his young pupil the basic techniques of his profession. Tiepolo was drawn to a melancholic style with strong contrasts of light and shade, or chiaroscuro. Such strong shadings of light and dark, coupled with a genuine dramatic feeling, may be seen in his first public work, "The Sacrifice of Isaac" (1716), for the church of Sta. Maria dei Derelitti, or Ospedaletto. Tiepolo's name first appears on the lists of the Venetian painters' guild as an independent painter in 1717. The fact that his studio was thriving at this time is attested by his marriage to Cecilia Guardi, the sister of the painters Giovanni Antonio and Francesco.

Venetian period

During this period, Tiepolo was influenced by the robust plastic modelling of his Venetian contemporary Giovanni Battista Piazzetta, as in such works as the monumental "Madonna of Carmelo and the Souls of Purgatory" (*c.* 1720). His artistic education, however, was complex and varied: he examined the works of both Venetian and foreign contemporaries and studied older painters as well, as demonstrated by his large production of etchings after 16th-century subjects. Through his intense artistic activity, Tiepolo mastered a wide variety of forms and moods, ranging from the drama of such works as "The Crucifixion" (1723–24), in the Oratory of Sta. Barbara Burano, to the narrative humour of the four mythological scenes now in the galleries of the Accademia in Venice. It seems unlikely that the young Tiepolo left Venice, and therefore he did not see the great decorative cycles that other Venetian painters were executing throughout Europe. Nevertheless, he understood their methods. His maturity of technique and originality of formal invention were already evident in his first frescoes, the "Glory of St. Theresa" in the Church of the Scalzi and "The Force of Eloquence" on the ceiling of the Palazzo Sandi-Porto (now Cipollato). It was not, however, until the frescoes of the Palazzo Arcivescovile of Udine, executed sometime after 1726, that Tiepolo, then about 30, reached full maturity of expression. In these frescoes, he gave up the chiaroscuro of his early works and greatly brightened his colour, while preserving his form intact. The decoration was commissioned by Dionisio Dolfin, the patriarch of the town of Aquileia, and Tiepolo probably began work with the ceiling above the main staircase, depicting the "Fall of the Rebelling Angels" in vigorous, dramatic forms; in the gallery, within the Baroque perspective framings of Mengozzi Colonna, his faithful collaborator, he narrated biblical episodes of varying complexity, in bright colour and with bold brush play.

At this same time, or shortly thereafter, in a melodramatic and agitated style, Tiepolo executed for the Dolfin family's Venetian palace ten scenes of Roman history. The enrichment of his colour during this period became particularly tasteful in his smaller paintings, such as the two versions of "Apelles Painting the Portrait of Campaspe" (Montreal Museum of Fine Arts and the National Gallery, London), both of which are subtle, almost ironic re-enactments of the classical episode.

Works in Milan

By the 1730s, Tiepolo's fame had gone beyond Venice. He was called to Milan in 1731, and there he decorated the Palazzo Archinto (destroyed by bombing in World War II) with mythical scenes, of which marvellous small models remain, and the Palazzo Dugnani, for which he painted graceful episodes from history within Baroque settings. In autumn of that same year, he began the decoration of the Cappella Colleoni at Bergamo, depicting stories of John the Baptist (1732), into which he introduced airy landscape backgrounds that marked an innovation in his style. In the fall of 1734, working "day and night without rest," as he himself put it, Tiepolo decorated the Villa Loschi, now known as Zileri dal Verme, at Biron, near Vicenza, for which he prepared a famous and very beautiful series of drawings. Indeed, Tiepolo was a tireless and prodigious sketcher, capable of suggesting with pen and skillful watercolouring the rapid conception of structures and images that he would later carry out in frescoes and paintings.

In 1736, Count Tessin, who had to select a painter to decorate the royal palace in Stockholm, described Tiepolo this way: "full of spirit . . . of infinite fire, dazzling colour, and astonishing speed." This is a fitting portrait of both the painter and the man. But Tiepolo would not leave the city of Venice, where the nobility and the clergy were by now contending for his work and where he was being praised as "the most famous of the virtuosi." Rather, he preferred to send his works abroad, as in the case of "The Adoration of the Trinity by Pope Clement" (*c.* 1735), which was sent to Nymphenburg and is now in the

Alte Pinakothek in Munich, or "The Martyrdom of St. Sebastian" (1739), which was sent to the church in Diessen. Sometime toward the end of the 1730s, Tiepolo painted the "Institution of the Rosary" on the large ceiling of the Church of the Gesuati (or Sta. Maria del Rosario), at Zattere, covering an enormous amount of space and reviving the triumphal taste of Roman Baroque decoration.

In the decade from 1740 to 1750, Tiepolo created works based on secular themes in which he experimented with forms and appearances of the great luminosity that was rediscovered in Venetian painting from 1730 by Piazzetta, Canaletto, and Guardi. During this time he became a close friend of Count Algarotti, an important personality in the international cultural life of the time. Tiepolo's general education had been unpretentious and provincial, but his meeting with Algarotti drew him closer to the classical taste of the time. Nevertheless, the world he depicted in his works of the period on the theme of the tales of Cleopatra ("The Banquet of Cleopatra" [1744; National Gallery of Victoria, Melbourne], two canvases [1747], in Arkhangelskoye, near Moscow, and the fresco complex at the Palazzo Labia in Venice [shortly before 1750]) is a fanciful image of antiquity; formally, this image is derived from the Venetian Renaissance master Veronese and parallels the melodramas on classical themes that were popular in the 18th century.

Movement toward the classical

An invitation to decorate some of the rooms of the Residenz in Würzburg came to Tiepolo at one of the happiest moments of his career, in the full maturity of his artistic genius, and he went there in 1750 with his two sons, 23-year-old Giovanni Domenico and 14-year-old Lorenzo. They painted a cycle of frescoes in marvellous accord with the style of Balthasar Neumann, the architect. The ceiling of the Kaisersaal, with its "Wedding Allegory," is the most boldly luminous work of Tiepolo's career. The wall frescoes narrate events of the Middle Ages with a supreme naturalness and a total indifference to history. The "Olympus," an assemblage of mythological and allegorical representations on the enormous ceiling of the main staircase, has been said to symbolize and exalt the humanistic aspirations of the 18th century. The rhythmic grandeur of these decorative sequences is also reflected in the solemn "Adoration of the Magi" (1753; Alte Pinakothek, Munich). (The influence of Rubens has been seen in these works, and it is possible that Tiepolo's stay in Germany did, indeed, give him the opportunity to become acquainted with artists such as Rubens and Rembrandt, neither of whom was well represented in Venetian collections.) Almost in direct contrast to the grandeur of this official production, the artist pursued an almost romantic, poetic theme, portraying episodes taken from the Italian Renaissance poet Tasso in four magnificent canvases depicting the story of Rinaldo and Armida, now in the Art Institute of Chicago. In their new treatment of landscape and their inclination toward lyric warmth, these canvases are direct precursors of his decoration for Villa Valmarana, near Vicenza (1757), in which the personality of his son Giovanni Domenico asserted itself in exotic rural scenes of carnival season. For the first time since his earliest attempts in 1748–49, Giovanni Domenico achieved something more than his previous depersonalized collaborations with his father and was able to express his own peculiar anecdotal and realistic–grotesque vein. The elder Tiepolo, on the other hand, drew on the poetry of Homer, Virgil, Ariosto, and Tasso to execute a nucleus of feelings ranging between the dramatic and the passionate, on an idyllic but sensually moving plane. This stay on dry land after his close contact with Venice gave him the magnificent new graphic observations documented in the lyrically intense landscape of the great altarpiece he executed for the Cathedral of Este in Italy, "St. Tecla Freeing Este from the Plague" (1759).

Tiepolo was now on the eve of his departure for Spain, from which he would never return. Before leaving Italy for the last time, he accepted the task of celebrating the last dream of power of a noble Venetian family, the Pisani family, who had built their own belated but splendid Versailles. In Tiepolo's magnificent "Apotheosis of the Pisani Family," the most attractive section is an array of children's portraits and a frieze of male and female satyrs, which give a stamp of sensual existentialism to the decorative ensemble. Interspersed among his many decorations, Tiepolo painted many portraits. A unique example is the superb portrait of the "Procurator Giovanni Querini (?)," owned by the Galleria Querini-Stampalia of Venice; it represents not only a man but also an undermined aristocracy destined to fall.

Venice's political equilibrium was shattered in 1756 by the Seven Years' War, but Spain remained outside the conflict, and Carlos III invited Tiepolo to Madrid to enhance the glory of the Spanish monarchy at the Palacio Nacional. Tiepolo arrived in 1762 with his active collaborators, Giovanni Domenico and Lorenzo. In 1764, this team finished the decoration, in which the elder Tiepolo continued to define, and in part carry out, the complex thematic conception of the three ceilings. Unfortunately, the concepts did not fit in with the architectural environment, and the chromatic vividness of the beautiful sketches was not completely realized in the finished work. Nevertheless, in "The Power of the Spanish Monarchy," "The Apotheosis of the Spanish Monarchy," and "Aeneas Led to the Temple of Venus," Tiepolo dared to create bold perspective inventions, sustained by rich chromatic orchestration. In contrast to the solemnity that pervaded the Spanish court, Tiepolo presented a poetic art of light and colour, based on an inner feeling of almost romantic melancholy, as may be seen in the religious canvases executed for Aranjuez and in the various sequences of the "Flight into Egypt" executed for private patrons. The ceilings were Tiepolo's last major undertaking; he died in Madrid on March 27, 1770.

Last years in Spain

The hostile attitude of the official Spanish milieu seems to have resounded in the 19th century, when connoisseurs and critics rejected Tiepolo, along with the Baroque and Rococo styles, in general. He was considered an unhealthy and bizarre genius. But the change in taste brought about by Impressionism late in the century prepared the way for the rediscovery of the great Venetian. Generations of critics in Italy and elsewhere have worked to reconstruct his enormous pictorial output and to reassemble his prodigious mass of quick sketches and brilliant etchings. Modern taste accepts him without reservation and without need for either historical perspective or cultural justification.

MAJOR WORKS

PAINTINGS: "The Sacrifice of Isaac" ("The Sacrifice of Abraham"; 1715–16; Sta. Maria dei Derelitti or Ospedaletto, Venice); "Repudiation of Hagar" (1717–19; Rasini Collection, Milan); "The Madonna of Carmelo and the Souls of Purgatory" (*c.* 1720; Brera, Milan); "Glory of St. Theresa" (*c.* 1720; Church of the Scalzi, Venice); "The Force of Eloquence" (*c.* 1724–25; Palazzo Cipollato, Venice); frescoes (*c.* 1726; Palazzo Arcivescovile, Udine, Italy); ceiling frescoes (1731, now destroyed; Palazzo Archinto, Milan); "The Adoration of the Christ Child" (1732; St. Mark's, Venice); frescoes (1732; Cappella Colleoni, Bergamo); frescoes, Chapel of S. Vittore (1737; S. Ambrogio, Milan); vault frescoes (*c.* 1739; Church of the Gesuati, Venice); frescoes (1740; Palazzo Clerici, Milan); vault frescoes (1743–44, now destroyed; Church of the Scalzi, Venice); frescoes (1743; Villa Cordellina, Montecchio Maggiore, Vicenza); "Time Revealing Truth" (frescoes, 1744–45; Palazzo Barbarigo, Venice); "Allegory of Fortitude and Wisdom" (frescoes, 1744–45; Ca' Rezzonico, Venice); "Story of Anthony and Cleopatra (frescoes, before 1750s; Palazzo Labia, Venice); "The Glorification of Francesco Barbaro" (fresco, *c.* 1750; Metropolitan Museum of Art, New York); "Gifts Offered to Cleopatra" (fresco, *c.* 1750; Necchi Collection, Pavia); "Timocleia and the Thracian Commander" (fresco, *c.* 1750; National Gallery of Art, Washington, D.C.); frescoes, Kaisersaal (1750–52; Residenz, Würzburg); "Olympus" (1753; Residenz, Würzburg); vault frescoes (1754–55; Church of the Pietà, Venice); frescoes for Villa Contarini, Mira (*c.* 1756; Musée Jacquemart-André, Paris); frescoes (1757; Villa Valmarana, Vincenza); "Apotheosis of the Pisani Family" (frescoes, 1762; Villa Pisani, Stra, Italy); "Apotheosis of the Spanish Monarchy" throne room (1764; Palacio Nacional Madrid).

OIL SKETCHES: These exist in many museums, including the Isabella Stewart Gardner Museum, Boston; National Gallery, London; Frick Collection, New York; Museum of Fine Arts,

Boston; and the Cleveland Museum of Art. Tiepolo also produced a great number of drawings and etchings.

BIBLIOGRAPHY. Contemporary sources and those of the late 18th century recognized the greatness of Tiepolo: VINCENZO DA CANAL, *Vita di Gregorio Lazzarini* (1732; ed. by G.A. MOSCHINI, 1809); A. LONGHI, *Compendio delle vite dei pittori veneziani storici più rinomati* (1762); FRANCESCO ALGAROTTI, *Opere*, 8 vol. (1764–65); A.M. ZANETTI, *Della pittura veneziana* (1771); LUIGI A. LANZI, *Stória pittorica della Italia*, 3 vol. (1795–96). Neoclassicism brought a disregard for the artist, who was often cited in negative criticisms and was admired only in evaluations of certain writers and painters of the second half of the 19th century, such as Gautier and Degas. It is necessary to come to the beginning of our century to discover a re-evaluation and a reconstruction of the work of Tiepolo in numerous monographs: POMPEO G. MOLMENTI, *G.B. Tiepolo: La sua vita e le sue opere* (1909); EDUARD SACK, *Giambattista und Domenico Tiepolo* (1910); ANTONIO MORASSI, *Tiepolo*, 2nd ed. (1950; Eng. trans., *G.B. Tiepolo: His Life and Work*, 1955); *A Complete Catalogue of the Paintings of G.B. Tiepolo* (1962); GUIDO PIOVENE and ANNA PALLUCCHINI (eds.), *L'opera completa di Giambattista Tiepolo* (1968). There are many studies on the painting cycles of the artist: ANTONIO MORASSI, *Tiepolo e la villa Valmarana* (1945); RODOLFO PALLUCCHINI, *Gli affreschi di Giambattista e Giandomenico Tiepolo alla Villa Valmarana di Vicenza* (1945); M.H. VON FREEDEN and CARL LAMB, *Das Meisterwerk des Giovani Battista Tiepolo: Die Fresken der Würzburger Residenz* (1956); PAOLO D'ANCONA, *Gli affreschi di Palazzo Clerici: Tiepolo a Milano* (1956); CARLA GUGLIELMI FALDI, *Tiepolo alla Scuola dei Carmini di Venezia* (1960). Catalogs from expositions have contributed to the diffusion of knowledge about the artist: GIULIO LORENZETTI, *Mostra del Tiepolo* (1951); ALDO RIZZI, *Catalogo della mostra del Tiepolo a Udine*, 2 vol. (1971). Important studies on his drawings are: DETLEV VON HADELN (ed.), *Handzeichnungen von G.B. Tiepolo*, 2 vol. (1927; Eng. trans., *The Drawings of G.B. Tiepolo*, 2 vol., 1928, reprinted 1970); GIORGIO VIGNI, *Disegni del Tiepolo* (1942); GEORGE KNOX, *Catalogue of the Tiepolo Drawings in the Victoria and Albert Museum* (1960); TERISIO PIGNATTI, *Le acqueforti dei Tiepolo* (1965); ALDO RIZZI, *Catalogo della mostra dei desegni del Tiepolo* (1965); *Tiepolo: A Bicentenary Exhibition, 1770–1970*, catalog by GEORGE KNOX (1970); ALDO RIZZI (ed.), *L'opera grafica dei Tiepolo. Le acqueforti* (1971; Eng. trans., *The Etchings of the Tiepolos*, 1972); ANNA PALLUCCHINI, *Giambattista Tiepolo* (1971), in Italian; H.D. RUSSELL, *Rare Etchings by Giovanni Battista and Giovanni Domenico Tiepolo* (1972).

Tiglath-pileser III

Tiglath-pileser III was the brilliant king mainly responsible for the creation of the last Assyrian Empire. During his reign (745–727 BC), he reformed the civil administration, bringing about the internal stability and peace that enabled the army he had reorganized to extend control over Syria and Palestine for the first time. He thus held sway from the Egyptian border to the Persian Gulf and over Cilicia, southern Anatolia, and western Iran.

His biography can be reconstructed from his annals, correspondence, and building inscriptions. He was the first to have annals (as opposed to formal inscriptions) written on the sculptured slabs adorning his palace walls at Calah (Nimrūd).

By courtesy of the trustees of the British Museum

Tiglath-pileser III, relief from Nimrūd, 8th century BC. In the British Museum.

Since the days of Tiglath-pileser's father, Adad-nirari III, Assyria had been politically and militarily weak, for its northern neighbour, Urartu, dominated the states controlling its main trade routes to the Mediterranean and to the Iranian plateau. Some portions of the empire had ceased to pay the tribute required by treaties. In the spring of 745 BC a rebellion against the weak Ashur-nirari V, a son of Adad-nirari III, brought another son, who was then governor of Calah, to power. This new ruler assumed the throne name of Tiglath-pileser (the Hebrew form of the Assyrian Tukulti-apil-esharra, "My trust is in the son of [the temple] Esharra"). This may have been a deliberate reference to an illustrious forebear, Tiglath-pileser I, *c.* 1100 BC, who had also had to rescue his country from the incursions of Aramaean and Caucasian tribesmen. The new ruler, an intelligent and vigorous man, acted swiftly.

Usurpation of the throne

He rearranged territorial governorships by subdividing the larger provinces that had tended to strive for independence from the central power. Outside the immediate home territory he appointed Assyrian officials to be directly responsible to him as well as to support their local ruler. By 738 there were 80 such provinces. The Assyrians had to report directly to the King, who thus was able to check continuously on the loyalty and efficiency of all of his civil servants. They were responsible for local taxation, the storage of military supplies, and the calling up of local forces to support the new Assyrian Army, now a skilled professional force compared with its predecessor, which had relied on somewhat haphazard conscription. A new intelligence system, using reports transmitted by staging posts, was also created.

Military campaigns

Tiglath-pileser was thus prepared to break the stranglehold of the surrounding tribes. He first moved eastward against Zamua (modern Sulaymānīyah), then north against the Medes. Both were brought back under control of the adjacent provincial governors. The tribal lands of Puqudu, northeast of Baghdad, were joined to the Arraphka (Kirkūk) province, thereby holding the Aramean tribes in check. This and contiguous operations strengthened the hands of Nabu-nasir (Nabonassar), the native king of Babylon, who maintained peace until his death in 734. All this was facilitated by Tiglath-pileser's policy of mass resettlement. Groups whose loyalty was assured, since they were now dependent on the King for protection in a foreign environment, were settled in troublesome border regions. In 742–741 alone tens of thousands were thus resettled.

Tiglath-pileser next attacked the Urartian ruler Sardur III and his neo-Hittite and Aramaean allies, whom he defeated in 743 BC. Advance westward was, however, barred by the capital of Arpad, which had to be besieged for three years—a technique now feasible to a standing army. The victory in 741 was far-reaching, as noted in the Bible (Isa. 37:13), and was to stem the barbarian pressures from the north that, after Tiglath-pileser, were to threaten the whole civilized world. Tribute was brought to him at Arpad from Damascus, Tyre, Cilicia, and other cities and regions. Before Menahem, ruler of Israel, died, he sent 1,000 talents of silver, collecting it from male Israelites on a per capita equivalent of the current price of a slave at Nineveh (II Kings 15:19–22).

The Assyrian king's skill is best seen in his handling of affairs in Syria and Palestine. From an independent military headquarters he bypassed the rebels' ringleader at Damascus, won over most coastal cities, cut off supplies of Lebanon timber from Egypt, and sent a force to Ashke-lon and Gaza. In 734 the border with Egypt was sealed. The tribes of Ammon, Edom, and Moab, who, with Israel, had attacked Ahaz of Judah—a vassal of Assyria—now had to pay tribute. Over the next two years Tiglath-pileser systematically broke the power of Damascus. Israel was made subject through the assassination of Pekah (Pakaha) and his replacement by a pro-Assyrian vassal Hoshea (Ausi; *cf.* II Kings 15:29–30). Galilee was taken from Israel and made part of an adjacent province.

The Assyrian sensed that these rebels were encouraged by Ukin-zer, the Chaldean chief who, in 734, had seized the throne of Babylon. Using consummate diplomacy, Tiglath-pileser sowed discord among other Aramean tribes, one of whose chiefs he won over. His strategy now paid off. He could move the Assyrian Army through areas held by loyal governors or vassals east of the Tigris. One force seized Babylon and another the rebel stronghold of Sapia. It proved a fitting culmination that in 729–728 Tiglath-pileser himself took over the throne of Babylon using his personal (or perhaps Babylonian) name of Pulu (II Kings 15:19; I Chron. 5:26). He died soon afterward, having set Assyria on the road it was to follow to its end.

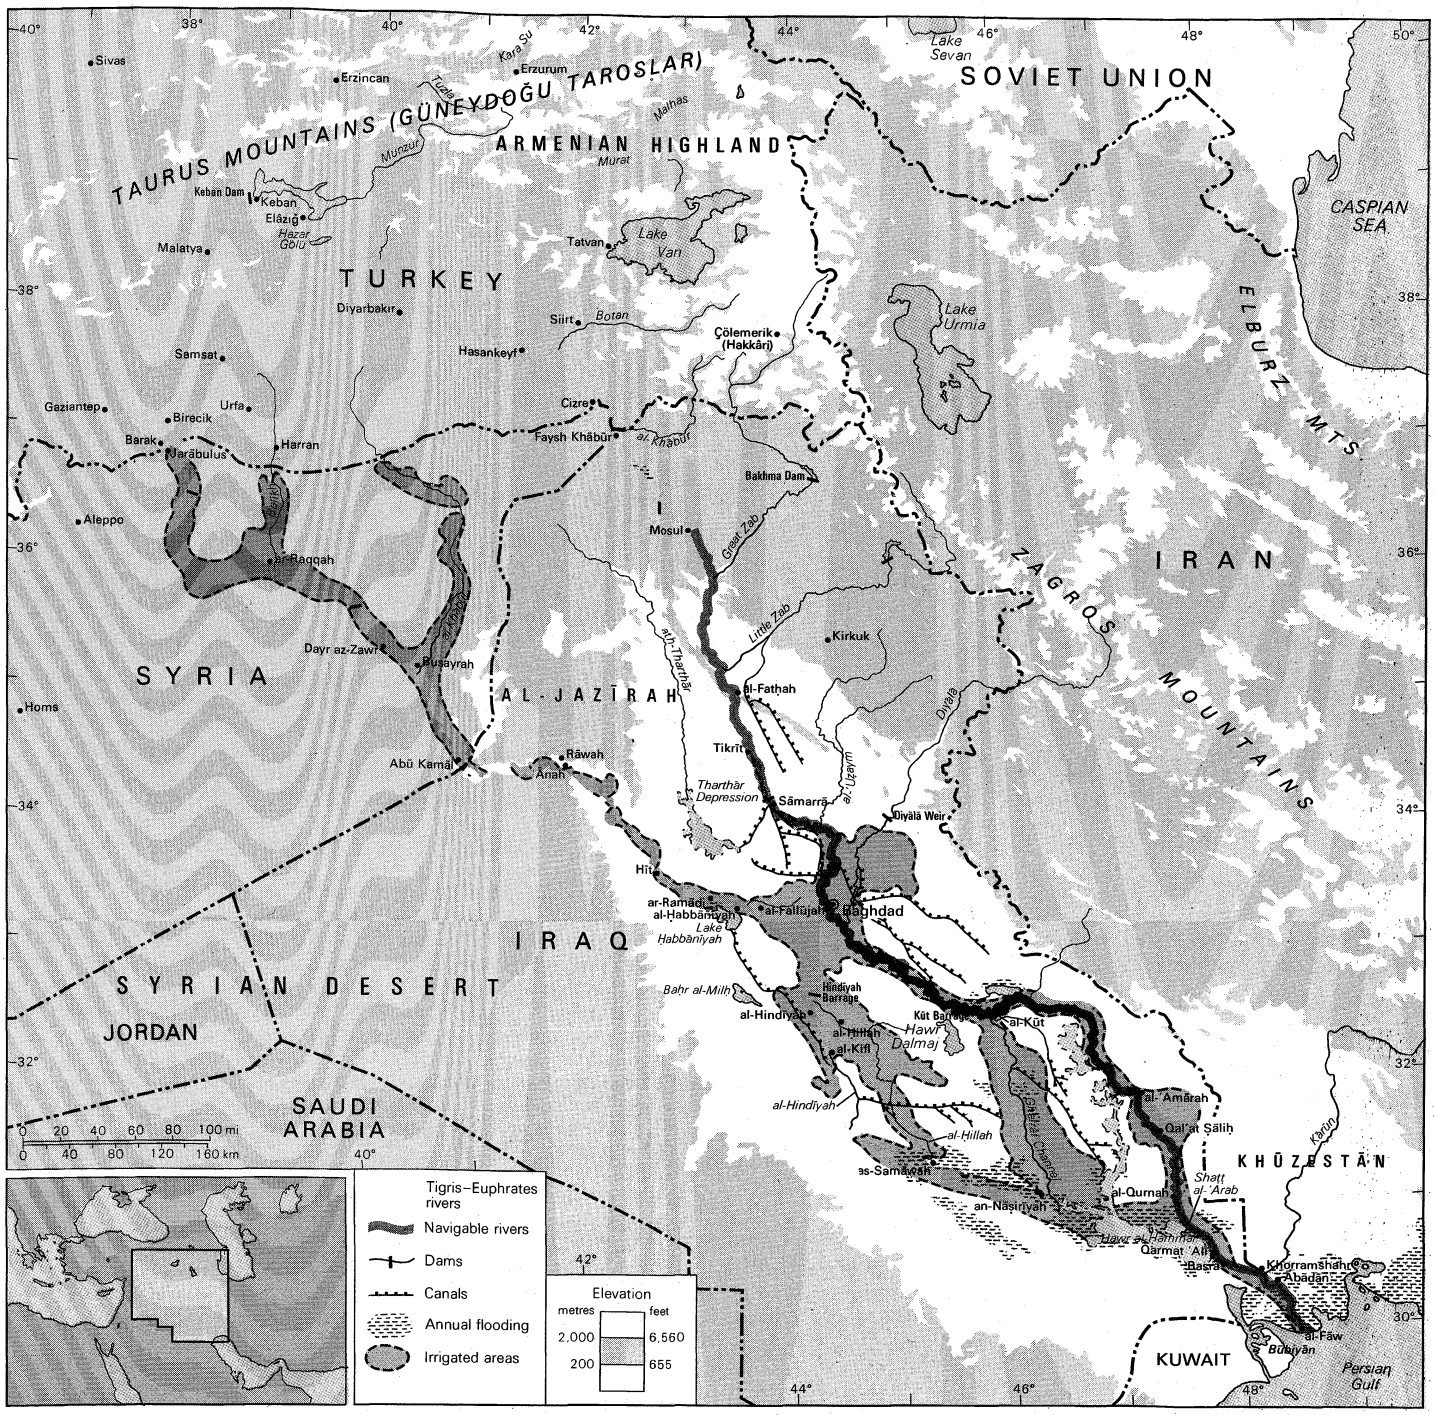
BIBLIOGRAPHY. No definitive life of Tiglath-pileser has been written. The *Cambridge Ancient History*, vol. 3 (1925), was based on PAUL ROST, *Die Keilschrifttexte Tiglat-Pilesers III* (1893), which is to be replaced by H. TADMOR, *The Inscriptions of Tiglath-pileser III of Assyria* (in prep.), a critical edition with introduction and commentary. New texts are given by H.W.F. SAGGS, "The Nimrud Letters, 1952," *Iraq*, 17:21–50, 126–154 (1955); and D.J. WISEMAN, "A Fragmentary Inscription of Tiglath-pileser III from Nimrud," *Iraq*, 18:117–129 (1956). RICHARD D. BARNETT and MARGARETE FALKNER, *The Sculptures of . . . Tiglath-pileser III* (1962), gives illustrations of the King and his campaigns.

(D.J.W.)

Tigris–Euphrates River System

The two greatest rivers of western Asia have widely separated sources in the mountains of eastern Turkey and travel in a southeasterly direction through north Syria and Iraq to the head of the Persian Gulf. The total length of the Euphrates (Akkadian Purattu; Turkish Firat; Arabic Furāt; Biblical Perath) is approximately 1,700 miles (2,700 kilometres)—that of the Tigris (Akkadian Idiklat; Biblical Hiddekel; Turkish Dicle; Arabic Dijla) about 1,180 miles (1,900 kilometres). Both rivers traverse two-thirds of their courses before reaching the fringes of the Mesopotamian Plain—the silt-filled depression that must be regarded as their combined delta. To the north of this an upper and a middle course is usually distinguished for each river; each upper course is restricted to the valleys and gorges of east Anatolia, at altitudes diminishing from those of their sources at 6,000–10,000 feet above sea level; each middle course proceeding more tranquilly through the uplands of north Syria and Iraq at elevations varying from 1,200 feet at the foot of the so-called Kurdish Escarpment to 170 feet where the alluvium begins at the head of the delta.

The Tigris and Euphrates derive the bulk of their water from the winter rains and snow of the Güneydoğu Toroslar and Zagros mountains. Both, in their middle courses, are joined by substantial left-bank tributaries. Tributary streams of the Tigris, the Great and Little Zab, which are fed in the spring with snow-melt waters from the high ranges of Iraqi and Iranian Kurdistan, are both more powerful and more unpredictable than the Balīkh and the (western) al-Khābūr, which flow into the Euphrates from springs beneath the Escarpment. The Tigris, therefore, is a more copious and swifter stream than the Euphrates, its character being reflected in the Arabic name Dijla, meaning arrow. Geologically, the most striking feature of both streams is the heavy content of silt which they carry in flood-time. At this season their mean discharge in Iraq is reckoned at about 175,000 cubic feet per second, and their water carries as much as 3,000,000 tons of eroded material from the highlands in a single day. The fact that little of this sediment reaches the sea explains the vast tract of alluvial soil of which the Mesopotamian Plain is composed.



The Tigris–Euphrates basin. After reaching the Syrian frontier 250 miles apart, the rivers in their middle courses gradually converge until they are separated only by a triangle of barren limestone desert, known as al-Jazīrah (the Island). On either side of this they have cut deep and permanent beds in the Tertiary rock, so that their courses have remained virtually unchanged since prehistoric times and are punctuated at frequent intervals by the ruins of ancient cities. The Tigris here traverses the homeland of the Assyrians, whose three great capitals—Nineveh, Calah (modern Nimrūd), and Ashur—still overlook the river. By contrast, when the alluvial plain is reached, the rivers are found to have so frequently bifurcated or altered their beds that their earlier courses, and the canals dependent upon them, can sometimes be traced only by the lines of *talls* ("mounds") representing ancient settlements. The *talls* increase in number as the territory of Babylonia is reached, and the mounds marking the sites of the great Sumerian cities in the extreme south suggest a pattern of occupation almost unrelated to the present system of waterways.

The two rivers, in their lower courses, tend to build up their beds to a level considerably above the plain across which they flow. They are, furthermore, confined between artificial bunds (embankments) to prevent the inundation of the adjacent agricultural lands in the high-water season. Consequently, when, in the past, these bunds have proved ineffectual or have been damaged intentionally, not only have vast areas of surrounding country been flooded but on occasion the rivers have changed their main courses. The high level of the rivers has nevertheless made possible the system of irrigation to which the country owes its prodigious agricultural potential.

Use of embankments

The Euphrates has no major right-bank tributaries in its delta, but is joined on its left bank by the Gharrāf Channel, which branches off from the Tigris at al-Kūt. The Tigris has two major left-bank tributaries. It is joined near Baghdad first by al-ʿUzaym and then by the even larger Diyālā. This produces a volume of water in excess of the river's capacity, which dissipates itself in extensive marshes on either side of its lower course. To the west the marshes merge into the waters of a great shallow lake, the Hawr al-Ḥammār. The Euphrates flows through this lake before uniting with the Tigris in a single channel, the Shaṭṭ al-ʿArab, which reaches the sea over 100 miles further south.

Physiography. *The Euphrates.* The headwaters of the Euphrates comprise two confluent streams known as the Murat and Kara Su. From their sources near Erzurum, Turkey, they traverse the high lava plain to the northwest of Lake Van and meet eventually at Keban, near Elâzığ, where, spanning a deep gorge, the rockfill Keban Dam is due to be completed in 1974. The stream, after breaking through the range of Güneydoğu Toroslar, drops down through the foothills of the ancient district of Commagene. Approaching to within 100 miles of the Mediterranean, it flows by Birecik in Turkey, where it is spanned by road, and Jarābulus on the Syrian side of the frontier, where it is crossed by the Iraqi Railway. From here its southeasterly course across Syria is through barren and thinly populated country, where its cultivable valley is no more than a few miles wide. After the western al-Khābūr joins the Euphrates, it flows through a broader agricultural province until it reaches Abū Kamāl, near the Iraqi frontier, after which the valley narrows again to a strip of alluvium between limestone escarpments. At intervals in the reach between the frontier and Hīt, small towns such as ʿĀnah and Rāwah occupy islands in mid-stream, subsisting upon a riparian system of cultivation that uses ingenious waterwheels for irrigation. Below Hīt, the rivercliffs recede and from this point onward irrigation begins on a large scale. Just south of the river below ar-Ramādī lies Lake Ḥabbānīyah, a large depression, enclosed on three sides by low hills, that has been converted into a controlled escape, to minimize the danger of floods and to be used for storage during the low-water period. Between ar-Ramādī and al-Hindīyah, over a distance of about 140 miles, the mouths of all the main controlled irrigation canals as well as most of the pumping installations are to be found. At al-Hindīyah itself, until early in the present century, the river split into two branches, al-Ḥillah and al-Hindīyah, each of which, over the centuries, had alternately assumed importance. In 1908 a barrage was built to canalize and control al-Ḥilah branch, thus making al-Hindīyah the main river channel. Below al-Kifl the river enters an unstable area where effective control is difficult. It bifurcates twice before reappearing above as-Samāwah as a single stream, which still maintains its

Tigris–Euphrates river system.

elevation above the surrounding marshes. Below an-Nāṣrīyah, numerous channels dispose of the waters, which make their way into the Hawr al-Ḥammār, from which, in turn, the outflow finds its way to the Shaṭṭ-al'Arab.

The Tigris. The Tigris rises in a small mountain lake, Hazar Gölü, southeast of Elâzığ, Turkey. Minor tributaries, flowing into it, drain a wide area extending eastward into Hakkâri *il* (province). Passing beneath the great basalt walls of Diyarbakir, and by a troglodyte settlement at Hasankeyf, it reaches the Syrian frontier at its junction with the eastern al-Khābūr near Cizre (Jazīrat ibn 'Umar), entering Iraq a few miles beyond at Faysh Khābūr. After passing Mosul, with the ruins of Nineveh on its left bank, the Tigris is joined by its two main tributaries, the Great and the Little Zab, which drain the mountain area of Iraqi Kurdistan. During the season of melting snows, the Zabs, laden with silt, double the volume of the main stream. The river next passes through the al-Fatḥah gorge, where rapids impede navigation, after which a further reach of 60 miles brings the Tigris to the head of the alluvial plain near Sāmarrā'. Here there is a barrage and a regulated escape that diverts surplus water into the Tharthār Depression to the west. From Baghdad onward, after receiving the waters of al-'Uẓaym and the Diyālā, the Tigris is increasingly confined between artificial embankments, from which the southward overspill keeps the great Hawr Dalmaj (Dalmaj Marsh) almost perennially supplied with water. At al-Kūt, 200 miles downstream from Baghdad, there is a barrage and the Shaṭṭ al-Gharrāf (Shaṭṭ al-Hai) Channel branches off southward. The Shaṭṭ al-Hai is a very ancient bed of the river, irrigating a wide interfluvial area before merging its surplus water with that of the Euphrates where it enters the Hawr al-Ḥammār. The main stream, meanwhile, both above and below al-'Amārah, again splits into a number of channels that disperse their water over rice-growing

From Baghdad to Basra

areas and extensive marshes on either bank. At al-Qurnah it joins an old bed of the Euphrates, now fed by the outflow of these same marshlands to become Shaṭṭ al-ʿArab. At Zarmat ʿAlī, a little above Basra, the main stream is joined by more waters from the Euphrates that have filtered through the Hawr al-Ḥammār.

Shaṭṭ al-ʿArab. On either side of the Shaṭṭ al-ʿArab, both above and below Basra, close settlement is limited to a belt of cultivation between one and three miles wide. These lands are irrigated by a network of creeks that fill with water from al-ʿArab when the sluices are opened at high tide and are famous for their groves of date palms, from which the fruit is exported all over the world. At Khorramshahr, al-ʿArab is joined by the Kārūn River, which flows southward from Khuzistan in Iran. From here to the sea an uneasy political agreement gives equal rights of navigation to Iraq and Iran. Basra on the right bank is, of course, the principal seaport of Iraq, while Khorramshahr, on the left bank, is Iranian. Two further ports on the lower course of al-ʿArab, Abadan (Iran) and al-Fāw (Iraq) are no more than specialized discharge points for exporting oil.

Climate. The countries traversed by the Tigris and Euphrates have a continental sub-tropical climate, with extremes of heat and cold in summer and winter, respectively, and a scanty rainfall. In the alpine regions, where the rivers have their upper courses, winter winds are weak and variable, and much of the light precipitation falls in the form of snow, which lies for four or more months in the higher valleys. At this season the mean temperature is much below freezing, so that agriculture is at a standstill and communications are restricted. After the snowfields melt in the spring the rivers are in spate. The mounting volume of their waters is augmented in their middle courses by seasonal rainfall, which reaches its maximum between March and May. Although in the rivers' lower courses intermittent rains continue during the winter months, the total rainfall rarely exceeds eight inches annually, and from May onward rain ceases altogether. In the alluvial plain, the most conspicuous climatic feature is the extreme heat of the summer months, with day temperatures rising as high as 120° F (49° C), and with the relative humidity as low as 15 percent. The fertility of the delta is therefore entirely dependent upon the seasonal flooding of the Tigris and Euphrates.

Vegetation and animal life. Dense communities of common reed and the narrowleaf cattail are found in the wide areas of marshland through which the rivers flow in south Iraq. The young shoots of both are used by Marsh Arabs for fodder. Along the rivers themselves in their lower courses the Euphrates poplar and a species of willow grow in small belts. The poplar is used for practical purposes such as boat building. Undergrowth in these riverain thickets is composed chiefly of five-stamen tamarisk and mesquite, which also extends northward to the middle course of the Tigris and to its tributaries, up to an altitude of 3,000 feet. It is often accompanied by licorice, from whose roots an exportable product is obtained.

Wild pigs are widespread in the marshes adjoining the rivers throughout their courses. In southern Iraq, jackals and occasional hyenas are to be seen among the riverside gardens, and a very large form of Indian jungle cat inhabits the more remote tamarisk thickets. The smaller Eastern wild cat is less common. Among smaller animals are several species of gerbils and the agile jerboa, which may be seen as far north as central Anatolia. Buxton's mole-rat, which covers the entrance to its burrow with a mound of earth, is also found in the riverbanks. Many birds migrating between Europe and Asia fly along the rivers' course.

Locally resident birds include babblers, bulbuls, scrub warblers, and sandgrouse. Among the larger species that frequent the marshes and occasionally breed there are pelicans, flamingoes, herons (including the huge giant heron), storks, spoonbills, and two kinds of bustard. Winter visitors are geese, white-fronted or graylag, and innumerable ducks, including all the common European kinds as well as the red-crested pochard and marbled duck. Gray cranes breed on the upper reaches of the Euphrates. Brilliant European bee-eaters visit the riverbanks on passage, and Persian bee-eaters remain to breed. Both the European and the Indian rollers nest in the vicinity of the rivers, particularly in the vertical banks of water channels.

Among the freshwater fish characteristic of the Tigris-Euphrates system, the carp family is the most conspicuous. The rivers harbour a variety of genera in this family, including small-scale forms recalling the Indian mahseer. A barbel genus is recorded as attaining a weight of 300 pounds. Besides carp, there are a few varieties of catfish as well as the spiny eel with its curious tubular nostrils.

Human ecology. With the exception of city dwellers, the Arab population on the rivers' banks live either by stock breeding or by agriculture. Their way of life varies from the nomadism of the desert bedouin to the settled condition of the peasantry (fellahin) in the agricultural districts. Both bedouin and fellahin, together with semi-settled Arabs, may be included within the organization of a single tribe. Over the past half century, however, tribal associations have begun to disintegrate. Among the fellahin an improved system of land settlement and legal reforms are breaking the authority of feudal landlords and encouraging the syndication of small holdings.

The Marsh Arabs

The uniform simplicity of village life among the fellahin extends to the limits of the delta. Almost the only variation is to be found among the Maʿdan, or Marsh Arabs, who occupy the vast triangle of swampland between an-Nāṣirīyah, al-ʿAmārah, and Basra. A distinctive culture emerges from their seminomadic life. They raise water buffalo and hunt wildfowl or pigs from their mashuf canoes. The giant mardi reeds found in these swamps reach a height of up to 25 feet, providing them with building material for their characteristic architecture.

North of al-Fatḥah gorge, the Tigris and its tributaries pass through country in which pure Arabs are increasingly in a minority. In the 17th century this region provided winter pasture for the Kurdish tribes but was then settled with Turkmen by Sultan Murad IV, in order to secure his lines of communication with Baghdad. To the north the Turkmen merge with the Iraqi Kurds, whose orchards and vegetable gardens are found along the Tigris tributaries and their smaller affluents. In their upper courses, both the Tigris and the Euphrates pass through mountain country whose inhabitants were once predominantly Kurdish. Today, however, the Kurds have become assimilated into the Anatolian population. Until recently the highland provinces, where both rivers have their sources, were underpopulated as a result of the departure of the Armenians early in the 20th century.

History of the rivers. History has little to record regarding physiological changes in the upper and middle courses of the two rivers. In the delta, by contrast, the pattern created by complex hydrological developments over a period of several millennia is available for study, even if it is as yet only partially understood. Different explanations, for example, have been given for the way in which the plains were formed and the present coastline created. Until recently it was thought that the head of the Persian Gulf once extended as far as the apex of the delta but must have receded southward until, in early historic times, it corresponded roughly to a line drawn through al-ʿAmārah and an-Nāṣirīyah. Nearer to the present coastline, meanwhile, the westward outflow from the Kārūn River had built up a barrier of silt, behind which a great lake formed. The lake had then gradually filled with alluvium, until only the Hawr al-Ḥammār and the marshes around it remained. In 1952, this long-accepted interpretation was refuted by geologists who detected a gradual subsidence in the basal rocks beneath the Euphrates estuary at a rate that was enough to maintain the alluvial deposit at a constant level. They accordingly concluded that the coastline had remained almost unchanged since historic times—a contention that still requires to be reconciled with conflicting archaeological evidence.

The tangle of waterways and ancient irrigation channels with which the Mesopotamian Plain appears to be covered, especially when seen from the air, gives an exaggerated impression of ancient prosperity, modified only if one remembers that at no time in the past were all these channels in simultaneous use. Of the major canal systems on which the country depended in early medieval times, for instance, some are today re-used and extended, while others are obsolete and forgotten. The five great Euphrates canals (Isa, Sarsar, Malik, Kutha, and Nil), on which the fertility of central Iraq depended in ʿAbbāsid times, have modern counterparts, but their overflow can no longer drain into the Tigris because of a change in level. East of the Tigris, now long neglected and dry, is the great Nahrawān Canal, which irrigated an area extending almost to the Persian frontier. Leaving the Tigris just north of Sāmarrāʾ and utilizing an ancient bed of the main river, this canal collected the waters of al-ʿUẓaym and the Diyālā, carrying them southeastward almost to al-Kūt. It was abandoned after the Mongol invasions, and only a small part of its former dependent territory is now supplied with water by the Diyālā Weir. The old Ishaqi-Dujaylah Canal that irrigated the farmlands west of the Tigris in the same era also now lies derelict.

The ancient canals

Hydrology. The rivers have two well-marked flood periods; the first, an irregular rise mainly due to the rain, that lasts from November to the end of March; the second, that of the main flood in April and May. During the second period, the rivers' combined discharge may reach 175,000 cubic feet per second, but the volume drops rapidly in June and rarely exceeds one-tenth of that amount in later summer and autumn. From the point of view of agriculture, the rivers are high at the wrong time of year for most crops (except rice), so that cultivation by direct inundation cannot be generally practiced.

Furthermore, the sheer volume of flood water endangers the bunds within which the rivers are confined in their lower courses. The primary requirement of river control is therefore to maintain an effective system of diversion and storage, both as a precaution against the kind of inundation that threatened the existence of Baghdad as recently as 1954 and as a means of retaining the flood waters for distribution in the hot season. To this end, in the early decades of the present century, barrages were built at al-Hindīyah and al-Kūt, and an important weir constructed on the Diyālā east of Baghdad. The diversionary escapes at ar-Ramādī on the Euphrates and at Sāmarrāʾ on the Tigris were both completed in 1956. An even larger storage basin has been created by the construction of a dam at Dukān on the Little Zab in 1958, and yet another is being built at Bakhma on the Great Zab.

Irrigation. The districts of northern Iraq and Syria, together with the piedmont area of southeastern Anatolia, through which the two rivers flow in their middle courses, have a milder climate than the plains in the south and sufficient rainfall to raise a crop of winter grain without irrigation. North of ʿĀnah on the Euphrates and of Tikrīt on the Tigris date palms disappear and are replaced by vines, olives, tobacco, and temperate fruits. There are no major canal systems in this area, and such irrigation as is required is supplied by mechanical lifts. By contrast, in the south the principal crops are wheat, barley, millet, and rice, as well as dates, all of which are dependent upon irrigation. Irrigation takes three forms. Water is distributed from rivers and canals by direct flow onto the land through small channels; by lifting water mechanically into such channels; and by direct inundation. The second of these methods is limited to land relatively close to rivers and canals; the third is useful only for rice cultivation. The relative importance of each method may be judged by the figures for 1942, an average and comparatively recent year; out of a total area cropped by irrigation, 1,700,000 acres were dependent on lifts, 1,500,000 on canals, and 250,000 on inundation. Canals are of two kinds; controlled canals, which receive water from regulators on the main river at all seasons, and uncontrolled canals, which are fed only when the river level reaches the canal head—an eventuality that unfortunately occurs mainly at the season when water is least in demand.

The three systems of irrigation

While the Tigris, at the northern extremity of the delta, flows at a slightly higher level than the Euphrates, before reaching Baghdad the relationship is reversed, and the Euphrates becomes the higher of the two by about 30 feet. There is a second reversal before the Tigris reaches al-Kūt. In antiquity, advantage was taken of these characteristics, which permitted irrigation from one river and drainage into the other, and the situation is still partially reflected in the operation of the controlled canal zones of the present irrigation system.

Five areas are dependent upon irrigation from large canals, controlled by barrages and sluice gates. The canal systems are the following: (1) the five left-bank Euphrates canals, running generally eastward between ar-Ramādī and al-Musayyib. Irrigation is perennial and is by free flow. (2) The Euphrates canals, depending directly on the Hindīyah Barrage. (3) The Diyālā canals, whose flow is maintained in summer by the Diyālā Weir. (4) The canal system on the Kūt Barrage, including the Gharrāf Canal, and the Dujaylah (an old bed of the Tigris). (5) Canals and spillways from al-ʿAmārah to Qalʿat Ṣāliḥ, on the left bank of the Tigris. Uncontrolled canal irrigation and inundation are predominantly practiced in rice-growing areas, such as in ash-Shāmīyah district (through which run the two branches of al-Hindīyah channel of the Euphrates) along the lower Euphrates around as-Samāwah, from an-Nāṣirīyah to the Hawr al-Ḥammār, and along the Lower Tigris below al-Kūt. Water-lifting machinery, consisting either of oil pumps or more primitive types of apparatus, is in use throughout the middle and lower courses of both rivers. Among the traditional devices in use, particularly on the middle Euphrates, are tall waterwheels, driven by the force of the current, which raise the water in earthenware jars attached to their rims. On the Tigris the height of lifts vary from six feet in the lowest reaches to 40 feet at Baghdad.

Areas dependent upon irrigation

In the great irrigated areas of lower Mesopotamia, where the system of extensive cultivation has traditionally been practiced, a primary threat is the gradual salinization of the soil. The irrigation water from the rivers is slightly saline and the heavy residue left by evaporation in hot weather is augmented by salt forced to the surface by groundwater. The resultant deterioration of the soil has been promoted by the pattern of irrigation canals, whose dikes, created by dredging, have divided the low-lying ground into small units, making it difficult to drain off water before evaporation occurs. Philologists have found evidence in cuneiform texts to suggest that the deterioration of land through salinization was already well understood as early as the third millennium BC, when the centres of agricultural prosperity began to shift northward from the original homeland of the Sumerians.

Navigation and river crossings. In 1836 a British expedition, led by Col. Francis Chesney, navigated the Euphrates by steamship from an-Nāṣirīyah to al-Qurnah, north of the Hawr al-Ḥammār. Today the Euphrates is not navigable except by local craft. From Basra to Baghdad, however, the Tigris is navigable by steamers with draughts of 4 ft 6 in. in the high water season and 4 ft at low water. Above Baghdad small steamers of three foot draught can, with some difficulty, reach Mosul. Much of the downstream traffic on both rivers consists of *kalaks*—rafts of timber and brushwood supported on inflated skins. *Kalaks* carry loads of up to 35 tons and take three or four days to cover the 275 miles from Mosul to Baghdad. Upon arrival, the timber is sold and the skins returned by road to their starting-point. Sailing craft include *muhaylahs* and *safīnahs* 30–80 feet long, with a capacity of up to 50 tons. Carrying smaller loads are *balams*—long, narrow double-ended, flat-bottomed craft with a shallow draft. Until recently *guffahs*—huge circular coracles of basketwork, coated with bitumen and capable of carrying up to 20 men—were in regular use in the vicinity of Baghdad.

Mediterranean followed the right bank of the Euphrates almost to Aleppo. The modern road and railway, after crossing the river at as-Samāwah, are diverted at al-Ḥillah toward Baghdad, but the road returns from Baghdad to the important Euphrates crossing at al-Fallūjah, after which it runs across the desert to Damascus. From Baghdad, with its four modern bridges over the mainstream, the railway follows the right bank of the Tigris to Mosul, then turns northwestward across the corner of Syria known as the "Bec-de-Canard" to follow the Turco-Syrian frontier to the Euphrates crossing at Jarābulus. On its way, it passes near the ruins of Haran (modern Harran), the "crossroads city" of the ancient world, and intersects a road that runs due north from ar-Raqqah to cross the headwaters of Euphrates once more at Samsat.

Among the mountains of east Anatolia, railways follow, in part, the upper course of the Tigris and both confluents of the Euphrates, bridging the Euphrates near Malatya.

Future prospects. In spite of recent engineering accomplishments, the full exploitation of the Tigris–Euphrates water supplies and the coordination of efforts between the three countries through which the rivers pass, have yet to be achieved.

In Iraq, where it has been estimated that 60 percent of the irrigated land suffers from some degree of salinity and a proportion of the cultivated land has had to be abandoned from this cause, it has been necessary to move away from piecemeal schemes of irrigation and toward the adoption of a single coordinated scheme for water use. An irrigation plan for the entire Tigris–Euphrates region, adopted by intergovernmental agreement, would allow further progress. At the moment, apart from an arrangement established in 1946 by which Turkey transmits flood warnings to Iraq, no intergovernmental water control agreements have been reached.

Tilak, Bal Gangadhar

Scholar, mathematician, and philosopher, Bal Gangadhar Tilak is remembered best as a man of action, who laid the foundation of India's independence by building his own defiance of British rule into a national movement. The popular leader of a militant school of nationalism, he was also the movement's chief theoretician, articulating its ideals and devising its programs. Passive resistance, the boycott of British goods, the organization of mass opinion, and other forms of effective political action that Gandhi later adopted were first introduced by Tilak.

Camera Press—Publix

Tilak.

Tilak was born on July 23, 1856, into a cultured, middle-class, Brahmin family at Ratnāgiri, on the west coast of India. His father was an educator and noted grammarian. After taking his university degree, Bal studied law but then decided to teach mathematics in a private school in Poona, which was to become the centre of his political career. He developed the school into a university college after founding the Deccan Education Society (1884), which aimed at educating the masses, especially in the English language, which Tilak and his associates consid-

ered a powerful force for the dissemination of liberal and democratic ideals. The life members of the society were supposed to follow an ideal of selfless service, but when some members began to keep their outside earnings for themselves, Tilak resigned. He then turned to the task of awakening the political consciousness of the people through two weekly newspapers: *Kesari* ("The Lion"), published in Marathi, and *The Mahratta,* published in English, of which he had become owner and editor.

Organization of religious festivals

In an attempt to rekindle the people's pride in their own history, religion, and culture, he organized two important festivals, Ganesh, in 1893, and Shivaji, in 1895. Gaṇeśa (Ganesh) is the elephant-headed god worshipped by all Hindus; Śivajī (Shivaji), the first Hindu hero to fight against Muslim power in India, was the founder of the Marāthā state, which in the course of time overthrew Muslim power in India. It was characteristic of Tilak that he sought inspiration in India's history, while Gandhi found his in Tolstoy and the Bible, and Nehru in the Socialist ideology of the English Fabian Society.

His activities aroused the nation and soon brought him into conflict with the British government, which prosecuted him for sedition and sent him to jail in 1897. The trial and sentence made him the idol of the country and earned him the title Lokamanya (Beloved Leader of the People). Fifty more years were to elapse before India achieved liberty, but the psychological change brought about by the trial laid the foundation for its independence.

Support of boycott and passive resistance

When Lord Curzon, viceroy of India, partitioned Bengal in 1905, Tilak strongly supported the Bengali demand for the annulment of the partition and advocated a boycott of British goods that soon became a movement sweeping the nation. The following year he set forth a program of passive resistance, known as the Tenets of the New Party, that he hoped would lead to the establishment of a parallel government and destroy the hypnotic influence of British rule and prepare the people for sacrifice in order to gain independence.

This was strong meat for the moderate party in the National Indian Congress, which believed in making "loyal" representations to the government for small reforms. Tilak aimed at Swarajya (independence), not piecemeal reforms, and attempted to persuade the Congress to adopt his militant program. On this issue, he clashed with the moderates at the Surat session of the Congress in 1907. Taking advantage of the split in the nationalist forces, the government again prosecuted Tilak on a charge of sedition and inciting terrorism and deported him to Mandalay, Burma, to serve a sentence of six years' imprisonment.

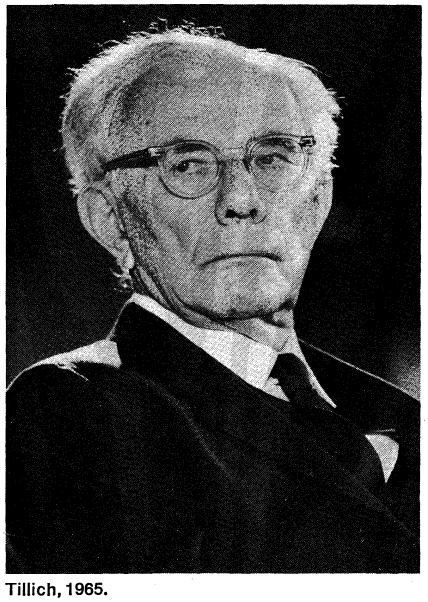
His major work, the *Bhagawadgita-Rahasya*

In Mandalay jail, Tilak, primarily a scholar and a politician only by necessity, settled down to write his magnum opus, the *Bhagawadgita-Rahasya* ("Secret of the *Bhagavadgītā*"), a daringly original exposition of the most sacred book of the Hindus. Tilak discarded the orthodox interpretation that the *Bhagavadgītā* taught the ideal of renunciation; in his view it taught selfless service to mankind. Earlier, in 1893, he had published an essay on the antiquity of the Vedas entitled *Orion,* which showed by astronomical calculations that certain hymns in the *Ṛgveda,* the oldest Hindu scripture, could not have been composed later than 4000 BC. In the sequel to *Orion,* published ten years later and called *The Arctic Home in the Vedas,* he attempted to prove that the North Polar region was the original home of the Aryans, the prehistoric ancestors of the Hindus and other Indo-Germanic peoples. He held therefore that "Aryan civilisation must be supposed to date back several thousands of years before the oldest Veda period."

On his release in 1914, on the eve of World War I, he once more plunged into politics and launched the Home Rule League with the rousing slogan: "Swarajya (independence) is my birthright and I will have it." In 1916 he rejoined the Congress and signed the historic Lucknow Pact, a Hindu–Muslim accord, with Mohammed Ali Jinnah, the future founder of Pakistan. In historical perspective, the partition of India might have been averted if, after Tilak's death in 1920, the Indian leadership had not departed from the ideal embodied into the pact of uniting Hindus and Muslims under a common Indian nationalism.

Tilak visited England in 1918 as president of the Indian Home Rule League. He realized, as no other Indian leader had before him, that the Labour Party was a growing force in British politics, and he established firm relationships with its leaders; his foresight was justified: it was a Labour government that granted independence to India in 1947.

When Tilak returned home in 1919, he attended the meeting of the Congress at Amritsar and advised the delegates to follow his policy of "responsive co-operation," in carrying out the Montagu–Chelmsford reforms which introduced a certain degree of Indian participation in regional government. But before he could give the new reforms a decisive direction, he died in Bombay on August 1, 1920. In their tributes, Mahatma Gandhi called him "the Maker of Modern India" and Jawaharlal Nehru, "the Father of the Indian Revolution."



BIBLIOGRAPHY. The first authoritative biography in English published outside India is D.V. THAMANKAR, *Lokamanya Tilak* (1956); S.L. KARANDIKAR, *Lokamanya Bal Gangadhar Tilak: The Hercules and Prometheus of Modern India* (1957), is a chronological treatment.

(D.V.T.)

Tillich, Paul

An eminent 20th-century theologian and philosopher who illuminated and bound together the realms of religion and culture, Paul Tillich was a central figure in the intellectual life of his time both in his native Germany and later in his adopted homeland, the United States. It is generally held that the 20th century has been marked by a widespread breakdown of traditional Christian convictions about God, morality, and the meaning of human existence in general. In assessing Tillich's role in relation to this development, some critics have regarded him as the last major spokesman for a vanishing Christian culture, a systematic thinker who sought to demonstrate the reasonableness of the Christian faith to modern skeptics. Others have viewed him as a forerunner of the contemporary cultural revolution, whose discussions of the meaning of God and faith served themselves to undermine traditional beliefs.

Henri Dauman—LIFE Magazine, © Time Inc.

Tillich, 1965.

Tillich himself believed he was a "boundary man," standing between the old and the new, between a heritage imbued with a sense of the sacred and the secular orientation of the new age. He asserted that his vocation was to mediate between the concerns voiced by faith and the imperatives of a questioning reason, thus helping to heal

the ruptures threatening to destroy Western civilization. He believed that from the beginning life had prepared him for such a role, and his long career as a theologian, educator, and writer—in Germany and the U.S.—was devoted to this task with single-minded energy.

Early life

Born in Starzeddel, a village in the Prussian province of Brandenburg, on August 20, 1886, Paul Tillich spent his boyhood years in Schönfliess, a small community east of the Elbe, where his father served as minister and diocesan superintendent in the Prussian Territorial Church. Life in Schönfliess—a walled town founded in the Middle Ages and surrounded by fertile fields and dark forests—left indelible marks on the impressionable boy: a strong sense of historical continuity, a feeling of intimacy with nature and its processes, and a deep attachment to the church as the bearer of sacred meaning in the centre of community life.

This life style, epitomized for Tillich in the person of his authoritarian and theologically conservative father, was challenged when Tillich first attended the humanistic secondary school in Königsberg-Neumark, where he was introduced to the classical ideal of free thought, untrammelled by anything except the rules of reason. He accepted that ideal enthusiastically. When his father was transferred to Berlin in 1900, he responded with the same enthusiasm to the kind of freedom that life in a thriving metropolis made possible.

Tillich's love of freedom, however, did not make him forget his boyhood commitment to a rich and satisfying religious tradition; and how to enjoy the freedom to explore life without sacrificing the essentials of a meaningful tradition became his early and lifelong preoccupation. It appears as a major theme in his theological work: the relation of heteronomy to autonomy and their possible synthesis in theonomy. Heteronomy (alien rule) is the cultural and spiritual condition when traditional norms and values become rigid, external demands threatening to destroy individual freedom. Autonomy (self-rule) is the inevitable and justified revolt against such oppression, which nevertheless entails the temptation to reject all norms and values. Theonomy (divine rule) envisions a situation in which norms and values express the convictions and commitments of free individuals in a free society. These three conditions Tillich saw as the basic dynamisms of both personal and social life.

His early attempts to solve the problem took the form of working out an independent position in relation to his conservative father; in this context he learned to examine personal experiences in terms of philosophical categories, for the elder Tillich loved a good philosophical argument. But the decisive, seminal encounter with the problem came during his theological studies at the University of Halle (1905–12), where he was forced to match the doctrinal position of the Lutheran Church, based on the established confessional documents, against the theological liberalism and scientific empiricism that dominated the academic scene in Germany at the beginning of the new century.

In his search for a solution Tillich found help in the writings of the German philosopher F.W.J. von Schelling (1775–1854) and the lectures of his theology teacher Prof. Martin Kähler. Schelling's philosophy of nature, which appealed to Tillich's own feeling for nature, offered a conceptual framework interpreting nature as the dynamic manifestation of God's creative spirit, the aim of which is the realization of a freedom that transcends the dichotomy between individual life and universal necessity. Kähler directed his attention to the doctrine of justification through faith, laid down by Saint Paul and reiterated by Martin Luther.

The "Protestant principle"

Tillich now concluded that this doctrine, which he called the "Protestant principle," could be given a far wider scope than previously had been thought. Not limited to the classical religious question of how sinful man can be acceptable to a holy God, it could be understood to encompass man's intellectual life as well, and thus all of man's experiences. As the sinner is declared just in the sight of God, so the doubter is possessed of the truth even as he despairs of finding it, and so cultural life in general is subject both to critical negation and courageous affirmation. The rigid formulas of the Lutheran Church could thus be rejected while their essential content was affirmed.

Tillich's first attempts to work out the details of this insight were in the form of Schelling studies, dissertations for a doctorate in philosophy (1911) and a licentiat in theology (1912). In the latter work especially, *Mystik und Schuldbewusstsein in Schellings philosophischer Entwicklung* ("Mysticism and Consciousness of Guilt in Schelling's Philosophical Development"), one can discern a probing of the implications of the Protestant principle for the very nature and structure of reality, especially in his explication of Schelling's view of sin and redemption as a cosmic event embracing all existence.

Ordained a Lutheran clergyman on the conclusion of his university studies, Tillich served as a military chaplain during World War I. The war was a shattering experience to him, not only for its carnage and physical destruction but as evidence of the bankruptcy of 19th-century humanism and the questionableness of the adequacy of autonomy as sole guide. The chaotic situation in Germany after the armistice made him certain that Western civilization was indeed nearing the end of an era.

The concept of *kairos*

His practical response to this crisis was to join the Religious-Socialist movement, whose members believed that the impending cultural breakdown was a momentous opportunity for creative social reconstruction, a time that Tillich characterized by the New Testament term *kairos*, signifying a historical moment into which eternity erupts, transforming the world into a new state of being. But ideas, rather than political activity, were his main interest. At teaching posts in the universities of Berlin, Marburg, Dresden, Leipzig, and Frankfurt he participated eagerly in discussion groups searching for a new understanding of the human situation. He also wrote extensively, publishing over 100 essays, articles, and reviews in the period 1919–33.

In most of these writings Tillich was using the insight he had gained at Halle as a norm in analyses of religion and culture, the meaning of history, and contemporary social problems. The remarkable work, *Das System der Wissenschaften nach Gegenständen und Methoden* ("The System of the Sciences according to their Subjects and Methods," 1923), was his first attempt to render a systematic account of man's spiritual endeavors from this point of view. As early as 1925, in Marburg, he was also at work on what was to become his major opus, *Systematic Theology* (3 vol., 1951–63).

Tillich's passionate concern for freedom made him an early critic of Hitler and the Nazi movement, and in retaliation he was barred from German universities in 1933—the first non-Jewish academician "to be so honoured," as he wryly put it. He then accepted an invitation to join the faculty at Union Theological Seminary in New York, and despite initial difficulties with a new language and adapting his thought pattern to pragmatic American mental habits, he emerged as an "apostle to the skeptics" in his new homeland during the years following World War II. At Union Seminary (1933–55), Harvard University (1955–62), and the University of Chicago (1962–65), he engaged graduate and undergraduate students in searching dialogue concerning the meaning of human existence. His public lectures and books reached large audiences who did not usually show an interest in religious questions. In his most widely read books, *The Courage to Be* (1952) and *Dynamics of Faith* (1957), he argued that man's deepest concern drives him into confrontation with a reality that transcends his own finite existence. Tillich's discussion of the human situation in these books shows a profound grasp of the problems brought to light by modern psychoanalysis and existentialist philosophy.

Systematic Theology

The publication of his *Systematic Theology* made available the results of a lifetime of thought. The most novel feature of this work is its "method of correlation," which makes theology a dialogue relating questions asked by man's probing reason to answers given in revelatory experience and received in faith—theonomy's answers to autonomy's questions. The dialogue of *Systematic The-*

ology is in five parts, each an intrinsic element in the system as a whole: questions about the powers and limits of man's reason prepare him for answers given in revelation; questions about the nature of being lead to answers revealing God as the ground of being; questions about the meaning of existence are answered by the New Being made manifest in Jesus Christ; questions about the ambiguities of human experience point to answers revealing the presence of the Holy Spirit in the life process; and questions about human destiny and the meaning of history find their answers in the vision of the Kingdom of God. Readers of this and other works by Tillich have been impressed by the broad reach of his thought but also baffled by the philosophical terminology that he used in discussing God and faith. Those who see him as an advocate of agnosticism or atheism, however, may have misunderstood his intent. He rejected the anthropomorphic "personal God" of popular Christianity, but he did not deny the reality of God, as the conventional atheist has done. Modern "Christian atheists" who cite Tillich in support of their "God is dead" claim overlook the fact that for Tillich the disappearance of an inadequate concept of God was the beginning of a grander vision of God. Like Spinoza, he was a "God-intoxicated man" who wanted to help his fellow human beings recapture a relevant and dynamic religious faith.

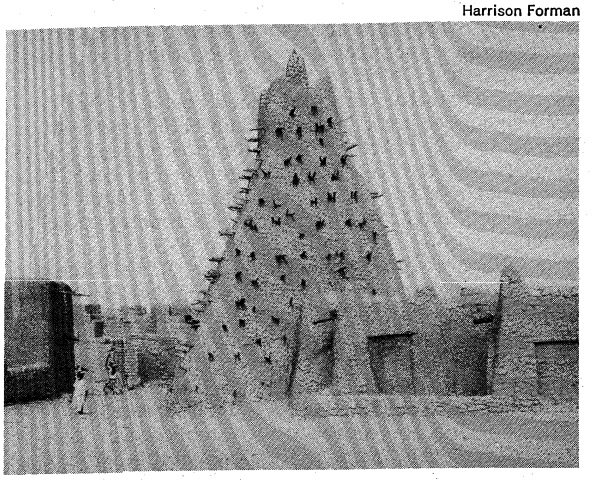
In his last years Tillich expressed some doubts about the viability of any systematic account of man's spiritual quest. But he never abandoned the insight that came to him at the University of Halle—that all of man's cultural and spiritual life could be illuminated by the "Protestant principle" of justification by faith; he was still working out its implications at his death on October 22, 1965.

BIBLIOGRAPHY. Autobiographical essays may be found in Tillich's writings: *The Protestant Era*, trans. by J.L. ADAMS (1948); *My Search for Absolutes* (1967); *On the Boundary* (1966); and *My Travel Diary: 1936*, ed. by J.C. BRAUER (1970). A good biographical study is ARNE UNHJEM, *Dynamics of Doubt: A Preface to Tillich* (1966).

The *Gesammelte Werke*, 11 vol. (1959-69), a collection of Tillich's writings, makes available his early and mostly untranslated works, including in vol. 1, *Frühe Hauptwerke*. *Systematic Theology*, 3 vol. (1951-63), is Tillich's major statement of the meaning of Christian faith, together with *The Courage to Be* (1952), and *The Dynamics of Faith* (1957).

Two important critical studies are CHRISTOPH RHEIN, *Paul Tillich: Philosoph und Theologe* (1957), with emphasis on Tillich's early development; and J.L. ADAMS, *Paul Tillich's Philosophy of Culture, Science, and Religion* (1965), the best overall view of Tillich's thought published in English. Other studies include: C.W. KEGLEY and R.W. BRETALL (eds.), *The Theology of Paul Tillich* (1952); D.H. KELSEY, *The Fabric of Paul Tillich's Theology* (1967); W.L. ROWE, *Religious Symbols and God: A Philosophical Study of Tillich's Theology* (1968); and R.P. SCHARLEMANN, *Reflection and Doubt in the Thought of Paul Tillich* (1969).

(A.U.)



Timbuktu

Timbuktu, or Tombouctou, is a West African city, important as the terminus of a trans-Saharan caravan route and as a centre of Islāmic culture in the period *c.* 1400–1600. It is located in the Republic of Mali, on the southern edge of the Sahara about eight miles north of the main bed of the Niger River.

History. In the almost total absence of archaeological data, knowledge of the city prior to the 19th century is based on local Arabic chronicles and on some references in the works of North African historians and travellers. Timbuktu was probably founded about AD 1100 as a seasonal camp by Tuareg nomads who came down from their winter grazing grounds at Arawan to pasture on the banks of the Niger during the summer. Gradually the encampment attracted traders and other travellers, who erected semipermanent straw huts around the Tuareg tents. Later, mud houses and a mosque were built, and a thorn stockade was replaced by a low wall.

At an uncertain date, but probably in the late 13th century, Timbuktu was incorporated within the expanding Mali Empire. In 1325 it was visited by the Mali sultan, Mansa Mūsā, as he returned from a lavish pilgrimage to Mecca. He built a tower for the Great Mosque (Djingereyber) and a royal residence, the Madugu (the former has since been rebuilt many times, and of the latter no trace now remains). Shortly after this the city was annexed by the Mossi kingdom of Yatenga, but when the North African traveller Ibn Baṭṭūṭah visited in 1353, he found it again governed by Mali.

Harrison Forman

Sankorey Mosque in Timbuktu, the focus of Islāmic scholarship from the 15th century.

Timbuktu only began to assume real commercial importance in the mid-14th century. Although scarcely remarked on by Ibn Baṭṭūṭah, by 1375 it was indicated on a Catalan map. The growth of Timbuktu is to be associated with two factors. First, during the late 14th century, Dyula merchants from Mali began to open up routes from Jenne, south of Timbuktu, to the gold fields of the Begho area (modern Ghana–Ivory Coast border). Second, the route from central Mali to North Africa through Walata began to decline; in its place grew up the Jenne-Timbuktu route along the Niger, and the two cities became focal points in the gold-salt barter trade. Commercial importance

In the wake of increased trade and the influx of North African merchants, came the settlement of Muslim scholars and saints, who were to earn Timbuktu its wide renown in the 15th–16th centuries. It made little difference that the Tuareg regained control of the city in 1433; they ruled from the desert and, though they plundered periodically, trade and learning suffered little.

In 1468 Timbuktu was conquered by Sonni ʿAlī, the Songhai ruler, during a movement of westerly expansion. He was generally ill-disposed to the city's Muslim scholars, but his successor—the first ruler of the new Askia dynasty, Mohammed I Askia of Songhai (reigned 1493–1528)—reversed the policy and used the scholarly elite as legal and moral counsellors. The Askia period as a whole (1493–1591) saw Timbuktu at the height of its commercial and intellectual development. Merchants from Wadan, Tuwat, Ghudāmis (Ghadames), Augila, and the cities of Morocco gathered there to buy gold and slaves in exchange for the Saharan salt of Taghaza and for North African cloth and horses. The city's scholars, many of whom had studied in Mecca or Egypt, attracted students from a wide area to their courses in Arabic grammar, Qur'ānic exegesis, theology, law, and other Islāmic sciences delivered in and around the Sankorey mosque. Although the city had a resident governor and tax collector appointed by the Askia, its judge (*qāḍī*) enjoyed considerable freedom of action, and his word carried weight with the Songhay rulers.

The year 1591 saw an abrupt change of fortune when a small but well-equipped force sent by Sultan Aḥmad al-Manṣūr of Morocco entered the city. The Moroccans already had defeated the Askia's army near Gao, and they now made Timbuktu the centre of their new administration. Two years later the city's scholars were arrested on suspicion of disaffection; some were killed during a struggle, others—mostly of the Aqit family, whose mem- The Moroccan conquest

bers had filled the office of *qāḍī* for a century—were exiled to Morocco.

The Moroccan conquest heralded an era of instability and stagnation that led to the commercial and intellectual decline of Timbuktu. The small Moroccan garrisons could not effectively protect the Niger Bend, which became prey to attacks from the Bambara, Fulani, and Tuareg. Intergroup rivalry among the Moroccans led to frequent changes of pasha (governor), especially after 1618, from which date the Moroccans in Timbuktu appointed from among their own number without reference to Marrakech.

In 1670 Timbuktu fell to the rising power of the Bambara kingdom of Segu. A century later (1787) the city was overrun by the Tuareg. Throughout the 17th and 18th centuries there were few decades untouched by either famine or epidemic, so that the population of Timbuktu had fallen from 25,000–40,000 in the 16th century to below 10,000 by *c.* 1800.

The 19th century saw other invasions. In 1826 the Fulani of Macina brought Timbuktu within their expanding theocratic state. On the death of their leader Shehu Ahmadu Lobbo (1844), an agreement was reached whereby the city regained a large measure of autonomy under the Moorish Kunta chief al-Bakkā'ī. It was again at the mercy of the Tuareg in 1893, when the French captured it.

French rule

The French presence was firmly established in 1894 by Maj. (later Field Marshal) Joseph Joffre, who constructed Fort Bonnier (now Fort el-Bekkay)—named after a French colonel killed by the Tuareg earlier that year. Timbuktu then began a new career as headquarters of a *cercle* (province) of French West Africa.

Timbuktu's history under French occupation is undistinguished. The French partly restored the city from the desolate condition in which they found it, but despite romantic illusions, no railway or tarmac road ever reached it. In 1960 it became part of the newly independent Republic of Mali.

It was in the 19th century that Europe obtained its first eyewitness accounts of Timbuktu since the publication of Leo Africanus' *Description of Africa* in 1550. The first European visitor to return alive (1828) was the Frenchman René Caillié, who stayed there in disguise (his British precursor, Maj. Alexander Gordon Laing, had been murdered by the Tuareg in 1826). The fullest description of Timbuktu is that of Heinrich Barth, a German scholar sent by the British government, who spent seven months in Timbuktu under the protection of al-Bakkā'ī in 1853–54.

Timbuktu today. Timbuktu is an administrative centre of the Republic of Mali. Small salt caravans from Taoudenni still arrive in winter, but there is no gold to offer in exchange, and trans-Saharan commerce is, in effect, dead. Apart from a recently introduced air service, the city still remains most easily accessible by camel and boat. Islāmic learning survives among a handful of aging scholars, and a Lycée Franco-Arabe teaches Arabic to the younger generation.

BIBLIOGRAPHY. Three locally written Arabic chronicles form the basis of our knowledge of Timbuktu prior to 1800. They are: AL-SA'DI, *Ta'rīkh as-Sūdān*; KATI, *Ta'rīkh al-Fattāsh;* and the anonymous *Tadhkirat an-Nisyān*. All have been published with French translations (1900, 1913, and 1890 respectively). No book has been specifically devoted to the history of Timbuktu, but parts of H. BARTH, *Travels and Discoveries in North and Central Africa*, 5 vol. (1858; reprinted 4 vol., 1965); J.P. ROUCH, *Contribution à l'histoire des Songhay* (1953); and E.W. BOVILL, *Golden Trade of the Moors*, 2nd ed. rev. by R. HALLET (1968), contain useful material. A very readable if somewhat flamboyant account of Timbuktu and its history was written by a French journalist, FELIX DUBOIS, *Timbuctoo the Mysterious* (Eng. trans. 1897), often drawing on the local chronicles. More scholarly and up-to-date information may be found in J.F.A. AJAYI and M. CROWDER (eds.), *A History of West Africa*, vol. 1, ch. 3, 7, and 13 (1971).

(J.O.H.)

Time

One facet of human consciousness is the awareness of time. Men feel the passage of time in their personal experience, both psychic and physical, and observe it in their environment, both human (social) and nonhuman (animate and inanimate). Time, as experienced, is a one-way flow at a pace that is slow enough to be perceptible. (Actually, only material fluids flow; but, like psychic experiences in general, that of time can be described only in the language of material phenomena.) Men feel and think in the time flow. They also act in it, either seizing opportunities or missing them. (A.J.T.)

The flow of time and man's experience of duration

I. Time and its role in the history of thought and action

NATURE AND DEFINITION OF TIME

Time appears to be more puzzling than space because it seems to flow or pass or else men seem to advance through it. But the passage or advance seems to be unintelligible. The question of how many seconds per second time flows (or one advances through it) is obviously an absurd one, for it suggests that the flow or advance comprises a rate of change with respect to something else—to a sort of hypertime. But if this hypertime itself flows, then a hyper-hypertime is required, and so on, ad infinitum. Again, if the world is thought of as spread out in space–time, it might be asked whether man's consciousness advances up a timelike direction of this world and, if so, how fast; whether future events pop into existence as the "now" reaches them or are there all along; and how such changes in space–time can be represented, since time is already within the picture. (Ordinary change can, of course, be represented in a space–time picture: for example, a particle at rest is represented by a straight line and an oscillating particle by a wavy line.)

Process philosophers versus philosophers of the manifold

In the face of these difficulties, philosophers tend to divide into two sorts: the "process philosophers" and the "philosophers of the manifold," respectively. Process philosophers—such as Alfred North Whitehead, an Anglo-American metaphysician who died in 1947—hold that the flow of time (or man's advance through it) is an important metaphysical fact. Like the French intuitionist Henri Bergson, they may hold that this flow can be grasped only by nonrational intuition. Bergson even held that the scientific concept of time as a dimension actually misrepresents reality.

Philosophers of the manifold hold that the flow of time or man's advance through time is an illusion. They argue, for example, that words such as past, future, and now, as well as the tenses of verbs, are indexical expressions that refer to the act of their own utterance. Hence, the alleged change of an event from being future to being past is an illusion. To say that the event is future is to assert that it is later than this utterance; then later yet, when one says that it is in the past, he asserts that it is earlier than that other utterance. "Past" and "future" are not real predicates of events, in this view; and change in respect of them is not a genuine change.

Again, although process philosophers think of the future as somehow open or indeterminate, whereas the past is unchangeable, fixed, determinate, philosophers of the manifold hold that it is as much nonsense to talk of changing the future as it is to talk of changing the past. If a person decides to point left rather than to point right, then pointing left *is* what the future was! Moreover, this thesis of the determinateness of the future, they argue, must not be confused with determinism, the theory that there are laws whereby later states of the universe may be deduced from earlier states (or vice versa). The philosophy of the manifold is neutral about this issue. Future events may well exist and yet not be connected in a sufficiently lawlike way with earlier ones.

One of the features of time that puzzled the Platonist Augustine, in the 5th century AD, was the difficulty of defining it. In contemporary philosophy of language, however (influenced by Ludwig Wittgenstein, a Cambridge philosopher), no mystery is seen in this task. Learning to handle the word "time" involves a multiplicity of verbal skills, including the ability to handle such connected words as "earlier," "later," "now," "second," and "hour." These verbal skills have to be picked up in very complex ways (partly by ostension), and it is

not surprising that the meaning of the word "time" cannot be distilled into a neat verbal definition. (It is not, for example, an abbreviating word like "bachelor.")

The philosophy of time bears powerfully on men's emotions. Not only do they regret the past, they also fear the future, not least because the alleged flow of time seems to be sweeping them toward their deaths, as swimmers are swept toward a waterfall. (J.J.C.S.)

PRESCIENTIFIC CONCEPTIONS OF TIME AND THEIR INFLUENCE

Temporal existence, death, and survival

The individual's experience and observation of time. The irreversibility and inexorability of the passage of time is borne in on a human being by the fact of death. Unlike other living creatures, he knows that his life may be cut short at any moment and that, even if he attains the full expectation of a human life, his growth is bound to be followed by eventual decay and, in due time, death.

Although there is no generally accepted evidence that death is not the conclusive end of life, it is a tenet of some religions (*e.g.*, of Zoroastrianism, Judaism, Christianity, and Islām) that death is followed by everlasting life elsewhere—in *sheol*, hell, or heaven—and that eventually there will be a universal physical resurrection. Others (*e.g.*, Buddhists, Orphics, Pythagoreans, and Plato) have held that people are reborn in the time flow of life on Earth and that the notion that a man has only one life on Earth is the illusion of a lost memory. It is said that the Buddha recollected all of his previous lives. The Greek philosophers Pythagoras and Empedocles, of the 6th and early 5th centuries BC, whose lives probably overlapped that of the Buddha, are likewise said to have recollected some of their previous lives. Such rebirths, they held, would continue to recur any number of times unless a person should succeed in breaking the vicious circle (releasing himself from the "sorrowful wheel") by strenuous ascetic performances.

The belief that a man's life in time on Earth is repetitive may have been an inference from the observed repetitiveness of phenomena in his environment. The day-and-night cycle and the annual cycle of the seasons dominated the conduct of human life until the recent harnessing of inanimate physical forces in the Industrial Revolution made it possible for work to be carried on for 24 hours a day throughout the year—under cover, by artificial light, and at an artificial temperature. There is also the generation cycle, which the Industrial Revolution has not suppressed: the generations still replace each other, in spite of the lengthening of life expectancies. In some societies it has been customary to give a man's son a different name but to give his grandson the same name. To name father and son differently is an admission that generations change; but to name grandfather and grandson the same is perhaps an intimation that the grandson is the grandfather reincarnate.

Thus, though every human being has the experience of irreversible change in his own life, he also observes cyclic change in his environment; hence the adherents of some religions and philosophies have inferred that, despite appearances, time flows cyclically for the individual human being, too.

Interpretations of time in different ages and lands

The human experience and observation of time has been variously interpreted. Parmenides, an Italiote Greek (Eleatic) philosopher (6th–5th century BC) and Zeno, his fellow townsman and disciple, found that change is logically inconceivable and that logic is a surer indicator of reality than experience; thus, despite appearances, reality is unitary and motionless. In this view, time is an illusion. The illusoriness of the world that "flows" in time is also to be found in some Indian philosophy. The Buddha and, among the Greeks, Plato and Plotinus, all held that life in the time flow, though not wholly illusory, is at best a low-grade condition by comparison, respectively, with the Buddhist Nirvāṇa (in which desires are extinguished) and with the Platonic world of Ideas; *i.e.*, of incorporeal timeless exemplars, of which phenomena in the time flow are imperfect and ephemeral copies.

It has been held, however—*e.g.*, by disciples of the Greek philosopher Heracleitus—that the time flow is of the essence of reality. Others have held that life in the time flow, though it may be wretched, is nevertheless momentous; for it is here that a man decides his destiny. In the Buddhist view, a person's conduct in any one of his successive lives on Earth will increase or diminish his prospects of eventually breaking out of the cycle of recurrent births. For those who believe in only one earthly life, however, the momentousness of life in the time flow is still greater because this life will be followed by an everlasting life at a destination decided by conduct in this brief and painful testing time. The view that life in time on Earth is a probation for weal or woe in an everlasting future has often been associated—as it was by the Iranian prophet Zoroaster (*c.* 600 BC)—with a belief in a general judgment of all who have ever lived to be held on a common judgment day, which will be the end of time. The belief in an immediate individual judgment was also held in pharaonic Egypt. Both of these beliefs have been adopted by Jews, Christians, and Muslims.

Cyclic view of time in the philosophy of history. The foregoing diverse interpretations of the nature and significance of the individual human being's experience and observation of time differ sharply from each other, and they have led to equally sharp differences in views of human history and of ultimate reality and in prescriptions for the conduct, both collective and individual, of human life. Thinkers have been divided between holders of the cyclic view and holders of the one-way view of time and between believers in the different prescriptions for the conduct of life that these differing views have suggested. Variations in the two basic views of time and in the corresponding codes of conduct have been among the salient characteristics distinguishing the principal civilizations and philosophies and higher religions that have appeared in history to date.

Environmental recurrences and religion. The cyclic theory of time has been held in regard to the three fields of religion, of history (both human and cosmic), and of personal life. That this view arose from the observation of recurrences in man's environment is most conspicuously seen in the field of religion. The observation of the generation cycle has been reflected in the cult of ancestors, important in Chinese religion and also in older civilizations and in precivilizational societies. The observation of the annual cycle of the seasons and its crucial effect on agriculture is reflected in a ceremony in which the emperor of China used to plow the first furrow of the current year; in the ceremonial opening of a breach in the dike of the Nile to let the annual floodwaters irrigate the land; and in the annual "sacred marriage," performed by a priest and priestess representing a god and goddess, which was deemed to ensure the continuing fertility of Babylonia. A cycle longer than that of the seasons is represented by the recurrent *avatāras* (epiphanies, incarnate, on Earth) of the Hindu god Viṣṇu (Vishnu) and in the corresponding series of buddhas and *bodhisattvas* (potential buddhas). Although the only historical Buddha was Siddhārtha Gautama (6th–5th century BC), in the mythology of the northern school of Buddhism (the Mahāyāna), the identity of the historical Buddha has been almost effaced by a long vista of putative buddhas extending through previous and future times.

Seasons, generations, eons

In contrast to northern Buddhism and to Vaiṣṇava Hinduism, Christianity holds that the incarnation of God in Jesus was a unique event; yet the rite of the Eucharist, in which Christ's self-sacrifice is held by Catholic and Eastern Orthodox Christians to be reperformed, is celebrated every day by thousands of priests and the nature of this rite has suggested to some scholars that it originated in an annual festival at the culmination of the agricultural year. In this interpretation, the bread that is Christ's body and the wine that is his blood associate him with the annually dying gods Adonis, Osiris, and Attis—the divinities, inherent in the vital and vitalizing power of man's crops, who die in order that men may eat and drink and live. "Unless a grain of wheat falls into the earth and dies, it remains alone; but, if it dies, it bears much fruit" (John 12:24).

The cyclic view in various cultures. The cyclic view of history, both cosmic and human, has been prevalent among the Hindus and the pre-Christian Greeks, the Chinese, and the pre-Columbian peoples of Central America; and it has reappeared in the modern West, although this civilization was originally Christian—that is, was nurtured on a religion that sees time as a one-way flow and not as a cyclic one.

Yin–Yang, Love–Strife, kalpas

The Chinese, Hindus, and Greeks saw cosmic time as moving in an alternating rhythm, classically expressed in the Chinese concept of the alternation between Yin, the passive female principle, and Yang, the dynamic male principle. When either Yin or Yang goes to extremes, it lops over into the other principle, which is its correlative and complement in consequence of being its opposite. In the philosophy of Empedocles, an early Greek pluralist, the equivalents of Yin and Yang were Love and Strife. Empedocles revolted against the denial of the reality of motion and plurality that was made by his Eleatic predecessors on the strength of mere logic. He broke up the Eleatics' motionless, and therefore timeless, unitary reality into a movement of four elements that alternately were harmonized by Love and set at variance by Strife. Empedocles' Love and Strife, like Yin and Yang, each lopped over into the other when they had gone to extremes.

Plato translated Empedocles' concept from psychological into theistic terms. At the outset, in his view, the gods guide the cosmos, and they then leave it to its own devices. But when the cosmos, thus left to itself, has brought itself to the brink of disaster, the gods resume control at the eleventh hour—and these two phases of its condition alternate with each other endlessly. The recurrence of alternating phases in which, at the darkest hour, catastrophe is averted by divine intervention is similarly an article of Vaiṣṇava Hindu faith. In guessing the lengths of the recurrent eons (kalpas), the Hindus arrived, intuitively, at figures of the magnitude of those reached by modern astronomers through meticulous observations and calculations. Similarly, the pre-Columbian Mayas rivalled the modern Westerners and the Hindus in the scale on which they envisaged the flow of time, and they kept an astonishingly accurate time count by inventing a set of interlocking cycles of different wavelengths.

Plato and Aristotle took it for granted that human society, as well as the cosmos, has been, and will continue to be, wrecked and rehabilitated any number of times. This rhythm can be discerned, as a matter of historical fact, in the histories of the pharaonic Egyptian and of the Chinese civilizations during the three millennia that elapsed, in each of them, between its first political unification and its final disintegration. The prosperity that had been conferred on a peasant society by political unity and peace turned into adversity when the cost of large-scale administration and defense became too heavy for an unmechanized economy to bear. In each instance, the unified state then broke up—only to be reunited for the starting of another similar cycle. The Muslim historian Ibn Khaldūn, writing in the 14th century AD, observed the same cyclic rhythm in the histories of the successive conquests of sedentary populations by pastoral nomads.

Cultural morphology in Vico and Spengler

In the modern West, an Italian philosopher of history, Giambattista Vico, observed that the phases through which Western civilization had passed had counterparts in the history of the antecedent Greco-Roman civilization. Thanks to a subsequent increase in the number of civilizations known to Western students of cultural morphology, Oswald Spengler, a German philosopher of history, was able, in the early 20th century, to make a comparative study of civilizations over a much broader spectrum than that of Vico. The comparison of different civilizations or of successive periods of order and disorder in Chinese or in pharaonic Egyptian history implied, of course, that, in human affairs, recurrence is a reality.

The application of the cyclic view to the life of a human being in the hypothesis of rebirth was mentioned earlier. This hypothesis relaxes man's anxiety about being annihilated through death by replacing it with a no less agonizing anxiety about being condemned to a potentially endless series of rebirths. The strength of the reincarnationist's anxiety can be gauged by the severity of the self-mortification to which he resorts to liberate himself from the "sorrowful wheel." Among the peoples who have not believed in rebirth, the pharaonic Egyptians have taken the offensive against death and decay with the greatest determination: they embalmed corpses; they built colossal tombs; and, in the Book of the Dead, they provided instructions and spells for ensuring for that portion of the soul that did not hover around the sarcophagus an acquittal in the post mortem judgment and an entry into a blissful life in another world. No other human society has succeeded in achieving this degree of indestructibility despite the ravages of time.

One-way view of time in the philosophy of history. When the flow of time is held to be not recurrent but one-way, it can be conceived of as having a beginning and perhaps an end. Some thinkers have felt that such limits can be imagined only if there is some timeless power that has set time going and intends or is set to stop it. A god who creates and then annihilates time, if he is held to be omnipotent, is often credited with having done this with a benevolent purpose that he is carrying out according to plan. The omnipotent god's plan, in this view, governs the time flow and is made manifest to man in progressive revelations through the prophets—from Abraham, by way of Moses, Isaiah, and Jesus, to the prophet Muḥammad (as Muslims believe).

Salvation history and the "axis age"

This belief in *Heilsgeschichte* (salvational history) has been derived by Islām and Christianity from Judaism and Zoroastrianism. Late in the 12th century, the Christian seer Joachim of Fiore saw this divinely ordained spiritual progress in the time flow as unfolding in a series of three ages—those of the Father, the Son, and the Spirit. Karl Jaspers, a 20th-century Western philosopher, has discerned an "axis age"—*i.e.*, a turning point in human history—in the 6th century BC, when Confucius, the Buddha, Zoroaster, Deutero-Isaiah, and Pythagoras were alive contemporaneously. If the "axis age" is extended backward in time to the original Isaiah's generation and forward to Muḥammad's, it may perhaps be recognized as the age in which men first sought to make direct contact with the ultimate spiritual reality behind phenomena instead of making such communication only indirectly through their nonhuman and social environments.

The belief in an omnipotent creator god, however, has been challenged. The creation of time, or of anything else, out of nothing is difficult to imagine; and, if God is not a creator but is merely a shaper, his power is limited by the intractability of the independent material with which he has had to work. Plato, in the *Timaeus*, conceived of God as being a nonomnipotent shaper and thus accounted for the manifest element of evil in phenomena. Marcion, a 2nd-century Christian heretic, inferred from the evil in phenomena that the creator was bad and held that a "stranger god" had come to redeem the bad creator's work at the benevolent stranger's cost. Zoroaster saw the phenomenal world as a battlefield between a bad god and a good one and saw time as the duration of this battle. Though he held that the good god was destined to be the victor, a god who needs to fight and win is not omnipotent. In an attenuated form, this evil adversary appears in the three Judaic religions as Satan.

Evolutionary and dialectical views

Observation of historical phenomena suggests that, in spite of the manifestness of evil, there has in truth been progress in the history of life on this planet, culminating in the emergence of man, who knows himself to be a sinner yet feels himself to be something better than inanimate matter. Charles Darwin, in his theory of the selection of mutations by the environment, sought to vindicate apparent progress in the organic realm without recourse to an extraneous god. In the history of Greek thought, the counterpart of such mutations was the swerving of atoms. After Empedocles had broken up the indivisible, motionless, and timeless reality of Parmenides and Zeno into four elements played upon alternately by Love and Strife, it was a short step for the Atomists of the 5th century BC Leucippus and Democritus to break up reality still further into an innumerable host of minute atoms moving in time through a vacuum. Granting that one single atom

had once made a single slight swerve, the build-up of observed phenomena could be accounted for on Darwinian lines. Democritus' account of evolution survives in the fifth book of *De rerum natura*, written by a 1st-century-BC Roman poet, Lucretius. The credibility of both Democritus' and Darwin's accounts of evolution depends on the assumption that time is real and that its flow has been extraordinarily long.

Heracleitus had seen in phenomena a harmony of opposites in tension with each other and had concluded that War (*i.e.*, Empedocles' Strife and the Chinese Yang) "is father of all and king of all." This vision of Strife as being the dominant and creative force is grimmer than that of Strife alternating on equal terms with Love and Yang with Yin. In the 19th-century West, Heracleitus' vision has been revived in the view of G.W.F. Hegel, a German Idealist, that progress occurs through a synthesis resulting from an encounter between a thesis and an antithesis. In political terms, Heracleitus' vision has reappeared in Karl Marx's concept of an encounter between the bourgeoisie and the proletariat and the emergence of a classless society without a government.

Apocalyptic views

In the Zoroastrian and Jewish–Christian–Islāmic vision of the time flow, time is destined to be consummated—as depicted luridly in the Revelation to John—in a terrifying climax. Present-day man has recently become aware that history has been accelerating—and this at an accelerating rate. The present generation has been conscious of this increase of acceleration in its own lifetime; and the advance in man's knowledge of his past has revealed, in retrospect, that the acceleration began about 30,000 years ago, with the transition from the Lower to the Upper Paleolithic Period, and that it has taken successive "great leaps forward" with the invention of agriculture, with the dawn of civilization, and with the progressive harnessing —within the last two centuries—of the titanic physical forces of inanimate nature. The approach of the climax foreseen intuitively by the prophets is being felt, and feared, as a coming event. Its imminence is, today, not an article of faith; it is a datum of observation and experience. (A.J.T.)

EARLY MODERN AND 19TH-CENTURY SCIENTIFIC PHILOSOPHIES OF TIME

Isaac Newton distinguished absolute time from "relative, apparent, and common time" as measured by the apparent motions of the fixed stars, as well as by terrestrial clocks. His absolute time was an ideal scale of time that made the laws of mechanics simpler, and its discrepancy with apparent time was attributed to such things as irregularities in the motion of the Earth. Insofar as these motions were explained by Newton's mechanics (or at least could not be shown to be inexplicable), the procedure was vindicated. Similarly, in his notion of absolute space, Newton was really getting at the concept of an inertial system. Nevertheless, the notion of space and time as absolute metaphysical entities was encouraged by Newton's views and formed an important part of the philosophy of Immanuel Kant (died 1804), a German critical philosopher, for whom space and time were "phenomenally real" (part of the world as described by science) but "noumenally unreal" (not a part of the unknowable world of things in themselves). Kant argued for the noumenal unreality of space and time on the basis of certain antinomies that he claimed to find in these notions—that the universe had a beginning, for example, and yet (by another argument) could not have had a beginning. In a letter dated 1798, he wrote that the antinomies had been instrumental in arousing him from his "dogmatic slumber" (pre-critical philosophy). Modern advances in logic and mathematics, however, have convinced most philosophers that the antinomies contain fallacies.

Static versus dynamic systems

Newtonian mechanics, as studied in the 18th century, was mostly concerned with periodic systems that, on a large scale, remain constant throughout time. Particularly notable was the proof of the stability of the solar system that was formulated by Pierre-Simon, marquis de Laplace, a mathematical astronomer. Interest in systems that develop through time came about in the 19th century as a result of the theories of the British geologist Sir Charles Lyell, and others, and the Darwinian theory of evolution. These theories led to a number of biologically inspired metaphysical systems, which were often—as in the French evolutionary philosopher Henri Bergson and the Anglo-American process philosopher Alfred North Whitehead—rather romantic and contrary to the essentially mechanistic spirit of Darwin himself (and also of present-day molecular biology). (J.J.C.S.)

II. Time as systematized in modern scientific society

TIME MEASUREMENT: GENERAL CONCEPTS

Time measurement involves two quantities: (1) epoch, which specifies the moment when an instantaneous event occurs in the sense of time of day, and (2) time interval, or duration of a continued event. The progress of any phenomenon that undergoes regular changes may be used to measure time. Such phenomena occur in astronomy, physics, chemistry, geology, and biology. To measure time some quantitative process is necessary. Two such processes have been adopted, and these define two, independent, fundamental measures of time.

Dynamical and atomic time distinguished

The concept of dynamical time is based on the laws of motion and gravitation published by Isaac Newton in 1687; this kind of time could be obtained in theory from the motions of any bodies subject only to the force of gravitation. It is obtained in practice from the orbital motions of planets and satellites for which nongravitational forces are negligible or small and is called Ephemeris Time (ET). (An ephemeris is a table that lists positions of such bodies as planets and satellites as functions of time.)

Electromagnetic time, the other measure of time, is based on the laws of electricity announced by James Clerk Maxwell in 1864. As measured through the operation of an atomic clock by counting cycles of electromagnetic radiation, it is called atomic time (AT). A fundamental distinction between the two types of time is that dynamical time involves the motions of material bodies whereas electromagnetic time does not.

Rotational time. Rotational time, in forms such as sidereal (measured by the stars) and mean solar time, is based on the rotation of the Earth about its axis. It is not dynamical time in the sense defined above; variations in rotational speed with a range of one part in 10,000,000 have occurred since 1820, for example, with respect to Ephemeris Time and atomic time. The speed of rotation is affected by winds, tides, turbulent motions within the Earth's core, and other geophysical phenomena, the effects of which cannot be computed as accurately as can those of gravitation. Rotational time, even if it is variable with respect to Ephemeris and atomic times, remains in common usage because it is of necessity required for civil purposes, navigation, geodetic surveying, and space-vehicle tracking.

Under the present system of time measurement, epoch is stated in terms of mean solar time and time interval in terms of atomic time. Ephemeris Time is used in celestial mechanics but not for common purposes.

Newtonian time and relativity. Time in the Newtonian sense was mentioned above as if there were a single absolute time. According to this concept, all events that occur anywhere in the universe could be arranged in a single, ordered sequence. Thus, of two events, A and B, either A would occur before B, B before A, or the two would be simultaneous. This intuitive concept of time was altered drastically by Albert Einstein in 1905. According to the theory of special relativity, separate coordinate systems in uniform relative motion each have a different time system, and none is preferred. Absolute simultaneity disappears in relativity, and it is possible that event A occurs before B as measured by the clocks of one coordinate system but that the reverse occurs according to the clocks of another system.

A multiplicity of times exists in relativity, and the role of time in the physical universe is more complex under relativity than under Newtonian mechanics. Fortunately, however, all time measurements of which man has knowledge have been made on or near the surface of the

Earth and for the most part do not involve relativity. This section of the article, therefore, begins with an investigation of time as if it were single valued. Relativistic effects are discussed later.

Astronomical time divisions. Measures of astronomical time are based upon (1) the rotation of the Earth about its axis, (2) the orbital motion of the Earth about the Sun, and (3) the orbital motion of the Moon about the Earth. The Earth's axis undergoes motions similar to the progressive and oscillating motions of a top. In consequence of these motions and their combinations, numerous kinds of days, months, and years are defined, including those listed in the accompanying Table. Those of chief interest are: the mean solar day; the synodic month, the interval from New Moon to New Moon; and the tropical year, the interval from equinox to the corresponding equinox. (Equinoxes, two of which occur each year, are the moments when the Sun crosses the celestial Equator.) Seasons are repeated, on the average, at intervals of a tropical year.

Astronomical Time Divisions

day	month	year
mean solar	synodic	tropical
apparent solar	sidereal	sidereal
mean sidereal	anomalistic	Besselian
true sidereal	draconic	eclipse
ephemeris	tropical	Julian

The week is not specifically related to any astronomical cycle. The period may have originated as an interval for market days; weeks of five, six, and 10 days have been observed. The seven-day week was in use in ancient times in Chaldea and was established as a measure of time in biblical times under the Mosaic Law. It may be related to the fact that the successive phases of the Moon (*e.g.*, new, first quarter, full, and last quarter) are nearly seven days apart; the average is 7.38. It is desired that the average number of calendar days in a year (Y_c) shall nearly equal the number of mean solar days in a tropical year (Y_t). This is achieved by designating some years as leap years. Values of Y_c are 365.25 in the Julian calendar and 365.2425 in the Gregorian calendar. The quantity Y_t varies slowly; its value in 1970 was about 365.24219 mean solar days. Because of variations in speed of rotation, Y_t cannot be predicted accurately for many centuries in advance beyond the fourth decimal. Hence, attempts to improve the calendar by modifying the leap-year rule are of doubtful value (see CALENDAR).

The calendar days in a tropical year

ROTATIONAL TIME

The Earth's rotation causes the stars and the Sun to appear to rise each day in the east and set in the west. The apparent solar day is measured by the interval of time between two successive passages of the Sun across the observer's meridian, a great circle in the sky passing through the zenith and through the celestial poles. One sidereal day (very nearly) is measured by the interval of time between two similar passages of a star. Fuller treatments of astronomical reference points and planes are given in the articles ASTRONOMICAL MAPS; and MECHANICS, CELESTIAL.

The plane in which the Earth revolves about the Sun is called the ecliptic. As seen from the Earth, the Sun moves eastward on the ecliptic 360° per year, almost one degree per day. As a result, an apparent solar day is nearly four minutes longer, on the average, than a sidereal day. The difference varies, however, from 3 minutes 35 seconds to 4 minutes 26 seconds during the year because of the Earth's elliptical orbit, in which at different times of the year it moves at slightly different rates, and because of a 23½° inclination of the ecliptic to the Equator. In consequence, apparent solar time is nonuniform with respect to dynamical time. A sundial indicates apparent solar time but becomes slightly fast or slow by civil, or mean solar (clock), time according to the time of year.

The 17th-century introduction of clocks and watches that marked a uniform rate of the passage of time made apparent solar time unsuitable for civil use. Therefore, mean solar time was introduced; it is defined as a measure of the rotation of the Earth. The difference between apparent solar time and mean solar time, called the equation of time, varies from zero to about 16 minutes.

The measures of sidereal, apparent solar, and mean solar time are defined by the hour angles of certain points, real or fictitious, in the sky. Hour angle is the angle, taken to be positive to the west, measured along the celestial equator between an observer's meridian and the hour circle (a great circle passing through the poles) on which some celestial point or object lies. Hour angles are measured from zero through 24 hours.

Sidereal time is the hour angle of the vernal equinox, a reference point that is one of the two intersections of the celestial equator and the ecliptic. Because of a small periodic oscillation, or wobble, of the Earth's axis, called nutation, there is a distinction between the true and mean equinoxes. The difference between true and mean sidereal times, defined by the two equinoxes, varies from zero to about one second.

Apparent solar time is the hour angle of the centre of the true Sun plus 12 hours.

Mean solar time is 12 hours plus the hour angle of the centre of the fictitious mean Sun. This is a point that moves along the celestial equator with constant speed and that coincides with the true Sun on the average. In practice, mean solar time is not obtained from observations of the Sun. Instead, sidereal time is determined from observations of the transit across the meridian of stars, and the result is transformed by means of a quadratic formula to obtain mean solar time.

Mean solar time

Time units. The mean solar day is divided as follows: one mean solar day equals 24 mean solar hours; one mean solar hour equals 60 mean solar minutes; one mean solar minute equals 60 mean solar seconds; thus one mean solar day equals 86,400 mean solar seconds. Analogous divisions are used for other kinds of time—for example, for sidereal, Ephemeris, and atomic time.

Reckoning of days and hours. The day begins at midnight and runs through 24 hours. In the 24-hour system of reckoning, used in Europe and by military agencies of the United States, the hours and minutes are given as a four digit number. Thus 0028 means 28 minutes past midnight, and 1240 means 40 minutes past noon. Also, 2400 of May 15 is the same as 0000 of May 16. This system allows no uncertainty as to the epoch designated.

In the 12-hour system there are two sets of 12 hours; those from midnight to noon are designated AM (ante meridiem, "before noon"), and those from noon to midnight are designated PM (post meridiem, "after noon"). The use of AM and PM to designate either noon or midnight can cause ambiguity. To designate noon, either the word noon or 1200 should be used. To designate midnight without causing ambiguity, the two dates between which it falls should be given unless the 24-hour notation is used. Thus, midnight may be written: May 15-16 or 0000 May 16.

Mean solar time of the Greenwich (England) meridian is denoted Universal Time (UT). Equivalent designations are Greenwich Mean Time (GMT), used in air and sea navigation, and Z, used in communications. The term UT is used in astronomy and other scientific work.

Zone time. Local mean solar time depends upon longitude; it is advanced by one hour for every 15° to the east. To avoid the inconvenience of numerous differences in local times, an international system of 24 time zones was adopted in 1884. Standard time is the same everywhere within a zone, the boundaries of which may zigzag. The time in any standard zone differs from UT by an integral number of hours: minutes and seconds are the same.

The International Date Line is a zigzag line in the mid-Pacific Ocean near 180° longitude. When travelling across it westward a calendar day is added; one day is dropped in passing eastward.

During World War I, daylight-saving time was adopted in various countries; clocks were advanced one hour to save fuel by reducing the need for artificial light in evening hours. During World War II, all clocks in the United

States were kept one hour ahead of standard time for the interval February 9, 1942–September 30, 1945, with no changes made in summer. Since then, the time in a large part of Europe has been kept one hour ahead of standard zone time without any change during summer. Beginning in 1967, by act of Congress, the United States observes daylight-saving time in summer, though state legislatures retain the power to pass exempting laws, and a few have done so.

Practical determination of rotational time. The determination of time is a specialized branch of astronomy that is usually conducted by a government observatory. The basic definitions concerning time determination are standardized by the International Astronomical Union. The Bureau International de l'Heure (International Time Bureau) at Paris provides data needed for the uniform reduction of observations, and it coordinates results.

The determination of Universal Time (UT) requires (1) a telescope for observing or automatically recording the crossing of a star of known position over a celestial reference line, usually a meridian; and (2) a clock on which the time of crossing is recorded. The observations give the difference between UT and the clock. One may then obtain UT thereafter by applying the difference to the clock time.

Coordinated time. The initial values of Universal Time obtained at various observatories, denoted UT0, differ slightly because of polar motion. A correction is added for each observatory to convert UT0 into UT1. An empirical correction to take account of annual changes in the speed of rotation is then added to convert UT1 to UT2.

Coordinated Universal Time, denoted UTC, is obtained from an atomic clock that is adjusted in epoch so as to remain close to UT2; the frequency of a clock on UTC is constant, that of atomic time.

The leap second

Beginning January 1, 1972, the practice was adopted of keeping UTC within about 0.5 second of UT2 by resetting a clock on UTC by exactly one second when necessary. Clocks on UTC had been retarded about once per year. Normally, the last second of each day is 23 hours 59 minutes 59 seconds, and the next second is 0 hour 00 minute 00 second of the next day. When clocks are to be retarded, however, that next second is designated 23 hours 59 minutes 60 seconds of the same day, and the second immediately following is designated 0 hour 00 minute 00 second of the next day. The day on which the leap second is inserted is selected by the International Time Bureau.

Precise clocks are maintained to indicate UTC, and time signals are broadcast on this system. In consequence, Universal Coordinated Time is the reference for time in common use.

EPHEMERIS TIME

Ephemeris Time (ET) may be obtained from the orbital motion of any planet or satellite. The orbital motion of the Earth about the Sun, as developed mathematically in the American astronomer Simon Newcomb's *Tables of the Sun* (1895), has been adopted to define the basic measure of ET. (The Earth and Sun are 180° apart; that is, opposite each other in the plane of the ecliptic, so that an observation of the Sun with respect to the stars gives the orbital position of the Earth.) Newcomb's *Tables* are used to form a solar ephemeris, or a table that gives the Sun's coordinates for successive values of Ephemeris Time.

An observed position of the Sun is obtained with a meridian circle, an instrument that works on the same principles as a surveyor's transit but is somewhat larger. The time at which such a position should be reached is found from the solar ephemeris, and this is the Ephemeris Time at which the Sun had the observed position.

Values of Ephemeris Time are also obtained from observations of the Moon by using the lunar ephemeris for the observed position. The lunar ephemeris, however, contains an empirical, nongravitational term, which arises from tides raised in the Earth by the Moon. The value of Ephemeris Time obtained from the Moon is, therefore, not strictly dynamical time, and the lunar ephemeris must be brought into accord with the solar ephemeris from time to time. In practice, the Moon is generally used to determine Ephemeris Time because of its rapid orbital motion. Very accurate positions of the Moon are obtained visually by observations of occultations of stars (an occultation is the passage of the Moon across the line of sight to the star, so that the star vanishes for a short time). Its position can also be measured with a meridian circle or photographically.

PRINCIPLES OF TIME MEASUREMENT

Chronometers. Time-measuring instruments can be astronomical, mechanical, or atomic depending upon the physical level to which reference is made.

Astronomical time-measuring instruments. The type of telescope formerly used to obtain accurate star positions from which to calculate precise times consisted of a small, visual transit instrument that could be moved only in the plane of the meridian. As much the same principles are still used, a brief description of them is of value here. An observer generated a signal at the instant that the image of the star was seen to cross a spider thread (the thinnest-possible cross hair obtainable up to the 1930s) in the meridian plane. This instrument has been largely replaced by two other, more accurate instruments that determine latitude as well as time.

Zenith tube and astrolabe

The first is the photographic zenith tube (usually called the PZT). It was adapted to determine time in 1934 at the United States Naval Observatory. The PZT is fixed with the telescope tube vertical; it photographs only stars that transit near the zenith. A motor drives the photographic plate so as to track the stars. Four exposures are made with the lens and plate reversed 180° between exposures. Signals initiated by the moving plate are recorded by a clock. Reflection from the surface of a mercury basin determines the vertical direction automatically and very accurately.

The second instrument, called an astrolabe, was designed about 1956 and utilizes a 60° prism and a basin of mercury to form the direct and reflected images of a star. These images coincide when the altitude of the star is exactly 60°. An observer manipulates a motor so as to keep the two images parallel to a spider thread (see above: a real spider thread was used in the 19th century as the best and thinnest cross hair; the term is now used for any such hair, no matter what the material used). The instant when the altitude is 60° is recorded automatically.

Mechanical clocks. A clock is a device that indicates intervals or the passage of time. It consists of two parts: (1) a part that vibrates or one in which some other repetitive event occurs at equal intervals of time; and (2) a counting part, which indicates the total count for an interval usually with hands and a dial or in digital form. An important achievement in timekeeping history was the discovery, about 1583, by Galileo that the oscillation period of a pendulum is virtually independent of the amplitude of its swing. The Dutch mathematician-astronomer Christiaan Huygens derived the theory of the pendulum and had the first pendulum clock constructed in 1656. Numerous improvements were subsequently made, and pendulum clocks reached a fairly high stage of precision by about 1925. The rates of the best pendulum clocks are constant to about 0.001 second per day. Pendulum clocks, not long ago the most exact timepieces known in the world, no longer are used in precise timekeeping, which for modern purposes in the 1970s must reach even higher precision. For detailed information concerning the phenomena on which atomic time is based, see ATOMIC STRUCTURE; ELECTROMAGNETIC RADIATION; ELECTRICITY; SPECTROSCOPY, PRINCIPLES OF. In the following sections, only a general summary can be made.

Quartz-crystal clocks. Quartz-crystal clocks work by exerting an extremely accurate control of the frequency of vibrations that measure time. A quartz crystal, if deformed, acquires a difference in electric potential across certain of its faces. Conversely, a difference in electric potential applied across these faces will deform the crystal. This property, known as the piezoelectric effect, en-

ables a quartz crystal to control the frequency of an electrical circuit; the frequency is that of the mechanical vibration of the crystal. Frequency f and period p of a cyclic occurrence are related, the frequency being the inverse of the period. In symbols, $f = 1/p$. Frequency is measured in cycles per second (cps); this unit is alternatively called the hertz (Hz). Frequently used multiple units are: kilohertz (kHz, 10^3 cps); megahertz (MHz, 10^6 cps); gigahertz (GHz, 10^9 cps); and terahertz (THz, 10^{12} cps).

Quartz-crystal clocks were introduced into timekeeping about 1930. Early performance was relatively poor; clocks were subject to large accelerations in rate and to frequent stoppages, often accompanied by sudden changes in rate. Performance improved, and, by 1960, highly reliable, precise quartz-crystal clocks were available. The best of them had very low accelerations, about one part in 10^{11} per day, which, however, could not be predicted accurately.

Atomic clocks. A new era in timekeeping was introduced with the development of the atomic clock. An atomic clock uses quantum transitions (energy changes) within atoms to produce extremely regular waves of electromagnetic radiation; like the recurrent events in other kinds of clocks, these waves are then counted. To be useful, the waves from individual atoms or molecules must be in phase with one another. Such radiation is called coherent (see LASER AND MASER).

Use of microwave spectral lines

The frequency, ν, of the radiation produced by a particular quantum transition depends upon the initial energy E_1 and the final energy E_2, and, if h is the number known as Planck's constant, the frequency is the difference between E_1 and E_2 divided by Planck's constant. In symbols this can be written: $\nu = (E_1 - E_2)/h$. Each transition produces a spectral line. The frequency of visible radiation (light waves) is about 5×10^{14} Hz, too high to permit counting of individual cycles. The development of methods of generating frequencies on the order of 10^{10} Hz opened the possibility of using spectral lines in the one-centimetre microwave region of the spectrum for frequency control. In 1946 principles of the use of spectral lines in the construction of an oscillator were described, and in 1947 an oscillator controlled by a quantum transition of the ammonia (NH_3) molecule was constructed. An ammonia-controlled clock was built in 1949 at the National Bureau of Standards, Washington, D.C. In 1954, an oscillator of higher precision, called a maser, which also utilized ammonia, was developed.

Cesium clocks. About 1939 a technique of projecting a beam of atoms and molecules was developed to facilitate their study. This led to several attempts to construct a cesium-beam atomic clock. In June 1955 a cesium-beam atomic standard of high precision was first placed in operation at the National Physical Laboratory, Teddington, England. From 1955 to 1958 a joint experiment was carried out by the National Physical Laboratory and the United States Naval Observatory to determine the relationship between the frequency of cesium and the second of Ephemeris Time as determined from observations of the Moon with a dual-rate moon camera. The value obtained for the ephemeris second was 9,192,631,770 cycles. Cesium-beam oscillators were subsequently constructed at a number of laboratories. Small commercial models weighing about 65 pounds (30 kilograms) and accurate to about two parts in 10^{12} have been made.

Hydrogen clocks. Hydrogen masers of very high stability have been developed at Harvard University. These have stabilities of about one part in 10^{14}. The absolute frequency, however, is uncertain by a larger amount. The frequency of hydrogen is 1,420,405,751.8 Hz.

Rubidium clocks. Gas cells of high stability using rubidium have been developed. The frequency depends on construction and adjustments, so that they do not have the absolute precision of cesium-beam clocks.

Precision in dealing with time. Assiduous efforts have been made in recent decades to define, correlate, and disseminate astronomical and atomic time with the utmost precision.

Precision of the concept of the second. The fundamental unit of time interval in the metric system was, by usage but not by formal adoption, the second of mean solar time: 1/86,400 of the mean solar day. Because of variations in speed of rotation of the Earth and, consequently, in the length of the mean solar day, this unit became unsatisfactory. In 1955 the International Astronomical Union defined the second of Ephemeris Time (ET) as 1/31,566,925.9747 of the tropical year for 1900 January 0 (same as December 31, 1899) at 12 hours ET. The length of the tropical year (see above *Astronomical time divisions*) changes according to the epoch because of gravitational perturbations, so that it must be defined for a particular period in time. This definition was adopted by the International Committee of Weights and Measures in 1956 and ratified by the General Conference of Weights and Measures in 1960. In 1964 the conference also defined an atomic second as 9,192,631,770 periods of radiation of a particular cesium-133 transition. In 1967 this became the sole definition of the second in the International System of Units (SI), the modern form of the metric system. The second of ET remains as the unit of time interval in the system of constants adopted by the International Astronomical Union in 1964.

In 1970 the atomic second was shorter than the mean solar second by about three parts in 10^8, and an atomic clock gained about one second per year on a clock showing mean solar time. The length of the mean solar day, which is always 86,400 mean solar seconds, was then 86,400.0026 seconds of atomic time.

Atomic-time scales. Using the preceding definition of the atomic second, any atomic clock can be used to generate an atomic-time scale after an initial epoch has been specified. The time scale obtained will depend, to some extent, on the clocks used. That determined by the International Time Bureau, denoted TAI, is based on about 50 highly accurate atomic clocks about the world.

Variations in the Earth's rotation. Variations in the Earth's rotation are classified as (1) secular, (2) irregular, and (3) periodic.

Difference between Universal Time and Ephemeris Time

Variations in the difference between Universal Time (UT) and Ephemeris Time (ET) in modern terminology were found by astronomers from studies of ancient observations—in particular, of solar and lunar eclipses. By 1875 the American astronomer Simon Newcomb suspected that the discrepancies were caused by variations in speed of rotation rather than by irregularities in the Moon's motion. This idea was established as correct in 1939. About this time attempts to detect annual and semiannual periodic variations were initiated. Quartz-crystal clocks were good enough by about 1955 to give sufficiently reliable values of time intervals for the very small periodic changes to be detected.

It was thought formerly that the irregular variation consisted of abrupt changes in speed, as large as three parts in 10^8 (three milliseconds per day). The comparison of UT with atomic time since 1955, however, shows that sudden changes in speed do not occur. Instead, sudden changes in acceleration and deceleration occur about every five years. The cause is not certain.

Tidal friction causes a progressive deceleration. Other geophysical effects are present, however, which can cause either a long-period acceleration or retardation—*e.g.*, changes in sea level from melting ice. These effects were under study in the early 1970s.

Tidal friction retards the speed of rotation but does not affect the orbital motion of the Earth. Hence, the number of mean solar days in one year must have been larger in the past than at present. An accurate extrapolation cannot be made, however, because the strength of tidal friction in the remote past is not known. A study of coral fossil growth rings, however, tends to indicate that several hundred million years ago there were about 400 days in a year. The age of the coral can be determined by radioactive dating, but there is difficulty in recognizing yearly growth patterns, superimposed on the daily pattern.

Time and frequency dissemination. Precise time and frequency are broadcast by radio in many countries.

Transmissions of time signals began as an aid to navigation in 1904; they are now widely used for many scientific and technical purposes. The seconds pulses are emitted on Coordinated Universal Time (see above), and the frequency of the carrier wave is maintained on some multiple of atomic frequency. Radio stations that provide such transmissions include those whose call signs are NBA (Panama Canal Zone); WWV (Fort Collins, Colorado); and GBR and MSF (Rugby, Warwickshire). The radio navigational systems Loran-C and Omega also provide precise time and frequency.

The accuracy obtainable from the signals varies from about one millisecond on high frequency to one microsecond for Loran-C. Frequency may be calibrated to about one part in 10^{11} in one day with transmissions of very low frequency and about one part in 10^{12} with Loran-C. The United States Naval Observatory also provides a service for synchronizing clocks around the world to about one microsecond through use of portable atomic clocks. Artificial satellites of the Earth also have been used in experiments to synchronize widely separated clocks to about 0.1 microsecond.

Radioactivity and time measurement. Atoms of a radioactive element (for details, see RADIOACTIVITY) decay at a rate that is independent of temperature, pressure, and other environmental factors. A clock could be constructed that would be based on radioactive decay, but it would not measure time interval with high precision. The process is useful, however, for measuring long intervals of time up to many millions of years.

Carbon-14 dating makes possible the age determination of objects containing carbon over the range of 100 to 50,000 years. Carbon-14, produced in the atmosphere by cosmic rays, enters living matter in a fairly constant ratio to carbon-12, which does not decay. The ratio of carbon-14 to carbon-12 in an object determines its age.

RELATIVISTIC AND COSMOLOGICAL EFFECTS

Time dilatation in special and general relativity

Relative motion. Let A and B be a pair of clocks fixed relative to each other and whose readings have been related by the exchange of electromagnetic (light) signals. Let the pair be in uniform motion relative to a clock C, which coincides successively with A and B. Then, as a consequence of Einstein's postulates of special relativity, the time interval of transit as measured by the single clock C will be less than that given by the difference in readings of the pair (see RELATIVITY). This holds irrespective of whether C is considered to be moving or at rest. The statement often made that, in effect, a moving clock runs slowly compared to the clock of a stationary observer, is misleading; three clocks should be included in the comparison. Several effects outside the scope of special relativity (which deals with nonaccelerated, linear motions) have been predicted; some have been confirmed.

Gravitational potential. A clock in a weaker potential (gravitational) field runs faster than one in a stronger field. Near the surface of the Earth the frequency increases about one part in 10^{16} per metre, and a clock 100 metres (330 feet) higher than a second clock will have a frequency higher by one part in 10^{14}.

Clocks on the Earth are affected by orbital motion about the Sun and by the gravitational potential of the Sun. The net effect is an average lowering in frequency of 1.5×10^{-8} plus an annual term with coefficient 3.3×10^{-10}, compared to a clock at rest at infinity. These effects are the same for all clocks on the Earth. They might be detected, possibly, by a comparison of atomic time with that derived from observations of certain pulsars that emit rapidly and uniformly varying radio-frequency radiation, because pulsars are external to the solar system.

Around-the-world experiment. A clock carried eastward around the world in an airplane should differ, at the end of the trip, from one fixed on the Earth because (1) the two clocks are in rotation at different speeds about nonrotating axes at the centre of the Earth and (2) there is a difference in gravitational potential. Moreover, effect (1) will be different for clocks carried eastward and westward at the same speed relative to the Earth, because the Earth rotates eastward. In experiments carried out in 1971 with atomic clocks of the U.S. Naval Observatory, the eastward-flying clock lost 0.06 microsecond and the westward one gained 0.27 microsecond, which confirmed the predicted relativistic effects.

Basis of Ephemeris Time. Newcomb's 1895 mathematical development of the orbital motion of the Earth (mentioned above) is based on celestial mechanics, which in turn is based on the laws of motion and gravitation of Newton; this development includes the disturbing gravitational effects (called perturbations) of the planets. The observations used to obtain the constants in the solution were obtained from observations of angles only. Modern studies of the Earth's orbital motion allow for effects predicted by general relativity and take into account extremely precise astronomical measurements of planetary distances by radar reflection. As a result, more precise measures of Ephemeris Time can be expected.

Cosmological theories have been proposed in which the gravitational constant, G, diminishes slowly, about one part in 10^{10} or 10^{11} per year, with respect to electrical constants. If such hypotheses are correct, then the frequency of an atomic clock with respect to Ephemeris Time would increase secularly. No secular change has been found thus far, however; G is constant within the errors of observation, four parts in 10^{10} per year.

(W.Ma.)

III. Contemporary philosophies of time

TIME IN 20TH-CENTURY PHILOSOPHY OF PHYSICS

Time in the special theory of relativity. Since the classic interpretation of Einstein's special theory of relativity by Hermann Minkowski, a Lithuanian–German mathematician, it has been clear that physics has to do not with two entities, space and time, taken separately, but with a unitary entity space–time, in which, however, timelike and spacelike directions can be distinguished. The Lorentz transformations, which in special relativity define shifts in velocity perspectives, were shown by Minkowski to be simply rotations of space–time axes. The Lorentz contraction of moving rods and the time dilatation of moving clocks turns out to be rather analogous to the fact that different-sized slices of a sausage are obtained by altering the direction of the slice: just as there is still the objective (absolute) sausage, so also Minkowski restores the absolute to relativity in the form of the invariant four-dimensional object, and the invariance (under all mathematical transformations) of the space–time interval and of certain fundamental physical quantities such as action (which has the dimensions of energy times time, even though neither energy nor time is separately invariant).

Minkowski space–time and Lorentz transformations

Process philosophers charge the Minkowski universe with being a static one. The philosopher of the manifold denies this charge, saying that a static universe would be one in which all temporal cross sections were exactly similar to one another and in which all particles (considered as four-dimensional objects) lay along parallel lines. The actual universe is not like this, and that it is not static is shown in the Minkowski picture by the dissimilarity of temporal cross sections and the nonparallelism of the world lines of particles. The process philosopher may say that change, as thus portrayed in the Minkowski picture (*e.g.*, with the world lines of particles at varying distances from one another), is not true Bergsonian change, so that something has been left out. But if time advances up the manifold, this would seem to be an advance with respect to a hypertime, perhaps a new time direction orthogonal to the old one. Perhaps it could be a fifth dimension, as has been used in describing the de Sitter universe as a four-dimensional hypersurface in a five-dimensional space. The question may be asked, however, what advantage such a hypertime could have for the process philosopher and whether there is process through hypertime. If there is, one would seem to need a hyper-hypertime, and so on to infinity. (The infinity of hypertimes was indeed postulated by John William Dunne, a British inventor and philosopher; but the remedy seems to be a desperate one.) And if

Possible fifth-dimensional hypertime

no such regress into hypertimes is postulated, it may be asked whether the process philosopher would not find the five-dimensional universe as static as the four-dimensional one. The process philosopher may therefore adopt the expedient of the French intuitionist Henri Bergson, saying that temporal process (the extra something that makes the difference between a static and a dynamic universe) just cannot be pictured spatially (whether one supposes four, five, or more dimensions). According to Bergson, it is something that just has to be intuited and cannot be grasped by discursive reason. The philosopher of the manifold will find this unintelligible and will in any case deny that anything dynamic *has* been left out of his world picture. This sort of impasse between process philosophers and philosophers of the manifold seems to be characteristic of the present-day state of philosophy.

The theory of relativity implies that simultaneity is relative to a frame of axes. If one frame of axes is moving relative to another, then events that are simultaneous relative to the first are not simultaneous relative to the second, and vice versa. This paradox leads to another difficulty for process philosophy over and above those noted earlier. Those who think that there is a continual coming into existence of events (as the present rushes onward into the future) can be asked "Which present?" It therefore seems difficult to make a distinction between a real present (and perhaps past) as against an as-yet-unreal future. Philosophers of the manifold also urge that to talk of events becoming (coming into existence) is not easily intelligible. Enduring things and processes, in this view, can come into existence; but this simply means that as four-dimensional solids they have an earliest temporal cross section or time slice.

When talking in the fashion of Minkowski, it is advisable, according to philosophers of the manifold, to use tenseless verbs (such as the "equals" in "2 + 2 equals 4"). One can say that all parts of the four-dimensional world exist (in this tenseless sense). This is not, therefore, to say that they all exist *now*, nor does it mean that Minkowski events are "timeless." The tenseless verb merely refrains from dating events in relation to its own utterance.

The clock paradox

The power of the Minkowski representation is illustrated by its manner in dealing with the so-called clock paradox, which deals with two twins, Peter and Paul. Peter remains on Earth (regarded as at rest in an inertial system) while Paul is shot off in a rocket at half the velocity of light, rapidly decelerated at Alpha Centauri (about four light-years away), and shot back to Earth again at the same speed. Assuming that the period of turnabout is negligible compared with those of uniform velocity, Paul, as a four-dimensional object, lies along the sides AC and CB of a space–time triangle, in which A and B are the points of his departure and return and C that of his turnaround. Peter, as a four-dimensional object, lies along AB. Now, special relativity implies that on his return Paul will be rather more than two years younger than Peter. This is a matter of two sides of a triangle not being equal to the third side: AC + CB < AB. The "less than" —symbolized < —arises from the semi-Euclidean character of Minkowski space–time, which calls for minus signs in its metric (or expression for the interval between two events), which is:

$$ds = \sqrt{c^2dt^2 - dx^2 - dy^2 - dz^2}).$$

The paradox has been held to result from the fact that, from Paul's point of view, it is Peter who has gone off and returned; and so the situation is symmetrical, and Peter and Paul should each be younger than the other—which is impossible. This is to forget, however, the asymmetry reflected in the fact that Peter has been in only one inertial system throughout, and Paul has not; Paul lies along a bent line, Peter along a straight one.

Time in general relativity and cosmology. In general relativity, which, though less firmly established than the special theory, is intended to explain gravitational phenomena, a more complicated metric of variable curvature is employed, which approximates to the Minkowski metric in empty space far from material bodies. Cosmologists who have based their theories on general relativity have sometimes postulated a finite but unbounded space–time (analogous, in four dimensions, to the surface of a sphere) as far as spacelike directions are concerned, but practically all cosmologists have assumed that space–time is infinite in its timelike directions. Kurt Gödel, a contemporary mathematical logician, however, proposed solutions to the equations of general relativity whereby timelike world lines can bend back on themselves. Unless one accepts a process philosophy and thinks of the flow of time as going around and around such closed timelike world lines, it is not necessary to think that Gödel's idea implies eternal recurrence. Events can be arranged in a circle and still occur only once.

Dilatation of time in gravitational fields and black holes

The general theory of relativity predicts a time dilatation in a gravitational field, so that, relative to someone outside of the field, clocks (or atomic processes) go slow. This retardation is a consequence of the curvature of space–time with which the theory identifies the gravitational field. As a very rough analogy, a road may be considered that, after crossing a plain, goes over a mountain. Clearly, one mile as measured on the humpbacked surface of the mountain is less than one mile as measured horizontally. Similarly—if "less" is replaced by "more" because of the negative signs in the expression for the metric of space-time—one second as measured in the curved region of space–time is more than one second as measured in a flat region. Strange things can happen if the gravitational field is very intense. It has been deduced that so-called black holes in space may occur in places where extraordinarily massive or dense aggregates of matter exist, as in the gravitational collapse of a star. Nothing, not even radiation, can emerge from such a black hole. A critical point is the so-called Schwarzschild radius measured outward from the centre of the collapsed star—a distance, perhaps, of the order of 10 kilometres. Something falling into the hole would take an infinite time to reach this critical radius, according to the space–time frame of reference of a distant observer, but only a finite time in the frame of reference of the falling body itself. From the outside standpoint the fall has become frozen. But from the point of view of the frame of the falling object, the fall continues to zero radius in a very short time indeed—of the order of only ten or a hundred microseconds. Within the black hole spacelike and timelike directions change over, so that to escape again from the black hole is impossible for reasons analogous to those that, in ordinary space–time, make it impossible to travel faster than light. (To travel faster than light a body would have to lie—as a four-dimensional object—in a spacelike direction instead of a timelike one.)

Time beyond infinite time

As a rough analogy two country roads may be considered, both of which go at first in a northerly direction. But road A bends round asymptotically toward the east; *i.e.*, it approaches ever closer to a line of latitude. Soon road B crosses this latitude and is thus to the north of all parts of road A. Disregarding the Earth's curvature, it takes infinite space for road A to get as far north as that latitude on road B; *i.e.*, near that latitude an infinite number of "road A northerly units" (say, miles) correspond to a finite number of road B units. Soon road B gets "beyond infinity" in road A units, though it need be only a finite road.

Rather similarly, if a body should fall into a black hole, it would fall for only a finite time, even though it were "beyond infinite" time by external standards. This analogy does not do justice, however, to the real situation in the black hole—the fact that the curvature becomes infinite as the star collapses toward a point. It should, however, help to alleviate the mystery of how a finite time in one reference frame can go "beyond infinity" in another frame.

Expanding universe; creation; τ time

Most cosmological theories imply that the universe is expanding, with the galaxies receding from one another (as is made plausible by observations of the red shifts of their spectra), and that the universe as man knows it originated in a primeval explosion at a date of the order of 10×10^9 years ago. Though this date is often loosely

called "the creation of the universe," there is no reason to deny that the universe (in the philosophical sense of "everything that there is") existed at an earlier time, even though it may be impossible to know anything of what happened then. (There have been cosmologies, however, that suggest an oscillating universe, with explosion, expansion, contraction, explosion, etc., ad infinitum.) And *a fortiori*, there is no need to say—as Augustine did in his *Confessions* as early as the 5th century AD—that time itself was created along with the creation of the universe, though it should not too hastily be assumed that this would lead to absurdity, because common sense could well be misleading at this point.

A British cosmologist, E.A. Milne, however, proposed a theory according to which time in a sense could not extend backward beyond the creation time. According to him there are two scales of time, "τ time" and "t time." The former is a time scale within which the laws of mechanics and gravitation are invariant, and the latter is a scale within which those of electromagnetic and atomic phenomena are invariant. According to Milne τ is proportional to the logarithm of t (taking the zero of t to be the creation time); thus, by τ time the creation is infinitely far in the past. The logarithmic relationship implies that the constant of gravitation G would increase throughout cosmic history. (This increase might have been expected to show up in certain geological data, but apparently the evidence is against it.)

Time in microphysics. Special problems arise in considering time in quantum mechanics and in particle interactions.

Quantum-mechanical aspects of time. In quantum mechanics it is usual to represent measurable quantities by operators in an abstract many-dimensional (often infinite-dimensional) so-called Hilbert space. Nevertheless, this space is an abstract mathematical tool for calculating the evolution in time of the energy levels of systems—and this evolution occurs in ordinary space–time. For example, in the formula $AH - HA = i\hbar(dA/dt)$, in which i is $\sqrt{-1}$ and $\hbar$ is $\frac{1}{2}\pi$ times Planck's constant, h, the A and H are operators, but the t is a perfectly ordinary time variable. There may be something unusual, however, about the concept of the time at which quantum-mechanical events occur, because according to the Copenhagen interpretation of quantum mechanics the state of a microsystem is relative to an experimental arrangement. Thus energy and time are conjugate: no experimental arrangement can determine both simultaneously, for the energy is relative to one experimental arrangement, and the time is relative to another. (Thus, a more relational sense of "time" is suggested.) The states of the experimental arrangement cannot be merely relative to other experimental arrangements, on pain of infinite regress; and so these have to be described by classical physics. (This parasitism on classical physics is a possible weakness in quantum mechanics over which there is much controversy.)

Conjugate relation of energy and time

The relation between time uncertainty and energy uncertainty, in which their product is equal to or greater than $h/4\pi$, $\Delta E \Delta t \geq h/4\pi$, has led to estimates of the theoretical minimum measurable span of time, which comes to something of the order of 10^{-24} second and hence to speculations that time may be made up of discrete intervals (chronons). These suggestions have not been vigorously followed up, however, and are open to a very serious objection, viz., that the mathematics of quantum mechanics makes use of continuous space and time (for example, it contains differential equations). It is not easy to see how it could possibly be recast so as to postulate only a discrete space–time (or even a merely dense one). For a set of instants to be dense, there must be an instant between any two instants. For it to be a continuum, however, something more is required, viz., that every set of instants earlier (later) than any given one should have an upper (lower) bound. It is continuity that enables modern mathematics to surmount the paradox of extension framed by the Pre-Socratic Eleatic Zeno—a paradox comprising the question of how a finite interval can be made up of dimensionless points or instants.

Time in particle interactions. Until recently it was thought that the fundamental laws of nature are time symmetrical. It is true that the second law of thermodynamics, according to which randomness always increases, is time asymmetrical; but this law is not strictly true (for example, the phenomenon of Brownian motion contravenes it), and it is now regarded as a statistical derivative of the fundamental laws together with certain boundary conditions. The fundamental laws of physics were long thought also to be charge symmetrical (for example, an antiproton together with a positron behave like a proton and electron) and to be symmetrical with respect to parity (reflection in space, as in a mirror). The experimental evidence now suggests that all three symmetries are not quite exact but that the laws of nature are symmetrical if all three reflections are combined: charge, parity, and time reflections forming what can be called (after the initials of the three parameters) a CPT mirror. The time asymmetry was shown in certain abstruse experiments concerning the decay of K mesons that have a short time decay into two pions and a long time decay into three pions.

Charge–parity–time symmetry

Time in molar physics. The above-mentioned violations of temporal symmetry in the fundamental laws of nature are such out-of-the-way ones, however, that it seems unlikely that they are responsible for the gross violations of temporal symmetry that are apparent in the visible world. An obvious asymmetry is that there are traces of the past (footprints, fossils, tape recordings, memories) and not of the future. There are mixing processes but no comparable unmixing process: milk and tea easily combine to give a whitish brown liquid, but it requires ingenuity and energy and complicated apparatus to separate the two liquids. A cold saucepan of water on a hot brick will soon become a tepid saucepan on a tepid brick; but the heat energy of the tepid saucepan never goes into the tepid brick to produce a cold saucepan and a hot brick. Even though the laws of nature are assumed to be time symmetrical, it is possible to explain these asymmetries by means of suitable assumptions about boundary conditions. Much discussion of this problem has stemmed from the work of Ludwig Boltzmann (died 1906), an Austrian physicist, who showed that the concept of the thermodynamic quantity "entropy" could be reduced to that of randomness or disorder. Among philosophers in this tradition may be mentioned Hans Reichenbach, a German–U.S. Positivist, Adolf Grünbaum, a contemporary U.S. philosopher, and Olivier Costa de Beauregard, a contemporary French philosopher-physicist. There have also been many relevant papers of high mathematical sophistication scattered through the literature of mathematical physics. Reichenbach (and Grünbaum, who improved on Reichenbach in some respects) explained a trace as being a branch system; *i.e.*, a relatively isolated system, the entropy of which is less than would be expected if one compared it with that of the surrounding region. For example, a footprint on the beach has sand particles compressed together below a volume containing air only, instead of being quite evenly (randomly) spread over the volume occupied by the compressed and empty parts.

Another striking temporal asymmetry on the macro level, viz., that spherical waves are often observed being emitted from a source but never contracting to a sink, has been stressed by Sir Karl Popper, a contemporary Austrian and British philosopher of science. By considering radiation as having a particle aspect (*i.e.*, as consisting of photons), Costa de Beauregard has argued that this "principle of retarded waves" can be reduced to the statistical Boltzmann principle of increasing entropy and so is not really different from the previously discussed asymmetry. These considerations also provide some justification for the common-sense idea that the cause–effect relation is a temporally unidirectional one, even though the laws of nature themselves allow for retrodiction no less than for prediction.

Statistics, causality, and the molar clock

A third striking asymmetry on the macro level is that of the apparent mutual recession of the galaxies, which can plausibly be deduced from the red shifts observed in their

spectra. It is still not clear whether or how far this asymmetry can be reduced to the two asymmetries already discussed, though interesting suggestions have been made.

The statistical considerations that explain temporal asymmetry apply only to large assemblages of particles. Hence, any device that records time intervals will have to be macroscopic and to make use somewhere of statistically irreversible processes. Even if one were to count the swings of a frictionless pendulum, this counting would require memory traces in the brain, which would function as a temporally irreversible recording device.

TIME IN 20TH-CENTURY PHILOSOPHY OF BIOLOGY AND PHILOSOPHY OF MIND

Organisms often have some sort of internal clock that regulates their behaviour. There is a tendency, for example, for leaves of leguminous plants to alter their position so that they lie in one position by day and in another position by night. This tendency persists if the plant is in artificial light that is kept constant, though it can be modified to other periodicities (*e.g.*, to a six-hour instead of a 24-hour rhythm) by suitably regulating the periods of artificial light and darkness. In animals, similar daily rhythms are usually acquired, but in experimental conditions animals nevertheless tend to adapt better to a 24-hour rhythm than to any other. Sea anemones expand and contract to the rhythm of the tides, and this periodic behaviour will persist for some time even though the sea anemone is placed in a tank. Bees can be trained to come for food at fixed periods (*e.g.*, every 21 hours), and this demonstrates that they possess some sort of internal clock. Similarly, man himself has some power to estimate time in the absence of clocks and other sensory cues. This fact refutes the contention of the 17th-century English philosopher John Locke (and of other philosophers in the Empiricist tradition) that time is perceived only as a relation between successive sensations. The U.S. mathematician Norbert Wiener has speculated on the possibility that the human time sense depends on the α-rhythm of electrical oscillation in the brain.

Temporal rhythms both in plants and animals (including man) are dependent on temperature, and experiments on human subjects have shown that, if their temperature is raised, they underestimate the time between events.

Despite these facts, the Lockean notion that the estimation of time depends on the succession of sensations is still to some degree true. People who take hashish and mescalin, for example, may feel their sensations following one another much more rapidly. Because there are so many more sensations than normal in a given interval of time, time seems to drag, so that a minute may feel like an hour. Similar illusions about the spans of time occur in dreams.

It is unclear whether most discussions of so-called biological and psychological time have much significance for metaphysics. As far as the distorted experiences of time that arise through drugs (and in schizophrenia) are concerned, it can be argued that there is nothing surprising in the fact that pathological states can make people misestimate periods of time, and so it can be claimed that facts of this sort do not shed any more light on the philosophy of time than facts about mountains looking near after rainstorms and looking far after duststorms shed on the philosophy of space.

The idea that psychological studies of temporal experience are philosophically important is probably connected with the sort of Empiricism that was characteristic of Locke and still more of the Empiricists George Berkeley and David Hume and their successors. The idea of time had somehow to be constructed out of men's primitive experience of ideas succeeding one another. Nowadays, concept formation is thought of as more of a social phenomenon involved in the "picking up" of a language; thus, contemporary philosophers have tended to see the problem differently: men do not have to construct their concepts from their own immediate sensations. Even so, the learning of temporal concepts surely does at least involve an immediate apprehension of the relation of "earlier" and "later." A mere succession of sensations, however, will go no way toward yielding the idea of time: if one sensation has vanished entirely before the other is in consciousness, one cannot be immediately aware of the succession of sensations. What Empiricism needs, therefore, as a basis for constructing the idea of time is an experience of succession as opposed to a succession of experiences. Hence, two or more ideas that are related by "earlier than" must be experienced in one single act of awareness. William James, a U.S. Pragmatist philosopher and also a pioneer psychologist, popularized the term "specious present" for the span of time covered by a single act of awareness. His idea was that at a given moment of time a person is aware of events a short time before that time. (Sometimes he spoke of the specious present as a saddleback looking slightly into the future as well as slightly into the past, but this was inconsistent with his idea that the specious present depended on lingering short-term memory processes in the brain.) He referred to experiments by the German psychologist Wilhelm Wundt that showed that the longest group of arbitrary sounds that a person could identify without error lasted about six seconds. Other criteria perhaps involving other sense modalities might lead to slightly different spans of time, but the interesting point is that, if there is such a specious present, it cannot be explained solely by ordinary memory traces: if one hears a "ticktock" of a clock, the "tick" is not remembered in the way in which a "ticktock" 10 minutes ago is remembered. The specious present is perhaps not really specious: the idea that it was specious depended on an idea that the real (nonspecious) present had to be instantaneous. If perception is considered as a certain reliable way of being caused to have true beliefs about the environment by sensory stimulation, there is no need to suppose that these true beliefs have to be about an instantaneous state of the world. It can therefore be questioned whether the term "specious" is a happy one.

Two matters discussed earlier in connection with the philosophy of physics have implications for the philosophy of mind: (1) the integration of space and time in the theory of relativity makes it harder to conceive of immaterial minds that exist in time but are not even localizable in space. (2) The statistical explanation of temporal asymmetry explains why the brain has memory traces of the past and not of the future, and hence helps to explain the unidirectional nature of temporal consciousness. It also gives reasons for skepticism about the claims of parapsychologists to have experimental evidence for precognition; or it shows, at least, that if these phenomena do exist they are not able to be fitted into a cosmology based on physics as it exists today.

Time Perception

Man experiences continual change; nights succeed days, winters follow summers; some die, others are born; nothing halts the flow of the river. Let man seek to free himself of these exterior changes and he will meet them again within himself in the tensions and satisfactions of his own bodily needs. Even were he to take refuge in thinking or in reverie, he again would find ceaseless introspective change.

Man subsumes the continuing quality of experience by saying that he lives in time (the dimension of his becoming) even as he lives in space (the dimension of his movements).

The human experience of change is complex. One primary element clearly is that of a succession of events; but distinguishable events are separated by more or less lengthy intervals that are called durations. Sequence and duration are fundamental aspects of what is perceived in change.

Manifestly, duration is relative to the events people isolate in the sequences through which they live: the duration of a kiss, of a meal, of a trip. A given interval always can be subdivided into a sequential chain delimiting briefer durations, as with the regular units that provide empirical measures of time: the second, the day, the year.

Indeed, human experience is not simply that of one single series of events, but of a plurality of overlapping changes. The duration of a radio program, for example, can combine with that of a breakfast, both being inserted within the longer period of an ocean voyage.

Early philosophical views of time

Man seems to be unable to live without some concept of time. Ancient philosophies sought to relate the concept of time to some objective reality to which it would correspond. René Descartes (1596–1650) inaugurated a critical era of philosophy by stressing the ancient problem of the origin of ideas, including the idea of time. Immanuel Kant (1724–1804), providing a radical answer to the epistemological problem of time, wrote that we do not appreciate time objectively as a physical thing; that it is simply a pure form of sensible intuition. Other philosophers of the 18th and 19th centuries sought to explain the notion of time as arising from association and memory of successive perceptions.

A move to empirical psychology emerged with the growth of research on the introspective data of experience. From about mid-19th century, under the influence of the psychophysical notions of Gustav Theodor Fechner, psychologists conducted experiments to study the relationship between time as perceived and time as measured in physics. Their work with adults gradually spread to the study of children and of animals. The psychologists then broadened their investigations of time to cover all forms of adaptation to sequence and duration.

SEQUENTIAL ACTIVITIES

Adaptation to successive events. One may respond to stimulation in an immediate way (as in unconditioned reflex action) without taking the element of time into account. Stimulation, however, can also signal an event to follow; then it has meaning only as part of the sequence of which it is the first term: bell announcing dinner, a road sign, or an approaching danger. People react to such stimuli with anticipatory behaviour that is adapted to a stimulus or action that has not yet occurred. The principles that govern such time-binding adaptation are none other than those of conditioning. One event becomes conditioned as the signal for another stimulus that is to be sought or avoided.

Time-binding adaptation as conditioning

The bottle-fed infant who initially reacts to the nipple on his lips with a simple sucking reflex is gradually conditioned to stop crying when he sees the bottle (the signal for feeding). Later he may learn to react to even more secondary signals that announce the arrival of the bottle; *e.g.*, being lifted from the crib or hearing the sounds of his mother warming the milk in the kitchen. His behaviour has come to incorporate the temporal dimension of the events.

According to the principles of instrumental conditioning, one stimulus becomes the signal for an ensuing event only if the second stimulus elicits an adaptive reaction (consummatory or aversive) and only if the order of the sequence is repeated. Conditioning tends to be established most rapidly when the interval between the signal (conditioned stimulus) and the unconditioned stimulus is quite brief. Ivan P. Pavlov estimated that the optimum interval

for such a sequence was 0.5 second, which corresponds approximately to the intervals characteristic of sequences that are most accurately discriminable perceptually (see below).

Aside from adapting the individual to the order of a sequence, conditioning also adapts to the duration between signal and immediately effective stimulus. Response to signal tends to occur after about the same interval that separated the two stimuli during conditioning. Thus, an animal may be trained to delay a response for some time after the signal (delayed conditioning).

This form of adaptation is most pervasive in human behaviour, permitting people to anticipate sequences of events in their environment so that they can prepare to cope appropriately with what is yet to happen.

Adaptation to periodic change. In 1912 one of Pavlov's students (I.P. Feokritova) demonstrated that a dog accustomed to being fed every 30 minutes would begin to drool toward the end of each half-hour period. It was clear evidence of conditioning to time; the between-feedings interval itself served as a conditioned stimulus.

That discovery underscores the ever-present periodicity of daily living, especially on the biological level: rhythms of activity and sleep, rhythms of eating and lovemaking. As conditioning intervenes, anticipatory experiences of hunger, fatigue, or arousal serve our adaptation to ecological demands.

Circadian rhythms in metabolic activity

Allowance should also be made for the daily, or circadian, rhythms in metabolic activity (*e.g.*, daily cycles of temperature change). There is evidence that these fundamental biological functions can synchronize with the rhythmic phases of environmental (exogenous) change. Thus within a few days after a factory worker has been assigned to the night shift, highs and lows of his daily fluctuations of temperature will be inversed. The rhythmic changes in body temperature persists, nevertheless, suggesting an innate (endogenous) basis for circadian phenomena. Such a hypothesis would mean that the gradual establishment of human circadian rhythms of sleep or temperature results from maturation of the nervous system rather than from conditioning in the strict sense. Experiments in 1962, in which men lived in caves or other enclosures for months deprived of temporal cues from the environment, also demonstrated the enduring nature of rhythms in body temperature and in sleep–wakefulness. The rhythmic periods, however, sometimes expanded, the subject beginning to live on an approximately two-day cycle without being aware of it.

Through conditioning to time and by way of circadian rhythms, human physiology provides a kind of biological clock that offers points of reference for temporal orientation (see also PERIODICITY, BIOLOGICAL).

PERCEPTION OF SEQUENCE AND DURATION

The psychological present. To perceive is to become aware of stimulation. Awareness of sequence or duration may, at first glance, seem inconsistent with the definition of perceiving. In a mathematical sense, certainly, the present is only a point along the continuum of becoming, an instant when future is transformed into past. Nevertheless, there is indeed a more prolonged psychological present, a brief period during which successive events seem to form a perceptual unity and can be apprehended without calling on memory. There is a perceptual field for time just as there is a visual field. The rate or speed of a sequence determines the limits of the time field.

When a metronome ticks two or three times a second, one perceives an integral sequence, becoming aware of a rhythmic auditory series characterized by a perceptually distinct frequency. When the ticks come less often, however—at intervals of three seconds, say—the frequency or sequence no longer is perceived. Each physically discrete sound impulse remains an isolated perceptual event; each tick is no longer perceived as belonging to the same temporal field as the one that follows. Similar effects can be achieved by playing a recording of music or speech at a very slow rate. Music or spoken sentences are recognizable only when their elements (melody, rhythmic patterns, phrase) are presented at an optimal speed that permits significant perceptual unity; that is, only when they belong to the relative simultaneity of the psychological present.

Relation of perceived time to number of elements presented

The perceived field of time also depends on the number of stimulus elements presented. When a clock strikes three or four times, one knows without counting that it is three or four o'clock. At noon one must count; the first chimes no longer belong to the psychological present that includes the last. Most people also can repeat a series of letters or numbers they hear, so long as there are no more than seven or eight elements. This ability varies with the degree of perceptual (*e.g.*, semantic) organization among the elements. While most adults can apprehend only about eight letters, they can grasp and repeat without fault sentences of 20 to 25 syllables (see also ATTENTION).

Perception of sequence. A series of physically discrete stimuli that impinge too rapidly on a sensory structure (*e.g.*, flashes of light on the retina) may produce perceptual fusion; the flashes will be indiscriminable and will appear to be uninterrupted light. The experience of fusion yields to one of discontinuity over distinctive critical ranges of frequency for some of the senses: visual flicker appears under prescribed experimental conditions at about 60 flashes per second, auditory flutter at about 1,000 interruptions per second, and tactual vibration at about 4,000 pulses per second. These values depend on differences in the persistence of the receptor systems (*e.g.*, how long an image is seen after removal of the stimulus).

The question of perceiving sequence hardly has meaning for the senses of taste and smell. Hearing appears to be particularly adapted to temporal perception, since the pattern of auditory excitement shows little inertial lag, closely following the physical duration of successive stimuli. Tactual function can give comparable results, but hearing has the practical superiority in everyday experience of reception at a distance.

When two heterogeneous stimuli (*e.g.*, a flash and a click) are successively presented, the critical threshold for passing from perceived simultaneity to an awareness of succession is found for intervals that vary between 0.02 to 0.1 second, depending on the training of the subjects. The maximum interval for perceiving sequence is more difficult to measure. The minimum time intervals are largely determined by the immediate physiological conditions of direct perceiving, while the maximum intervals are obscured by the effects of other cognitive activities. Determining when direct perception ends and when memory takes over is difficult.

At any rate, awareness of unitary sequence ceases for pairs of auditory or visual stimuli when the interval between them increases to approximately two seconds. For perceptually organized stimuli (as in a rhythm, a melody, or a phrase) the interval may reach five seconds, as indicated by one's ability to reproduce the pattern.

Between the upper and lower limits there are optimal values that seem most likely to produce perception of sequence. In the simple case of two homogeneous stimuli the optimum interval seems to be about 0.6 to 0.8 second. This is inferred from a series of clues: the same interval defines the tempo most frequently adopted in spontaneous motor activity (*e.g.*, tapping, walking) and corresponds to the heart rate. It is the interval that is most precisely reproduced by subjects in experiments; shorter intervals tend to be overestimated and longer ones underestimated. Stimuli repeated at that rate are subjectively judged to proceed most comfortably, without appearing to rush each other as in faster tempos and with no tendency to be separately perceived as at slower frequencies.

Full and empty duration

Perceived duration. Duration, the interval between two successive events, may be distinguished as full or empty (filled or unfilled) in terms of the sensory stimulation that intervenes. An empty interval is bounded by two perceptually discrete stimuli (*e.g.*, two clicks in succession); a duration is full when there is continous stimulation, being delimited by an onset and cessation (*e.g.*, a light stays on throughout the interval). To experience an empty duration is to perceive sequence, while full duration corresponds to the temporal length of a stimulus.

Human subjects need a minimum of about 0.1 second of visual experience or about .01 to .02 second of auditory experience to perceive duration; any shorter experiences are called instantaneous. Direct, unitary perception of duration occurs up to a maximum period of approximately 1.5 to 2 seconds from the beginning to the end of a continuous sensory stimulus.

This roughly two-second maximum for directly perceived duration seems to have a biological basis and can be considered the upper temporal limit of some sort of integrated neural mechanism. The immediate physiological process triggered by a stimulus endures beyond the period of stimulation, and may be measured as the duration of electrical impulses (*e.g.*, in the optic nerve) evoked by simple stimulation. This initial activity appears to be integrated subjectively into a cognitive unit that embraces the rapidly ensuing perceptual processes as well. The optimum range of 0.6 to 0.8 second noted earlier seems to represent the typical duration of this integrating mechanism, as inferred from studies of sensory physiology and from reaction-time experiments.

At any rate, only within these limits can the quality and precision of direct human perception (as opposed to estimation and recall) of duration be studied. Such perception can be absolute or relative. Absolute perception corresponds to estimates expressed in subjectively qualitative terms as long or short. In making such estimates, people can discriminate four to five different durations between 0.1 and 1.0 second and six to seven between 0.5 and 5.0 seconds. In studies of relative perception, subjects attempt to reproduce intervals that are presented, or are told either to produce durations of specified length or to compare two successively presented durations. These tasks, especially comparison, give rise to constant time-order errors; that is, errors in estimation that depend on which interval is presented first.

Experimentally, the perception of empty duration is found to vary with the sense that marks the limits. With duration constant, interval estimates tend to be greater (1) when the limits are visual rather than auditory or tactual, (2) when they are of low intensity, or (3) when auditory limits are higher pitched. If the unfilled limits are defined by successive stimuli from different places, duration appears longer when the distance between the two sources is greater; this is called the S effect or kappa effect. The reverse is the tau effect, in which the distance is perceived as being wider when the interval between successive stimuli is longer.

Kappa and tau effects

The perception of filled duration also varies with the stimulus. Holding the interval constant, interrupted stimulation (*e.g.*, several successive clicks) appears to last longer than does a continuous stimulus; and auditory stimuli appear to last longer than visual. Filled durations seem longer as stimulus intensity (*e.g.*, loudness) or auditory pitch rises.

One interval can be perceived as longer or shorter than the next when the difference is about 7 to 10 percent (both full and empty durations). This relative difference threshold is lowered by practice. Such studies also reveal that apparent duration remains proportional to the objectively measured length of the interval.

ESTIMATING DURATION

When an interval lasts more than a few seconds, it no longer is directly perceivable as a whole, but its length can be estimated on the basis of memory function. Since common experience shows how imprecise these estimates are, people generally calculate time from such indicators as the position of the sun or with clocks and watches. Duration then is inferred rather than perceived.

Estimates, however, often are made, including those of absolute duration in which an activity is appreciated as brief or prolonged. Lacking a watch, one may make crude estimates based on such quantitative aspects of activity as distance travelled, number of dishes washed, or number of pages read. Or one may estimate directly as in subjectively counting seconds.

Factors that affect time estimation. *Type of activity.* The more often a task is broken up or interrupted, the longer it seems to take. As a corollary, a period of doing nothing appears longer than when one is doing something. Similarly, relatively passive activities appear longer than do those requiring active participation; *e.g.*, time passes faster for the student who is taking notes than for one who passively listens.

Level of motivation. The more one is motivated by a given task, the shorter it appears to last. Clearly, motivation and the type of activity pursued are interdependent factors. Lack of motivation tends to interrupt attention to a task; a task in which perceptual focus frequently shifts rarely corresponds to one for which there is strong motivation. The more one notices change during an interval, the longer it is judged to be. More generally, it may be said that time has subjective duration only when one notices it; *e.g.*, in awaiting the arrival of a friend (as opposed to the actual meeting) or in hoping to finish a task (in contrast to working at it).

Change as a factor in judging time

Personality traits. Although inadequacies in quantifying personality traits and difficulties in studying estimates of time spans exceeding a few seconds have hampered scientific study, simple observation reveals marked individual differences in the ability to estimate time. Sex differences have not been reliably established, but the influence of age is well known. Experimental data indicate that children use the same criteria as do adults, but give more variable estimates of duration. One reason for this seems to be that they are less able to compensate for differences in the nature of a task or in personal motivation; also they are inexperienced in making inferences based on the volume of work they have accomplished. Elderly people tend to find time shorter, probably since they are likely to notice long-accustomed changes less frequently.

Children are as accurate as adults in reproducing various series of metronome clicks that last about two seconds or less. But estimates of longer intervals require processes for organizing experience that develop only with age, and very young children seem to depend only on limited criteria: "It lasts because it's longer; because there's more of it; because it goes faster." According to Jean Piaget, estimates based on more or less explicit comparison with standard units of duration imply concrete cognitive operations that are developed only after about the age of seven or eight. Adolescents typically construct more sophisticated notions of time abstracted from such concrete experimental data.

Physiological effects: drugs. The precision with which time is perceived has not been found to be related to heart rate or to electroencephalographic data. It has been shown, however, that perception of time as in clapping or counting accelerates or decelerates with the rise and fall of body temperature. The precise metabolic basis for such temperature effects awaits further study.

The influence of body temperature

Ethical considerations sharply limit the dosage level of drugs employed for experiments on human beings. Understanding of the interactions between drug effects and personality traits in studies of time estimation is, therefore, quite incomplete. Within the dosage ranges investigated, however, stimulating drugs (*e.g.*, thyroxine, caffeine, amphetamines) produce overestimates of duration, while depressants and anesthetics (*e.g.*, barbiturates, nitrous oxide) promote underestimates. Under the influence of hallucinogens (*e.g.*, marijuana, mescaline, LSD), subjects tend to estimate absolute duration as very long. In addition, a marijuana user may underestimate the speed of a motor vehicle, increasing the chances of accident.

Sensory deprivation and hypnosis. Relatively complete sensory deprivation (*e.g.*, prolonged stays in experimental isolation chambers) compresses the experience of time to the point that short or long intervals (from about a minute to a day) seem to pass about twice as fast as usual. Time spent under these unpleasant conditions paradoxically seems shorter than normal time. Thus, the 58 objective days of a subject's first stay in a cave were underestimated as 33 days.

Under hypnosis, durations ordinarily are estimated at least as precisely as ever. Time distortion, however, can be readily induced among hypnotized subjects by simple

suggestion. Such a subject, for example, may be exposed to two clicks that delimit an objective, 10-second interval but be told that it lasts 10 minutes. On being asked to count objects for 10 minutes, he may report having counted several hundreds without difficulty over what the experimenter's stopwatch shows to have been 10 seconds.

BIBLIOGRAPHY. P. FRAISSE, *Psychologie du temps* (1957; Eng. trans., *The Psychology of Time*, 1963), provides the most complete synthesis of the psychological works on time. A comparison with M. STURT, *The Psychology of Time* (1925), shows how this problem has developed and evolved. The collective works edited by J.T. FRASER, *The Voices of Time* (1966); and R. FISHER, "Interdisciplinary Perspectives of Time," *Ann. N.Y. Acad. Sci.*, vol. 138, article 2 (1967), present the most varied aspects of the problem of time, ranging from religious conceptions to scientific data from physics and biology. E. BUNNING, *The Physiological Clock* (1964), provides a very sound study of the problems of the temporal regulation of organisms. M. SIFFRE, *Hors du temps* (1963; Eng. trans., *Beyond Time*, 1964), reports the psychological disorientation of a subject who stays for a long period in an environment deprived of temporal references. L.F. COOPER and M.H. ERICKSON, *Time Distortion in Hypnosis* (1954); and M. FRANKENHAEUSER, *Estimation of Time* (1959), present original researches. The point of view of genetic epistemology is developed by JEAN PIAGET, *Le développement de la notion de temps chez l'enfant* (1946; Eng. trans., *The Child's Conception of Time*, 1969).

Timur

A Turkic conqueror, of Islāmic faith, whose nomad hordes ranged from China to the Mediterranean, Timur (or Tamerlane) is remembered chiefly for the barbarity of his conquests and the cultural achievements of his dynasty.

By courtesy of the Topkapı Sarayı Museum, Istanbul

Timur, miniature, 16th century. In the Topkapı Sarayı Museum, Istanbul.

Timur was born in 1336 in an oasis valley between Samarkand (Samarqand) and the Hindu Kush (mountains) in Central Asia, a member of the Turkic Barlas clan, not of imperial Mongol origin. He first led a small nomad band and by guile and force of arms established dominion over the lands between the Oxus and Jaxartes rivers (Transoxiana) by the 1360s. He then, for three decades, led his mounted archers to subdue each state from Mongolia to the Mediterranean. He was the last of the mighty conquerors of Central Asia to achieve such military successes as leader of the nomad warrior lords, ruling both agricultural and pastoral peoples on an imperial scale. The poverty and desolation caused by campaigns gave rise to many legends, which in turn inspired such works as Marlowe's *Tamburlaine the Great.*

Military campaigns

By defeating the Ottoman sultan Bayezid at Angora (modern Ankara) in 1402 and thus preventing him from extending his domain into Europe, the fall of Constantinople and the death agony of Byzantium were delayed half a century by this Muslim nomad.

Timur's impact on the grand duchy of Moscow was also great, for he routed the Golden Horde, the descendants of the Mongol conqueror Genghis Khan, whose dominion stretched from Siberia to the Caucasus.

The name Timur Lenk signified Timur the Lame, a title of contempt used by his Persian enemies, which became Tamburlaine, or Tamerlane, in Europe. He was heir to a political, economic, and cultural heritage rooted in Central Asia. His nomad stock cultivated the military arts and discipline of Genghis Khan and, as mounted warriors, scorned the settled peasants. Irrespective of his ability, his victories were not fortuitous. He started his campaigns when remnants of the great Khan's empire were weakened by factional strife. Moreover, a long-term shift in the weather patterns of Central Asia brought rain to hitherto desert areas that provided fresh pasture for livestock, oases for the caravan trade, and bases for flourishing nomad societies.

Timur never took up a permanent abode. Continually in the saddle, he personally led his almost constantly campaigning forces, enduring extremes of desert heat and lacerating cold. When not campaigning he moved with his army according to season and grazing facilities. His court travelled with him, including his household of one or more of his nine wives and concubines. He strove to make his capital, Samarkand, the most splendid city in Asia, but when he visited it he stayed only a few days and then moved back to the pavilions of his encampment in the plains beyond the city.

In 1404 he returned to Transoxiana to celebrate his victories and to prepare his grandest campaign—that waged against the Ming dynasty in China. He assembled the entire forces of the steppes and all his booty. Here were the caravans of elephants and treasure from the plains of the Punjab and the sultanate of Delhi; the loot of the Volga region and the steppes; the tribute from Egypt of gold, ostriches, and a giraffe; florins from Byzantium; tapestries from Castile; master craftsmen from Damascus; scholars from Baghdad; captive Turks from Anatolia; merchants from the bazaars of the Mediterranean and from China. From Hormuz, on the Indian seaboard, to Chistopol, on the Volga, lay the ruins of intransigent towns and regions, with towers built by Timur's warriors from the skulls of their victims. Later in the year he set out to conquer China with an enormous expedition, still suffering from the excesses of his celebrations. He died in February 1405, near Chimkent, probably from a fever provoked by excessive drinking.

Personality and assessment

He was unlettered but not ignorant; his physical vigour was matched by his mental vitality. He delighted in the company of scholars and in playing chess. He could discuss with the leading scholars of Islām questions of history, religious dogma, and practical science. He was above all master of the military techniques developed by Genghis Khan, using every weapon in the military and diplomatic armory of the day. He never missed an opportunity to exploit the weakness (political, economic, or military) of the adversary or to use intrigue, treachery, and alliance to serve his purposes. The seeds of victory were sown among the ranks of the enemy by his agents before an engagement. He conducted sophisticated negotiations with both neighbouring and distant powers. which are recorded in diplomatic archives from England to China. In battle, mobility and surprise were his major weapons of attack, but this chess-playing nomad knew when to hold back and wait. His disposition was such that he could change course or target whenever circumstances provided superior alternatives. The French Orientalist René Grousset criticized Timur's campaigns on the grounds that they lacked geographical coherence, but this was irrelevant to flexible nomadic tactics. The demands

of Islām to wage war against the infidel, the needs of his kingdom in Central Asia, and the predatory appetites of the nomad lords provided Timur with the necessary elements for successful aggressive campaigns.

Few records of him have survived five centuries of strife, but those that have are richly varied. Court records of the campaigns were composed in Persian prose and Turkic verse. The great Arab historian Ibn Khaldun left an account of meetings with Timur at the time of the Syrian campaign. The Spanish ambassador describes his experiences at Timur's court in Samarkand, as does the Pope's envoy. Some of his diplomatic correspondence is preserved in the archives of Oriental and Western capitals, and there are collections of coins struck by Timur, showing his triangular device, in many museums. His living memorials are the Timurid monuments of Samarkand, covered in azure, turquoise, gold, and alabaster mosaics; these are dominated by the great cathedral mosque, ruined by an earthquake but still soaring to an immense fragment of dome. His mausoleum, the Gūr-e Amīr, is one of the gems of Islāmic art. Within the sepulchre he lies under a huge but broken slab of jade. Beside him are his chief divine and some of his descendants. The tomb was opened in 1941, having remained intact for half a millennium. The Soviet Archaeological Commission found the skeleton of a man who, though lame in both right limbs, must have been of powerful physique, tall for a Tatar, and of haughty bearing. With these remains there were bristles of a chestnut moustache. From this evidence a bust was reconstructed that probably gives a more realistic impression of his appearance than do the finely drawn features in the Persian miniatures.

Timur's successors

Sons and grandsons fought over the succession when the Chinese expedition disbanded, but Timur's dynasty survived in Central Asia for a century in spite of fratricidal strife. Samarkand became a centre of scholarship and science. It was here that Ulūgh Beg, his grandson, set up an observatory and drew up the astronomical tables that were later used by the English royal astronomer in the 17th century. During the Timurid renaissance of the 15th century, Herāt, southeast of Samarkand, became the home of the brilliant school of Persian miniaturists. At the beginning of the 16th century, when the dynasty ended in Central Asia, his descendant Bābur established himself in Kābul and then conquered Delhi, to found the Muslim line of Indian emperors known as the Great Mughals.

BIBLIOGRAPHY. The most scholarly study of the evidence relating to Timur's life is in the English translation of V.V. BARTHOLD, *Four Studies on the History of Central Asia*, vol. 1, *A Short History of Turkestan: History of Semirechyé* (1956), and vol. 2, *Ulugh-beg* (1958). Based substantially on this work is the account of his life given in HILDA HOOKHAM, *Tamburlaine, the Conqueror* (1962), which also contains the fullest available bibliography of works in English. Another account of Timur is given in HAROLD LAMB, *Tamerlane, the Earth Shaker* (1929).

(H.H.H.)

Tinamiformes

The Tinamiformes, or tinamous, are a group of ground-dwelling, chicken-like birds of Central and South America. They have a superficial resemblance to partridges and quail (gallinaceous birds) but are placed in a distinct order related to the much larger rheas. Tinamous long have interested scientists because of many peculiar features of their skeleton and biology that link them to the large flightless birds or ratites: the ostriches, emus, cassowaries, and rheas.

Tinamous, considered by hunters to be among the finest game birds in sport and in palatability, are heavily hunted in many parts of South America. Market hunting has been curtailed by law but is still practiced in some countries. Frozen tinamous from Argentina were formerly sold in the United States under the name South American quail. Although no species of tinamou was listed as endangered in the 1971 list of the International Union for the Conservation of Nature, habitat destruction and heavy hunting have reduced many populations.

General features. The 46 species of tinamous range in size from that of a small quail, about 15 centimetres (6 inches) long and about 150 grams (5 ounces) in weight, to that of a large grouse, 45 centimetres long and about 2 kilograms (4 pounds) in weight. Tinamous are rather uniform in body proportions and stance, resembling guinea fowl (Numididae). The head is small and the bill medium sized, relatively thin, and slightly downcurved. The long, slender neck is clothed in short feathers. The body is heavy, with a high rump outline from the enormous development of rump feathers, which generally hide the extremely short or even rudimentary tail. The short, rounded wings are inconspicuous on the standing bird; the primary flight feathers are hidden by the full plumage of the flanks. The bare legs are rather thick and of medium length. There are three short front toes, with the hindtoe elevated or absent.

The sexes are alike, except that the female is generally slightly heavier and has brighter coloration. The plumage coloration is highly concealing, in spotted or barred patterns of brown, gray, rufous, or tan, depending on the environment. The crested tinamous of the genus *Eudromia* have a long, slender crest that the bird directs forward when it is excited. The colour of the legs or of the bill is vivid and diagnostic in several species, such as the yellow-legged tinamous (*Crypturellus noctivagus*).

Protective coloration in spotted or barred patterns

Natural history. *Locomotion.* Highly adapted for ground dwelling, tinamous normally walk rapidly (especially the savanna species) and can run with amazing swiftness. If forced into extended running, however, as when chased by men or dogs, they tire quickly and are likely to stumble and fall. They are best able to escape notice by standing motionless with the neck extended or by quietly slipping away, making use of all available cover. Some species may crouch or feign death, rising in flight only when almost stepped upon. Small tinamous that live in open terrain sometimes hide in amimal holes, such as the burrows of armadillos.

The flight of tinamous is clumsy but swift and accompanied by an easily audible rumbling or whistling noise produced by the stiff, curved primaries. The elegant crested tinamou (*Eudromia elegans*) of the open tableland of Argentina alternates periods of flapping with short glides. When flushed, forest species sometimes collide with branches and tree trunks and may injure themselves. If forced to make several flights in short succession, tinamous soon become exhausted, apparently because of a low circulation rate, related in turn to the surprisingly small size of the heart and lungs. The flight muscles are well developed, but the circulatory system seems to be insufficient for sustained activity.

Unlike the gallinaceous birds, tinamous sleep on the ground at night. Exceptions are members of the genus *Tinamus*, which roost in trees, choosing thick, horizontal branches of tangled lianas high above ground.

Vocalizations. The voices of tinamous are among the strongest and most pleasant of any in the neotropics. They consist of loud, stereotyped, but melodious whistles, varying from the long and astonishingly songlike sequence of the brown tinamou (*Crypturellus obsoletus*) —astonishing because most relatives of the tinamous do not produce elaborate vocalizations—to the monosyllabic call of the cinereous tinamou (*C. cinereus*). The calls of the male and female are similar but discernibly different to the human ear. The female solitary tinamou (*Tinamus solitarius*) has a special call given during the time before egg laying, and another call is uttered by both sexes of this species after perching at dusk.

Habitat selection and food habits. Collectively, tinamous are adapted to many types of habitat, including dense woodland, thickets, open woodland, savanna, and even to the brunchgrass-covered plateaus of the high Andes, where they occupy the ecological niche held by the grouse in other parts of the world. In some forest regions as many as five species of tinamous coexist, inhabiting slightly different types of plant communities. The grassland tinamous do not occur north of the Amazon River; there the tinamou niche is occupied by the crested bobwhite (*Colinus cristatus*), a quail.

Seasonal variation in feeding

The food taken by tinamous varies with the season and habitat. In summer the red-winged tinamou (*Rhynchotus rufescens*), for example, eats mainly animal material—largely insects, but its mouth is large enough to swallow mice. In the stomach of one bird 707 termites were counted. In winter this species shifts over to vegetable food. It occasionally becomes a pest in agricultural areas, using its strong bill to dig up the roots of manioc, or cassava (*Manihot esculenta*). The small tinamous of the genus *Nothura* take mostly seeds, but the spotted tinamou (*Nothura maculosa*) occasionally eats ticks in pastures. The forest-inhabiting solitary tinamou prefers small fruits and berries, collected on the ground, but is not above taking a frog when it finds one. Members of the genus *Nothoprocta* are considered beneficial to agriculture because of their large consumption of insects. Young tinamous of all species are more dependent upon insects than are adults. Unlike the gallinaceous birds, tinamous do not scratch for food, as is evident by their weak toes and short nails; instead, they turn over leaves and other debris with the bill or dig with it.

Reproduction. Courtship behaviour has been described for only a few species of tinamous. Certain species have well-defined breeding periods, and others breed throughout the year. Courting birds are reported to raise the thickly feathered rump and display the brightly coloured undertail coverts. A similar display can be seen in a frightened *Crypturellus:* it presses the breast to the ground, raises the rump, spreads the terminal feathers like a fan, and exhibits the sharply marked undercoverts. Courting birds have been observed to chase each other around on the ground.

Multiple mating is the rule among tinamous, although a few species such as the ornate tinamou (*Nothoprocta ornata*) maintain stable pairs. All forms of polygamy exist, the conditions varying between and even within species. Many species have uneven sex ratios; preponderance of males seems to be more frequent, the ratio reaching four to one in the variegated tinamou (*Crypturellus variegatus*). The ratio in the ornate tinamou is about one to one. For the solitary tinamou, on the other hand, there appears to be a preponderance of females.

Parental behaviour by the male

The nest, a shallow depression in the ground, is constructed and defended by the male. The eggs are among the most beautiful of all bird eggs, always monochromatic and highly glazed. The colours include light chocolate brown, near black, purple, dark bluish green, light yellowish green, and gray when laid, but the shell pigments fade when exposed to light. One hen, or more, places her eggs in the nest of a male; when several females provide the eggs, the clutch may become quite large, eight to 16 eggs. Incubation, which lasts 19 to 20 days, is done entirely by the male, who broods and guides the chicks for several weeks after hatching. The chicks, blotched and streaked like the young of the rheas, are able to run as soon as they are hatched. When frightened, they squat and freeze, becoming almost invisible.

Paleontology and classification. There is no doubt that the tinamous represent one of the oldest stocks of birds on the South American continent. Three genera of fossil tinamous, of one species each, have been described from a single deposit from the upper Pliocene of Argentina (about 4,000,000 years ago). Most other fossil tinamous, mostly representing species still extant, have been found at scattered sites from the upper Pleistocene (less than 1,000,000 years ago) of South America.

Many authors have noted anatomical and biological resemblances between the tinamous and rheas, or nandus (Rheidae). The structure of the bony palate, an important feature in the taxonomy of ratite birds, quite clearly links the two groups, but most authorities prefer to maintain them as separate orders, Rheiformes and Tinamiformes, each with a single family, respectively, Rheidae and Tinamidae.

Tin Products and Production

Tin (chemical symbol Sn, from the Latin *stannum*) is a soft, bluish-silver-white element that is highly malleable and ductile but has little mechanical strength. The main uses of tin are as thin coatings on steel sheet to be used as containers; in alloys such as bronze, solder, bearing metals, pewter, and type metal; and as chemical compounds. The most common alloying elements are copper, antimony, lead, and bismuth.

Relatively rare despite its worldwide use, tin is found in the ore cassiterite, or tinstone, the oxide of tin, either in lodes or alluvial deposits. The chief producing countries are Malaysia, Bolivia, U.S.S.R., Thailand, China (mainland), and Indonesia. Tin exists in two crystalline forms; common or white tin (beta tin), which is stable at temperatures above 13.2° C (55° F), and gray tin (alpha tin), the transformation product. When white tin disintegrates into a gray tin in powder, the condition is known as tin pest or tin disease. Although the transformation temperature is moderate (13.2° C), the change from white to gray tin does not occur unless the metal is of great purity and has been exposed to temperatures well below 0° C (32° F). Small amounts of bismuth, antimony, and lead, the impurities normally present in commercial grades of tin, retard such transformation. Thus, the spontaneous appearance of gray tin at low temperatures is a rare occurrence.

Tin has a highly crystalline structure, demonstrated when a sheet of tin is bent: the squeaking sound (tin cry) is produced by the twisting of the crystals. White tin—its industrial form—crystallizes in a tetragonal structure, and gray tin in a diamond-type cubic structure. The atomic number of tin is 50; its atomic weight is 118.69; the specific gravity of white tin is 7.28 and of gray tin is 5.75; melting point is 231.9° C (449.4° F) and boiling point is 2,270° C (4,118° F). It appears in group IVa of the periodic table. Further information on the physical and chemical properties of tin can be found in the article CARBON GROUP ELEMENTS AND THEIR COMPOUNDS.

History. Tin, in the form of its alloy bronze, was widely used in ancient times. Bronze implements with tin contents of 10 to 18 percent dating from about 3500 BC have been found in Ur (Iraq). Tin mining was reported in Caucasia as early as 1500 BC, and later in Persia (now Iran), Great Britain, France, and Spain. The Phoenicians are believed to have played an important part in spreading the early bronze culture by their trade in tin, which their ships brought to the eastern Mediterranean from Great Britain and Spain at least as early as 1100 BC. The Cornish tin mines were famous by the time the Romans conquered Great Britain in the 1st century AD. Tin-producing areas gradually opened up in other parts of the world, in Malaya (now West Malaysia) and China in the 9th century and in Indonesia and Thailand in the 18th century. Bolivia, Republic of Zaire, and Nigeria became important sources by the early 20th century.

Early trade in tin

Pliny the Elder in AD 79 described two alloys of tin and lead, now commonly called solder. The Romans are known to have used solder and tinned-copper vessels. Tinned-iron vessels appeared in Bohemia in the 14th century. Tinned-steel sheet (tinplate) was manufactured in England and Saxony by the middle of the 17th century.

*Expressed in terms of metal obtainable from ore in metric tons (1 metric ton = 1.1023 short tons). †Preliminary. ‡U.S. Bureau of Mines estimate.
Source: U.S. Dept. of Interior, Bureau of Mines, *Minerals Yearbook, 1964, 1967, 1969, 1971 Preprint.*

The development of modern high-speed machinery and rail transportation was facilitated by the invention in 1839 of Babbitt metal, an alloy containing 89 parts of tin, 9 of antimony, and 2 of copper; the antimony combined with the tin to form hard particles in the otherwise soft matrix. The metal was developed to provide bearings for steam engines.

The 20th century has witnessed a proliferation of applications of tin in both pure and alloy form. Its principal uses, in addition to tinplate, include piping, wire, tubes, sheet, foil, and anodes for electroplating. By 1971 the world production was about 233,000 metric tons (257,000 tons), of which more than one-third was used for tinplate.

Economic importance. Ninety percent of the world's production of tin comes from nine countries, with the leading producer Malaysia. Table 1 shows the principal producers. Small tonnages are also produced in Canada, Japan, Portugal, and Spain. Tin is especially important to the economy of Bolivia and the producing countries in Southeast Asia.

The principal user of tin is the U.S., which imports about one-third of all the primary tin produced and augments this supply with secondary tin recovered from scrap. Industrial requirements for tin in the U.S.S.R. have been rising; in the early 1970s imports amounted to about 5,000 metric tons (5,510 tons) a year. Consumption of tin by countries is given in Table 2.

MINING, REFINING, AND RECOVERY

Cassiterite the major tin ore

The mineral cassiterite, or tin dioxide, is the major tin ore of the world. In lode deposits, as found in Bolivia, tin sulfide minerals such as stannite, teallite, cylindrite, and canfieldite are found with the cassiterite in granite and quartz.

Because cassiterite is both heavy and chemically resistant, it forms large placers, or residual concentrations, from which lighter, less stable materials have been removed by various natural forces. Alluvial placers, by far the largest in number and most productive, are deposited in streams where the water flow is slack. Almost 60 percent of the tin production in Southeast Asia comes from alluvial deposits, which yield about 0.4 pound of tin metal per cubic yard.

Residual placers form on top of a bedrock source of cassiterite as chemical decay removes other minerals. In Zaire, residual placers grade downward into weathered lodes and are mined either as placers or open-pit lodes.

Eluvial placers occur at the bottom of slopes after the gravity separation of cassiterite from the decayed tin-bearing rock debris that has been washed or wind blown down the slope. Marine placers lie beneath seawater. Seagoing dredges work such placers off the coasts of Thailand and Indonesia.

Mining techniques. Alluvial deposits lend themselves to mining by water-washing methods and gravity separation of the cassiterite. Lode deposits require the more complex operations, including rock blasting and crushing prior to gravity separation.

Placer tin is mined either by marine methods, using bucketline dredges and gravel pumps, or through land-mining techniques, especially open-pit methods. Bucketline dredges are quite similar to the floating dredges that are used to mine other types of placer deposits (see MINING AND QUARRYING). The tin-bearing mud is excavated at depths down to 140 feet (43 metres) below the water level. In either method, final concentration and removal of associated minerals is carried out on shore using a variety of techniques. Final concentrates, ready for direct smelting, contain almost pure cassiterite (between 70 and 77 percent tin).

In gravel-pump and hydraulic mining methods, water jets break up the tin-bearing material, and the material is then conveyed by various methods to the washing apparatus, or launders. In gravel-pump mining, a pump elevates the watery mud up to a wooden trough, or palong. In hydraulicking, a natural head of water flushes the ore down the gently sloping palong, trapping the heavy tin oxide particles behind wooden slats, or riffles. The preliminary rough concentrates are collected periodically and transferred to dressing sheds for final concentration. In open-pit operations the material is excavated dry by power shovels and transported via conveyor belt to a washing plant and dressing shed.

Underground lode deposits can be found at high altitudes (12,000 to 15,000 feet [3,700 to 4,600 metres] above sea level in Bolivia) or low ones (down to 1,300 feet [400 metres] below sea level, as in Cornwall, England). The lodes are reached by lateral passages driven into the side of a mountain or by vertical shafts. The ore is broken up by blasting and drilling and then taken above ground for further crushing and grinding. The finely divided ore is then concentrated by the same types of separations used for alluvial deposits.

Ore beneficiation. Concentrates from alluvial deposits are smelted without further beneficiation, or further concentration through refinement. Lode deposits of only 40 to 60 percent tin, on the other hand, must be roasted and acid-leached (see below) to remove sulfur and other metallic impurities.

Roasting. Typically, the crushed concentrates are loaded into the top of a six-hearth so-called Herreshoff furnace and are moved down to succeeding lower hearths

by rotating rakes (rabble arms) and the force of gravity. Temperatures inside the gas-heated furnace range from 315° C (600° F) in the lowest discharge hearth to 760° C (1,400° F) in the middle hearths. Most of the roasting is done in two-hour stages between 650° C (1,200° F) and 760° C (1,400° F). This step of the process removes most of the sulfur and some of the arsenic; the sulfides of iron, copper, bismuth, and zinc are converted to oxide; and lead sulfide is oxidized to sulfate. Adding 1 to 5 percent salt removes some of the volatile chlorides of lead, bismuth, arsenic, antimony, and silver in the fume; the chlorides remaining are water soluble.

Some Bolivian ores contain up to 9 percent tungsten, which is recovered by mixing sodium carbonate with the roasted concentrate and heating it to 600° C (1,100° F) to form sodium tungstate, a water-soluble compound from which the tungsten can be recovered by evaporation.

Acid leaching. The roasted concentrates are leached with hydrochloric acid to remove most of the iron, zinc, lead, silver, bismuth, and copper impurities. After washing and drying, the purified concentrate is ready for smelting.

Problems of tin metallurgy

Smelting. The metallurgy of tin is comparatively simple, though it does present a few problems: (1) the temperature required to reduce tin dioxide with carbon also reduces the oxides of other metals in the ore (reduced iron, for example, forms hard compounds with tin); (2) since tin at smelting temperatures is extremely fluid, it finds the most minute openings for escape and soaks into porous refractories; (3) tin reacts with furnace linings, thus producing slags that must be retreated.

Because of those problems and the resulting high tin content of the slag, smelting is accomplished in two stages: (1) primary smelting in either reverberatory or blast furnaces and (2) retreatment of slags (unwanted hard compounds of tin and iron) and refinery dross. Most large tin-smelting plants use reverberatory furnaces for both primary smelting and retreatment processes. Operations are more easily controlled, and cleaner slags are produced than in the older blast furnaces (see METALLURGY). Loss of tin dust is much smaller when the reverberatory furnace is used to smelt finely divided ores and concentrates.

The reverberatory tin-smelting furnace is a relatively new and special type of blast furnace, in which heat is reflected from the roof of the furnace onto the material. Thus, the material does not come into contact with the fuel. The hearth slopes toward a taphole that is near the centre and to one side and low enough to drain the furnace completely. The size of the hearth varies, the largest being 30 to 40 feet (9 to 12 metres) long and 12 to 15 feet (3.7 to 4.6 metres) wide. The larger reverberatory furnaces will take an 8- to 15-ton load that contains tin concentrates, 15 to 20 percent anthracite, and smaller amounts of limestone, slag, sand, and by-products from the refining steps.

Batch operations. Tin smelting is a batch operation in which one load is smelted and tapped before the next is added. The furnaces are operated at 1,200° to 1,300° C (2,200° to 2,400° F); the time for each load is 10 to 12 hours. The batch is stirred at intervals. It is customary to limit the amount of reducing agent in the primary furnace and to permit a considerable amount of tin to flow out as slag. This practice produces metallic tin low in iron.

The completed batch is tapped into a settler, from which the slag usually overflows into cast-iron pots. The molten tin is cast from the bottom of the settler into slabs of about 75 pounds (34 kilograms) and is ready for further refining.

The slag, containing 10 to 25 percent tin, is resmelted in the same kind of furnace used for smelting the ore. But a higher temperature, up to 1,480° C (2,700° F), is required because the reduction of the tin silicate in the slag is more difficult than the reduction of the tin oxide in the ore. Fine anthracite coal serves as the reducing agent; limestone flux and metallic iron may be added to aid in the reduction. The aim is to produce a discardable slag containing no more than 2 percent tin. During the resmelting considerable iron–tin compound is formed and returned to the system.

Electric smelting. Electric furnace smelting was first used in 1934 at Geomines in Shaba (formerly Katanga), now in Zaire. The modern three-phase Héroult electric-arc furnaces, rated at 1,000 kilovolt-amperes, are cylindrical shells lined first with insulating brick and then with firebrick. The graphite electrodes are 1.3 feet (40 centimetres) in diameter (see METALLURGY).

Refining. The crude tin produced by smelting must be refined by further heat or by an electrolytic process. Heat treatment includes two steps: liquation and boiling.

Liquation and boiling

In liquation, crude tin placed on the sloping hearth of a small reverberatory furnace is heated to just above its melting point. The fluid tin runs into a boiling kettle, while metals whose melting points are sufficiently higher than that of tin remain on the hearth as dross. Iron is largely removed, and arsenic, antimony, and copper are partly removed; but lead and bismuth, also with low melting points, flow with the tin into the kettle, where the final refining (boiling) is carried out.

The molten tin in the boiling kettle is agitated with steam, compressed air, or poles of green wood, which produce steam. The remaining impurities form a light scum, which is removed and recirculated through the smelting cycle. The pure tin is cast in iron molds, usually in the form of 100-pound (45-kilogram) ingots. The purity of grade A tin is guaranteed to exceed 99.8 percent tin.

Electrolytic refining. Electrolytic refining produces a purer grade of tin than that obtained by fuel-fired heat refining; but costs are higher and the demand for pure grades (99.99+ percent) is low. One modern electrorefining facility has developed an economical method by processing low-grade concentrates. First it upgrades them by roasting, leaching, and fire refining, to give a crude tin of approximately 93 percent tin, 3 percent antimony, 2 percent lead, 1 percent arsenic, and 0.5 percent copper. The final electrolytic process produces a metal in the range of 99.97 percent tin.

Recovery from scrap. Several thousand tons of tin are recovered each year from metal scrap, mostly in the form of tin-bearing alloys and clean tinplate clippings. In the U.S. secondary tin metal recovered from scrap may average 3,050 metric tons annually, while 18,300 metric tons of tin are recovered in the form of tin alloys and tin compounds. Other major consuming countries have similar salvage programs.

Detinning tinplate scrap

In salvage operations, often called detinning, clean tinplate scrap is placed in perforated steel-plate drums that revolve in a vat of hot caustic soda solution, containing an oxidant such as sodium nitrate or nitrite. Steam coils maintain a temperature of 96° to 99° C (205° to 210° F). The tin dissolves, forming sodium stannate in solution, which can be treated in three ways: (1) evaporation of the solution to crystallize the sodium stannate; (2) electrolysis to recover tin metal; or (3) acidification by carbon dioxide, sulfuric acid, or acidic gases to precipitate tin hydrate that can be further processed to tin oxide, smelted to tin metal, or converted to tin chemicals. About 711,000 metric tons (784,000 tons) of tinplate scrap are treated in this way annually in the United States.

Tin-bearing alloy scrap is handled by secondary smelters as part of the production of primary metals and alloys. Lead refineries recover metals from solder and tin dross, Babbitt metal, and type metal. Copper refineries rework scrap tin, bronze, and tin-containing brass.

METALLIC TIN PRODUCTS

Smelters control purity of tin between 99.8 and 99.98 percent; about 90 percent of all tin produced is Grade A, which has a minimum purity of 99.8 percent. Ingots of 28, 56, and 100 pounds are purchased from metal brokers by steel mills, copper and lead refiners, solder and bearing manufacturers, and metal and alloy dealers. Smaller consumers may purchase individual ingots of pure or alloyed tin from metal dealers; or they may purchase fabricated products such as sheet, tube, or powder. The

primary industrial use of tin is for tinplate and tin coatings on iron, copper, and other metals; other uses are as alloys, chemical compounds, and pure tin products.

Pure metal. As a first step in the production of tin products, ingots often must be remelted. Tin, because of its low melting point, can be remelted in cast-iron or steel pots, which resist corrosion by molten tin. The tin may be poured, ladled, or pumped into open molds or hinged molds of cast iron, sand, plaster, rubber, or other materials. Shrinkage on solidification is about 3 percent. Cast bars or slabs are readily rolled into sheet and foil, extruded into tubes and pipe, or drawn into wire. Tin is pliable during cold-working and does not harden when worked.

Tin pipe. Molten tin is cast into a cylindrical tubing mold that forms the chamber of an extrusion machine. After the metal solidifies, a ram descends into the chamber and extrudes the metal through a die. The most common diameter sizes for tubes are from about 0.25 inch (6.3 millimetres) up to about 0.75 inch (19 millimetres).

Tin piping is used for conveying distilled water and for draft-beer tubing from barrels to counter taps. Ancillary equipment for these operations requires tin-lined brass valves and fittings. In lining valves, the tin metal is cast into the fluxed, cleaned body, and the openings are machined out. Brass pipe can be tin-lined by inserting tin tubing into the pipe and drawing a steel ball through the tube to expand the tin against the wall in a tight bond.

Tin wire. Cylindrical billets with a diameter of 2 to 3 inches (51 to 76 millimetres) are extruded as wire from a press at a diameter of about $\frac{3}{16}$ inch (4.8 millimetres). This wire can be reduced on normal wiredrawing machines to as fine as 0.2 millimetre. Tin wire is used for electrical fuses and other special purposes.

Collapsible tubes. Collapsible tubes of tin, in which shaving cream, toothpaste, and other pastelike materials are packaged, are formed by impact extrusion. Cone-shaped slugs or disks of tin containing about 0.2 percent copper as a hardener are oiled and fed into the die of the press, which is capable of exerting hundreds of tons of pressure per square inch. The ram of the press descends on the slug, squeezing tin out through the narrow annulus, or ringlike opening, of the die and forming a tube enveloping the ram. The tin-clad ram then returns upward out of the die, swings forward, and is simultaneously cleared of the tin by a blast of compressed air. The tubes are hand-stacked vertically over close-fitting pegs on a conveyor belt. The nozzles may be formed with their screw threads in this same operation. The tubes are printed and dried while still on the pegs.

Impact extrusion

Collapsible tubes are light; a body of 4½ inches (114 millimetres) in length and 1 inch (25 millimetres) in diameter weighs only $\frac{1}{40}$ pound (12 grams). Wall thickness ranges from 0.005 to 0.01 inch (0.13 to 0.25 millimetre).

Tin-coated lead tubes, cheaper than all-tin, can also be impact extruded from slugs. A slab of lead is placed between two sheets of tinfoil of a thickness proportional to that desired on the wall of the tubes. Two roll passes weld the tin to the lead. The extrusion process is the same as for all-tin tubes.

Tin sheet and foil. In producing sheet and foil, tin is cast into slabs in either open or book molds. The slabs are rolled soon after casting because the grain size can enlarge on standing. The first pass through the rollers reduces thickness to one-half. The next pass, which sometimes is made across the direction of the first rolling, reduces the thickness by one-half again. Successive reductions to sheet or foil are about nine-tenths on each pass. On the way to the reelers, the foil passes over high-speed polishing rollers. A smear of pure olive oil serves as a lubricant in the early stages.

Tin anodes. Tin anodes for electroplating processes can be cast, extruded, or rolled from billets to any shape or size. Connector hooks are attached by drilling and tapping. Large, 9,000-pound anodes for tinplate production are cast in iron molds.

Tin powder. Tin powder is produced by spraying molten tin from nozzles under slight pressure in a vertical tower in which an inert atmosphere is maintained. The tower is sufficiently high to allow the atomized powder to solidify and cool in its downward path. The fine powder is graded and classified by screening.

Tin in glass manufacture. Clear, flat glass is produced by allowing molten glass to solidify while it floats on a pool of molten tin, avoiding the costly polishing and grinding required in making plate glass (see GLASS PRODUCTS AND PRODUCTION).

Tinplate. Tinplate is a low-carbon steel sheet (see STEEL PRODUCTION) thinly coated with pure tin. The strength and formability of steel are combined with the corrosion resistance, solderability, and appearance of tin. Tinplate is ductile and can be drawn and folded into complicated shapes. The tin surface can be enamelled, lacquered, or painted. Tinplate is used for food cans because tin is nontoxic and resists corrosive attack by air and by food acids. Oxygen or dry air combines with tin to form an invisible and protective oxide film on the surface that thickens as the temperature is raised. In vacuum packing (in the absence of oxygen), tin resists a wide range of acids by retaining a film of hydrogen.

World production of tinplate in 1968 was more than 11,000,000 metric tons (12,000,000 tons) containing about 75,000 tons of pure tin. About 93 percent of world tinplate production is by electrolytic tinning and 7 percent by hot-dip tinning.

Electrolytic tinning. A coating of tin can be deposited on most metals in high-speed electroplating processes. Tin alloy coatings can be achieved by including salts of other metals such as copper, lead, zinc, cadmium, and nickel in the electrolyte. The world's first commercial electrolytic tinplate line was installed at the United States Steel Corp. plant in Gary, Indiana, in 1937.

In the halogen tin-plating process, using the halogen compounds stannous chloride and alkali fluorides with addition agents as the electrolyte, the sheet travels at 1,500 to 2,000 feet per minute horizontally instead of following vertical paths in individual plating vats or cells. One side of the sheet is plated on one level; the direction is then reversed, and the other side is plated on an upper level. An alkaline process is based on an alkaline solution of sodium stannate and sodium hydroxide that functions as the electrolyte. The plating speed (500 feet per minute) is lower than that in the other processes. The Ferrostan process uses a stannous sulfate bath containing phenol sulfonic acid and addition agents.

The cold-reduced steel is handled as a continuous band through all operations, including electrolytic cleaning, treatment with dilute acid (light pickling), electrodeposition of the tin coating, rinsing and drying, brightening of the dull matte coating by induction heating, chromate treatment, rinsing and drying, oiling with a thin film of dioctyl sebacate, and coiling. Shipped coils weigh up to 20,000 pounds (9,000 kilograms). Coils may be diverted to shears that cut the finished tinplate into sheets 20 × 14 inches (51 × 36 centimetres).

Thickness of electrolytic tinplate

Electrolytic tinplate is produced in five grades, with tin-coating thickness ranging from 0.000015 inch (0.00038 millimetre) on both sides of 0.25-pound (0.11-kilogram) tinplate to 0.00006-inch (0.0015 millimetre) on both sides of one-pound (0.45-kilogram) tinplate. Differential tinplate with a heavier coating on the surface that is to form the inner side of a container in which corrosive foods are to be packed is also produced.

Double-reduced tinplate, introduced in the 1960s, involves a base sheet that has been cold-rolled a second time to reduce its thickness to about 0.006 inch (0.15 millimetre) and bring out the inherent strength of the steel.

Hot-dip tinning. Molten tin wets and adheres to most metals and is highly fluid, draining rapidly from an article before solidification and leaving a thin, even coating that is bright, lustrous, and nontoxic. The coating protects the underlying metal from oxidation and chemical attack from weak acids, alkalies, and electrolytes; the coating also has lubricating properties and aids in forming and drawing operations; and the tin coating makes possible the joining of metals that are difficult to solder. The hot-dip process, though it is used to make less than 1

percent of the total tinplate produced in the U.S., is important in other countries.

A modern hot-tinning unit comprises a thermostatically controlled vessel of molten tin held at about 316° C (600° F). A submerged mechanism of rollers and guides conducts clean, cold-reduced steel sheets downward through a layer of zinc chloride flux into the tin and then upward and out of the tin through a thick covering layer of palm oil. The sheets are subjected to the squeegeeing action of immersed tinned-steel rollers that regulate coating thickness. The tinned sheets are cooled by an air blast and then cleaned and polished, usually by a combination of washing with alkaline detergent and dry cleaning.

Hot-dip tinplate is used primarily for packaging corrosive foods such as acid fruits. It has a minimum tin-coating thickness of 1.25 pound per 31,360 square inches. Special grades with coating thickness up to three pounds of tin per 31,360 square inches are produced for noncontainer uses such as gas meters, light engineering parts, kitchen utensils, and electrical equipment.

Other tin-coated articles. Fabricated articles made of cast iron, steel, copper, and copper alloys are given a smooth, bright tin coating by immersion in liquid tin. Coatings also may be electroplated, using either acid or alkaline electrolytes. The dull-plated tin can be brightened in hot oil, but proprietary bright-tinning processes are in commercial use. The coating thickness on fabricated articles is usually in the range of 0.0001 to 0.002 inch, depending on requirements and corrosion protection desired.

Varieties of tin coatings

For tin-coated copper vessels and cast-iron bearing shells, liquid tin is poured onto the surface and wiped smooth with a cloth pad. Copper tubing and aluminum pistons can be protected from corrosion with a thin tin coating applied by immersion in a solution of tin salts.

Alloys and alloy-coated products. Tin is easily alloyed. Copper, antimony, bismuth, cadmium, and silver when alloyed to tin increase its hardness, mechanical strength, corrosion resistance, and workability. High-tin alloys are noted for their conformability, low coefficient of friction, retention of oil films on the surface, and good casting properties. When tin is a minor constituent in alloys, it can provide specific or unusual effects. (For bronze, bell metal, and gunmetal see COPPER PRODUCTS AND PRODUCTION. The principal constituent of those alloys is copper.)

Solder. After tinplate, the largest use of tin is in solders for joining metals at temperatures below 427° C (800° F); tin also is used in filler metals (materials for filling in holes and dents in automobile bodies) that melt well below that temperature. Tin–lead alloy solders constitute the largest portion of all solders in use. Alloys ranging from 2 to 70 percent tin, with the balance lead, and melting between 183° and 312° C (361° and 594° F) are used for joining copper, brass, nickel–silver, iron, tinplate, and other coated metals. For special purposes, tin–antimony, tin–antimony–lead, tin–silver, tin–zinc, and lead–tin–silver alloys are used. Special low-melting alloys (fusible alloys) melting below 150° C (300° F) contain bismuth, cadmium, tin, lead, and indium. The composition, melting characteristics, and applications of commonly used solders are given in the article WELDING, BRAZING, AND SOLDERING. The melting characteristics are given in terms of the temperature below which the alloy is completely solid (its solidus) and above which it is completely molten (its liquidus). With the melting points of both tin and lead low and fairly close together, they can be alloyed in iron pots or crucibles.

Because of the large differences in the specific gravities of tin and lead (7.28 and 11.34, respectively), mechanical stirring is necessary throughout melting and casting to keep the lead from sinking to the bottom. Molten solder may be poured into separate molds to solidify into ingots or may be cast continuously by feeding the molten metal into a water-cooled graphite die at such a rate that billets are produced without interruption. A travelling saw divides the issuing billet into convenient lengths. Billets may be remelted to form solder strip that can be rolled to solder foil and then cut to any shape. Short billets may be extruded through a die, coiled, and drawn to form wire solder in sizes ranging in diameter from 0.128 inch (10 standard wire gauge) to 0.028 inch (22 standard wire gauge).

Hollow wire or tubes of various shapes, diameters, and configurations are manufactured containing a flux core that is introduced as a warm liquid during drawing and solidifies when cold. The flux can be noncorrosive or corrosive.

Solder also is made in powder form as paste solder, an alloy suspended in a mixture of emulsifying material and flux. It is particularly useful in mechanized soldering, in which premeasured quantities of solder and flux are applied automatically.

Fusible alloys. Alloys that melt at temperatures below the melting point of tin are formed mainly with metals of similarly low melting points, such as bismuth, cadmium, lead, and indium. They are termed fusible alloys because they melt rapidly when the melting temperature is reached. Two groups of alloys stand out. The first, containing 15.5 percent tin, 52.5 percent bismuth, and 32 percent lead, melts at 96° C (205° F); the second, containing 13.1 percent tin, 49.5 percent bismuth, 27.3 percent lead, and 10.1 percent cadmium, melts at 70° C (158° F).

Contraction of alloys during solidification results in castings of dimensions smaller than those of the mold. But alloys containing bismuth and antimony may expand as well as contract during solidification, depending on the proportion of the metals present. Fusible alloys that are dimensionally stable with the mold are suitable for making foundry patterns and dies. Fusible alloys play a key role in safety devices that operate when the surrounding temperature reaches their melting points—*e.g.*, fire alarms, water-sprinkler devices, and fire-door closers. Other uses include: low-temperature soldering, to avoid damaging heat-sensitive materials; and tube bending, in which the alloy is poured into the tube, which is then bent and the alloy melted out.

Babbitt metal. Babbitt metal (tin and lead-base bearing metals or white-metal bearing alloys) serves as the lining for bearing shells of cast iron, steel, bronze, or gunmetal. Babbitt metal, which is white in colour and has very low friction, may be made of: (1) high-tin alloys that are substantially lead-free; (2) intermediate alloys in which some tin is replaced by lead; and (3) high-lead alloys. All are low-melting materials consisting of hard compounds in a soft matrix. The compounds found in each group are similar; it is in the composition and properties of the matrix that they differ. Typical compositions are given in Table 3. In compounding bearing metal, the tin is melted first; the copper and antimony strips are then dipped in tinning flux and lowered into the molten tin, where they dissolve below 400° C (752° F) without oxidation. Sometimes master alloys, 50 percent antimony and 10 percent copper, instead are immersed in the tin. When lead is added, the molten metals must be well stirred. Users of Babbitt metal usually buy ingots of the required composition and melt them in iron kettles from which they can ladle or pump the molten alloy.

Lining bearing shells

The bearing shell or backing is precoated with tin for tin-base bearings or with lead–tin for lead-base bearings. While the coating is still molten, the white metal is cast onto the backing and allowed to solidify from the bond inward to prevent contraction cavities at the bond and to restrict the growth of intermetallic compound (alloy layer) at the interface between the bearing shell and the white metal alloy. Pouring temperatures are usually 50° C (122° F) above the point at which the metal is completely molten. The lining is machined to a mirror-bright finish and specified thickness.

High-tin alloy bearings are used for high unit loads and high operating temperatures. They hold oil films and readily adapt their shapes to conform to the shaft. Foreign matter not carried away by the lubricant is embedded below the surface and rendered harmless. Lead-base alloy bearings are prone to separate into elemental lead and tin and have a lower thermal conductivity than tin-base bearings.

Table 3: Composition and Uses of Tin Alloys

trade name or type	composition (percent)											uses
	Cu	Sn	Pb	Sb	Ni	Al	Si	Ti	Zr	Cr	Fe	
Tin base and lead base												
Babbitt metal (grade 1)	4.5	91		4.5								turbines, centrifugal pumps
Babbitt metal (grade 2)	3.5	89		7.5								automotive bearings
Babbitt metal (grade 3)	8	84		8								
Babbitt metal (grade 4)	3	75	10	12								
Babbitt metal (grade 5)	2	65	18	15								bearings
Jeweler's white metal		92		8								costume jewelry
Pewter (casting)	0.5	92		7.5								plates, domestic utensils
Pewter (spinning)	2	91		7								tea and coffee service, trays, tankards
Pewter (soft)	2	95		3								
Britannia metal	1–3	90–95		4–8								castings, ornamental objects
Linotype		3–5	balance	11–12								type metal
Stereotype		6–8	balance	13–15								type metal
Monotype		7–8	balance	15–17								type metal
Foundry type		10–13	balance	20–25								type metal
Aluminum base												
Alcoa 80S	1	6.5			0.5	balance	1.5					solid bearings subject to high loads
Aluminum–Tin	1	20				balance						automotive bearings-connecting rod, main camshaft
Miscellaneous												
Alpha titanium		2.5				5		balance				structural material for aircraft and spacecraft
Zircaloy-2		1.5			0.05				balance	0.10	0.12	nuclear power reactor fuel cladding
Superconducting Nb_3Sn		33.4										solenoid magnets
Dental amalgam*		12										fillings

*Plus mercury, silver balance.

Aluminum–tin bearing alloys. Aluminum–tin bearing alloys are of two types. The 6.5 percent tin alloy, usually the material in sand or gravity die castings, is rarely bonded to a stronger backing. Its high fatigue strength enables it to carry higher fluctuating loads than either the tin-base or softer copper–lead alloys, but its ability to embed foreign matter is low. The finished bearings, usually electroplated with tin, serve as connecting rod and main bearings for tractors and heavy-duty gasoline and diesel engines.

The other type of aluminum–tin alloy (20 percent tin) is used for connecting rod, main, and camshaft bearings for passenger cars, especially in Europe. This type of bearing withstands high loads and fatigue at elevated temperatures. The aluminum–tin alloy in sheet form can be bonded directly to a soft steel backing. Both surfaces are scratchbrushed and rolled together in a single pass so that the total reduction is at least 45 percent. By annealing for one hour at 350° C (662° F), the tin is distributed throughout the aluminum matrix in discrete particles and provides a constant bearing surface.

Pewter. Pewter is an alloy of tin hardened with antimony and copper. Modern pewter compositions are given in Table 3. The best grades contain no lead.

Pewter played an important part in the development of civilization as a medium of artistic expression and as a material from which domestic utensils were fashioned (see METALWORK). Pewter exceeds most other metals in ductility and ease of working. It may be stretched, compressed, and bent into almost any desired shape; and it does not harden sufficiently on cold working with tools to make annealing necessary. Pewter is melted and cast like other tin-base alloys. Slabs for rolling can be cast in open or hinged molds, which may be of cast iron, plaster of paris, wood, papier-mâché, or rubber. Articles also can be cast in sections and assembled by soldering.

Pewter ingots are rolled to sheet, which is a starting material for articles made by simple forming, spinning (forming while rapidly rotating), stretching, or hammering. Modern pewter can be given a mirror-bright finish or a soft satin sheen by polishing, and it retains its brightness indefinitely. It is used for tankards, domestic utensils, plates, trays, and tea and coffee services. Reproductions of objects from the 17th and 18th centuries are often made, some cast from the original molds.

Type metal. Type metal compositions are shown in Table 3. Different kinds of typecasting and printing processes each require special alloy properties that are obtained by altering, within fairly narrow limits, the proportions of tin, antimony, and lead (see PRINTING).

Alloyed cast iron. Alloyed cast iron, with a 0.1 percent tin content, is used in automotive engine blocks, transmissions, and heat-resistant applications. The tin acts as a stabilizer. The iron has a higher and more uniform hardness, better machinability, and better wear resistance with tin. The pure tin is added to the ladle in the form of shot or pieces of wire just before casting.

Tin as a stabilizer of cast iron

Miscellaneous alloys. Alpha-type titanium alloys are particularly suitable for structural materials in aircraft and spacecraft because of their light weight, strength, weldability, and resistance to creep.

Zircaloy-2, an alloy of tin and zirconium, is technically feasible for use in all nuclear power reactors using pressurized water as a coolant and moderator. The low neutron absorption of zirconium makes it an attractive structural material and fuel cladding for nuclear power reactors, but it has low strength and highly variable corrosion behaviour. The addition of 1.5 percent tin overcomes these disadvantages.

Niobium–tin is important in the construction of high-field superconducting solenoid magnets. The alloys are excellent superconductive materials at low temperatures.

Tin-alloy-coated articles. Coatings of tin–lead alloys containing 63 percent or more tin can be applied to articles by hot dipping and by electrodeposition from a special electrolyte. The solderability of the coating is useful, particularly in the electronics industry, for parts made of copper, brass, or steel. Tin-alloy coatings on fabricated articles are generally harder, brighter, and more resistant to corrosion than pure tin coatings.

Tin–copper-coated articles (12 percent tin) have the appearance of 24-karat gold. Tin–zinc coated articles (75 percent tin) are readily solderable and have excellent corrosion resistance. Tin–nickel plated articles (66 percent tin) have decorative and functional uses. The coating is used to resist etching of certain areas in the manufacture of printed circuits.

Terneplate is low-carbon steel sheet or strip coated with terne metal, a lead–tin alloy. Lead alone does not alloy with iron, but, when from 7 to 20 percent tin is added, the

Terne metal

tin readily wets the steel and forms a solid solution with the lead. A composition of 80 to 85 percent lead and 20 to 15 percent tin is usually preferred. The clean, cold-reduced, mild-steel strip is coated by hot dipping, as in the tin-plating process, except at a higher temperature (370° C [700° F]). Its main uses are for roofing materials, automotive parts, casket linings, and packaging for paints and greases.

CHEMICAL COMPOUNDS

Tin compounds have been known since 1605 when Andreas Libavius, the 16th-century German author of the first textbook on chemistry, described a method of preparing tin tetrachloride. This compound was widely used for weighting silk fabrics until the 1930s, when synthetic fibres supplanted silk. Large amounts of white tin oxide were produced to give opacity to pure white ceramic glazes on bathroom fixtures until cheaper substitutes, such as zirconium oxide, appeared.

In the early 1940s, production of inorganic tin chemicals surged with the invention of the continuous electrolytic tin-plating processes for can stock. In the same period, the organotin stabilizer was invented. Organotin compounds, in which a tin atom carries one, two, three, or four alkyl or aryl groups, are prepared from tin tetraalkyl or tetraaryl compounds. When about 2 percent of an organotin compound is added during the heat processing of clear polyvinyl chloride polymers, decomposition and darkening are prevented, and the polyvinyl chloride is stabilized against degradation by sunlight. In the early 1970s, about 10 percent of the total production of vinyl chloride polymers was stabilized with tin compounds.

In the 1950s a Dutch chemist, G.J.M. Van der Kerk, discovered that trialkyltin and triaryltin compounds had biocidal and fungicidal properties; he concluded that toxicity results when the tin atom combines directly with three carbon atoms and reaches a maximum when the total number of carbon atoms in the molecule is about 12. Hundreds of tons of tin compounds have come into use as industrial fungicides in wood preservation, papermaking, and textile manufacture; as disinfectants in hospitals; as antifoulants for paint; and as agricultural sprays for root crops, fruit, and nut trees.

About 60 percent of tin chemicals are by-products of the process of detinning tinplate scrap. The United States, Great Britain, West Germany, The Netherlands, and Japan are the principal producers of tin chemicals.

Inorganic compounds. About 15 inorganic tin compounds of industrial importance are produced from either pure tin or basic tin compounds—sodium stannate and hydrated tin oxide—obtained from detinning tinplate scrap. Sodium stannate and hydrated tin oxide react with hydrochloric acid to form stannous chloride, an important intermediate in making other tin compounds.

Stannous chloride. Stannous chloride is made by dissolving granular tin in hydrochloric acid. When the solution is evaporated, crystals of hydrated stannous chloride are formed. The hydrate melts and decomposes at 38° C (100° F).

Uses of stannous chloride

Stannous chloride is a constituent of tin-plating electrolytes, the tin–nickel-alloy-plating electrolytes, and immersion-tinning processes. It is used as an activator for plating plastics and for silvering mirrors, an additive to drilling muds, an antisludge agent for oils, a stabilizer of perfume in soaps, and a catalyst in organic reactions. Careful neutralization of a solution of stannous chloride precipitates stannous oxide, a starting material for other tin compounds.

Stannous fluoborate. When stannous oxide is dissolved in fluoboric acid, stannous fluoborate is produced. This product, a salt, is sold commercially as a 47-percent solution for use in preparing the tin fluoborate electrolyte used in tin-plating.

Stannous fluoride. Stannous fluoride is obtained by dissolving stannous oxide in hydrofluoric acid. The chief use of this salt is in toothpaste formulations for preventing demineralization of teeth.

Stannous oxide. Stannous oxide is prepared by precipitating the hydrate from a solution of stannous chloride with alkali carbonate. Its principal use is as an intermediate in preparing other stannous chemicals, such as stannous fluoride. It also is essential to the manufacture of gold–tin and copper–tin ruby glass.

Stannous pyrophosphate. Stannous chloride and sodium pyrophosphate combine to form the salt stannous pyrophosphate, which acts as a polishing agent in fluoride toothpastes and plays a part in electroplating with copper–tin alloy (bronze).

Stannous sulfate. There are two methods of producing stannous sulfate: (1) from stannous oxide and sulfuric acid, or (2) by reacting granulated tin with an excess of sulfuric acid at 100° C (212° F) and evaporating in a vacuum. Stannous sulfate is the principal ingredient in the Ferrostan electroplating solution (see above *Electrolytic tinning*). It has found a large use in "liquor finishing," in which a copper–tin coating is applied to steel wire by immersion in a solution of stannous sulfate and copper sulfate. The coating acts as a lubricant in drawing the wire to thinner gauges and protects the wire from oxidation in storage.

Stannic bromide. The reaction of tin with bromine produces stannic bromide, which is thermally stable and can be purified by distillation at a boiling point of 202° C (396° F). Because of its low melting point (31° C [88° F]) and the high specific gravity (3.34 at 35° C [95° F]) of the compound it is used in heavy-media separation of minerals in metallurgical processes.

Stannic chloride. The commercial preparation of stannic chloride is by direct chlorination of tin under pressure. The chlorine must be dry and the temperature in the vessel not over 38° C (100° F). The liquid is purified by distillation and can be shipped in steel drums of special design to keep out moisture.

Stannic chloride (with pyrophosphates) acts as a replacement for the gum extracted during the processing of silk (weighting silk). It acts as a colour fixative in the dyeing of silk. Its largest application in the early 1970s was in the preparation of other inorganic tin compounds and organotin compounds. When sprayed on glass and fired, it forms a conductive coating and strengthens the glass. Minor uses are in stabilizing the perfume in soaps, as an additive to diesel oils and transformer oils, and in making blueprint paper.

Uses of stannic chloride

Stannic oxide. In the industrial production of stannic oxide, tin metal is atomized and the finely divided metal burned. It is also prepared by calcining (heating to a high temperature) the hydrated oxide obtained by the hydrolysis (by boiling or by treatment with weak acid) of sodium stannate.

The soft white colour of fired porcelain enamel coatings opacified with stannic oxide is considered most desirable for the highest quality finish on bathtubs and other vitreous products. Stannic oxide is also used in making coloured ceramic glazes such as chrome–tin pink and vanadium–tin yellow. Substantial quantities of stannic oxide are consumed as a putty powder for polishing marble and granite.

Potassium stannate. Potassium stannate is prepared by dissolving tin in potassium hydroxide or by decomposing tin hydrate in potassium hydroxide. Potassium stannate is an ingredient in high-speed, high-conductivity tin-plating and tin-alloy-plating baths. It is the basis of a process for tin-plating aluminum pistons by immersion.

Sodium stannate. The commercial preparation of sodium stannate is accomplished by detinning scrap tinplate in a hot caustic soda solution containing oxidizers. The stannate is recovered by purifying the solution by evaporation and crystallization. Sodium stannate formed the basis of the first successful alkaline-tin electroplating bath. The plating speed and current-carrying capacity are less than those of the potassium stannate bath, but the process is cheaper and popular in job-plating shops.

Metal stannates. Ceramic dielectric bodies are made from alkaline earth and heavy metal stannates, particularly stannates of barium, cadmium, copper, lead, and nickel. A soluble salt of the metal is reacted with sodium or potassium stannate, and the insoluble compounds are recovered.

Organotin compounds. Stabilizers, biocides and fungicides of varying toxicity, and catalysts all are industrially important organic tin (organotin) compounds.

Grignard and Wurtz processes

Reaction processes. The commercial production of stabilizers and biocidal compounds depends on either the Grignard or the modified Wurtz processes. In the Grignard process, a tin tetrahalide reacts with an excess of alkylmagnesium halide to produce tetraalkyltins, the starting materials for many organotin compounds. Under the modified Wurtz method, dibutyltin dichloride, butyl chloride, and sodium react to yield tetrabutyltin. Tetrabutyltin can be converted to dibutyltin dichloride by treatment with stannic chloride and part of the product recycled.

Organotin compounds can also be prepared by reacting aluminum alkyls with stannic chloride or by direct synthesis in which tin metal reacts with alkyl halides in the presence of suitable catalysts at elevated temperatures to produce dialkyltin halides.

Stabilizers. A number of different organotin compounds are useful as chemical stabilizers, to prevent various types of deterioration. One of these is dibutyltin dilaurate, prepared from the dichloride, which is hydrolyzed with caustic soda to form dibutyltin oxide. The oxide is then treated with lauric acid to yield dibutyltin dilaurate. This was one of the first compounds used as a stabilizer for polyvinyl chloride plastics. It also is added to poultry feed to control worms in chickens.

Biocidal and fungicidal compounds. The toxic properties of many tin compounds make them useful as insecticides and fungicides. Some of the more important of these compounds are as follows:

1. Bis-tributyltin oxide manufactured by the caustic hydrolysis of tributyltin chloride and industrially available in a number of formulations for use in antifouling paints, sanitary formulations, and for the control of micro-organisms in industrial-process water. Various proprietary formulations serve other purposes: tributyltin sulfide for ship-bottom paints; tributyltin benzoate and salicylate for treating textiles and leather against mildew, fungi, and gram-positive bacteria; and linoleate compounds for the similar treating of plastics.
2. Tributyltin chloride, as a rodent repellent, especially in coatings for exposed electrical cables.
3. Triphenyltin hydroxide, for controlling potato blight, leaf spot on sugar beets and celery, and pecan blight; it is used also on cotton and other crops. The acetate derivative, obtained by reacting the hydroxide with acetic acid, also is effective.
4. The hydroxide of tricyclohexyltin chloride, as a control of plant-feeding mites; its low order of mammalian toxicity allows its use on apple, pear, and citrus trees, as well as on vegetables and some field crops.

Catalysts. Stannous octoate, a stannous soap, acts as a catalyst in curing silicone oil emulsions. When mixed with certain amines, it catalyzes production of polyurethane foam rubber. Proprietary formulations for stannous soaps derived from the reaction of stannous oxide and oleic and stearic acid also are used as catalysts in foam rubber production. Stannous oxalate is one type of catalyst utilized in the hydrogenation of coal.

Tintoretto

Tintoretto (Jacopo Robusti), one of the greatest artists of the late Renaissance, was a painter with a wholly personal, constantly evolving technique and vision. Although it is almost certain that his family was originally from Lucca, Tintoretto (a nickname meaning "little dyes" [after his father's profession of silk dyer, or *tintore*]) is considered a Venetian painter, not only by birth but because he always lived in Venice and because with his innumerable works he contributed to creating the face of that city. He was not only an exponent of the witness to the life of the city, of the sacred and profane complex pictorial developments of Venetian art but a myths of a society that formed a part of the dramatic history of 16th-century Italy.

Giraudon

Tintoretto, self-portrait, oil painting. In the Louvre, Paris.

Background and early life. The exact date of Tintoretto's birth is not known. A death certificate, dated in May 1594, gives his age as 75. In a portrait of the year 1588, his age is given as 70. Taking into account the known dates of his career, the hypothesis that he was born in 1518 seems warranted. In a will of 1539 he called himself an independent professional man—not a surprising description in view of his imposing and forceful personality. No documents have survived regarding Jacopo's artistic education. His biographers, among them Carlo Ridolfi, whose book was published in 1648, speak of an apprenticeship of Tintoretto with Titian that was broken off because of the master's resentment of the pupil's proud nature and exceptional accomplishment. On the other hand, a contemporary pointed out that Tintoretto's style was formed by studying formal elements of the Tuscan school, especially those of Michelangelo, and of pictorial elements derived from Titian. This explains a story of a sign that Tintoretto reportedly placed in his

studio: "Il disegno di Michelangelo e'l colorito de Tiziano." The story, however, in no way does justice to the development of a style of painting that was in fact much more complex.

Apprenticeship and early influences

Most probably, Jacopo's precocious talent prompted his father to place him in the workshop of some undistinguished painter, but one with a solid artisan tradition so that Tintoretto might learn the foundations of his craft. Traces of an absolute style in his youthful works tend to corroborate this hypothesis. But he soon became aware of the variety of approaches tried by painters working between 1530 and 1540 in Venice and already reacting against the style of Giorgione, who was the first to merge forms and to subordinate local colour in a picture to its pervading tone. It was above all the emigration of Roman artists to Venice in 1527 after the sack of Rome by imperial troops, as well as subsequent contacts with painters from Tuscany and Bologna, that induced the painters of the Venetian school to return to greater plasticism, without altering the fundamental chromatic nature of the Venetian tradition. The influence of Michelangelo, the visit of the art historian Giorgio Vasari to Venice in 1541, and the journeys of Venetian artists to central Italy renewed Venetian painting in depth, giving it means of expression adapted to different types of pictures. In the renewed idiom, form and colour were blended in a synthesis in which light dominated so as to express a richly fantastic and visionary spirit. Thus the early works of Tintoretto were affected by all of these Venetian influences. Critics have identified a group of youthful works of Tintoretto, above all *Sacre Conversazioni*, the most important of which is in the Wildenstein Collection, New York. Painted in 1540, it represents the Virgin with the Child on her knees, facing away from her, and six saints. While the style echoes various elements of the Venetian art of Tintoretto's time, it also shows a definite Michelangelesque influence.

Career. A group of 14 octagonal ceiling paintings with mythological themes in Modena, at the Galleria e Museo Estense (originally painted for a Venetian palace), with their singular refinement in perspective and narrative clarity, also belong to Tintoretto's first phase. Among other influences, they recall the fashion of partitioned ceiling paintings imported to Venice by Vasari. At this time Tintoretto probably had greatly enlarged his circle of clients and had formed friendships with literary men and artists.

This was also the period of Tintoretto's closest collaboration with Andrea Meldolla (called Lo Schiavone); together they decorated the Palazzo Zen with frescoes. The fresco technique had an important part in the formation of Tintoretto's idiom, for it suggested to him the quickness of execution that was to become fundamental to his manner of painting. Unfortunately only some 18th-century prints of his frescoes and a few fragments of the numerous frescoed facades that adorned Venice survive.

Tintoretto's drawing exercises were made from nature, from statues, and from small wax models posed in various ways and artificially illuminated, as in tiny stage sets. These methods were suited to the painter's concern with resolving problems of form and light. Not much of his abundant graphic work has survived: individual figures, some groups, many sketches of details. Only one complete graphic composition still exists (now in the Kupferstichkabinett, Berlin), which Tintoretto drew for the painting "Vulcan Surprising Venus and Mars" (in the Alte Pinakothek in Munich). The indefatigable draftsman acquired a narrative fluency that allowed him to trace with a brisk brushstroke and fanciful inspiration the series of biblical stories (now in Vienna), the mythological episodes for the poet Pietro Aretino's house in Venice (1545), and sacred compositions such as "Christ and the Adulteress," in which figures set in vast spaces in fanciful perspectives are illuminated in a distinctly Mannerist style. Tintoretto returned to an earlier form of composition in his masterpiece of 1547, the "Last Supper" of S. Marcuola, in which the choice of rough and popular types succeeds in endorsing the scene with a portrayal of ordinary everyday reality struck with wonder by the revelation of the miracle.

Early fame

A few months later Tintoretto became the centre of attention of artists and literary men with his "S. Marco Freeing the Slave." A letter from Aretino, full of praise, yet also intended to temper Tintoretto's youthful exuberance, confirmed the fame of the 30-year-old painter. Relations between Tintoretto and Aretino did not come to an end at this point, even though one of Aretino's letters contains hints of dissension, for which apparently Titian was responsible. Although Aretino was no longer to write laudatory letters to Tintoretto, he commissioned him to execute family portraits. And after his death, his likeness was to appear in Tintoretto's huge "Crucifixion" of the Scuola Grande di S. Rocco (1565). The painting "S. Marco Freeing the Slave" is so rich in structural elements of post-Michelangelesque Roman art that it is reasonable to assume that Tintoretto had visited Rome.

Tintoretto mastered a precise and varied complex Mannerist style that enabled him to conceive the fanciful scene of the "S. Rocco Among the Plague-Stricken" for the church of S. Rocco (1549), a work that had earned Vasari's praise. That style is also evident in the altarpiece "St. Augustine Healing the Plague-Stricken," in which a realistic study from life dissolves into fanciful arabesques of contorted and deformed bodies.

But Tintoretto did not interrupt his artistic experiments. Stories from Genesis, painted for the Scuola della Trinità (1550–53), show a new attention to Titian's manner of painting as well as a palpable awareness of nature. The masterpiece of this phase is undoubtedly "Susanna Bathing"; the light creates Susanna's form in crystalline clarity against a background evoked with a fresh poetic sense.

Marriage and family

In 1555 Tintoretto, now a famous and sought-after painter, married Faustina Episcopi. The young wife, affectionate and devoted, bore him eight children. At least three of them, Marietta, Domenico, and Marco, learned their father's trade and became his associates. Although Marietta is known to have been an able painter and musician, no record of her work is extant. On the other hand, innumerable works by Domenico are known; they exhibit a certain independence of style from his father, above all in portraiture.

An artist of indefatigable activity, of a veritable fury of creativity, Tintoretto spent most of his life in the bosom of his family and in his workshop. But the love of solitude to which his biographer alludes did not prevent the painter from forming friendships with several artistic personalities, including the composer Gioseffo Zarlino, who created new polyphonic and choral structures. These men undoubtedly shared Tintoretto's highly innovative and anticonformist outlook.

Influence of Veronese

This particular period in Tintoretto's career, marked by greater vivacity of colour, by a predilection for a variegated perspective, and by a highly decorative quality, coincided with his growing admiration for the art of Paolo Veronese, who had been working in the Doges' Palace. The assimilation and transformation of the Veronesian elements in Tintoretto's work are discernible in his very beautiful ceiling paintings of Bible stories, now in the Prado. In these fabulous tales, such as "Joseph and Potiphar's Wife" and "The Finding of Moses" (*c.* 1555), Tintoretto created the most significant documents of Venetian Mannerism, painting the figures in subtly luminous colours and achieving harmony by the use of elegant linear arabesques.

The use of a colour that absorbs light yielded new possibilities for suggesting spaces no longer structured by the pure play of perspective. And in those spaces the painter introduced crowds in harmonized order with the rest of the picture, a feature that had until then been missing in Venetian art. It was at that time that Tintoretto began to participate in the decoration of the church of the Madonna dell'Orto and the private chapel of the Contarini family contained within it, which in 1563 became the final resting place of the great Cardinal Gasparo, who played an important role in the city's religious life. Tintoretto's works for the Madonna dell'Orto, which occupied him for approximately a decade, also give an idea of the evo-

lution of the idiomatic elements of his art: the "Presentation of the Virgin in the Temple" (1552) was according to Vasari "a highly finished work, and the best executed and most successful painting that there is in the place"; in "St. Peter's Vision of the Cross" and in "The Decapitation of St. Paul" (*c.* 1556), the figures stand out dramatically on a space suffused with a vaporous, unreal light. In the two enormous canvases depicting the Jews worshipping the golden calf while Moses on Mt. Sinai receives the tables of the law and a Last Judgment, Tintoretto painted two works of the highest rank with a great richness of narrative means, with an awareness of the thematic link between the two scenes that attests to a knowledge of scripture and of contemporary spiritual movements. The high figurative quality of the two paintings implies that Tintoretto made a number of experiments in this decade. Proof of this is, above all, the dramatic style in which the scenes are executed, a style that firmly impresses their romantic pathos on the beholder. Tintoretto's spatial conception has a dynamic character. As a modern critic has noted, Tintoretto conveys a feeling of an almost precipitate falling forward or of an equally swift rise. The contrasted movements give the figures a similar instability. To achieve such effects Tintoretto used formulas that were invariably different: in "The Pool of Bethesda" in the church of S. Rocco (1559), the evangelical episode is realized in a compressed space through which the foreshortened ceiling seems to weigh upon the milling crowd; in the "St. George and the Dragon," Tintoretto sets the fable in a landscape of considerable depth, intersected by the white walls of the city. A series of canvases that the philosopher and physician Tommaso Rangone, grand guardian of the Scuola di S. Marco, commissioned from Tintoretto in 1562 contains similar elements. Of these pictures the most beautiful is probably the "Finding of the Body of St. Mark," now in the Brera in Milan.

Continuing experiments in dramatic style

In May 1564 the councillors of the Scuola Grande di S. Rocco decided to have the Sala dell'Albergo decorated with paintings, in place of the movable decorations used during feast days. S. Rocco (St. Roch) is the protector against plagues; the numerous epidemics of that period had given new impetus to the cult of the saint and caused great riches to flow to the Scuola, which built a splendid centre to assist the poor and the infirm. When Tintoretto presented the Scuola with his oval painting the "Glorification of S. Rocco," the directors decided to entrust him with the decoration of the Sala. Vasari relates that designs were invited from various prominent artists, including Paolo Veronese, but Tintoretto, who presented his work already installed in the Sala, won hands down over his competitors. Similar episodes are counted by contemporary sources as proof that when it came to his work the painter knew no scruples. He was indeed a man devoured by the passion for painting and not for pecuniary gain, for he committed himself to grandiose undertakings for exceedingly modest remuneration.

Work for the Scuola Grande di S. Rocco

The question of who assisted Tintoretto in his dizzying activity is still open: at that time Marietta was only about nine and Domenico four. But it is known that in 1560 his studio began to be visited by young painters, especially from the Netherlands and Germany. In 1565 his immense "Crucifixion" was displayed in the Sala dell'Albergo of the Scuola Grande di S. Rocco. Around Christ, in the centre, many figures revolve in a livid light that, muting the picture's colours, invests it with dramatic power. The decoration of the chamber was completed in 1567; it included other scenes of Christ's Passion, remarkable for their thematic innovations. Although working on the *teleri* for the walls of the Scuola, Tintoretto also executed between 1566 and 1567 a "Last Judgment" for the Sala del Scrutinio of the Doges' Palace (which was destroyed by the fire of 1577); painted the "S. Rocco in Prison" for the church of S. Rocco; and for the church of S. Cassiano, finished the "Crucifixion" and the "Descent of Christ into Limbo," paintings in which the powerful realism of the portraits of the donors contrasts with fanciful inventions.

Vasari, who visited Venice in 1566 to bring his *Lives of the Most Eminent Italian Architects, Painters and Sculptors* up to date, thus had an opportunity to follow Tintoretto's work in progress. Undoubtedly he had the painter's most recent works in mind when he wrote that Tintoretto was "the most extraordinary brain that the art of painting has produced." For all his fundamental reservations about Tintoretto's style, Vasari sensed his greatness.

Vasari's judgment of Tintoretto

In 1576, with renewed zeal, Tintoretto resumed the decoration of the Scuola Grande di S. Rocco. He had finished the huge central panel of the upper hall with "The Erection of the Brazen Serpent" in time for the feast of the saint on August 16 and promised to paint a certain number of canvases, "wishing to demonstrate the great love that I bear for the saint and our venerable school, because of my devotion to the glorious Messer San Rocho." In 1581 all the ceiling paintings were completed (ten ovals and eight rhomboid chiaroscuro panels; the latter restored in the 18th century) and ten *teleri* on the walls. Certainly the fundamental idea goes back to the conception elaborated in the rough illustrations of the *Biblia Pauperum—i.e.*, the concordance of the Old and New Testaments. It is not known who assisted Tintoretto in choosing the themes of this work, but it can be assumed that the painter himself devised, with the aid of religious texts, the complex iconographic structure by means of which he succeeded in composing his biblical poem with the greatest freedom, completely disregarding the commands of the Counter-Reformation censuring "the abuses of painters."

In his work Tintoretto exalted the charitable purpose of the Scuola and the theme of salvation from the physical and moral miseries of the human condition. The three huge paintings on the ceiling—"The Erection of the Brazen Serpent," "The Gathering of Manna," "Moses Striking the Rock"—allude to miraculous liberation from illness, hunger, thirst, while the canvases on the walls, depicting the life of Christ, celebrate the victory over spiritual evils through the institution of "baptism" (water), of "communion" (bread), as well as the certainty of victory over temptation ("The Temptation of Christ") and over death ("Resurrection"). In comparison to the works in the Sala dell'Albergo, in which the spatial relationship of the composition was precisely defined and the colour was still rich, in the great Sala the use of colour is reduced to much more emphatic chiaroscural contrasts.

In the ten *teleri* of the walls the painter's inexhaustible powers of invention created several of the masterpieces of his career. In "The Nativity," dividing the picture into two superimposed planes, he achieved a multiplicity of vision. In "The Baptism of Christ" the threadlike throng is evoked in a landscape in depth; "The Last Supper," rich in realistic detail, unfolds in an ample space created by the foreshortened table, while "The Ascension" remains one of the most spontaneous and visionary compositions, foreshadowing the fantasies of El Greco, Tintoretto's real spiritual heir. The order of execution of these paintings, which were finished in 1581, has not been established.

It seems almost impossible that in the same year the painter should have executed the four mythological allegories for the Doges' Palace, of which the most famous is that of "Ariadne, Bacchus, and Venus." All are works of great elegance, with an almost academic finishing touch. But the real Tintoretto is certainly to be found in S. Rocco, where he bears witness to his great faith and, like the medieval mosaicists, offers an illustrated Bible to the crowds of the poor who frequented the beneficent institution. His deep but independent faith in the religious myths, unrestricted by any rules of the Counter-Reformation, is apparent as much in the striking sketch of "The Council of Trent" (Turin, private collection), executed for the Doge Da Ponte, as in the altarpiece of S. Trovaso, executed in 1577 for Milledonne, a participant and historian of the Council, with the semi-nude women who tempt St. Anthony.

By 1577 Marietta, born around 1556, and Domenico, born in 1560, already officers of the painters' guild, could help their father, together with other future artists of the close of the 16th and the beginning of the 17th century. Certainly the presence of collaborators is obvious in two

Workshop productions

cycles: the eight scenes of the "Gonzaga Cycle" (Alte Pinakothek, Munich), with vivid scenes of battles, painted between 1579 and 1580, and the many paintings for the halls of the Scrutinio and of the Maggior Consiglio in the Doges' Palace, which the Republic wanted to adorn with new canvases after the fire of 1577. It was certainly more his wish to finish his immense work in the decoration of S. Rocco than it was his advanced age that induced the painter to leave the canvases of the Doges' Palace largely to his workshop.

In the canvases executed between 1583 and 1587 for the lower hall of the Scuola Grande di S. Rocco, depicting episodes of the life of Mary and Christ, Tintoretto follows a new direction: light in its most lyrical meaning dominates the paintings, dissolving the colour in a flash of diaphanous brushstrokes. Space is multiplied in unlimited successions of perspectives; the scenery at times prevails over the human figure, as in the two great works in the ground floor hall, with the "St. Mary of Egypt" and the "St. Mary Magdalene" immersed in an incandescent hazy atmosphere in which things are animated with a life of their own: an invitation to the contemplative life of the 70-year-old painter, more than ever leaning toward the view of man and his destiny offered by the Christian faith. A marvelous model (in the Louvre) of the "Paradise" for the Doges' Palace (executed later with different aims and with the help of many assistants) and "The Last Supper" of S. Giorgio Maggiore, with the incorporeal apparitions of angelic creatures, finished a few months before his death, are proof of Tintoretto's deep spiritual bent. He died on May 31, 1594, and was buried in the church of Madonna dell'Orto next to his favourite child, Marietta.

Assessment. His work as a portrait painter has often been underestimated in comparison to the work of Titian. Tintoretto's portraits, often incorporated in his compositions, can be dated from 1545 up to almost the end of his activity. If the early ones are marked by a Mannerist elegance, reminiscent of painters of the Tuscan school—*e.g.*, his "Portrait of a Young Man" at Hampton Court—the artist very soon places the stamp of his almost brutal introspective force on that extraordinary group of the Soranzo family. At times he seems to approach the chromatic softness of Titian, as in the "Portrait of a Woman in Black." And he knows how to clothe authoritative personages with solemnity and majesty, such as "Doge Alvise Mocenigo and Family Before the Madonna and Child" or the victor of Lepanto, "Sebastiano Venier" (private collection, Turin). But, above all, his portraits of old men are unforgettable, with that inner spiritual force that conquers physical decay—from the "Bearded Man with Fur" (Kunsthistorisches Museum, Vienna) to the spectral image of the "Old Man" (formerly in the Cook Collection, Richmond, Surrey). His self-portraits together with the witty verbal portrait that was left by one of his contemporaries in a letter give an idea of what Tintoretto looked like.

Tintoretto's art was much discussed and highly appreciated in 17th-century Venice, above all in the acute evaluations of Marco Boschini, the great 17th-century critic of Venetian painting. Roger de Piles, following in the latter's footsteps, exalted Tintoretto's luministic idiom. But to the 18th century, the closer it drew to 19th-century Neoclassical rationality, Tintoretto appears excessive and too remote from its own sensibility. Ruskin's romantic enthusiasm inaugurated a new attitude toward the art of Tintoretto. And modern art historiography will come to recognize in him the greatest representative of that wide-ranging European movement that was Mannerism, interpreted in accordance with the great Venetian tradition.

MAJOR WORKS

RELIGIOUS, MYTHOLOGICAL, AND HISTORICAL SUBJECTS: "Madonna and Child with Six Saints" (1540; Wildenstein Collection, New York); 14 ceiling paintings (*c.* 1540; Galleria e Museo Estense, Modena); "Supper at Emmaus" (*c.* 1540; Museum of Fine Arts, Budapest); "Apollo and Marsyas" (1544–45; Wadsworth Atheneum, Hartford, Connecticut); "St. Demetrius Altarpiece" (*c.* 1545; S. Felice, Venice); "Christ and the Adulteress" (*c.* 1547; Gemäldegalerie, Dresden); "Last Supper" (1547; S. Marcuola, Venice); "Christ Washing the Feet of the Apostles" (1547; Prado, Madrid); "S. Marco Freeing the Slave" (1548; Accademia, Venice); "Esther Before Ahasuerus" (1548; Hampton Court Palace, Middlesex); "St. Martial with SS. Peter and Paul" (1549; S. Marziale, Venice); "S. Rocco Among the Plague-Stricken" (1549; S. Rocco, Venice); "St. Augustine Healing the Plague-Stricken" (*c.* 1549; Museo Civico d'Arte e Storia, Vicenza, Italy); "Susanna Bathing" (*c.* 1550; Kunsthistorisches Museum, Vienna); "St. George and the Dragon" (*c.* 1550; National Gallery, London); "Presentation of the Virgin in the Temple" (1552; Madonna dell'Orto, Venice); "Miracle of the Loaves and Fishes" (late 1550s; Contini Bonacossi Collection, Florence, replica in the Metropolitan Museum of Art, New York); "The Finding of Moses" (1555; Prado); "Joseph and Potiphar's Wife" (*c.* 1555; Prado); "The Pool of Bethesda" (1559; S. Rocco, Venice); "Finding of the Body of St. Mark" (*c.* 1562; Brera, Milan); "The Law and the Golden Calf" (*c.* 1562; Madonna dell'Orto, Venice); "The Last Judgment" (*c.* 1562; Madonna dell'Orto, Venice); "Crucifixion" (1565; Scuola Grande di S. Rocco, Venice); "S. Rocco in Prison" (1567; S. Rocco, Venice); "Descent of Christ into Limbo" (1568; S. Cassiano, Venice); "Crucifixion" (1568; S. Cassiano, Venice); "Doge Alvise Mocenigo and Family Before the Madonna and Child" (*c.* 1573; National Gallery of Art, Washington, D.C.); ceiling paintings, upper hall and walls (1564–81; Scuola Grande di S. Rocco, Venice); "The Virgin and Child Adored by SS. Mark and Luke" (*c.* 1570–80; Staatliche Museen Preussischer Kulturbesitz, Berlin); "Ariadne, Bacchus, and Venus" (1581; Doges' Palace, Venice); "Glorification of S. Rocco" (finished 1588; Scuola Grande di S. Rocco, Venice); "Paradise" (1588–90; Doges' Palace, Sala del Maggior Consiglio, Venice); "A Battle Between Turks and Christians" (1580s; Prado); "The Last Supper" (1594; S. Giorgio Maggiore, Venice).

PORTRAITS: "Portrait of a Young Man" (1545; Hampton Court Palace, Middlesex); "Self-Portrait" (*c.* 1546; Victoria and Albert Museum, London); "Portrait of a Man" (1547; Rijksmuseum Kröller-Müller, Otterlo); "Knight of Malta" (*c.* 1551; Hampton Court Palace); "Portrait of a Young Lady" (*c.* 1551; Kunsthistorisches Museum, Vienna); "Portrait of a Woman in Black" (*c.* 1553; Gemäldegalerie, Dresden); "Portrait of a Venetian Gentleman" (1555; National Gallery of Ireland, Dublin); "Portrait of a Gentleman with a Gold Chain" (*c.* 1556–60; Prado); "Portrait of Jacopo Sansovino" (*c.* 1556; Uffizi, Florence).

BIBLIOGRAPHY. For documentation of the works and an examination of the artist, see the following Venetian sources: CARLO RIDOLFI, *La Vita di Giacopo Robusti detto il Tintoretto* (1642) and *Le maraviglie dell'Arte*, 2 vol. (1648; rev. by DETLEY VON HADELN, 1914–24); MARCO BOSCHINI, *La Carta del Navegar pitoresco* (1660; ed. by ANNA PALLUCCHINI, 1966); and ANTONIO M. ZANETTI, *Della pittura veneziana . . .* (1771). At some distance from the historiography of the 17th century is JOHN RUSKIN, *The Stones of Venice*, 3 vol. (1851–53; abridged ed. by J.G. LINKS, 1960), which approaches Tintoretto with a new interpretation, inaugurating the tradition of Anglo-Saxon studies. The following works have all contributed to an understanding of Tintoretto: BERNHARD BERENSON, *The Venetian Painters of the Renaissance*, 3rd ed. (1897); JOHN B. STOUGHTON HOLBORN, *Jacopo Robusti, Called Tintoretto* (1907); EVELYN M. PHILLIPPS, *Tintoretto* (1911); FRANCIS P.B. OSMASTON, *The Art and Genius of Tintoretto*, 2 vol. (1915); and ERIC NEWTON, *Tintoretto* (1952).

German critical work, primarily philological, has made an important contribution. It was initiated with the fundamental volume of HENRY THODE, *Tintoretto* (1901). M. DVORAK, *Geschichte der Italienischen Kunst im Zeitalter der Renaissance*, vol. 2 (1929), identified the inclination toward a Mannerist element in Tintoretto's work, comparing it to Michelangelo. ERICH VON DER BERCKEN, *Die Gemälde des Jacopo Tintoretto* (1942), uses this presupposition to make a catalog of his works. MARY PITTALUGA, *Il Tintoretto* (1925), adds to the historical position adopted by Thode. LUIGI COLETTI, *Tintoretto*, 3rd ed. (1951), enlarges the critical examination of Tintoretto's work, making it the major representation of the Mannerist tendency in Venice. RODOLFO PALLUCCHINI, *La giovinezza del Tintoretto* (1950), is also attracted by this concept as a means of describing the formation of the artist. LUIGI RUDRAUF, "Vertiges, chutes et ascension dans l'espace pictural du Tintoretto," in *Venezia e l'Europa* (1955), examines the new concept of Tintoretto's space. HANS TIETZE and ERICA TIETZE-CONRAT, *The Drawings of the Venetian Painters in the 15th and 16th Centuries* (1944), is essential for an understanding of Tintoretto's drawing activities. A well-written monograph is HANS TIETZE, *Tintoretto: The Paintings and Drawings* (1948).

For the school of San Rocco, see RODOLFO PALLUCCHINI, *Tintoretto a San Rocco* (1937); and EDOUARD HUTTINGER, *Die*

Bilderzyklen Tintorettos in der Scuola di San Rocco zu Venedig (1962). Particularly noteworthy contributions are F. ARCANGELI, "La 'Disputa' del Tintoretto a Milano," *Paragone*, 6:21–35 (1955); and ANNA PALLUCCHINI, "Considerazioni sui grandi 'teleri' del Tintoretto alla Madonna dell' Orto," *Arte Veneta*, 23:54–68 (1969). A complete edition of the work of Tintoretto is offered in CARLO BERNARI and PIERLUIGI DE VECCHI, *L'opera completa del Tintoretto* (1970).

Tirpitz, Alfred von

Alfred von Tirpitz, as an admiral, created the German high-seas fleet in the 17 years before World War I and, in his political role, exerted a dominant influence on German foreign policy of the period.

Tirpitz, 1915.
By courtesy of the Archiv fur Kunst und Geschichte

Tirpitz was born at Küstrin in Brandenburg, Prussia, on March 19, 1849, the son of a Prussian civil servant. He enlisted in the Prussian Navy as a midshipman in 1865, attended the Kiel Naval School, and was commissioned in 1869. After serving as commander of a torpedo-boat flotilla and as inspector general of the torpedo fleet, he demonstrated his technical ability and devised the tactical principles that developed systematically when he became chief of staff of the Navy High Command. Promoted to rear admiral in 1895, Tirpitz was sent to command the German cruiser squadron in East Asia from 1896 to 1897 and selected Tsingtao as a future German naval base in China. In June 1897 Tirpitz became secretary of state of the Imperial Navy Department, an appointment that marked the beginning of his two-decade buildup of the German fleet in close collaboration with Emperor William II.

Early career and rise to power

In 1898 Tirpitz introduced the First Fleet Act, for the reorganization of Germany's sea power. The nucleus of the navy was intended only for coastal defense and consisted of armoured vessels for tactical operations, light reconnaissance ships, and torpedo-boat flotillas for escort duty. Only seven battleships, two heavy cruisers, and seven light cruisers were newly ordered, but they enabled Germany to have one squadron of eight ships in both the Baltic and the North seas and to have one squadron in reserve. In addition, a few overseas stations were manned. While the 1898 act was designed to meet the need for a high-seas battle fleet, Tirpitz's Second Fleet Act of 1900 laid down an ambitious program—to build a larger and more modern oceangoing fleet—that the navy was never able to fulfill. Tirpitz knew how to stimulate public interest in a bigger navy and, a secretary of state from 1897, he displayed great skill as a parliamentarian. Tirpitz was ennobled in 1900 and awarded the Order of the Black Eagle; and in 1911 he rose to the rank of grand admiral.

In the meantime not even the 1900 navy law had evoked any significant political response in Britain. The reactions were late in coming: not until the British formed their alliances of 1904 (with France) and 1907 (with Russia) and launched the "Dreadnought" (1906) in an an effort to score an important technical advantage by constructing oversized capital ships. Their building program turned out to be a miscalculation, however, because not only all the other great powers but even many countries with small navies such as Chile and Turkey immediately followed suit. Nevertheless, because Britain had had a head start since 1905, when it had an edge of seven capital ships over its principal rival, Germany, and because of rapidly increasing British and declining German construction, there were 49 British battleships either in service or being built in 1914 as against 29 German vessels of the same type.

Critique of Tirpitz's policy

The decisive question in considering Tirpitz's objectives is whether it was good policy to augment the navy laws to the point where they could not be implemented and must inevitably result in political difficulties. From 1900 onward, when the so-called *Risikoflotte* ("risk fleet"—*i.e.*, a deterrent for potential attackers) was established under the second navy law, it became obvious that the navy was intended not only for actual defense, but also as an alliance asset in time of peace. The Emperor and Tirpitz hoped to be able, through mounting financial and military pressure, to force Britain to loosen its alliances. But when the British war minister Lord Haldane finally arrived in Berlin in 1912 for talks, political concessions were no longer obtainable from Britain. By that time Germany had discontinued its four-per-year naval vessel production rate and had abandoned the naval armament race with Britain. Thus, Tirpitz's naval policy was no longer an actual threat, but it may have continued to play such a role in the minds of the British public.

Tragically, the incipient *détente* between Germany and England had advanced no further by July 1914, when war was declared. However eagerly Tirpitz may have wanted the high-seas fleet to go into action in World War I, he was forced to realize that, given the vastly superior naval strength of the Allies, his policy of naval deterrence had failed and that the conditions for a decision at sea were unfavourable to Germany. Even unlimited submarine warfare, which he favoured but for which the necessary vessels had still to be built, could no longer have had any more than a temporary impact. Faced with mounting opposition, Tirpitz drew the correct conclusion from the failure of his plans by resigning in March 1916. With anxiety he saw the loss of morale on the home front; he thus became cofounder of the patriotic rallying movement known as the Fatherland Party, which, however, made only a small impact on an increasingly war-weary nation. Once again Tirpitz sat in the Reichstag, from 1924 to 1928 as a deputy of the German National People's Party. But, as circumstances had changed completely, he had lost the power to persuade. He retired to Upper Bavaria, where he died, at Ebenhausen near Munich, on March 6, 1930.

Assessment

Tirpitz was, by the standards of his time, a modern naval officer. He possessed a sound knowledge of the world, a dedicated mind, and an active interest in technology, and he was a brilliant organizer. He was obsessed by his work; he therefore tended to be biassed and, once he had enunciated his principles, raised them to the status of a doctrine. The continuous and steady implementation of the naval laws took priority over other technical, tactical, and political considerations. Naval construction and its impact were to determine how the navy was to be used and hence its political value and not vice versa. With the largest German navy, which under him became the world's second largest, Tirpitz forged an efficient military weapon that did not see the action for which it was intended in the war and finally collapsed from within.

BIBLIOGRAPHY. ALFRED VON TIRPITZ, *Erinnerungen* (1919; Eng. trans., *My Memoirs*, 2 vol., 1919), and *Politische Dokumente*, 2 vol. (1924–26), were composed and published by Tirpitz to justify himself. ULRICH VON HASSELL, *Tirpitz, sein Leben und Wirken* (1920), is the first Tirpitz biography based on family papers. ADOLF VON TROTHA, *Grossadmiral von Tirpitz: Flottenbau und Reichsgedanke* (1932), explains the naval policy from the viewpoint of the collaborator. More

recent studies of Imperial German naval policy include WALTHER HUBATSCH, *Die Aera Tirpitz* (1955) and *Der Admiralstab* (1958); WILHELM SCHUESSLER (ed.), *Weltmachtstreben und Flottenbau* (1956); and JONATHAN STEINBERG, *Yesterday's Deterrent: Tirpitz and the Birth of the German Battle Fleet* (1965).

(W.C.H.)

Tissue Culture

Tissue culture, which is a method of research, involves removing from animals or plants small fragments of tissue, called explants, and placing them in an environment in which they can survive outside the parent organism. A tissue in culture may consist of a population of cells (a cell culture) or a part of an organ in which different cell types retain their natural relationships to each other (an organ culture). The life of plants and animals, which (except for the simplest forms) contain many kinds of highly specialized cells, requires the coordination and interdependence of the functions of all cell types. Cells in culture may grow in the sense that they increase in size and number; they may differentiate from simple cells into cells with specialized functions; or they may perform specialized functions. Cultures of muscle cells, for example, may contract; those of specialized cells in the pancreas may produce the hormone insulin; and cultures of cells from the deadly nightshade plant produce the alkaloid compound atropine.

Cultures of cells and organs or organ fragments are useful in studying functions, behaviour, and interactions of specific cells. In addition, the large-scale development of animal-cell culture techniques has been of value in the production of viral vaccines that provide immunity to several viral diseases when given to man. Cell and organ cultures have been extensively used to study cancerous cells from animals and plants; experiments concerned with basic analyses of differences between normal and cancerous cells, the process by which normal cells transform into malignant ones, and tumour-inhibiting drugs have all been especially valuable.

General background. *Important terms.* The cell, the ultimate unit of autonomous life, contains at least one nucleus, in which is found the genetic material, deoxyribonucleic acid (DNA), in units called chromosomes. The nucleus is surrounded by a highly structured and dynamic environment called cytoplasm, in which many of the metabolic and specialized functions of the cell are carried out. The process by which somatic cells (*i.e.*, body cells as distinguished from reproductive cells) increase in number is called mitosis. During mitosis, the structures of the parent cell replicate and are divided between two or more daughter cells, which thus carry the genetic information and capabilities of the parent cell. Cells in tissue cultures sometimes produce daughter cells with abnormal numbers of chromosomes; such cells, for example, may have double the normal number of chromosomes or a number different from, but not an exact multiple of, the normal number.

A tissue is a structural and functional aggregation of cells and intercellular material; *e.g.*, muscle and connective tissue are tissues found in animals; cambium and xylem are tissues found in plants. An organ is a more complex structural unit, usually well-defined, and composed of several tissues; *e.g.*, lung, liver, and brain are organs of animals, root and stamen are organs of plants. A clone is a population of cells derived from a single cell. Clones derived from somatic cells and grown as cells in culture generally remain similar to the parent cell, unless a change in the genetic material by mutation or unequal cell division results in a modification of the daughter cells.

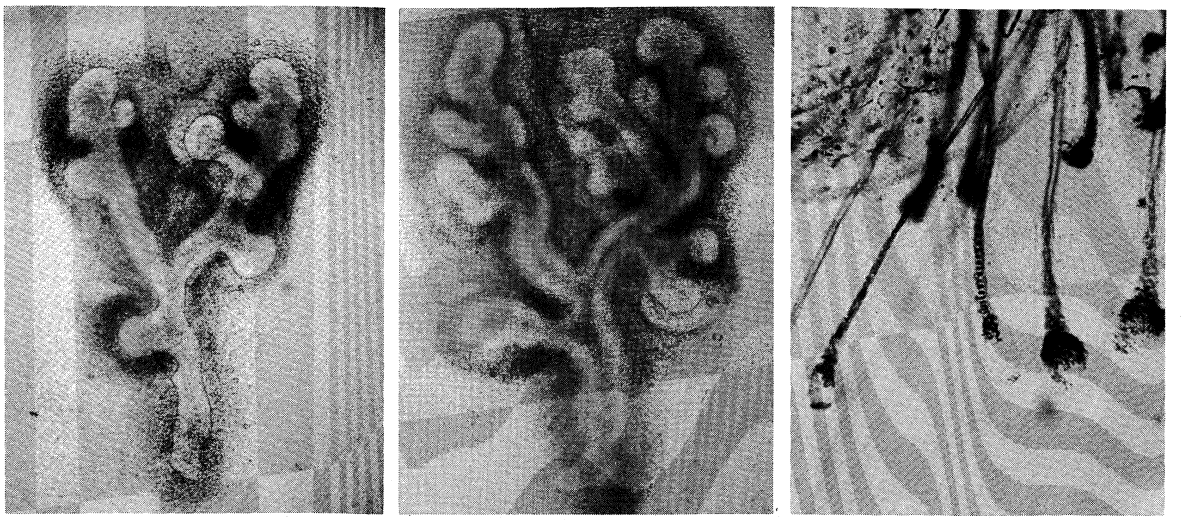
Types of media

The medium, or milieu, of cells in culture substitutes for the nutritional environment normally provided by blood and interstitial fluids in animals or by sap in plants. Media are either of biological origin (*i.e.*, composed of natural fluids derived from animals or plants) or of chemical origin (*i.e.*, synthetic mixtures of nutrient substances). A synthetic medium may be supplemented with natural fluids; the mixture is called a semidefined medium.

History. In 1839 a German zoologist, Theodor Schwann, suggested that individual cells could probably be grown outside an organism; actual demonstration of the growth of cells in this way, however, was dependent on the development of suitable techniques. An early observation of living cells undergoing mitosis outside an organism occurred about 1887, when white blood cells, or leukocytes, were collected from a frog and transferred to glass dishes for microscopic study. The first attempt to grow cells from higher plants in nutrient media was made about 1902. By 1907, the successful demonstration (by an American zoologist, Ross G. Harrison) of the growth of processes from frog nerve cells in a medium of clotted lymph had made it clear that the technique of tissue culture was not only feasible but that it could be useful in biological research. A student of Harrison developed the cell culture technique and applied it to cells of birds and mammals, using a medium containing clotted blood plasma. He collaborated with the Nobel Prize-winning surgeon and experimentalist Alexis Carrel in developing many refinements in cell culture methodology, particularly the use of embryonic tissue extracts combined with blood plasma.

The media first used for tissue cultures were composed of biological fluids; *e.g.*, lymph, blood serum, plasma, and tissue extracts for animal cells and coconut milk for plant cells. About 1911, the first attempts to culture animal cells in a synthetic medium consisting of salts, carbohydrates, and other nutrients were followed by studies of the effects on the cells of variations in certain components of the medium. It was recognized that the study of cell behaviour would best be carried out in a controlled environment; *i.e.*, a completely defined medium. These initial studies resulted in the development and use of numerous chemically defined nutrient media containing salts, amino acids, vitamins, and other components necessary for the growth of specific cells; *e.g.*, hormones, fatty acids, and trace metals.

Chemically defined media for plants, whose requirements are less complex than those of animal cells, were introduced in the U.S. about 1934 by Philip R. White, a leader in the development of tissue culture, and in France about 1939 by Roger Gautheret. Various semidefined media for animal cells, containing small amounts of proteins and tissue extracts, began to appear in the 1930s, and the first completely defined animal-cell culture media became available about 1949.



The technique of growing cells in a blood plasma-embryonic tissue extract medium made possible the successful culture of organs, both whole embryonic organs, such as bone, and fragments of larger organs, such as pituitary or mammary glands.

Organ culture

An English school of organ culture developed at the Strangeways Research Laboratory in Cambridge from about 1929; other European pioneers of organ culture work in The Netherlands, France, and Yugoslavia. Many laboratories in the U.S. and Japan now use organ culture techniques. Plant cultures are usually organ, rather than cell cultures, unless specific methods are used to separate cells from each other. A clonal culture of tomato root was maintained for more than 30 years, during which weekly transfers of small pieces of root were made into fresh chemically defined medium.

Advantages and disadvantages of cell culture techniques. *Advantages.* Early cell culture work was based on the premise that cells should be placed in an environment imitating as closely as possible the local environment in the organism from which the cells were removed (*i.e.*, in vivo condition); hence the early use of such biological media as blood plasma and tissue extracts. The use of biological media whose composition is complex and variable allows a greater degree of experimental control than that attainable with organs or tissues under conditions of limited survival, but a lesser degree of experimental control than that attainable with organs or tissues grown in chemically defined media.

Cells in culture, especially those grown in single layers on a glass or plastic surface, can be examined directly by light microscopy and photographed using the techniques of photomicrography and cinephotomicrography, which includes time-lapse moving pictures that emphasize cell

Organ cultures.

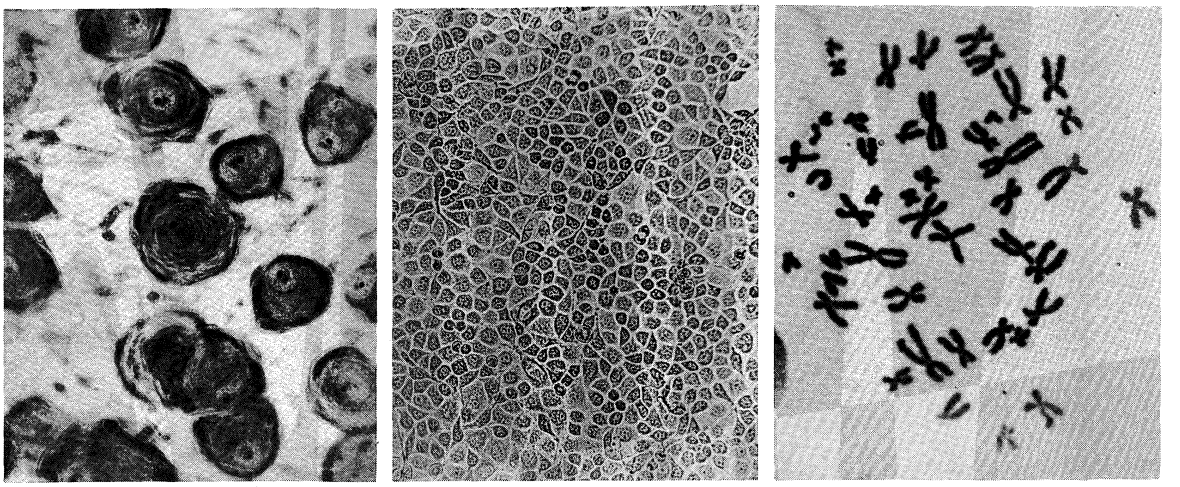
movements and behaviour; specialized optical systems make possible the detailed study of individual living cells. Cells in culture can also be fixed (*i.e.*, killed so that the structural parts of the cells remain as similar as possible to those in the living cells) and then either selectively stained so that specific structures can be studied, or sliced into very thin sections so that detailed ultrastructural features can be examined.

Cells in culture may be treated experimentally in numerous ways; cancer-producing chemicals or viruses, for example, may be added, as well as vitamins, hormones, drugs, and disease-causing micro-organisms; cells may be irradiated. The ability of particular cells to act as hosts for viruses may be studied with cells in culture, and the effects of viral infections upon the metabolism of host cells may be investigated. Cells from cell cultures also can be injected into animals or used for biochemical investigations. Tissue culture makes possible the study of the interactions of one cell type with another. One application of cell-to-cell interaction is cell hybridization; *i.e.*, the combination of nuclei from two cells into one nucleus within one cytoplasm. Using cell culture techniques, the genetic material (chromosomes) of two different cells, which may be from two such different species as man and mouse, can be placed within the cytoplasm of one cell. Specific human chromosomes are lost in human-mouse hybrid cells, but specific genetic properties of the remaining human chromosomes, difficult to investigate by other methods, can be studied.

Cell hybridization

Cells from different species or genetically different members of the same species are normally rejected when transplanted from a host to a recipient. This tissue discrimination is minimal, however, in vertebrate cells grown in cultures; hybrid organs (for example, a mouse-duck testicle) have been grown in organ culture.

Special properties of particular cell types can be identified in cell cultures. Skin cultured in the absence of vitamin A, for example, hardens; that is, it becomes keratinized. Keratinization stops in the presence of vitamin A, and active secretion of mucous substances takes place; the process can be studied using tissue culture techniques. Cultures of endocrine glands are useful in studying hormone production and the means by which the secretory functions of these specialized organs can be enhanced or diminished. The reactions of particular cell types to viruses, their responses to drugs, and comparisons between normal and cancerous cells of similar origin are other special properties that can be studied with cell cultures.



Techniques have been developed by which cells may be stored in a condition of suspended life for long periods of time at very low temperatures in liquid nitrogen; such cells can be grown again in cell cultures after months or years in cold storage.

Disadvantages. The principal disadvantages of cell and organ culture are the reverse of the advantages; *e.g.*, examined microscopically, living cells in culture look unfamiliar to the pathologist accustomed to observing sections of fixed and stained, dead cells. Although cells in culture are no longer subjected to the regulatory controls normally exercised upon them in the organism and therefore behave differently in culture, this sometimes is regarded as the justification for the cell culture technique.

Cell culture techniques. *Apparatus.* Cultures are usually grown either as single layers of cells (monolayers) on a solid surface such as glass or plastic or as a suspension in a fluid medium. Cellulose sponges have been used to grow cells in order that some of the normal three-dimensional characteristics of tissue growth can be maintained; foam prepared from a protein called fibrin, which is responsible for normal blood clotting, also has been used for this purpose. Monolayer cultures may also be grown on semisolid supporting materials; *e.g.*, gels, blood clots, or surfaces coated with the protein collagen. Cells in suspension culture are kept from settling to the bottom of the growth vessel by various devices that stir, shake, or rotate the cells in their fluid medium.

Because the kinds of media that support cell growth are also good nutrients for contaminant organisms (*e.g.*, bacteria, pleuropneumonia-like organisms, and fungi), sterile media, glassware, and plasticware must be used in cell culture work; in addition, cultures must be prepared and handled in a very clean environment, which is created by filtering the air and disinfecting all working surfaces. The addition of antibiotics to tissue culture media has somewhat reduced the need for stringent sterility conditions, at least for cultures that are grown for only a short time, and has made obsolete some previously used extreme precautions, modified from hospital procedures used during surgery. Apparatus for growing cells and organs may be very simple or very complex. A culture that will be used only a short time, for example, may be prepared simply as a hanging drop; *i.e.*, in a drop of fluid or semisolid medium on a small square piece of glass inverted over a piece of glass with a depressed area in the centre, a depression slide. Monolayer cultures, growing in media contained in flasks, bottles, tubes, or dishes, can be maintained for longer periods. After the cells have exhausted the nutrients in a medium, it may be replaced by fresh medium, and culture growth continued. Cultures may be maintained in this way for long periods of time, often months or years. As the number of cells in a cell culture increases, it also may be subdivided into daughter cultures, thus allowing the propagation of numerous cultures of specific types of useful cells. Organs in organ cultures can be grown in simple devices; *e.g.*, watch glasses, depression slides. It is often desirable to grow organ

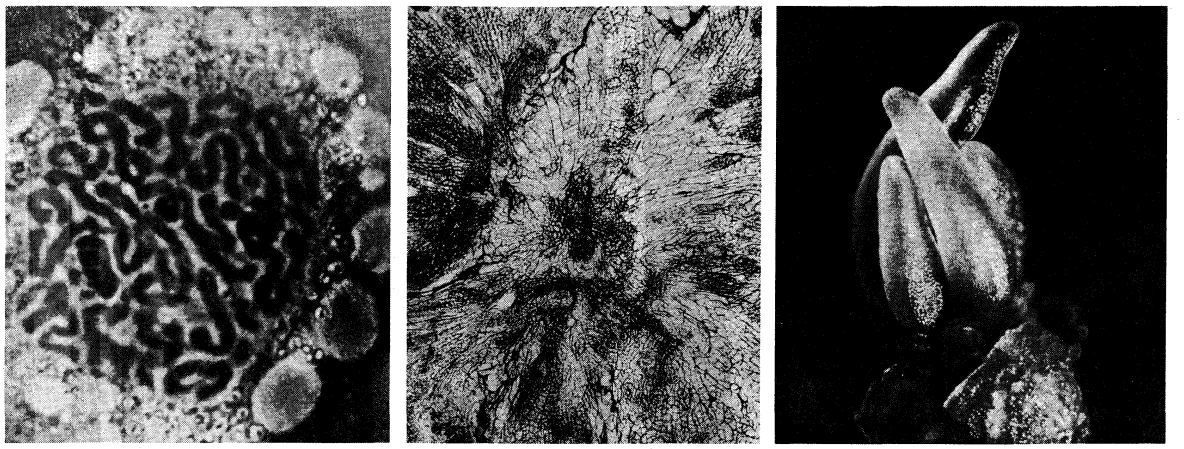
cultures on, rather than in or under, the nutrient medium; in this case, the tissue fragments may be floated on paper or rayon or supported on expanded metal grids. Special equipment that permits continuous microscopic observation of cells, as well as time-lapse filming of their activities, may be designed to allow the addition of fresh medium to the growth vessel or the injection of drugs into the organ without disturbing the position of the culture. Complex equipment developed for maintaining cells in continuous culture on a large scale permits periodical harvesting of the cells and continuously supplies fresh nutrients and gases. Monitoring devices attached to some equipment automate the continuous operation.

Nutrient media. Although media for cell and organ culture may be of many different kinds, minimal conditions for the culture of particular cell types, rather than the best conditions, often are achieved. For example, some survival, growth, differentiation, and function of many cell types can be accomplished in cell cultures maintained in biological media; *i.e.*, blood serum, blood plasma, and tissue extracts. Many chemically defined nutrient media have been designed for particular cell types or cells whose growth requirements are not very strict. Since all of the minor requirements of cells with exacting needs are not yet known, a defined medium is commonly supplemented with small amounts of blood serum, and the medium is considered a semidefined one. Every nutrient medium must contain (1) such major inorganic ions (charged particles) as sodium, potassium, calcium, magnesium, chloride, and phosphate, which are necessary to maintain normal fluid balance and to act with certain enzymes (biological catalysts); (2) energy sources, usually glucose or another simple sugar for animal cells, sucrose for plant cells; sugars also provide a major source of carbon atoms for the formation of certain cell constituents (*e.g.*, lipids, polysaccharides); (3) nitrogen-containing compounds, mainly the amino acids, which are the basic building blocks for proteins and nucleic acids of the cell; (4) essential enzymes, which require water-soluble vitamins and traces of certain metal ions (*e.g.*, iron, copper, zinc); (5) certain hormones, which may be required to influence specific functions of particular cell types; (6) special substances, other than hormones, required for specific functions (*e.g.*, certain proteins, fat-soluble vitamins, fatty acids); (7) respiratory gases necessary to sustain life, oxygen for animal cells and carbon dioxide for those of green plants; and (8) water. Biological media may not supply these requirements in the best proportions to sustain particular cell types. Many of the numerous chemically defined media are available commercially throughout the world.

Composition of nutrient media

Not only must media for cell culture have an appropriate chemical composition, with proper proportions of the various components, but they also must be appropriately acid or alkaline—*i.e.*, most animal cells require slightly alkaline conditions, while plant cells require acid conditions. The pressure exerted by media used for cultures of vertebrate animal cells should not cause the cells to shrink or swell. For invertebrate animals such as insects, the optimum pressure of the media varies with the species over a wide range.



Because plant cells are capable of synthesizing complex nitrogen-containing compounds from simple sources, the large number of amino acids required by animal cells in culture is not needed in media for plant culture. The simplest amino acid (glycine) and an inorganic nitrogen compound may provide sufficient nitrogen for growth, although the addition of other amino acids may be beneficial, and other organic nitrogen sources (*e.g.*, arginine, urea, asparagine) may be substituted for glycine.

Initiation and growth of cultures. Cultures may be initiated from fragments of a tissue or from a tumour taken from the parent organism. Sometimes, the tissue is broken down into a cell suspension by various mechanical, chemical, or enzymatic means that separate the cells from each other. Blood leukocytes, normally found in the blood of animals, may be used to initiate cultures, especially if abnormalities of the hereditary material (chromosomes) are of interest. Leukocytes usually are forced to undergo cell division (mitosis) by treatment with products called phytomitogens, which are found in the red kidney bean, in *Phytolacca americana* (pokeweed), and in several other plants; at a stage in mitosis when the chromosomes become visible microscopically, the process is stopped by adding a compound originally isolated from the autumn crocus (*Colchicum autumnale*), colchicine.

Use of leukocytes

After cells or organs have been placed in or on a nutrient medium, they are incubated at a temperature either close to that of the organism from which they were removed, for animals or plants without a temperature-regulating mechanism, or close to that of the normal environment of the organism, for animals with a constant body temperature; *e.g.*, 39° C for chick; 37° C for man, rabbit, or mouse; 28° C for mosquito; 20° C for oyster; 22° C for plant cells. Media for animal cells usually contain the compound sodium bicarbonate and carbon dioxide gas to maintain the correct degree of alkalinity; the vessels in which the cultures are grown, therefore, must be either closed with an airtight seal or placed in a special incubator containing air fortified with carbon dioxide to prevent the escape of carbon dioxide gas. Efforts to develop animal-cell culture media employing nonvolatile compounds in place of carbon dioxide show promise. Plant tissues, which grow in much more acid media than do those of animals, use atmospheric carbon dioxide.

As stated previously (see above *Apparatus*), cultures can be grown in a variety of vessels—from small hanging

drop or test-tube cultures to flasks or bottles capable of yielding large quantities of cells weighing several grams. An early method of measuring growth, which involved measuring the area of outgrowth of cells from explants in blood-plasma clots, is unreliable as a measure of increase in cell mass or number because most of the increase is the result of migration of pre-existing cells from the explant; the number of mitoses in the areas of outgrowth, however, provides a rough measurement of culture growth. More commonly used methods for growth measurement involve growing cells as monolayers or in suspension, harvesting, and counting them in measured samples of cell suspension, either directly (under the microscope or with an electronic cell counter) or indirectly; *e.g.*, by measuring packed cell volume in a small tube within which the cells can be spun in a centrifuge; or by chemical assay of protein or DNA content. Large cultures, especially plant cultures, may be weighed. Certain types of animal organ cultures are suitable for direct growth measurements; *e.g.*, increases in length and thickness of bone explants.

In some tissue cultures, growth rate, or any measurement involving increase in number or size of cells, may not be an important criterion; in cell or organ cultures from endocrine glands, for example, the production of a specific hormone may be the measurement of choice. In other cases, morphological and developmental changes and the progress of differentiation of cells or organs are the important criteria. Sometimes functional capacity may be the criterion of choice; *e.g.*, the ability of muscle cells to contract, the production of antibodies by specific cells. The ability of cells to generate tumours may be the important criterion; it is tested by implanting the cells into appropriate animal or plant hosts.

Use of clones

Experimentation. The changes that can occur in cells when they are grown in culture can be studied in a population of cells derived from a single cell (clone). Clones may be produced either by enclosing a cell in a restricted environment in which it can divide and give rise to a large population or by placing small numbers of cells on a semisolid medium and allowing each cell to give rise to a small colony of cells that can be isolated and used to grow a clonal population. Clones of human cells with a normal chromosome complement, however, usually undergo only a limited number of successive cell divisions in culture, after which the cells either die or undergo chromosomal changes that make them abnormal. Human cells containing the normal chromosome number are widely used to prepare vaccines against such diseases as poliomyelitis, measles, and influenza. Caution is necessary in such procedures, however, because human cells may carry infective viruses other than those against which a vaccine is developed.

With time-lapse moving pictures, the direct effects of light, heat, ionizing radiations, drugs, and chemicals, including oxygen and other gases, may be readily seen. In addition, moving pictures are used to record the interactions between two or more cell types; *i.e.*, cell fusions, one cell entering another and moving around in its cytoplasm, and the effects of micro-organisms on different cells. Although the process of phagocytosis, or cell eating, has long been recognized as a means by which certain scavenger cells remove debris and bacteria from tissues, the related process of pinocytosis, or water uptake by cells, was discovered only after studies of time-lapse moving pictures of cells in culture.

The process of mitosis is significant in understanding the ways by which the components of the cell are able to replicate. An important experimental procedure, therefore, is to treat cells in culture so that their mitoses are synchronized; *e.g.*, cycles of cooling and warming or treatment with certain chemical substances, which block specific processes in the mitotic cycle so that mitosis occurs at the same time in many cells. Such bursts of mitoses permit the detailed study of biochemical events associated with mitosis; in addition, synchronized cells behave more uniformly than a population of cells in which all stages of cell division are occurring at any given time.

The use of radioactive chemicals, which may be incorporated into proteins, nucleic acids, and other important cellular constituents, has made possible the detailed mapping of chemical changes that occur during a complete cycle of growth and division of cells in culture (see CELL AND CELL DIVISION).

Importance. *Biological research.* Cell and organ culture techniques have made possible detailed investigations, under controlled conditions, of the nutrition and metabolism of many kinds of cells. Many cell types from vertebrate animals are grown in cell cultures; *e,.g.*, muscle, kidney, spleen, lung, liver, skin, bone, bone marrow, intestine, brain, nerve, testis, ovary, uterus, retina, tongue, salivary glands, pancreas, adrenal, pituitary, thymus, blood leukocytes. Although embryonic cells of vertebrates usually are easier to grow in culture than are those of adult tissues, many cells from adults also are grown. Cultures of cells of various invertebrate animals, including insects and their larvae, mollusks (such as oysters and mussels), and such annelid worms as the earthworm, are useful in studying agents that may have economic importance in agriculture and marine ecology. Plant tissues (*e.g.*, from root and stem tips, flower and fruit parts, callus tissue derived from cambium, phloem, or xylem of woody plants) also are grown in culture and studied to increase knowledge of plant growth and metabolism, viral specificity, and transformation of normal cells to cancerous ones. Tumours removed from plants and animals and grown in cultures provide opportunities to compare normal and cancerous growth. Features common to cancer in plant and animal cells have been studied extensively, in the hope that knowledge of the mechanisms that cause abnormal growths of one type of organism will help to clarify the nature of cancerous changes in another.

Types of cells studied

It is possible to select and grow cells with particular

biochemical properties; *e.g.*, nutritional variants may or may not require certain specific nutrients (amino acids such as asparagine or arginine, vitamins such as biotin or inositol), antigenic variants may or may not react to the presence of certain substances. Cells also may differentiate in culture; *i.e.*, primitive cells with many potential functions may give rise to cells capable of performing only specific functions. In addition, biochemical mechanisms important to mitosis may be studied with synchronized cell cultures, as can hereditary properties, which can be manipulated in cell cultures in ways that are not possible with whole organisms. At one time, it was generally thought that cells were potentially immortal and could divide indefinitely, that death could be regarded as a breakdown at the organizational, rather than at the cellular, level. Evidence gathered from cells in culture, however, indicates that normal cells (as contrasted with cancerous cells) can age; in addition, a general correlation is found between the degree of differentiated function of a cell and its potential for growth; *i.e.*, highly differentiated cells such as those of the brain lose the capacity to divide, and other cells such as those found in connective tissue retain the capacity to regenerate in the organism (as in wound healing) or to produce many generations of daughter cells in culture.

Growth and development can be studied in cultures; the earliest stages of hair development in the mouse, for example, which occur before the mouse is born, have been elucidated in organ culture. The early phases of feather formation, which occur before birds hatch, have been studied in cultures of chick embryo skin. Whole plants have been produced from single cells of such plants as carrot and phlox.

Culture techniques allow the development of fertilized mammalian eggs to many-celled stages. Animals with four parents have been created through the fusion, in culture, of fertilized eggs from two animals whose hereditary material may not be the same. Fused eggs may be implanted in foster mothers and undergo normal development and birth; the animals may have unusual and interesting genetic patterns, which are unattainable by normal methods of reproduction.

Applied research. The demonstration, in 1949, that the causative agent of a viral disease, poliomyelitis, would grow in cultures of human cells resulted in the preparation of vaccines that provide immunity against several viral diseases, including poliomyelitis, influenza, measles, and mumps. Cells in culture are also used to demonstrate and diagnose the damaging effects of viruses on cells. A naturally occurring viral inhibitor, called interferon, formed in response to the stimulus of a viral infection, as well as several other viral inhibitor agents, have been produced in cell cultures. The effects of these inhibitors upon cells containing viruses also has been examined in cell cultures.

Many of a large group of inherited disorders in man, so-called inborn errors of metabolism, are known to be caused by the lack of a specific enzyme (biological catalyst), which, in turn, prevents a biochemical reaction. Cells from persons with, or suspected of carrying, such disorders have been isolated so that the biochemical nature of specific defects can be studied. In some cases, the disorder can be corrected by medical treatment; even if treatment is not feasible, however, the identification of persons carrying, but not necessarily exhibiting, detrimental hereditary traits is useful to couples whose children might inherit a disorder.

Culture techniques for treating growing cells (*e.g.*, from blood, from a small piece of skin, or from the uterine fluids of a pregnant woman) so that the chromosomes of dividing cells can easily be counted and examined were developed about 1952; in 1956, the normal chromosome number in man was found to be 46, not 48 as had been previously believed. Defects associated with mental deficiency (*e.g.*, mongolism) may be identified by examination of cells cultured from a pregnant woman.

Other diagnostic applications of cell cultures include classification of brain tumours and identification of a chromosome of unusual conformation, called the Philadelphia chromosome, which is associated with a cancerous condition of white blood cells (chronic granulocytic leukemia). Cells from a type of virus-related cancer first found in African children (Burkitt's lymphoma) also carry a characteristic chromosome, called a marker chromosome, which is similar to the marker chromosome in the cells of patients with infectious mononucleosis, a noncancerous viral disease.

Tissue culture has made many contributions to the understanding of the transformation of normal cells into malignant ones, which may occur both in cultures of cells and in animals as a result of the influence of certain viruses and chemical carcinogens, or without the intervention of a known agent. Air pollutants from smog have been added to cell media in tests for the presence of carcinogenic chemicals in them; although the smog material alone is relatively ineffective, a combination of smog with viruses is more effective in effecting a malignant transformation of cells than are the viruses alone.

Tissue culture techniques are of increasing value in the production of hormones from cultures of cells or organs. Attempts once were made to grow organ cultures of parathyroid glands removed from unborn humans and to transplant them into patients with underactive glands or none at all. Limited success was achieved by this method because such transplants, like others, suffered from the probability of tissue rejection. Tissue culture methods, which are used to determine compatibility between a potential donor and a recipient in tissue transplants, involve the examination of mixed cultures of one type of white blood cells (lymphocytes) from the two persons. The previously mentioned techniques for fertilizing eggs with sperm and following early development of the embryo now are used to test the efficiency of antifertility agents.

Tissues and Fluids, Animal

As the smallest structural and functional component of an organism, the cell is the basic unit of life. Although some animals and plants, such as protozoans and certain algae, consist of only one cell, they can, nevertheless, exist independently and may even have highly specialized parts that are analogous to tissues of more complex organisms. By definition, however, a tissue is a collection of cells having similar structures and performing special, as well as similar, functions. Those tissues, such as muscle, that consist almost entirely of cells devoted to a single purpose are known as simple tissues. Other tissues, such as those lining the alimentary canal (digestive tract) of higher animals, may serve a variety of functions; therefore, they are called composite tissues.

Very early in the evolution of animals, different tissues tended to become aggregated into organs, and the organs themselves divided into specialized parts. The simple pouchlike outgrowth of glandular cells from the side of the alimentary canal of amphioxus, a primitive chordate animal, for example, is now represented in complex vertebrates by a separate liver, pancreas, and gallbladder. Thus, an animal can be considered as a collection of tissues that are often, but not always, united into organs

and organ systems. The fluids that are produced by tissues and in which they are bathed usually are considered as tissues only when, as in the case of blood, they have a definite and continuing cell content.

CLASSIFICATION OF TISSUES

Anatomical classification. The classification of tissues has always been determined by the methods available for their study. Hence, because early investigators were accustomed to dividing an animal body into its organ systems, tissues were first classified anatomically according to the organ system from which they came—*i.e.*, nervous tissues, digestive tissues, reproductive tissues, and so on. This system proved inadequate, however, when it became obvious that there were more tissues than could be accounted for by the few types that were peculiar to a specific organ system. This realization led to an attempt to classify tissues according to the cell types of which they are composed: tissues composed of epithelial cells covered the outside of organs; those composed of endothelial cells lined the inside of organs; and those consisting of stroma cells were thought to serve as a functionless matrix in which other functional cells were embedded. Tissues that did not have an obvious function were collectively called connective tissue because it was thought that their sole purpose was to connect one type of cell to another. This category included the elastic tissue of tendons, the cartilage of joints, the main skeletal elements, and even blood, although there appears to be no logical connection in structure or function between blood and bone. Despite such seeming inconsistencies, however, this method of classification was useful in drawing attention to the similarities that occur throughout the animal body. A particular type of epithelial cell, for example, may be found in many different locations and in many kinds of organs.

Inadequacies of classification systems

Embryological classification. The great surge in structural embryology (the study of the formation and development of the embryo in plants and animals) that occurred when tissues were being classified according to cell types led to a system of tissue classification based on embryological origin. In the course of embryological development in most animals, it is fairly easy to recognize those cells that originate on the outside of the embryo (ectodermal cells), those that originate on the inside of the embryo (endodermal cells), and those that lie between the inside and outside of the embryo (mesodermal cells). This classification, although valuable for the information it reveals concerning evolution, is of far less value when applied to specific tissues. The epidermal and mesodermal elements of skin, for example, are confused; how far back the mouth ectoderm goes by infolding before true endoderm starts has been the subject of endless semantic arguments.

Functional classification. The most useful of all systems is to classify tissues according to the functions that they perform. On this basis tissues can be divided into three distinctive classes and a miscellaneous class. One of the distinctive classes contains those tissues that are used for assimilation, storage, transport, and excretion of food or waste products—*i.e.*, those tissues that serve an animal's needs for growth, repair, and energy. Involved in assimilation are the alimentary tissues, which not only break down food products to derive energy but also transform energy into utilizable sources that can be stored and released as required (see DIGESTION AND DIGESTIVE SYSTEMS). In any but the smallest animals the products secured by the alimentary tissues or liberated from the storage tissues are transported to other areas of the body, a function that is performed by blood and lymph. The role of tissues such as those in the lung and kidney is to excrete waste products from the body.

Another group of tissues classified according to function contains those used for coordination. This group includes those tissues that coordinate the organism in relation to its external environment as well as those that coordinate the parts of the organism internally. External coordination is performed by the central nervous system (brain and spinal cord) and its associated sense organs; internal coordination, though aided by the sense organs, is largely the responsibility of the chemical secretions (hormones) of specialized endocrine glands.

The third distinctive group of tissues according to the functional classification contains those required for support and movement, the skeletal and muscular tissues. The fourth group includes tissues used for reproduction; the hemopoietic tissues, which are concerned with the production of blood cells; and tissue fluids.

TISSUES FOR ASSIMILATION, STORAGE, TRANSPORT, AND EXCRETION

Alimentary tissues. The principal tissues involved in assimilation lie along the alimentary canal, the anterior end of which is the mouth. Lining the mouth is a simple form of covering tissue, or epithelium, known as squamous (scaly) epithelium because it consists of flattened, overlapping cells. It is also called stratified epithelium because there are several layers of cells. In such an arrangement, which is necessary in an area of rough usage like the mouth, cells that are detached from the surface can be replaced quickly by those underneath. Because they are in direct contact with the

air, these tissues must be kept moist. Interspersed among the epithelial cells, therefore, are numerous cells that secrete a slimy fluid called mucus. In many animals these cells are aggregated into small glands. Surface tissues (epithelia) containing mucous cells are called mucous membranes; irrespective of the type of epithelium involved, such membranes line the entire alimentary canal.

Tongue and salivary glands

The mouth of terrestrial animals also contains the tongue, which is the main food-gathering organ of many amphibians, some reptiles, and even a few mammals. Regardless of the organism, the interior of the tongue invariably consists of a mass of well-vascularized (blood-filled), interlacing muscle fibres; the tissues covering the surface of the tongue, on the other hand, differ from one group of animals to another. The squamous epithelium on the upper surface of most, if not all, animals is cornified epithelium; it is capable of producing keratin, the tough material that comprises horns, hooves, and nails. The surface of the mammalian tongue contains pits that extend down to the underlying mucus-producing tissues, from which arise pillars of various shapes. With this arrangement, sensory nerve endings in the pits can be kept constantly moist; yet, the organ itself is so tough on the surface that it can be used for scraping or rasping.

Mammals require such large quantities of mucus to moisten food and to protect oral membranes that they have developed specialized glands, the salivary glands, with ducts leading into the mouth. Anatomically, these glands are botryoidal; physiologically, they are merocrine; and biochemically, they are mixed. These terms also apply to many other glands. A botryoidal gland is one with many branching ducts, each of which finally terminates in a hollow spherical gland, thus giving the appearance of a bunch of grapes. A merocrine gland is one in which no part of the cytoplasm (the part of a cell exclusive of the nucleus) of the secreting cell is lost; all the granules of the secreted product pass through the cell membrane and into the lumen (cavity) of a duct, in which they are dissolved and distributed. A mixed gland is one that produces a number of products; thus, the salivary glands yield a serous fluid called mucus, which is a dispersion of a protein in water, and small quantities of the digestive enzymes ptyalin and maltase. (Enzymes are proteins that control chemical reactions in living matter.) The total of all these secretions is saliva, the importance of which is indicated by the fact that its daily output in man exceeds that of urine.

After leaving the mouth, food passes down the esophagus, a muscular tube that histologically—*i.e.*, in terms of its tissue structure—is little more than an extension of the mouth. Internally, the esophagus is lined with a thick coat of the same type of stratified squamous epithelium as is found in the mouth. There is a longitudinal layer of striated muscle (muscle in which the bands, or striations, represent areas of different composition), the contractions of which control swallowing, and a thin circular layer of nonstriated muscle that is separated from the epithelium-lined lumen by a cushion of connective tissues. The esophagus enters the stomach, an organ of variable tissue construction in different animals; it is primarily a sack, or a series of sacks, that holds, churns, and partially digests the contents. In the human stomach the entire inner surface is covered with a simple columnar-shaped epithelium from which thousands of pits, or gastric glands, descend into the underlying layer of connective tissue. In the stomachs of some animals the glands are confined to small areas, and much of the inner stomach wall is composed of stratified squamous, and even occasionally keratinized, epithelium. The outer stomach wall consists of three layers of nonstriated muscle fibres that run longitudinally, circularly, and diagonally.

Esophagus and stomach

Interesting tissues in the stomach are the gastric glands, which are simple in structure but complex in cellular makeup and function. In most organisms the glands are S-shaped tubular structures, but sometimes they are branched. The cells forming the glands are of four types. In the gastric pit, the part of the gland that opens into the stomach, the cells resemble the general epithelial lining and are active secretors of mucus. Just below the pit is the isthmus, a section of the gland containing a few mucus-producing cells and many hydrochloric-acid-secreting ones; the acid is necessary in the digestive process. Between the isthmus and the base of the gland is the neck, which contains additional mucus cells and a few that produce hydrochloric acid. The base of the gland consists mostly of cells that secrete an enzyme that catalyzes the breakdown of proteins in the stomach; the base also includes several of another type of cell, the exact function of which is still in doubt.

After partial digestion in the stomach, from which only a very few simple substances are absorbed, the food passes to the small intestine. In higher vertebrates all the tissues and structures of the small intestine are modified for the sole purpose of absorption, which is a direct function of surface area. The inner wall of the small intestine consists of a series of connecting ridges. Arising from the ridges are millions of finger-like projections called villi, the centre of each of which contains blood vessels that remove absorbed materials. The tightly packed epithelial cells covering the villi are themselves covered with even smaller projections (microvilli). This combination of villi and microvilli results in a total absorptive surface of the small intestine that is approximately 10,000 times greater than that of a smooth tube. The tissues of the remaining length of the alimentary canal are primarily devoted to the recycling of water. They do not have villi and are usually covered with a simple epithelium containing numerous mucus-secreting cells.

Small intestine

In lower vertebrates the glands that produce the enzymes necessary to convert food substances into absorbable molecules are found along the entire length of the small intestine. In all higher forms, however, the larger surface area creates a greater demand for enzymes. As a result, the glands are located in a completely separate organ, the pancreas, which, in tissue structure and secretory function, closely resembles a salivary gland.

Digested food materials of all types, as well as undigested droplets of fat, are picked up by the blood from the small intestine and transported to other parts of the body either for storage or for immediate use. Fat is stored in fat cells, which develop from undifferentiated cells in connective tissue. At an early stage of their development, the undifferentiated cells become filled with small fat droplets; later, these coalesce into a large single fat droplet. In some lower vertebrates, particularly amphibians, fat cells are localized, forming fat bodies that are distinct from the surrounding tissue. In most higher forms, however, fatty (adipose) tissue is dispersed throughout the body, although fat cells do tend to aggregate into fat masses in certain areas, particularly in the layers beneath the surface of the skin.

Fatty tissue

Liver tissues. The bulk of nutrient-bearing blood goes to the liver, which is probably the most important single tissue in the maintenance of the mammalian body. The evolutionary mechanism by which the liver reached this important function is not entirely clear. Many invertebrates and such lower vertebrates as amphioxus have outgrowths from the anterior region of the alimentary canal, apparently for the purpose of increasing the secretory area. In the cyclostomes (*e.g.*, lamprey, hagfish) the lumen of a much-branched outgrowth remains open; hence, the liver in these animals is a series of intercoiled tubes. In higher forms, however, there is no lumen; instead, the liver consists essentially of many-sided (polygonal) cells so closely pressed together that all trace of a tubular origin is lost. The cells cluster about much-branched blood vessels, from which phagocytes (cells that ingest and destroy foreign materials) migrate and become interspersed among the liver cells. There is also a network of branching ducts, originating as intercellular spaces, that collect bile (a fluid secreted by the liver that aids in digestion) and form the bile duct, which leads to the gallbladder. Despite the fact that they perform a multiplicity of functions, all liver cells appear to be of the same type.

When blood reaches the liver from the small intestine, its carbohydrate content is adjusted either by the removal of excess sugars and their conversion to glycogen parti-

cles that are stored in the liver or by the addition of sugar through the breakdown of previously stored glycogen. Poisonous substances carried by the blood are either detoxified, if possible, or removed from the blood and stored. Partially broken down erythrocytes (red blood cells), arriving from the spleen at the rate of about 3,000,000 per second, are picked up by the phagocytes and broken down further; the breakdown products are either recycled or, as in the case of excess pigments, excreted through the bile. Liver cells also control the synthesis and distribution of fat in the form of large molecules composed of both lipid and protein (lipoprotein); the synthesis of all proteins in blood plasma; and the synthesis of urea, a nitrogenous waste that is subsequently excreted by the kidney.

Blood and lymph. To refer to blood as a tissue is a semantic, not a scholarly, definition, because in some invertebrates (*e.g.*, annelids) the blood is almost acellular (lacking in cells), and in the great majority of invertebrates it contains at the most only a few leukocytes (white blood cells). Only at the vertebrate level do the oxygen-carrying pigments of the blood become localized in specific blood cells, and only at the mammalian level do they lose their nuclei. The acellular portion of blood is called plasma when it is in a blood vessel and lymph when it passes out through the walls of capillaries (tiny blood vessels) to bathe the cells in surrounding tissues (see BLOOD AND LYMPH).

Respiratory pigments

The most important function of blood is to carry oxygen, which is transported by a respiratory pigment; the best known pigments are the hemoglobins. These compounds, which contain iron, are found in all vertebrates and also in many annelids, insects, and a few mollusks. Other respiratory pigments include the hemocyanins, which contain copper, and the hemovanadins, which contain vanadium. All of these pigments function in much the same manner: they pick up oxygen from the air and transport it to the cells, where it is released. The blood of most animals also contains leukocytes of various forms and functions.

Blood plasma contains approximately 7 percent dissolved proteins, including the globulin fraction, which is of great immunological importance; other constituents include nutrients and hormones. The most important function of plasma is to maintain a proper fluid balance among the various tissues of the body. The lymph that passes through the walls of capillaries and bathes the tissues collects in lymph vessels and is recycled back into the bloodstream.

Kidney tissues. The original function of the vertebrate kidney was to remove water from the body cavity (coelom) of aquatic animals. The primitive kidney consisted of little more than a longitudinal duct opening at its posterior end into the cloaca (a passage into which waste products are discharged) and contained at its anterior end a series of funnels with cilia (lashing hairlike projections) to remove the excess fluid. This type of kidney is found in the larvae (*e.g.*, tadpoles) of many vertebrate animals. Early in the evolutionary history of aquatic vertebrates a tissue was developed that permitted excess blood fluids to be removed by a similar mechanism: a small, tangled mass of capillaries (the glomerulus) entered a pouch in the side of the longitudinal coelomic duct. With the adaptation of early vertebrates to terrestrial life, however, it was necessary that water be conserved; the coelomic funnel disappeared, and the glomerulus with its pouch (Bowman's capsule) no longer led directly into the excretory duct but into a highly complex series of tubules designed to concentrate and recycle water while permitting the removal of some water-soluble wastes.

Adult vertebrates known as the anamniota (fishes and amphibians) have a kidney structure very much like that of the embryo; the adult kidney of amniotes (reptiles, birds, and mammals), however, is derived from the posterior end of the embryonic kidney (see EXCRETION AND EXCRETORY SYSTEMS). In the anamniotic kidney, venous blood goes directly into a large sinus (a cavity or hollow space within a structure of the body). Located in this sinus are branched, tangled tubules, each of which terminates in a Bowman's capsule containing arterial blood that comes directly from the heart through a series of branches of the main artery in the body. After its passage through the glomerulus, the arterial blood empties into the sinus, which, at its anterior end, drains into a large vein.

Embryonic amniotes have a very similar structure, but a pouched outgrowth from the posterior end of the collecting tubule develops completely new units around it. This outgrowth becomes the ureter (the duct that carries urine from the kidney to the urinary bladder), and the pouch becomes the renal pelvis (a saclike cavity at which the ureter is attached to the kidney). The excretory units (nephrons), each of which consists of a Bowman's capsule, glomerulus, and tubule, then develop in the surrounding tissue and become attached through one or more branches to the renal pelvis. Arterial blood enters the kidney through the renal artery directly from the dorsal aorta (the main posterior artery from the heart). It then passes through arterioles (tiny arteries) to the glomerulus in the Bowman's capsule; a great deal of water and all but the largest molecules in the blood are forced through the walls of the glomerulus by the high pressure of the blood. (The human kidney excretes about two gallons [7.5 litres] of water an hour through the glomeruli; of course, most of this is subsequently reabsorbed.) Blood leaves the glomerulus through another set of arterioles that form a network of capillaries around the coils of the kidney tubules; it then returns to the heart through the venous system.

Nephrons

Histologically, the kidney tubule is divided into three parts: a thick proximal section that is adjacent to the Bowman's capsule and consists of columnar or cubical epithelial cells with large numbers of microvilli on their surface; a distal portion of very similar structure that leads to the collecting duct; and, between the two, a long, but variable, length of thin-walled tubule. The proximal portion of the tubule has the dual function of reabsorbing materials to be recycled—*e.g.*, water, glucose, amino acids, ascorbic acid, sodium, chlorides, and bicarbonates—and of removing from the blood in the arterioles surrounding the tubule those substances that do not pass through the walls of the glomerulus. The thin-walled portion of the tubule further concentrates the urine, and in the final convoluted section the water, sodium, and phosphate contents of the urine are adjusted to the requirements of the body.

Apart from the capillaries and tubule cells described, there are a few specialized tissues in the kidney. Located around the neck of each arteriole, where it enters the glomerulus, is a cuff of juxtaglomerular cells; these are thought both to control the flow of blood into the glomerulus and to secrete an enzyme. Another interesting cellular adaptation is the presence of podocytes in the walls of the Bowman's capsule. As the name podocytes indicates, these are "footed" cells that protrude from the wall of the capsule and press against the glomerulus, thereby improving fluid flow by maintaining a clear space between the blood vessels of the glomerulus and the wall of the capsule.

Lung tissues. Animal tissues to secure oxygen and excrete carbon dioxide are extremely variable (see RESPIRATION AND RESPIRATORY SYSTEMS). In many small invertebrates, gas exchange takes place directly through the body wall or through external gills, which are thin, often tufted extensions of the body wall through which the blood circulates. The protected gill first appears in the pelecypod mollusks (*e.g.*, clam, oyster, scallop); it is a folded sheet of parallel anastomosing (connecting) blood vessels that are covered first by the mantle (the tissue covering the soft body organs of a mollusk) and then the shell. Adaptation for life on land, however, required the development of the lung, an internal sac with a heavily vascularized wall into which air could be drawn and from which waste gases could be expelled by the expansion and contraction of adjacent structures. The first such organ appears in the gastropod mollusks (*e.g.*, snail, slug, whelk); an analogous structure, in the form of an outgrowth from the anterior end of the alimentary canal,

Respiratory structures in animals

was developed by the lungfish and persists in most adult amphibians, in which the walls of the sac begin to show folding. The increased demand for oxygen occasioned by rapid movement on land resulted in the evolution of multilobed, heavily vascularized lungs in reptiles, birds, and mammals. Gases were inhaled and exhaled first by the simple contraction of the thoracic (chest) walls and later with the assistance of the diaphragm (a muscular partition that separates the thoracic cavity from the abdominal cavity).

Two other mechanisms for gas exchange were developed by the arthropods (*e.g.*, insects, spiders, crustaceans). In scorpions the interior surface of a series of four pairs of ventral pouches is folded into a number of lamellae (thin plates). Because of the pagelike appearance of this arrangement, it is called a book lung. In insects and a few other groups (*e.g.*, onycophorans and centipedes), thin-walled ducts, supported by rings of chitin (a horny substance), conduct atmospheric gases to small pouches that are in direct contact with tissues. That this system is extremely efficient in small animals is indicated by its ability to meet the extraordinary oxygen demands of, for example, the flight muscles of many insects. But because it cannot be adapted to large organisms, terrestrial arthropods that use this system have never reached the sizes attained by those animals that have lungs.

TISSUES FOR COORDINATION

None of the tissues so far described would be able to function satisfactorily were they not coordinated in relation to both the external and the internal environment of the animal. Coordinating tissues are broadly classified into those that are physical (nervous and sensory tissues) and those that are chemical (endocrine tissues).

Physical coordinators. It may be stated as a broad generalization that both physical and chemical coordination in invertebrates are performed by the same tissues, because the nervous tissues of many invertebrates also serve as hormone sources. Hormones, chemical substances secreted into the bloodstream by endocrine glands, have specific effects on other organs). In vertebrates most endocrine functions are isolated in specialized glands, several of which, such as the pineal and hypophysis in the brain, are derived from nervous tissue. The basic unit of all nervous tissue is the neuron, which, with few exceptions, consists of a cell body from which protrude numerous branching cytoplasmic processes (dendrites) and one long fibre (the axon). The dendritic fibres act as interconnections between neurons; the axon either transmits impulses to an organ (efferent axon) or collects impulses from sensory organs (afferent axon; see NERVE IMPULSE; NERVES AND NERVOUS SYSTEMS). Internally, the cell body of the neuron contains considerable quantities of what were once called Nissl bodies, which consist of stacks of rough-surfaced endoplasmic reticulum (a convoluted membranous network in cells) with large numbers of ribosomes (granular structures consisting of protein and ribonucleic acid—RNA) sandwiched between them. The presence and structure of the Nissl bodies indicate that RNA plays a major role in the functioning of the nerve cell and is probably responsible for the storage of information (memory). Aggregations of neurons are known as ganglia.

The neuron

In addition to neurons, and also associated with the central nervous system, ganglia, and the axon itself is a tissue that may be either in the form of glia cells or Schwann cells. The former, which are also known as neuroglia cells, constitute a special type of connective tissue that is interspersed among nerve cells and fibres. The Schwann cells are large, flattened cells that are wrapped in such a tight spiral around the axon that most of their cytoplasm has been squeezed out through their membrane. In effect, the axon is wrapped in many layers of membrane with only a little cytoplasm on the inner and outer surfaces. Membranes have a central lipid (fatty) layer; the nerve, therefore, is covered by an insulating layer of lipids that is commonly known as the myelin sheath.

There are three principal types of neuroglia cells: astrocytes, which, as the name indicates, are star-shaped cells with numerous branches at their ends; oligoglia (also called oligodendroglia or oligodendrocytes), which have fewer but thicker branches than astrocytes and are generally smaller; and microglia, which are the smallest of the three. It was once thought that these cells serve merely as connective tissue to support neurons. Evidence is accumulating, however, that they may play a more active role not only in transmitting nutrients and forming enzymes but also in the conduction of neural impulses. Because the short ends of some oligoglia are wrapped tightly around the capillaries in the brain, they could form a direct conducting path for hormones. The astrocytes become active principally when there is neural damage, at which time they assume a phagocytic function.

Types of neuroglia cells

A slice across the brain or spinal cord shows it to be divided into two regions, descriptively called gray matter and white matter. The former, which is on the outside of the brain and on the inside of the spinal cord, contains the neurons; the white matter owes its appearance to the lipid content of the myelin sheaths around the nerves of which it is largely composed. A typical neuron has about 100 dendritic branches; these may form junctions (synapses) either with dendritic branches from other cells (axodendritic synapses) or with the surface of another neuron (axosomatic synapses). Impulses originating in one neuron may or may not be transmitted through the synapses to other neurons; the mechanism of such selective transmission, on which depend thought, reason, and memory, is not at present fully understood.

A neuron not only receives and transmits impulses to other dendrites but it may also receive an impulse from a sense organ in an outlying part of the body or transmit an impulse to an outlying muscle. The bundles of axons through which these impulses are carried are called nerves. At the terminal end of a transmitting axon in, for example, a muscle, there is a short spray of branches known as axonal telodendria, each of which terminates in a structure called a bouton. When an impulse reaches the boutons, they secrete the chemical acetylcholine, which, because the boutons are in molecular contact with the membrane of the muscle, causes the muscle to contract. Although the nerves leading to the abdominal muscles of the viscera are structurally similar, they operate by a different method. Because visceral muscles are not anchored to joints or bones, they are in a constant state of partial contraction, and movement is produced either by increasing (exciting) or decreasing (depressing) this state. The excitatory nerves mediate their action through the release of acetylcholine; the depressant nerves, through the release of adrenaline or noradrenaline.

There are a few specialized types of neurons in the central nervous system. In many invertebrates and vertebrate larvae, giant neurons carry impulses directly across areas at which they would otherwise be interrupted. Another highly specialized type of giant neuron, the Purkinje cell, lies at the junction of the cerebral cortex and the medulla of the cerebellum, an area in the brain that coordinates locomotor functions and is most highly developed in birds and mammals. Each Purkinje cell has many dendritic branches that ramify through the whole of the outer (molecular) layer of the cerebral cortex. The only afferent nerves leaving the cerebral cortex are those that are made up of the axons of Purkinje cells. In the inner (granule) layer of the cerebellar cortex are large numbers of small granular cells, the dendritic branches of which receive impulses from the axons of incoming (afferent) nerves. Each granular cell has a single axon that rises vertically through the molecular layer and then divides into two branches that run in opposite directions and synapse with the dendrites of some of the Purkinje cells. The union of all the Purkinje cells with the granular cells, which has been likened to a telephone distribution system, is the mechanism for the transmission of the extremely complex nervous impulses required for the locomotor responses of mammals and birds.

Afferent nerves (those that conduct impulses toward the brain and spinal cord) reaching other areas of the central nervous system come from sense organs (receptors) that

receive either internal or external stimuli. For higher animals the most important of these are the photoreceptors, the light-sensitive nerve endings located in the rods and cones of the retina of the eye (see PHOTORECEPTION).

Chemoreceptors

Chemoreceptors, or taste buds, usually consist of two types of cell pressed together into a small, pear-shaped Y. The receptor cells, which are elongated into an apical process that is in contact with the medium to be tasted, are heavily innervated by terminal buds of the afferent nerves; they are separated from each other by the sustentacular (supporting) cells that lie beneath the surface and are not innervated. There is considerable argument as to whether the human perception of sweet, sour, salty, metallic, and bitter are sensed by the same nerve endings or by different ones; there is still more argument as to which of these senses are present in lower vertebrates. Catfish have "taste buds" in slender projections on their lips, called barbels, and insects have very similar structures both in their antennae and, in the case of butterflies, in their feet (see CHEMORECEPTION).

The vibroreceptors (those sensitive to mechanical vibrations) apparently are present in relatively few animals. Except for the ear, the most developed of such organs are located in the fish, in which they extend in lines along the length of the body (see MECHANORECEPTION and SOUND RECEPTION). Although the function of sensory structures in animals other than man is difficult to determine, it appears that most organisms possess heat and cold receptors, which are different organs; each apparently consists of a single cell permeated by a terminal treelike branching of a nerve. Pressure sensors, on the other hand, usually consist of a fluid-filled cavity and several cells bunched around the end of a nerve. In man these receptors, called pacinian corpuscles, are very large (up to four millimetres, or 0.2 inch); they are found in the deeper layers of the skin and throughout the body, at points at which pressure sensation is necessary—*e.g.*, joints, tendons, ligaments.

Chemical coordinators. In many invertebrates chemical stimulators are secreted by the neurons themselves and then move to their place of action along the axon. Such is the case with the hormone in crustaceans that controls the lightening or darkening of the body in response to the environment. The hormonal activities of neurons, however, are nowhere better shown than in the insects, the principal endocrine glands of which are the corpora allata (wing-shaped bodies) and the corpora cardiaca (heart-shaped bodies) that lie alongside the brain. Neurons in the brain secrete large colloidal (jellylike) granules that pass beyond the axon to the heart-shaped bodies and then to the wing-shaped bodies. Some evidence indicates that these colloid granules are also liberated directly into the hemolymph (the fluid in invertebrate tissues and body cavities).

Endocrine glands

The principal endocrine tissues of the higher vertebrates are the thyroid gland, parathyroid glands, endocrine constituents of the pancreas, interrenal chromaffin tissues of the adrenal gland, and the pituitary gland (see ENDOCRINE SYSTEMS). Of these the thyroid gland presents the clearest evolutionary and histological picture. In mammals this gland secretes not only the hormone thyroxine (tetraiodothyronine) but also smaller quantities of another hormone, triiodothyronine; both have a powerful effect on both rate of maturation and general metabolism. A similar product (monoiodotyrosine) is synthesized by many algae, and both monoiodotyrosine and diiodotyrosine are found in all invertebrates, in many of which the synthesis is apparently centred in the pharyngeal region (the portion of the digestive tract lying between the mouth and the esophagus and forming the respiratory organs of aquatic vertebrates). In the most primitive vertebrates (the cyclostomes) there appears, as an outgrowth of the pharyngeal region, an exocrine gland (one that secretes through a duct, as for example, the digestive glands) that is not unlike a salivary gland in structure. In all higher forms, embryological development of the thyroid gland begins with a duct connected to the pharynx, just as in the lower vertebrates. Ultimately, however, it becomes a ductless (endocrine) gland that is divided into lobes and lobules, which are small, spherical collecting pouches surrounded by cells that secrete the hormone into the lumen of the pouch. Blood vessels in the organ pick up the thyroxine and transport it around the body. The thyroid is chemically linked to the pituitary gland by a system of negative feedback; that is, as the secretory activity of one increases, that of the other decreases.

The parathyroids are also pharyngeal derivatives that are represented in most teleost (bony) fishes by structures called ultimobranchial bodies and in higher forms by four small endocrine glands imbedded in the back part of the thyroid, two on each side. These glands, which have completely lost their lobular structure, consist of a tangled mass of cellular cords, the secretory products of which pass directly to capillaries. The secretions appear to have their principal effect on the calcium–phosphorus ratio in blood.

The endocrine portions of the pancreas (a large gland located behind the stomach that secretes digestive enzymes as well as hormones) are called the islets of Langerhans. In some lower vertebrates, however, the islets are individual glands, completely separated from the pancreas. Like the parathyroids, the islets also consist of tangled cords; they contain four kinds of cells that are designated by the first four letters of the Greek alphabet —alpha, beta, gamma, and delta. The alpha cells are filled with dense masses of granules that yield the hormone glucagon, which, because it it antagonistic to the hormone insulin, prevents the synthesis of glycogen, protein, and fat. The beta cells, which are the most numerous cells in the islets, also consist of large masses of granules that produce insulin, a hormone that controls the sugar (glucose) content of the blood. The function of the gamma and delta cells is not yet known.

Although in mammals interrenal and chromaffin cells are combined into the adrenal gland, the former being the cortex (outside) and the latter the medulla (inside), both tissues are quite distinct. (There are two adrenal glands in mammals, one associated with each kidney.) The interrenal tissues, which exist as separate glands in all vertebrates except birds and mammals, secrete hormones, of which cortisone is a typical example. The cells of these tissues are usually distinguished by the presence in their cytoplasm of large vesicular mitochondria (granular or rodlike bodies, which, in this case, contain fluid-filled cavities). Chromaffin cells, which occur in most animals as scattered clumps, secrete the hormones adrenaline and noradrenaline. The cells are large and ovoid, resembling neurons in all but their lack of axons and dendrites.

The pituitary, which has a dual origin and a dual function, is the most important endocrine gland of the body. It originates from two separate locations: one part, the adenohypophysis, develops as an upgrowth from the roof of the mouth; the other part, the neurohypophysis, develops as a downgrowth from the floor of the brain. The adenohypophysis is divided into three regions, the anterior lobe, the intermediate lobe, and a third lobe that connects to the neurohypophysis. Like most endocrine glands, the anterior lobe consists of tangled masses of cords with numerous types of secreting cells. The hormones secreted by this region mostly interact with the secretions from other endocrine glands to control the internal environment of the body. The neurohypophysis not only has direct axonic connections with the brain but also contains numerous neurosecretory cells (neurons that produce one or more hormones). The products of these cells pass directly to the anterior lobe, the activities of which they control. Thus, through the neurohypophysis the brain can control the secretions of the anterior lobe and thereby adjust the internal environment to the external environment, conditions of which are communicated to the brain by the sense organs. A typical example of such control is found in birds. When the brain becomes aware of increasing day length through impulses from the eye, it stimulates the neurohypophysis to secrete neurohormones. These, in turn, stimulate the anterior lobe to release hormones that cause the rapid development of the gonads, thus assuring that the bird will be in condition to breed in the spring.

Neurohormones

TISSUES FOR SUPPORT AND MOVEMENT

Connective tissues. Connective tissues hold the body together. Most such tissue is of the white fibrous type, which is divided into two kinds, loose and dense, although the two actually grade imperceptibly into each other. White fibrous connective tissue has several roles—it envelops and often penetrates organs to hold them together, encloses muscles, and forms a considerable proportion of the spongy layers of the skin. It is composed of a loose meshwork of a relatively inelastic fibrous protein (collagen), the fibres of which are interspersed in a gelatinous matrix that contains numerous leukocytes derived from the blood. When glandular organs contain considerable quantities of connective tissue—as do, for example, the spleen and thymus—the leukocytes increase in number and become star-shaped cells, the terminal processes of which anastomose to form a loose three-dimensional network. This is best seen in such invertebrates as flatworms, in which a stellate reticulum (a network of star-shaped cells) fills all the space not occupied by discrete internal organs. Mucoid connective tissue, which contains much more gelatinous substance than connective tissue, is found in all embryos as the initial stage in the development of connective tissue; and though rare in adult animals, it does form in the main bulk of such outgrowths as cockscombs and turkey wattles.

Connective tissue of great structural strength consists of almost pure collagen fibres arranged in parallel layers, as in tendons. In ligaments, fibres of elastin, a fibrous protein that is brownish in colour, are mixed with collagen fibres, in which case the tissue is often called yellow elastic connective tissue.

Cartilage. Although usually classified as connective tissues, cartilage and bone are better regarded as supportive in function. Cartilage is the product of cells known as chondrocytes, which secrete around themselves a clear, jellylike mass of a sugar-like substance containing sulfur, (chondroitin sulfate). Cartilage of this type, which is found in the adult skeletons of cyclostomes as well as in small sharks and rays, is called hyaline cartilage. In larger sharks the deposition of calcium salts modifies the hyaline cartilage into calcified cartilage, which, because it resembles bone in composition but not in structure, must be clearly differentiated from bone. Another modified form of cartilage is fibrous cartilage, which grades almost imperceptibly into fibrous connective tissue at, for example, the junction of tendons with bone or cartilaginous joints. Elastic cartilage (Figure 2) contains yellow elastic fibres; one of the places at which this type of cartilage appears as a supporting structure is in the outer ears of mammals.

Cartilage is also found in some invertebrates, such as in the cranial capsule (head covering) of cephalod mollusks (*e.g.*, squid, octopus), but the principal skeletal substance of invertebrates is chitin—a hard, waterproof, inelastic nitrogenous polysaccharide. Among the animals in which it is found are cnidarians (*e.g.*, hydroids, corals, sea anemones), mollusks, bryozoans ("moss animals"), nematodes (roundworms), and acanthocephalians (spiny-headed worms) as well as the better known arthropods (see SKELETAL SYSTEMS).

Chitin

Bone. Bone is derived from cells called osteoblasts, which lay down crystals of calcium phosphate known as apatite, in bone. When calcium phosphate is deposited in connective tissue, the resulting structure is called direct bone; when it is deposited as a replacement for cartilage, the resulting structure is called indirect bone. Because the osteoblasts move into a thick, fibrous sheet of white connective tissue during direct bone formation, the somewhat misleading term of membrane bone is often used. At the beginning of direct bone formation, the osteoblasts produce columnar structures (trabeculae) arranged so as to provide the maximum support for the bone that forms on both sides. The space between the trabeculae is filled with red bone marrow. As the osteoblasts become encased in bone, they turn into stellate cells known as osteocytes, which maintain contact with each other through long, branching surface projections. Because the osteocytes cluster around blood vessels, a cross section through a bone appears as a series of concentric rings with a small opening in the centre, called the haversian canal; this opening is actually the space occupied by the blood vessel. Membrane bones, such as those of the growing skull, frequently change their shape with the aid of cells known as osteoclasts. Osteoclasts break down the existing bone into material that can be redistributed to new positions by osteoblasts.

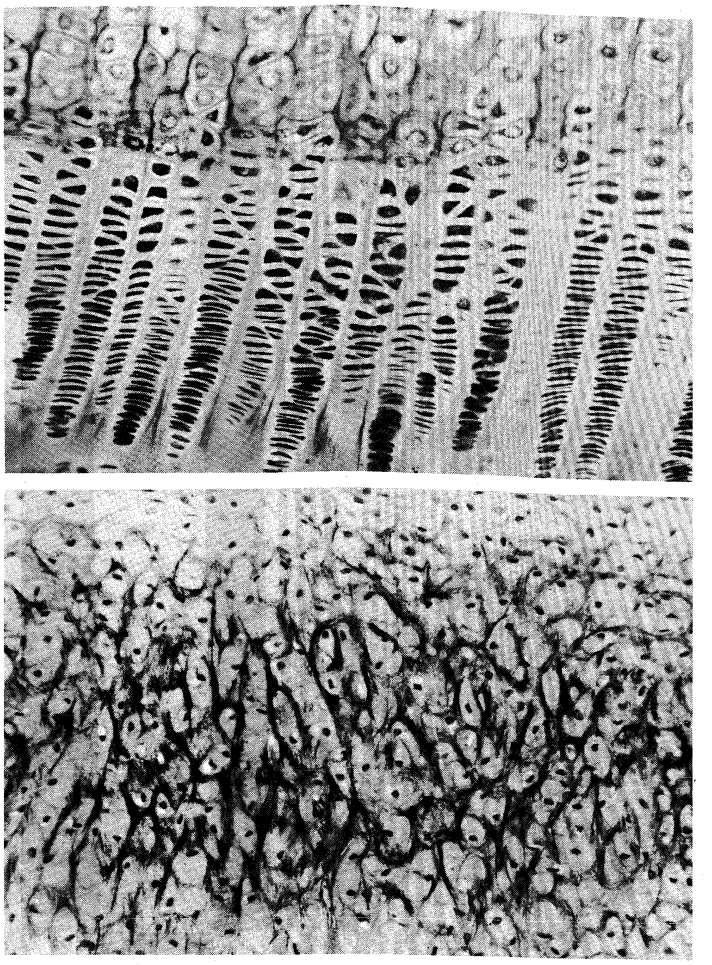

Figure 2: *Photomicrographs of cartilage.*
(Top) Hyaline cartilage of the epiphyseal plate (rabbit tibia).
(Bottom) Elastic cartilage.
Don W. Fawcett, M.D.

Indirect bone formation, in which bone replaces cartilage (Figure 2), occurs in the shaft bones (those of the arms and legs) of all animals and in the jawbones of most of them. A cell known as chondroclast dissolves the chondroitin sulfate, leaving a soft mucus-like material into which the osteoblasts move. As in the case of direct bone formation, the osteoblasts first build internal trabeculae and then encase them with solid bone. On the shank of bones (the long portion between the ends) there is always a lamellar layer of bony plates wrapped around the outside.

Muscle. Muscle, a relatively simple tissue of complex function, has primarily two kinds of cells. One cell type, found in smooth muscle, contains one nucleus; it is controlled by the autonomic nervous system (the nerves outside the central nervous system that control involuntary body functions, such as breathing and digestion) and is concerned with the maintenance of the body's interior environment. The other cell type makes up striated (striped) muscle, which is also known as skeletal muscle; it is a multinucleate cell (cell with many nuclei) innervated by the central nervous system. Because the latter is under voluntary control, it can coordinate the organism with its external environment. Although cardiac (heart) muscle consists of striated cells (fibres) that are branched and interlocking, this type of muscle is under autonomic nervous control and has a unique system for the conduc-

tion of nerve impulses (see MUSCLE SYSTEMS; MUSCLE CONTRACTION).

Smooth muscle tissue generally occurs in simple sheets that are wrapped around, or run along, internal organs. At points at which the cell membranes are fused, the individual cells are interconnected by projections (called nexuses) that run from one cell into the other. Only a relatively few cells contain nerve endings, the impulses being transmitted from cell to cell through the nexuses. This arrangement can readily result in such rhythmic movements as the peristalsis (wavelike muscle contractions) of the intestine.

The striated cells that make up skeletal muscles are very different from those of smooth muscle cells. Each cell consists of numerous long, minute, threadlike structures

Myofibrils

(myofibrils) that are of two kinds: large fibrils composed of the protein myosin give rise to dark-banded striations; thin fibrils composed of the protein actin give rise to light-banded striations. The myosin bands are designated as the A bands and the actin bands as the I bands after the manner in which they refract (bend) light. When a muscle cell contracts, the thin actin fibres slip in between or coil around the thick myosin fibres; even when fully stretched, the actin fibres still slightly overlap the myosin fibres. This system permits a large degree of extension and contraction without breaking cytoplasmic continuity.

Because striated muscle cells have several nuclei, it is customary to refer to them as muscle fibres rather than cells. These fibres are grouped together into strands, each surrounded by a thin layer of connective tissue. The strands, in turn, are gathered into bundles that are connected by a thicker layer of connective tissue, and the bundles are held together as a muscle. At each end of a muscle the tissue is infiltrated by white fibrous connective tissue, which itself becomes a ligament for attachment. Unlike smooth muscle, in which only a few cells contain nerve endings, each fibre of a striated muscle is in contact with the terminal of an afferent nerve.

The muscles of the heart were, until very recently, regarded as a single large syncytium (a multinucleate mass of cytoplasm resulting from a fusion of cells). It now appears, however, that fine divisions do exist between the fibres. The muscle fibres in this organ branch and are interlaced; they continue to contract rhythmically long after all connections to the nervous system have been severed.

OTHER TISSUES

Reproductive tissues. The most important of the reproductive tissues, the gonads (ovaries and testes) produce the gametes (eggs and sperm, respectively). These organs are simplest in the teleost fishes, in which each gonad consists of a simple closed sac, the anterior wall of which carries the spermatogonia (the precursors of mature sperm) in the male and the oogonia (the precursors of mature eggs) in the female. These gamete-producing cells are inactive except during the breeding season, when they proliferate so rapidly that the distended sac often occupies 60 percent of the total body space.

Male reproductive tissues

In all other vertebrates the testes develop as an independent body of tubules surrounding a lumen. The distal end of the tubules contains spermatogonia, and the resulting sperm accumulate in many different forms in a central area in the testes. The network of tubules leads to a duct that may, in some forms, have both a spermatheca (a small bulbous sac) for the accumulation of sperm and an ejaculatory pouch for the expulsion of seminal fluid (the sperm and the liquid secretions in which they are carried). In addition to the seminiferous tubules (those in which the sperm are formed), the testes of vertebrates contain interstitial cells (undifferentiated connective tissue cells lying between the testicular tubules) that secrete male hormones (Figure 3). In vertebrates the sperm duct (vas deferens) joins with the kidney duct (ureter) just before leaving the body. In some invertebrates, notably flatworms, the testes are diffuse structures, actually clumps of spermatogonia scattered throughout the body with ducts leading to a short vas deferens. Although many annelids (*e.g.*, earthworms) contain two or more pairs of segmentally arranged tests, the sperm still leaves the organism by a single duct.

The principal features of the male reproductive system —testes and sperm duct—are common throughout the animal kingdom, but in all groups there are many accessory sexual glands, some of unknown function. In mammals the main accessory glands are the prostate and Cowper's gland. In the former, which is a mass of branched tubules embedded in a matrix of fibrous connective tissue, the secreting tubules open by numerous ducts into the urethra (the duct that conducts urine from the urinary bladder to the exterior); it is the excretion of the prostate that forms the main mass of seminal fluid. Cowper's glands also lead into the urethra; they consist of branched tubules that secrete a thick, viscous substance for which no useful function has yet been found in most mammals. In rodents, however, the substance forms a vaginal plug that apparently helps to keep the sperm in the vagina of the female.

Female reproductive tissues

In many animals in which fertilization occurs outside the body, the female reproductive system consists of an egg-producing gland (the ovary) and a tube (the oviduct) to convey the eggs to the exterior. In all vertebrates except bony fishes, no direct connection exists between the ovary and the oviduct; the latter terminates internally as an open funnel that is pressed against the ovary only at the time of ovulation (release of the egg from the ovary). In both oviparous and viviparous forms, the tissues of the oviducts are divided into specific areas for specific functions. In oviparous vertebrates (those that lay eggs) the upper portion of the duct is lined with a mucous epithelium containing simple tubular glands that secrete a dense albuminous fluid, a protein that constitutes egg white. As the egg twists in its passage through this region, each of the ends of the thick albumin is twisted into a chalaza, one of the two spiral cords for holding the egg in the centre of the shell. The next region of the oviduct contains two types of tubular glands that are sometimes branched. One set of these glands secretes additional albumin; the other set of glands secretes a substance that constitutes the liquid portion of the egg white. The next oviduct region

lays down a coat of keratin as the base over which the next section deposits the calcareous shell.

In viviparous mammals (those who bear live young) the term oviduct is usually applied only to the region that lies between the internal funnel and the uterus (the organ in which the embryo and fetus develop). The tissues of this oviduct are quite simple, consisting of ciliated epithelium, with a few mucus-secreting cells, thrown into longitudinal folds that fill most of the lumen. At the time of ovulation the blood vessels in the oviduct become engorged with blood, and a circular band of smooth muscle contracts rhythmically so that the lip of the open funnel strokes the ovary and thus secures the egg. The epithelium of the uterus is also deeply folded and contains numerous blood vessels and mucus-secreting glands. The vagina is a simple tubular structure that, in virgins, is coated with ciliated epithelium; ultimately, this is replaced at its distal end with stratified epithelium that becomes cornified in some mammals.

The ovarian tissue is one of the most complex in the body. It consists essentially of a surface epithelium in which the oogonia are developed and a central matrix composed largely of collagen fibres and fibroblasts (cells in the connective tissue that form and maintain the fibres in such tissue). Oocytes (cells derived from mature oogonia that eventually become eggs) are budded into the matrix, in which each is surrounded by a flattened layer of what are called nurse cells. As the egg matures, it becomes surrounded by a membrane and lies into a small cavity (follicle) filled with a fluid secreted by the nurse cells. When the egg is fully mature (Figure 3), the follicle moves to the surface of the ovary and ruptures, after which the egg is taken up by the oviduct. The cleft in the follicle then closes, and because it becomes filled with yellow pigmented cells, it is known as the corpus luteum, or yellow body. The luteal cells secrete a hormone that both inhibits further egg production and assists in preparing the uterus for implantation of the egg. In such animals as the frog, in which large quantities of eggs are produced at the same time, no corpora lutea are formed; instead, the remnants of the ovary survive as a shrivelled body that does not commence egg production again until the next breeding season. In forms having heavily yolked eggs, such as birds, a dense mesh of blood vessels surrounds the follicle; yolk is transferred to the egg through the nurse cells, which remain in contact with the outer surface of the egg.

Hemopoietic tissues. Hemopoietic tissues, which produce the cellular components of blood, have an interesting evolutionary history. In the cyclostomes they appear in scattered masses throughout the intestinal wall, but by the time the level of lungfish is reached, the tissues have become aggregated into a rather well-defined mass in the wall of the stomach. In amphibians and reptiles the hemopoietic tissues are segregated as a distinct organ, the spleen; it is filled with a red pulp consisting primarily of large cells (hemocytoblasts) from which are differentiated all the various types of blood cells. The spleen in these organisms is permeated by arteries that divide into extremely thin-walled arterioles through which the white cells enter the blood; there is still some argument, however, concerning the manner in which the red cells get into the blood.

Production and destruction of blood cells

In mammals the spleen has lost entirely its hemopoietic function; its sole concern is to sort out and destroy erythrocytes that are no longer useful. The production of the cellular constituents of blood has been transferred to the red bone marrow, which fills the spaces in trabecular, or spongy, bone. Here are produced large cells called myeloblasts, which, as the need develops, differentiate into three types of leukocytes; into erythroblasts, from which the erythrocytes are formed; or into multinucleate megakaryocytes, which ultimately produce the blood platelets (minute granular bodies that function in blood clotting). In a normal human, erythrocytes are produced at the rate of about 3,000,000 per second, a figure that may double following serious injury and blood loss. Simultaneous with production, 3,000,000 erythrocytes per second are broken up in the spleen and the pieces passed to the liver, where they are broken down further. Excess pigments are excreted as bile pigments; the remainder are recycled.

Tissue fluids. The most important tissue fluid is lymph, which, as mentioned previously, is a colourless substance derived from blood that filters through the walls of capillaries to bathe the cells in all the tissues of the body. Lymph is returned to the bloodstream by lymph vessels, some of which, particularly those in the vicinity of the principal veins into which they lead, form lymph hearts. These are little more than slightly muscularized tubes with a valve at each end to secure a one-way flow of the returning lymph. Lymph is also conducted by the vessels to lymph nodes, which consist essentially of sinusoids (enlarged areas in channels of the circulatory system) that are lined with cubical epithelium and in which the composition of the lymph is adjusted in a manner that is not yet well understood.

Another blood fluid of great importance but of little-known function is cerebrospinal fluid. This colourless watery substance, which fills the cavities of the brain and spinal cord, is, to all intents and purposes, identical with the aqueous fluid that fills the eye. Cerebrospinal fluid is a specialized form of lymph; as such, it contains a few lymphocytes, a type of white blood cell that is formed in lymphoid tissues found in such organs as the spleen, tonsils, and lymph nodes. The fluid reaches the cavities of the central nervous system through a complex of tangled capillaries known as the choroid plexus, which is located in the roof of one of the brain cavities. It is through the walls of the finer blood vessels in the choroid plexus that the lymphocytes get into the cerebrospinal fluid.

Milk

A third body fluid of immense importance is that secreted by the milk-producing glands located in the breasts of female mammals. These are actually greatly enlarged sebaceous glands (saclike structures, usually opening into hair follicles, which secrete an oily fluid that lubricates the skin and hair); it is the large fat drops secreted by these glands into the fluid of the breasts that produces the familiar white emulsion known as milk. In most mammals the glands are activated by a hormone contained in the placenta (the vascular organ that connects the fetus with the maternal uterus), which is eaten by the mother shortly after the birth of its young. Hormones from the corpus luteum of the ovary also enter into the mechanism for initiating milk production. In primitive mammals, such as the duck-billed platypus, milk is not elaborated; instead, the secretion of slightly enlarged sebaceous glands is licked from the surface of the skin by the newborn, which, unlike other mammals, are hatched from eggs. Some birds also produce "milk," so called because of its opaque white appearance; female pigeons, for example, grind grain in the gizzard (a muscular enlargement of the alimentary canal), predigest it to a milky substance, and then regurgitate it for the young.

Tissues and Fluids, Plant

The plant body is constructed of various types of cells usually organized to form tissues. Tissues have been classified on the basis of their position in the plant, the types of cells they contain, and the function of these cells. No single criterion, however, adequately expresses the complex interaction of cells and their association in the form of specific tissues.

Tissues with cells that continuously divide to produce new cells are termed meristematic tissues. They give rise to the mature tissue systems of the plant of which three can be distinguished: (1) the dermal tissue system, which makes up the outer layers or protective tissue of the plant; (2) the vascular tissue system, which includes the water- and food-conducting tissues, xylem and phloem, respectively; and (3) the fundamental or ground tissue system, which includes all other tissues exclusive of dermal and vascular. Although mature tissues may consist of one cell type (simple tissues), they more often are made up of a variety of cell types (complex tissues).

MERISTEMATIC TISSUES

All tissues of the plant are derived from cell-producing tissues called primary tissue meristems, which begin to form early in embryonic development. The primary tissue meristems are designated protoderm, procambium, and ground meristem. Protoderm functions to produce the dermal or "skin" tissue system of the plant; procambium gives rise to the vascular or conducting tissue system; and ground meristem is the precursor of the fundamental or ground tissue system.

As the young embryo develops, protoderm tissue, which forms from the peripheral cells, is clearly delimited from the other tissues as the embryo elongates and becomes bilaterally symmetrical—that is, with mirror-image halves. At this stage procambium is also evident. The ground meristem originates from the embryonic tissue situated between protoderm and procambium.

Root and shoot systems

The cotyledons or first leaves (seed leaves) are the first organs formed. Soon after they begin to develop, the shoot apical meristem forms between them. At the end of the embryo opposite the cotyledons, the root apical meristem forms. The root and shoot apical meristems continuously contribute cells to the primary tissue meristems, which, following differentiation and maturation, give rise to the primary tissues and the primary plant body. The primary tissues include primary xylem, primary phloem, cortex, pith, and epidermis. In young stems the arrangement of tissues as seen in cross section is as follows: outermost tissue, the epidermis; cortex; primary phloem; and primary xylem. The pith occupies the centre of the stem (see Figure 1).

In many plants vegetative development is essentially complete when the primary tissues have matured. This is true in many lower vascular plants such as club mosses, horsetails, and some ferns; in monocotyledons (flowering plants with parallel-veined leaves, such as grasses, orchids, and palms); and in some nonwoody dicotyledons (flowering plants with net-veined leaves, such as violets and poppies). In other herbaceous dicotyledons, however, and in woody plants, formation of new tissues continues after primary growth is complete. The production of these tissues and the continuation of growth in such plants are attributable to the lateral meristems, regions of cell division that contribute to growth in stem thickness. These meristems, called the vascular cambium and the cork cambium, are responsible for producing the secondary tissues—secondary xylem, secondary phloem, and periderm—that form the secondary plant body (see Figure 2). The vascular cambium is chiefly responsible for increasing the diameter of the plant.

Apical meristems. The cells of the shoot and root apical meristem are organized in precise patterns that are characteristic of various plant groups. Knowledge of the arrangement and organization of cells at the apex is useful for descriptive purposes and for making structural comparisons between plants. Apical organization, however, is known to vary during normal development and is often influenced by seasonal changes.

Various regions of the apex can be distinguished from each other by examination of such features as cell and nucleus size, frequency and planes of cell division, and wall thickness. At the summit of the shoot apex a group of meristematic cells constitutes a so-called initiation zone, which gives rise to cells of the surface layer and a region below, the zone of central mother cells, which divide infrequently. Surrounding the latter zone is the peripheral zone, within which most of the apical activity takes place—cell divisions are frequent and leaf primordia and procambium cells are initiated. Below the central mother cell zone lies a zone termed the rib meristem, whose cells are arranged in radial, regular, longitudinal rows and divide transversely; much of the fundamental tissue system is derived from the rib meristem. Various kinds of mature tissues are produced in the plant body because the cells of the shoot apex divide at different rates and in different planes. Although in some plants, apical meristems lack distinguishable zones, the cells of the shoot apex retain the ability to divide at different rates and in different planes.

Function of apical meristems

Despite the structural differences in apical meristems of various groups of plants, they function in similar ways. All apical meristems (1) produce cells that differentiate into primary-tissue meristems, which in turn produce the primary tissues of the plant; (2) initiate organs, primarily leaves and branches, in a coordinated manner and in a genetically determined pattern; and (3) contribute to the increase in length of the plant.

Lateral meristems. The vascular cambium, which produces xylem and phloem cells, originates from procambium that has not completely differentiated during the formation of primary xylem and primary phloem. The cambium is thought to be a single row of cells that produces new cells: externally, the secondary phloem, and internally, the secondary xylem. Because it is not possible to distinguish the cambium from its immediate cellular derivatives, which also divide and contribute to the formation of secondary tissues, the cambium and its immedi-

ate derivatives are usually referred to as the cambial zone.

Unlike the apical meristems, which consist of a population of similar cells, the cambium consists of two different cell types; the fusiform initials and the ray initials (see Figure 2). The fusiform initials are elongated tapering

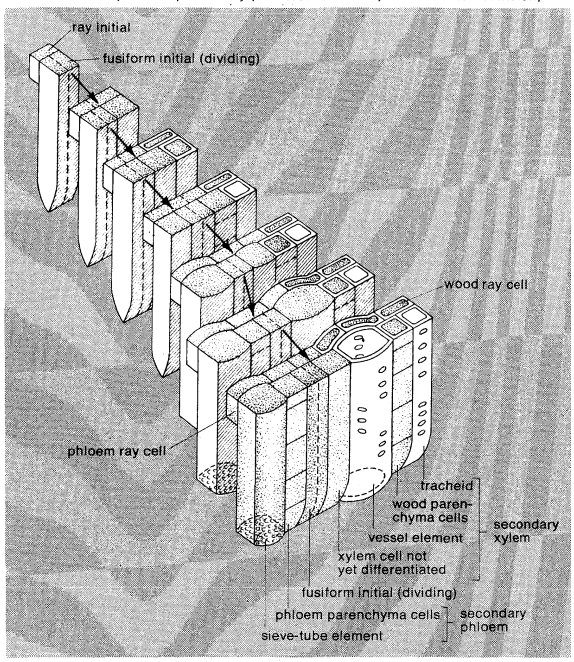

Figure 2: Production of secondary xylem and phloem cells by cambial initials.

cells that give rise to all cells of the vertical system of the secondary phloem and xylem. The ray initials are isodiametric cells—about equal in all dimensions—and they produce the vascular rays, which constitute the horizontal system of secondary tissues. The fusiform and ray initials of the cambium divide in a tangential plane (*i.e.*, parallel to the stem surface) generating xylem mother cells toward the inside and phloem mother cells toward the outside. These cells in turn continue to divide tangentially, producing new cells that add to the xylem and to the phloem. Divisions of the cambium cells and xylem and phloem mother cells do not result in the production of equal amounts of secondary xylem and secondary phloem; because the cambium produces more cells internally than externally, more secondary xylem is produced than secondary phloem. Because divisions in the fusiform and ray initials are primarily tangential, new cells are regularly arranged in well-defined radial rows, a characteristic pattern for secondary vascular tissues.

Divisions in the cambium not only produce secondary vascular tissues but also increase the circumference of the cambium. As new cells are continuously added to the inside of the cambium, the cambium increases laterally (in circumference) to keep pace with the growth of the stem. In some plants this is accomplished simply by radial division of the fusiform and ray initials. In other plants, the mechanism for increasing cambial diameter or increasing the number of cambial cells is more complex. If cambial activity is extensive, the primary tissues lying outside the cambium, such as primary phloem, cortex, and epidermis, may be crushed by the pressure of new secondary tissue growth or become torn and obliterated because they cannot accommodate to the rapidly increasing diameter of the plant.

As growth proceeds the cork cambium forms in living cells of the epidermis, cortex, or, in some plants, phloem and produces a secondary protective tissue, the periderm. The cork cambium is, like the vascular cambium, a lateral meristem that produces cells internally and externally by tangential divisions. Unlike the cambium, the cork cambium consists of one cell type.

Intercalary meristems. Another type of meristem active in certain plants, especially horsetails and grasses, is the intercalary meristem. These cells possess the ability to divide and produce new cells, as do apical and lateral meristems. They differ, however, in being situated between regions of mature tissue, such as at the base of grass leaves, which are themselves located on mature stem tissue. In many instances intercalary meristems function for only a short time and eventually completely differentiate into mature tissues. Intercalary meristems are usually located at positions on the stem where leaves have emerged (nodes) and are largely responsible for elongation in grass shoots and leaves.

MATURE TISSUES

Dermal (protective) tissues. *Epidermis.* The epidermis, or surface cell layer, which covers all organs of the plant including stem and root, leaf, flower, fruit, and seed, functions in a variety of ways. It limits transpiration —evaporation of water from the surface of the plant, especially the leaf. Specialized cells facilitate gaseous exchange between the outside air and internal tissues. The epidermis also serves as a protective barrier, restricting insect and bacterial invasion of the underlying cells. In view of the many functions of this tissue, it is not surprising that it is also structurally variable. The epidermis may consist of either one cell layer or several.

Function of epidermis

The epidermis forms from protoderm, one of the primary tissue meristems. In addition to cellulose, the main carbohydrate component of wood, epidermal cells produce a fatty substance, cutin, which permeates the cell wall, eventually forming an outer layer, the cuticle. Although a cuticle covers the epidermis of all higher plants, the extent to which it develops depends on the plant species and the environment in which it grows. The cuticle is responsible for the protective functions of the epidermis. In some plants wax is also deposited on the cuticle and within the matrix of the cell wall. Waxy deposits may occur as thin layers or as thick layers such as those seen on leaves of the Brazilian wax palm, *Copernicia cerifera*, from which the commercially important carnauba wax is collected. The wax covering further serves to control water loss. Other substances, such as lignin, crystals, and mucilage, occur in epidermal cell walls of certain plants.

The epidermis is not continuous over the surface of the plant but is interrupted by pores that serve as channels to the interior tissues. The pores are bordered by specialized, often kidney-shaped epidermal cells, called guard cells. The combination of pore and guard cells is referred to as the stoma. Two to several epidermal cells, called accessory cells, may be adjacent to the guard cells and participate in stomatal opening and closing. The accessory cells and the stoma constitute the stomatal apparatus. There is considerable variation in the development, structure, and distribution of the stomatal apparatus in plant species. The size, shape, and wall thickenings of the guard cells are important in stomatal function and gaseous exchange.

Another important group of structurally modified epidermal cells includes hairs (trichomes) which occur as outgrowths of epidermal cells and, when present, are usually characteristic of the particular plant. Trichomes may be either glandular, consisting of a stalk terminating in a globular head, or nonglandular, consisting simply of elongated, often tapering structures. Both types may be single celled or multicellular. The glandular trichomes usually produce and secrete volatile and nonvolatile substances, such as volatile oils, mucilages, and resins. In addition, trichomes on many carnivorous plants produce digestive enzymes (biological catalysts). Nonglandular trichomes, which may function in reducing transpiration and excessive water loss, are variable in structure and occasionally provide commercially important products, such as cotton and kapok.

Root hairs

Hairs are found on the surfaces of roots. Root hair cells are initiated behind the meristematic zone of the root apex and continue to elongate as the distance of the epidermal cells from the meristem increases. Root hairs usu-

ally live and function only for a few days; the sequential nature of the production near the root apex, however, insures a continuous supply. Root hairs increase the water absorbing ability of the plant.

Periderm. In plants in which substantial secondary growth—increase in stem thickness—occurs, a protective tissue, the periderm, forms. It arises from the activity of a cork cambium and is a complex tissue consisting largely of cork cells. Periderm serves the secondary plant body in much the same way as the epidermis serves the primary plant body, restricting water loss from the tissues within, protecting against attack by organisms—particularly after tissue damage—and preventing mechanical injury to the underlying tissues. The protective nature of periderm results largely from the properties of cork cells, many layers of which form on the outer side of the cork cambium. Cork cells produce a fatty substance known as suberin, which is deposited over the primary cellulose walls; in addition, some wax may also be deposited. The combination of wax and suberin makes the cork relatively impermeable to the passage of water and gases. In certain plants some cork cells remain thin walled and alternate with thick-walled cells. Neither cell type is alive when mature. At maturity all cork cells become filled with air or, in some instances, with resins or tannins that produce the dark pigmentation characteristic of certain types of cork and may have a protective function.

As secondary growth continues, the outer periderm layers crack and peel, and new layers of periderm form in tissues underlying the older periderm. In certain parts of the periderm, loosely arranged groups of cells often project above the other cells, forming prominent markings on the outer surface of the plant. These groups of cells, called lenticels, are similar to stomata in that they provide for passage of air to the interior tissues. The term bark is a nontechnical one usually referring to all tissues outside the vascular cambium. It may include parts of the phloem, cortex, and epidermis as well as periderm.

Vascular (conducting) tissues. All vascular plants, such as ferns, gymnosperms, and angiosperms, possess a well-developed vascular system that conducts water and food materials through the plant axis to the various organs; it usually also functions in support. The vascular system consists basically of two complex tissues, the xylem and phloem (see Figure 3). The two tissues are

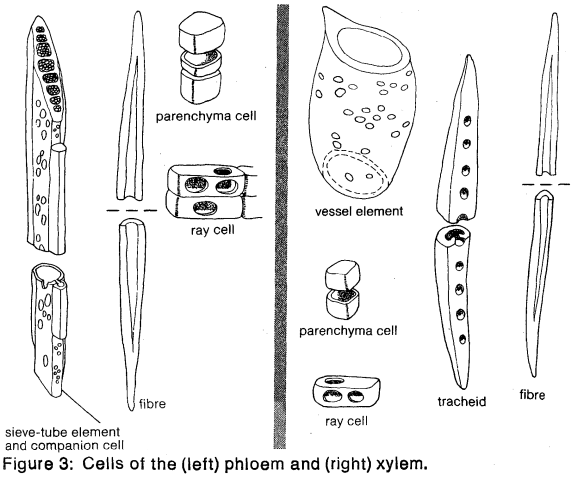

Figure 3: Cells of the (left) phloem and (right) xylem.

distinctive, each being made up of several different cell types and each functioning in its own way. Movement of water and dissolved salts from the root system to other parts of the plant takes place through the xylem. Transfer of food materials produced in photosynthetic tissue or accumulated in storage organs occurs through the phloem (see also PLANT INTERNAL TRANSPORT).

Function of xylem and phloem tissues

Vascular tissue is usually classified into primary xylem and primary phloem, which are produced by the procambium, and secondary xylem and secondary phloem, which are produced by the cambium. The first cells of primary xylem and primary phloem to differentiate, called protoxylem and protophloem, are followed by additional vascular elements called metaxylem and metaphloem. Because protoxylem and protophloem ordinarily mature while the axis is elongating, they are often partially or completely destroyed during growth. Since metaxylem and metaphloem mature after elongation is complete, the cells composing them are not destroyed. In grasses and some other monocotyledons, the vascular tissues are formed until all the procambium has differentiated; the vascular bundle is then said to be closed to further development. In other vascular plants, however, residual procambium is present, and the bundle is said to be open to additional growth. The cambium formed from this procambium continues to produce new xylem and new phloem. Differentiation of vascular tissues in roots is similar to that in stems.

Xylem. The xylem (wood) of most angiosperms is made up of cells called tracheids, vessel elements, and wood fibres collectively known as tracheary elements. It also contains parenchyma cells, which are often relatively simple thin-walled cells (see Figure 3). During development the walls of primary xylem cells thicken in a characteristic way. The thick walls of the first formed cells of protoxylem are deposited in discrete rings. These annular or sometimes helical thickenings become stretched and extended by the elongation of the tissue, occurring at this time. The deposition of thick walls of later formed cells of metaxylem is much more complete. The thickened bands join to form scalariform and reticulate thickenings. The newest cells of metaxylem have their entire inner surface covered by thick walls except for regions containing thin places, the pit areas. These pitted elements are characteristic of the latest formed primary xylem and of the secondary xylem.

Tracheids and vessel elements are elongated cells, which, at maturity, have thickened lignified walls, usually bearing numerous pits. They contain no living material (protoplast), and water flows unimpeded through the cell lumen (interior). Vessel elements differ from tracheids in being perforated at their ends; tracheids are imperforate cells that communicate only through the pits between overlapping walls of adjacent cells. The perforations usually occur on the end walls but may also form on the side walls. In either case this area of the cell wall is known as a perforation plate. Vessel elements, usually arranged in longitudinal rows, one above the other, form a connected series of elements known as a vessel. Vessels provide the major pathway for longitudinal conduction of water in most angiosperms. The length of a vessel varies, and the end members are imperforate. If vessel length is limited, a continuous network of overlapping vessels that transports water to terminal parts of the plant is maintained. Water moves longitudinally through the vessels and also through the pits on the lateral walls of the vessels into adjacent vessels. This combination of lateral and longitudinal flow is necessary for effective water transport. In certain primitive angiosperms and in gymnosperms (conifers) and some lower vascular plants that lack vessels (*e.g.*, certain ferns and club mosses), the movement of water occurs entirely through pits on lateral walls of tracheids to adjacent elements.

Water movement

The bulk of tissue in most trees is secondary xylem or wood. Perhaps the most conspicuous feature of secondary xylem and one that commonly distinguishes it from primary xylem is the presence of vascular rays. These form a transverse (extending from the stem centre to the surface) system of living tissue intimately associated with the tracheary elements. The extent of secondary xylem development is dependent on the activity of the cambium. Its activity, like that of most other meristems, is usually periodic, and the tracheary elements produced during the beginning of the growth period are distinct from those produced toward the end of the growth period. The periodic activity of the cambium is thus apparent in the structure of the xylem. The amount of xylem produced during one growth period is called a growth ring; when growth rings concide with annual growth activity, the term annual ring is often employed.

Phloem. Because of its importance in long distance translocation of food, the phloem has been extensively studied. Despite the information that has accumulated, the characteristics of the functioning phloem cells are not yet known. The major difficulty is that when phloem tissue is injured or killed, as it must be for most studies, changes occur in the conducting cells. Because intact phloem cells are under a positive pressure, any injury results in a rearrangement of the cell contents. The position and physical state of the cellular components in an injured cell may differ considerably from those of the intact, functioning cell. Although it has not yet been possible to describe fully a functioning conducting cell, the components that are present can be described, and the features that have been consistently observed can be indicated.

In angiosperms, phloem is composed of sieve-tube elements and companion cells together with other cells such as phloem fibres (see Figure 3). Sieve-tube elements are arranged end-to-end in a connected series, forming a sieve tube. In gymnosperms the equivalent of sieve-tube elements and companion cells are the sieve cells and albuminous cells. Sieve cells differ from sieve-tube elements primarily in the nature of their sieve areas, which are thin places in the cell wall with pores through which conducting strands link adjacent cells. In sieve cells the sieve areas are unspecialized; that is, clusters of pores similar in size and number are distributed on the lateral and tapering end walls. In sieve-tube elements, on the other hand, a few sieve areas on the end walls usually have larger pores and are termed sieve plates. In the sieve tube the individual sieve-tube elements join at their sieve plates. In tissue containing sieve cells, the cells overlap one another, and the sieve areas of adjacent cells are associated, forming a continuous link from cell to cell.

The pores in sieve areas contain callose, a carbohydrate. The amount of callose in the pores increases as the cell ages or after the cell has been chemically or mechanically treated. Deposits of callose are believed to plug the sieve areas and to interfere with food conduction. Whether or not callose deposition in sieve areas occurs in functioning conducting elements remains controversial. Evidence suggests that callose, ordinarily present in small quantities, increases in amount after tissue manipulation. Its presence in fixed material (*i.e.*, tissues prepared for microscopic examination) is a diagnostic feature of phloem.

The nature of the conducting strands is not yet clearly understood. Presumably they are composed of cytoplasm and are similar in some ways to plasmodesmata—cytoplasmic connections from cell to cell. The conducting strands may be larger than plasmodesmata and often are packed with protein in fixed material. In mature sieve cells and sieve-tube elements, the vacuolar membrane (*i.e.*, the membrane surrounding the internal watery sac in the centre of the cell) breaks down, resulting in a mixing of cytoplasm and vacuolar contents. Protein initially present in the cytoplasm may move through sieve areas and be continuous from cell to cell. It has been difficult to determine whether or not the protein plays a role in the transfer of food. Phloem protein (P-protein), once called slime, is often observed in conducting cells of the phloem where it forms slime plugs that lie against the sieve areas. It is essential that the relationship between protein and the conducting strands be clarified before the mechanism of transport through phloem can be fully explained. Although sieve-tube elements and sieve cells commonly lose their nuclei as they mature, they do retain functional cytoplasm. The companion cells and albuminous cells of the phloem are also thought to be essential for translocation of food.

Phloem cell contents

Fundamental (ground) tissues. The axis of most plants is composed of relatively large amounts of fundamental, or ground, tissues. The most common are parenchyma, collenchyma, and sclerenchyma (see Figure 4). These are simple tissues, but parenchyma and sclerenchyma are often found as components of complex tissues.

Parenchyma. Parenchyma is made up of thin-walled, commonly polyhedral (many-sided) living cells. The most common tissue in vascular plants and perhaps the most primitive, parenchyma is the chief constituent of the cortex and pith, the photosynthetic tissue of leaves, the pulp of fruits, and the endosperm (starchy nutrient tissue for the developing embryo) of many seeds. It is also found associated with the primary and secondary xylem and phloem. Although structurally simple, parenchyma cells may be highly specialized in a physiological sense. Some cells, especially those of the leaf and cortex, contain chloroplasts, which are small membrane-enclosed pigment bodies active in photosynthesis. Parenchyma containing chloroplasts is known as chlorenchyma. Other parenchyma cells may function in the production and storage of food substances necessary for maintenance of the plant. Parenchyma cells containing starch, lipid (fats), or protein are common in fruits, seeds, and especially in storage organs, such as rhizomes (creeping horizontal stem structures), bulbs, and tubers (underground storage stems, such as potatoes). Some parenchyma cells synthesize and accumulate other products such as crystals of calcium oxalate, tannins, mucilages, and resins. In addition, water, pigments, and soluble salts are found

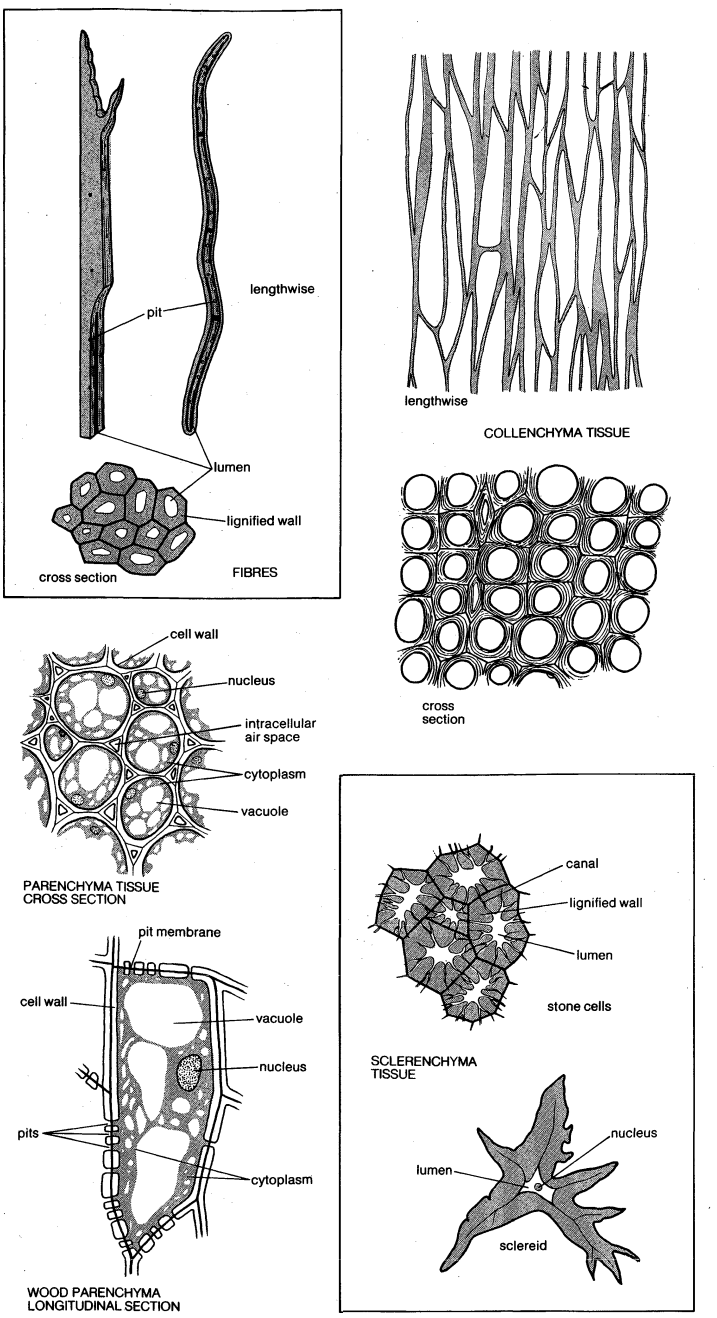

Figure 4: Cell types and tissues.
From T. Weier, C. Stocking, and M. Barbour, *Botany* (1970); John Wiley & Sons

within parenchyma cells. Parenchyma tissue is therefore of primary importance to the plant.

Collenchyma. Collenchyma is basically a supporting tissue that provides structural rigidity for many plant organs. It is found chiefly in the cortex of stems and in leaves. For many herbaceous plants it is the chief supporting tissue, especially during early stages of development. In plants in which secondary growth occurs, the collenchyma tissue is only temporarily functional and becomes crushed as woody tissue develops. Collenchyma is located along the periphery of stems beneath the epidermal tissue. It may form a complete cylinder or occur as discrete strands that constitute the ridges and angles of stems and other supporting structures of the plant.

Collenchyma cells, polygonal in cross section, are much longer than parenchyma cells. The strength of the tissue results from the unevenly thickened cell walls and the longitudinal overlapping and interlocking of the cells. The cells have protoplasts, often containing chloroplasts, and they produce a thick cellulose wall. The wall is not uniformly thick in all cells, and thickening may occur predominately in longitudinal strips at the corners of the cell, on the tangential (*i.e.*, outer, toward the stem exterior) surface of the cell, or around the spaces between adjacent cells. Pits are present and provide a mechanism for intercellular communication. An important feature of collenchyma is that it is extremely plastic—the cells can extend and thus adjust to increase in growth of the organ.

Location of collenchyma wall thickenings

Sclerenchyma. The major function of sclerenchyma is support. Unlike collenchyma, mature cells of this tissue are generally nonliving and have heavily thickened walls containing lignin. The size, shape, and structure of sclerenchyma cells are not uniform. Two distinct types of cells occur: those that are greatly elongated are termed sclerenchyma fibres; those that are essentially uniform in diameter are called sclereids (see Figure 4). The division is arbitrary, and intermediate and overlapping types of sclerenchyma cells commonly occur, even within one plant organ.

Fibres may occur singly or in groups of few to many cells with their long, tapering ends interlocked, thus providing maximum support. They may be found almost anywhere in the plant body and are classified according to position. Cortical fibres and phloem fibres are characteristic of the stems and roots of many plants. Fibres also partially or completely surround vascular bundles in leaves and in the plant axis. Most fibres have extremely thick cell walls containing pits, and the cell lumen is very narrow or completely obscured.

Sclereids occur singly or in groups and are present in various tissues of the plant such as periderm, cortex, pith, xylem, and phloem. They also occur in leaves and fruits and constitute the hard shell of nuts and the outer hard coat of many seeds. Sclereid walls are commonly pitted, and the pits may be extensively branched. Sclereids are extremely variable in form and are classified according to shape. Brachysclereids or stone cells are isodiametric; macrosclereids are rod shaped; osteosclereids are bone shaped; that is, elongated with enlarged ends; and asterosclereids are star shaped or otherwise branched. The utility of this classification is limited by the occurrence of sclereids that do not fit into any of the categories.

Endodermis. The endodermis, another kind of ground tissue, usually consists of a layer of cells surrounding the vascular system and separating it from the cortex. The endodermis is a prominent feature of the roots in most vascular plants and of shoots of many lower vascular plants. The endodermal cells have distinctive wall markings caused by the deposition of suberin in a strip along the transverse and radial walls (*i.e.*, on all walls except the inner and outer ones that are parallel to the root surface) of the cells; it is known as the Casparian strip. The Casparian strip is often impregnated with lignin. The combination of suberin and lignin in the cellulose matrix of the wall restricts the passage of water and solutes. In some plants, as a result of the continued deposition of encrusting materials, these endodermal cells appear to be thick walled. Cells adjacent to the xylem that fail to thicken are identified as passage cells. The functional significance of the endodermis tissue remains obscure despite the attention given it by many investigators.

Casparian strips

Titanium Products and Production

Titanium, a metallic element of light weight—0.163 pounds per cubic inch (4.51 grams per cubic centimetre)—and of high strength particularly in alloy form, is used extensively in many aerospace applications; and because of its excellent corrosion resistance, it has many applications in the chemical-process industries. Although the element titanium had been known since its initial discovery in 1791 by William Gregor in England, and its identification in rutile in 1795 and in ilmenite in 1797, it was not until William Justin Kroll, a German refugee in the U.S., invented a magnesium-reduction process in 1936 that the production of metallic titanium became feasible. The process, which Kroll gave to the U.S. Bureau of Mines for development, remains in its original form or modifications thereof, the principal method used today for winning titanium metal from its ores.

Mining. Titanium ores are plentiful, and numerous deposits of highly concentrated titanium minerals are readily accessible and easily mined. Rutile in the beach sands of Florida and Australia is merely scooped up and shipped to a mill for processing. Ilmenite, such as occurs in many near-surface deposits in North America, is similarly mined with large, mechanical shovels and transported to the processing plant.

Titanium ores

Rutile and ilmenite are the two important ores of titanium. Rutile is almost pure (98–99 percent) titanium dioxide (TiO_2), containing small amounts of iron, silicon, and other elements as impurities. Ilmenite is a combined iron(II)-titanium dioxide usually expressed as iron(II) titanate ($FeO\text{-}TiO_2$) containing about 32 percent titanium and 37 percent iron. Rutile is the preferred ore for the production of titanium because of its high titanium content and the ease with which titanium tetrachloride, the starting material for the production of metallic titanium, can be produced from it (see Table 1).

Most of the world's rutile supply comes from the beach sands of New South Wales and Queensland along the east coast of Australia. Other sources include Florida, India, Brazil, and South Africa. Ilmenite is much more abundant than rutile, and large deposits are known to exist in the United States, Canada, South America, Africa, and Europe, including the U.S.S.R. (See Table 1.) In addition to rutile and ilmenite, many other minerals contain titanium but not in sufficient concentration to be of commercial importance.

Refining and recovery. The production of titanium metal from its ores is accomplished in several steps, each involving chemical reactions and each designed to eliminate the gaseous elements oxygen and nitrogen from the chemical reactions. Titanium dioxide is produced from rutile or ilmenite by dissolving the ore in a sulfuric acid solution and precipitating the iron compounds. The solution is then hydrolyzed, producing a hydrous titanium oxide, which is washed and calcined. Titanium has a great affinity for oxygen and nitrogen, and unlike other metals, it actually dissolves oxygen and nitrogen in both the liquid and the solid states in addition to reacting to form oxides and nitrides. To eliminate oxygen and nitrogen from the titanium production processes, the oxide prepared from the ore is first converted to titanium tetrachloride ($TiCl_4$) by reacting the titanium dioxide with chlorine gas in the presence of a reducing agent, usually carbon.

The resultant titanium tetrachloride—a liquid when at room temperature—contains many impurities, principally other metal chlorides, and it must be purified before being

reduced to titanium metal. A sequence of distillations at temperatures above or below the boiling point is used to remove these undesired compounds. The high-purity titanium tetrachloride produced is reduced to metallic titanium by reaction with magnesium or sodium. The Kroll process, which uses magnesium, and modifications that use sodium, as the reducing agents, are batch processes conducted in large reactors. An argon or helium atmosphere is used within the reactor because all air and moisture must be excluded from the reaction to prevent oxygen, nitrogen, or hydrogen contamination of the final product. Both processes produce titanium in the form of a highly porous material, termed titanium sponge, with magnesium chloride or sodium chloride entrapped in the pores. This sponge is crushed to a suitable size for handling and then leached with water and acid or heated in a vacuum to remove the entrapped chlorides. Titanium sponge is the raw material from which ingots of titanium and titanium alloys are melted. The sponge's purity is dependent on the purity of the titanium tetrachloride from which it was made, the purity of the magnesium or sodium reducing agent, and the purity of the atmosphere during the reduction process. Common impurities in sponge titanium are oxygen, nitrogen, carbon, hydrogen, and iron.

The Kroll process

The metal and its alloys. Titanium in pure form is a soft, ductile metal. It has a density of 4.51 grams per cubic centimetre (0.163 pounds per cubic inch), which is about midway between aluminum (2.70 grams per cubic centimetre) and iron (7.86 grams per cubic centimetre). It has a silvery gray colour and can be polished to a high lustre. It is not, however, as lustrous as chromium or stainless steel. Titanium melts at 1,675° C (3,045° F). The common impurities, carbon, oxygen, and nitrogen, raise the melting point; most metallic impurities, such as iron, manganese, chromium, and copper, lower the melting point. There are two crystal structures of titanium. At temperatures below 882° C (1,620° F), titanium has a hexagonal close-packed structure; this form is known as the alpha phase. At temperatures between 882° C and its melting point, titanium has a body-centred cubic structure, known as the beta phase (see below). Titanium is paramagnetic and has very low electrical and thermal conductivity. It occurs in three valence forms, 2, 3 and 4, the most stable of which is 4. The most common oxide is titanium dioxide, TiO_2.

Like stainless steel and aluminum, titanium, because of the formation of an oxide surface film that is relatively inert chemically, has excellent corrosion resistance, in many environments. Titanium will resist corrosive attack by oxidizing acids such as nitric acid and aqua regia, organic acids, moist chlorine gas, chloride solutions, dilute solutions of sulfuric acid and hydrochloric acid, and dilute solutions of alkalies. Although at room temperatures titanium is resistant to oxidizing atmospheres, at elevated temperatures it reacts with the oxygen in the air. At temperatures as low as 260° C (620° F), the surface of titanium becomes tarnished, forming an oxide film that ranges in colour from blue to gold. At higher temperatures, a thicker, yellow-brown oxide film, or scale, is formed. The rate of oxidation increases as the temperature is increased, but it is not until temperatures are above about 1,200° F (648° C) that oxidation becomes a problem if long-time exposures are involved. At temperatures between 1,200° and 2,200° F (1,215° C), short-time heating can be carried out in air. Forging and fabrication of titanium alloys are done at these temperatures with no detrimental effects as long as the oxide scales are removed after fabrication. In the liquid state, however, titanium is very reactive and reduces all known refractories.

Corrosion resistance

Titanium will ignite and burn in dry chlorine gas and is attacked by hydrofluoric and phosphoric acids and moderate concentrations of the alkalies. Titanium is severely attacked by fuming red nitric acid. The corrosion resistance of titanium is outstanding in marine atmospheres and seawater. No noticeable corrosion of titanium has been found after exposure to seawater for over three years.

Perhaps the most important property of titanium is its ability to be alloyed with most of the other metals and many of the nonmetals. Alloying additions increase the strength of titanium both at room temperatures and at elevated temperatures. Pure titanium has a tensile strength of about 40,000 pounds per square inch (psi). By alloying it, tensile strengths as high as 200,000 psi can be obtained, thus making it useful as a structural metal.

The major alloying elements that are added to titanium are aluminum, vanadium, molybdenum, manganese, iron, and chromium. All of the titanium-base alloys contain one or more of these elements. The gaseous elements—oxygen, nitrogen, and hydrogen—and carbon are present in small quantities in almost all titanium alloys.

Titanium alloys can be classed in three basic types: alpha, alpha-beta, and beta alloys. Alpha alloys contain elements that dissolve in the hexagonal close-packed alpha phase. Alpha-beta alloys contain limited quantities of elements that dissolve in the body-centred cubic beta phase resulting in a two-phase alpha-beta alloy. Beta alloys contain large quantities of elements that dissolve in the beta phase resulting in an all-beta structure. Alpha alloys have medium strengths (120,000 to 150,000 psi) and good elevated-temperature strengths, can be welded, and are used mostly as forgings. Alpha-beta alloys are the most versatile. In the annealed condition, they have medium strengths but can be heat treated to very high strengths. These alloys have good forming characteristics and can be used in both sheet and bar-stock form. Generally, they are not weldable. Beta alloys have medium strengths and excellent forming characteristics but contain large quantities of high-density alloying additions. They also can be heat treated to high strength levels. Compositions and properties of typical alloys are listed in Table 2.

Titanium has long been used as a deoxidizer in steel, to which it is added as a ferrotitanium or a ferrocarbontitanium alloy. More recently, it has been used as an alloy-

Table 2: Typical Alloys

type of alloy	composition (balance titanium)	tensile strength (psi)	elongation (percent)
Alpha	5% Al–2.5% Sn	130,000	15
Alpha-beta	6% Al–4% V	140,000	15
Alpha-beta (heat treated)	6% Al–4% V	180,000	7

Beta (heat treated)	13% V–11% Cr–3% Al	200,000	6

ing addition to many steels to reduce grain size and control carbon content in stainless steel. In aluminum it is used to refine the grain size, while in copper it produces a precipitation-hardening alloy. In high-temperature nickel–cobalt–chromium alloys, titanium is added to produce a precipitation-hardening reaction providing high strengths at temperatures up to 1,500° F (815° C). Titanium is used in permanent magnet alloys of the iron–cobalt–nickel–titanium type.

Chemical compounds: preparation and uses. Titanium dioxide (TiO_2) is the most important compound of titanium. It is used extensively in the pigment industry because of its excellent hiding power or opacity. A pure white compound having high reflectivity, it is ideal for use in white paints, enamels, and lacquers and can be used in conjunction with other compounds in coloured paints.

Use in the pigment industry

It is also used in pigments for rubber, paper, oilcloth, leather, textiles, inks, and cosmetics. The two main sources for titanium dioxide are rutile and ilmenite. Since less pure titanium dioxide can be used in pigments than can be used in producing titanium metal, most of the titanium dioxide produced from ilmenite is used by the pigment industry. The preparation of titanium dioxide for the pigment industry follows the same procedures as those already described.

Titanium tetrachloride, the raw material for producing titanium metal, is the next most important compound. It is produced by chlorinating titanium dioxide, or titanium ores, in the presence of carbon. The minor amounts of iron, silicon, oxygen, and other impurities remaining after chlorination are removed by fractional distillation. Titanium tetrachloride is used, along with titanium dioxide, as a catalyst in many chemical reactions and as a smoke-producing compound for skywriting or smoke screens. Titanium carbide, a compound produced by reacting carbon with a titanium compound, is used in conjunction with a tungsten carbide in cutting tools and dies. Thin coatings of pure titanium carbide (3,800 on the Vickers diamond hardness scale as compared to about 1,300 for tungsten carbide) are applied by vapour deposition on tools, dies, punches, and other components. Many other compounds of titanium exist, but their uses are limited.

Economic importance. Titanium became an important structural metal with the advent of the space age. Its primary uses are as components in the compressor sections of jet engines, and as structural and nonstructural components of airframes and space-vehicle systems. These applications exploit the high strength-to-weight ratios of titanium alloys and their retention of strength in moderately high temperatures. In addition, titanium and its alloys are used in chemical-process equipment in which the excellent corrosion resistance can be used to advantage.

In the early days of titanium-sponge production (the 1950s), titanium sponge sold for about $5 per pound. As the quantity of titanium-sponge production increased, the price of sponge gradually fell until it sold at about $1.30 per pound with mill products selling for $3 to $20 per pound, depending on the complexity of the production process.

Titanium sponge is produced in the United States, Japan, U.S.S.R., and Great Britain. United States consumption (see Table 3) of sponge increased annually from 1960 to 1967, the year that government stockpiling was stopped; production in that year peaked at about 30,000,000 pounds. U.S. production accounted for about two-thirds of consumption, the remainder being imports principally from Japan. The prognosis for the titanium industry remained favourable, with predictions of increased consumption through the 1970s.

Titian

Titian was recognized early in his own lifetime as a supremely great painter, and his reputation has never suffered a decline in the intervening centuries. The art theorist Giovanni Lomazzo in 1590 declared him "the sun amidst small stars not only among the Italians but all the painters of the world." The universality of Titian's genius is not questioned today, for he was surpassingly great in all aspects of the painter's art. In his portraits he searched and penetrated human character and recorded it in canvases of pictorial brilliance. His religious compositions cover the full range of emotion from the charm of his youthful Madonnas to the tragic depths of the late "Crucifixion" and the "Entombment." In his mythological pictures he captured the gaiety and abandon of the pagan world of antiquity, and in his paintings of the nude Venus ("Venus and Adonis") and the Danae ("Danae with Nursemaid") he set a standard for physical beauty and often sumptuous eroticism that has never been surpassed. Other great masters—Rubens and Nicolas Poussin, for example—paid him the compliment of imitation.

EARLY LIFE AND WORKS

The traditional date of Titian's birth was long given as 1477, but today most critics favour a later date of birth —1488/1490. Titian (in Italian Tiziano Vecellio), son of a modest official, Gregorio di Conte dei Vecelli, and his wife, Lucia, was born in the small village of Pieve di Cadore, located high amid mountain peaks of the Alps, straight north of Venice and not far from the Austrian Tyrol. At the age of nine he set out for Venice with his brother, Francesco, to live there with an uncle and to become an apprentice to Sebastiano Zuccato, a master of mosaics. The boy soon passed to the workshop of the Bellini, where his true teacher became Giovanni Bellini, the greatest Venetian painter of the day. Titian's early works are richly evident of his schooling and also of his association as a young man with another follower of the elderly Giovanni Bellini, namely, Giorgione of Castelfranco (1477–1510). Their collaboration in 1508 on the frescoes of the Fondaco dei Tedeschi (the German Exchange) is the point of departure for Titian's career, and it explains

Influence of Giorgione

Titian, self-portrait, oil painting. In the Staatliche Museen Preussischer Kulturbesitz, Berlin.

why it is difficult to distinguish between the two artists in the early years of the 16th century. Only ruined outlines of the frescoes survive, the "Allegory of Justice" being the chief scene assigned to Titian. The etchings (1760) of the frescoes by Antonio Maria Zanetti, already in a much faded condition, give a better notion of the idealism and the sense of physical beauty that characterize both artists' work. The problem of distinguishing between the paintings of Giorgione and the young Titian is virtually insuperable, for there is little solid evidence and even less agreement among critics about the attribution of several works. The present tendency among Italian writers is to assign far too much to Titian in his youth.

It is certain that Titian's first independent commission was for the frescoes of three miracles of St. Anthony of Padua. The finest in composition is the "Miracle of the Speaking Infant"; another, the "Miracle of the Irascible Son," has a very beautiful landscape background that demonstrates how similar in topography and mood were Titian's and Giorgione's works at this time. In fact, after Giorgione's death in 1510, Titian assumed the task of adding the landscape background to Giorgione's unfinished "Sleeping Venus" (Gemäldegalerie, Dresden), a fact recorded by a contemporary writer, Marcantonio Michiel. Still Giorgionesque is the somewhat more lush setting of Titian's "Baptism of Christ" (*c.* 1515, Capitoline Museum, Rome), in which the donor, Giovanni Ram, appears at the lower right.

The authorship of individual portraits is the most difficult of all to establish, but the "Gentleman in Blue" (so-called "Ariosto") is certainly Titian's because it is signed with the initials T.V. (Tiziano Vecellio). The volume and the interest in texture in the quilted sleeve seem to identify Titian's own style. On the other hand, "The Concert" has been one of the most debated portraits, because since the 17th century it was thought to be most typical of Giorgione. The pronounced psychological content as well as the notable clarity of modelling in the central figure has led 20th-century critics to favour Titian. Technique and the clear intelligence of the young Venetian aristocrat in the "Young Man with Cap and Gloves" has led modern critics to attribute this and similar portraits to Titian.

The earliest compositions on mythological or allegorical themes show the young artist still under the spell of Giorgione in his creation of a poetic Arcadian world where nothing commonplace or sordid exists. The inspiration lies in the idyllic world of the love lyrics of the 16th-century Italian poets Jacopo Sannazzaro and Pietro Bembo. "The Three Ages of Man," where the erotic relationship of the young couple is discreetly muted and a mood of tenderness and sadness prevails, is one of the most exquisite of these. The contemporary "Sacred and Profane Love" is likewise set in a landscape of extraordinary beauty, but here the allegory is less easily understood. The most generally accepted interpretation holds that the two women are the twin Venuses, according to Neoplatonic theory and symbolism. The terrestrial Venus, on the left, stands for the generative forces of nature, both physical and intellectual, while the nude Venus, on the right, represents eternal and divine love. Essentially an ideally beautiful young woman rather than a cruel biblical antiheroine is the lovely "Salome."

MATURE LIFE AND WORKS

Marriage

Sometime in the early 1520s Titian brought to his house in Venice a young woman from Cadore whose name was Cecilia. Two sons were born in 1524 and 1525, first Pomponio, who became a priest, and second Orazio, later a painter and Titian's chief assistant. During Cecilia's grave illness in 1525, Titian married her. She recovered and later gave birth to two daughters, Lavinia (born 1529/30) and another who died in infancy. On Cecilia's death in 1530, the artist was disconsolate and he never remarried.

Mythological paintings. Titian's fame had spread abroad, and Alfonso I d'Este sought him as one of the chief masters in a cycle of mythological compositions for his newly rebuilt rooms called the Alabaster Chambers in the castle at Ferrara. Two of the canvases are now in the Prado at Madrid: the "Worship of Venus" and "The Andrians"; one of the most spectacular, the "Bacchus and Ariadne," is in the London National Gallery. The gaiety of mood, the spirit of pagan abandon, and the exquisite sense of humour in this interpretation of an idyllic world of antiquity make it one of the miracles of Renaissance art. Warmth and richness of colour help to balance the intentionally asymmetrical grouping of the figures, placed in richly verdant landscape that is also an integral part of the design. At this time Titian partially repainted the background of Giovanni Bellini's "Feast of the Gods" (National Gallery of Art, Washington, D.C.), so that the picture would better fit the series in the same room at Ferrara.

The standard for the reclining nude female obliquely placed in the picture space was established by Giorgione in the "Sleeping Venus." In Titian's "Venus of Urbino" the ideal rendering of the body and the position remain virtually unchanged, except that the goddess is awake and reclines upon a couch within the spacious room of a palace. For sheer beauty of form these two works were never surpassed. Despite the inherent eroticism of the subject, Titian managed it with restraint and good taste. Variations on the theme recur throughout his career.

The "Assumption"

Religious paintings. Among the religious paintings Titian produced between 1516 and 1538 is one of his most revolutionary masterpieces, the "Assumption" (1516–18). This large and at the same time monumental composition occupies the high altar of Sta. Maria dei Frari in Venice, a position that fully justifies the spectacular nature of the Virgin's triumph as she ascends heavenward, accompanied by a large semicircular array of angels, while the startled Apostles gesticulate in astonishment at the miracle. When the painting was unveiled it was quickly recognized as the work of a very great genius.

The posture of the Madonna in the "Assumption" and the composition of Titian's "Madonna and Child with SS. Francis and Alvise and Alvise Gozzi as Donor" reveal the influence of Titian's contemporary Raphael; and the pose of St. Sebastian in the "Resurrection Altarpiece," the influence of Michelangelo. These influences, however, are of secondary importance since the landscapes, the physical types, and colour are totally Titian's own.

In the "Pesaro Madonna" (1519–26) Titian created a new type of composition, in which the Madonna and Saints with the male members of the Pesaro family are placed within a monumental columnar portico of a church. The picture is flooded with sunlight and shadows. This work established a formula that was widely followed by later Venetian Renaissance painters and served as an inspiration for some Baroque masters, including Rubens and Van Dyck.

Such a quantity of masterpieces by Titian followed that only a few can be mentioned. The poetic charm of the artist's pictures with landscape continues in the "Madonna and Child with St. Catherine and a Rabbit" and the "Madonna and Child with SS. John the Baptist and Catherine of Alexandria" (*c.* 1530). The "Entombment" is his first tragic masterpiece, where in a twilight setting the irrevocable finality of death and the despair of Christ's followers are memorably evoked. The stately "Presentation of the Virgin in the Temple," a very large canvas, reflects the splendour of Venetian Renaissance society in the great architectural setting, partly in the latest style of the contemporary architects Serlio and Jacopo Sansovino. The pageantry of the scene also belongs to well-established tradition in Venetian art, but the organization, with its emphasis on verticals and horizontals, constitutes Titian's interpretation of the High Renaissance style.

Portraits. One of Titian's great triumphs came when he answered the call to Bologna in 1530 at the time of Charles V's coronation as Holy Roman emperor. In 1531, in keeping with his social state, he moved to a Venetian palace known as the Casa Grande, which survives as a 20th-century slum. Titian returned to Bologna to portray Charles V again on the occasion of the second meeting of Charles V and Pope Clement VII in the winter of 1532–33. The portrait of "Charles V in Armour" (1530) and another painted in January 1533 are lost, while only a less important work, "Charles V with Hound" (1532–33, Prado, Madrid), a copy of a portrait by Jakob Seisenegger, survives. Charles was so pleased with Titian's work that in May 1533 he bestowed upon the artist the most extraordinary honour of knighthood. Thereafter, the Austrian-Spanish Habsburgs remained Titian's most important patrons. Charles attempted to induce Titian to go to Spain in 1534 to prepare a portrait of the Empress, but the artist wisely refrained from undertaking the arduous journey.

Titian and Charles V

Titian's other portraits in the 1520s and 1530s provide a gallery of the leading aristocrats of Italy. A splendid example is "Alfonso d'Avalos, Marques del Vasto" (1533), brilliantly rendered in gleaming armour ornamented with gold. He is accompanied by a small page whose head reaches his waist. The introduction of a secondary figure to give scale is a device frequently adopted by Titian. Another refulgent portrait in armour, but without the secondary figure, is that of "Francesco Maria della Rovere, Duke of Urbino" (1536–38). Emphasis here is given to the Duke's military career, not only by the armour but also by baton in hand and the three others in the background. These works are essentially idealized state portraits, although the heads are very convincingly rendered. "Doge Andrea Gritti" is to a greater extent a symbol of the office—that is, that of ruler of Venice. The gigantic body in a canvas of large size is sweeping in design and commanding in presence. In later works, too, Titian very effectively managed the scaling of a figure to appear massive by filling the space of the canvas—in his portraits of Pietro Aretino, for example, where he gives his subject a leonine bulkiness. Allowing more space around the figure in "The Englishman," he projected a personality of cultivated elegance and human warmth.

LATE LIFE AND WORKS

Travels and commissions. *Portraits.* The large number of masterpieces in portraiture that Titian continued to create throughout the rest of his life is astounding. Pope Paul III and his grandson, Cardinal Alessandro Farnese, began to compete with Emperor Charles V for Titian's services. At the request of the Pope, the painter travelled to Bologna in May 1543 and there prepared the celebrated official portrait of "Pope Paul III Without Cap." Although a state symbol of the Pontiff, the characterization of the crafty statesman, bent with age, comes through.

Titian's next major association with the Farnese came in 1545–46, when he made his only visit to Rome, lodged in the Belvedere Palace of the Vatican. For the first time Titian was able to see the archaeological remains of ancient Rome and also the Renaissance masterpieces of Michelangelo, Raphael, Sebastiano del Piombo, and others. The effect upon the master's own style was relatively slight, understandably enough, since he was already a mature and world famous artist.

Of portraits of the Farnese family carried out at this time, few remain. The most celebrated of all is "Paul III and His Grandsons Ottavio and Cardinal Alessandro Farnese" (1546; Museo e Gallerie Nazionali di Capodimonte, Naples). A painting of a family group, it is most searching in psychological revelation. The feeble Pope, then aged 78, appears to turn suddenly in his chair toward Ottavio Farnese, his 22-year-old grandson. Ottavio's overobsequious bow and his shrewd Machiavellian profile demonstrate Titian's sheer genius in understanding and recording character. As a foil, the great churchman Cardinal Alessandro Farnese stands quietly by. It is no wonder that the portrait is not completely finished, for Paul III must have found it too revealing of the feud within the Farnese family.

"Paul III and His Grandsons"

If one were forced to name Titian's two greatest portraits, the choice might fall upon the Farnese group and upon another, "The Vendramin Family." Here the situation is quite different, for the two heads of the clan kneel in adoration of a reliquary of the Holy Cross, accompanied by seven sons ranging from about eight to 20. This monumental portrait group is a tour de force in technical brilliance, richly beautiful in colour, running the emotional gamut from gravity to the innocence of childhood.

On his departure from Rome, in June 1546, Titian's association with the Farnese ended. He received no payment for his pictures, and his hopes for recompense in the form of a benefice for his son Pomponio were never realized. Titian decided to throw in his lot with the Habsburgs. Consenting to undertake the arduous journey to Augsburg, he set out in the depths of winter in January 1548 to cross the Alps to reach the Emperor's court. There he carried out one of his most memorable works, the equestrian "Emperor Charles V at Mühlberg," designed to commemorate the Emperor's victory over the Protestants the year before. It is the great state portrait par excellence, intended to show the Emperor as a Christian knight, as he wished posterity to remember him. Titian minimized the disfiguring lantern jaw and gave great dignity of bearing to his subject. In sheer mastery of the painter's art, the picture is unsurpassed. The handsome armour, with its gleaming highlights and reflected colour, the rose sash across the chest (a symbol of the Catholic party and the Holy Roman Empire), and the superb sunset landscape all contribute to make it one of the masterpieces of all time.

In December 1548 Charles instructed Titian to proceed to Milan to prepare likenesses of Prince Philip on his first trip outside of Spain. Once again, in the fall of 1550, Charles obliged Titian to travel to Augsburg to remain until May 1551, when he executed one of his greatest state portraits, the "Philip II" in full length. In this portrait of Philip, when still a prince aged 23, Titian achieved another tour de force in sheer beauty of painting, and he treated gently the surly face of the arrogant young man.

Religious paintings. Like some of Titian's earlier religious paintings, "Christ Before Pilate" is a work in which Titian managed a large crowd in a processional manner leading to the focal point, the figure of Christ at the left. Here the people are in a state of turmoil as they demand Christ's crucifixion. The composition, however, marks a new phase in Titian's development, far removed from the Renaissance serenity of the "Presentation," which is not explainable by the subject alone. The compact massing of figures, the oblique position of the steps and the wall at the left, and the general effect of excitement are indicative of the mid-16th-century style known as Mannerism. Titian assimilated and recreated, however, to produce a masterpiece far surpassing anything of which the Mannerist artists were capable.

"Christ Before Pilate"

Titian's religious compositions after his visit to Rome in 1545—46 reveal to some degree his contact with ancient

art and the works of Michelangelo. In "Christ Crowned with Thorns" the burly muscular figures are thus explained, as perhaps is the violence of the whole interpretation.

Last years in Venice. On his return to Venice in 1551, Titian remained there for the rest of his life except for summer visits to his native city of Pieve di Cadore. In his last 25 years his productivity was undiminished in quantity and in creative ideas.

Portraits. Among his portraits is the full-length, dashingly rendered figure of the Duke of Atri, who is dressed in red velvet. One of the latest and most dramatic was "Jacopo Strada," in which this brilliant antiquarian, writer, and art collector is shown presenting to the spectator a small statue, a Roman copy of an Aphrodite of Praxiteles. Here again, the scope and variety of Titian's invention is astonishing in this new composition, so notable for lively action, psychological preception, and pictorial beauty. One must not forget Titian's "Self Portrait," in which he presents himself with great dignity, wearing the golden chain of knighthood. The intelligent, tired face is fully rendered, while the costume is sketched in lightly with a free brush. One of the most remarkable late works is the "Triple Portrait Mask" or "Allegory of Prudence," in which Titian, gray-bearded and wearing a rose-coloured cap, represents old age, his son Orazio, maturity, and presumably Marco Vecellio stands for youth.

"Self Portrait"

Religious paintings. The "Trinity" (or "La Gloria"), painted for Charles V's personal devotion, reflects central Italian art to a lesser degree than the earlier "Christ Crowned with Thorns." The glowing richness of colour predominates in this adoration of the Trinity in which Charles V and his family appear among the elect. The "Martyrdom of St. Lawrence" marks a further step in new compositional directions that culminate in Baroque form in the following century. St. Lawrence upon his gridiron is placed obliquely in space, and the steps reverse the direction to the right. Although dramatic power invests the main action in the foreground, the night scene with the tall flares and mysterious light suggests the supernatural. In his late religious pictures Titian veils the human forms in shadowy light and so increases the dominant mood of spirituality. One sees this effect in the late "Entombment," in which muted colour prevails, and in the awesome tragedy of the "Crucifixion." The "Christ Crowned with Thorns," employing essentially the same composition as in the earlier version, is now seen through a veil of darkness, and the colour is broken into tiny spots and areas. All is miraculous in the "Annunciation," in which Gabriel rushes in and an assembly of angels in glory hovers about the Virgin. Titian's final word and last testament is the "Pietà," intended for his own burial chapel but left unfinished and completed by Palma il Giovane. The master and his son, Orazio, appear as tiny donors on the small plaque to the right. The monumentality of the composition is established by the great architectural niche flanked by Moses and the Hellespontic sibyl, while the figures are grouped in a long diagonal. The subdued colour befits the all-prevailing sorrow and the immutability of death in this, one of the artist's most profound achievements.

"Pietà"

Mythological paintings. The "Venus and Cupid with an Organist" and the "Venus and the Lute Player" are variations on the theme of the earlier "Venus of Urbino." Aside from the emphasis on the idealized beauty of the nude goddess, it is generally believed that symbolism is involved in these pictures, although the precise meanings have been variously interpreted. Beauty of sound (music) and beauty of vision are common to both. In the first example, a Renaissance garden with fountain and trees in perspective, completes the background, which is separated from the figures by a dark red velvet curtain. More symbolism of an erotic nature is present in the embracing couple, a stag, and the satyr on the fountain. In the second picture, the background consists of a broad river valley and the distant Alpine peaks so dear to Titian's heart. This late landscape, painted in the artist's free illusionistic style, is extraordinarily beautiful.

The "Venus with a Mirror" (National Gallery of Art, Washington, D.C.), the one original among several versions, is a natural theme for the goddess of love and beauty. Yet Titian is the first artist to show her with a mirror held by Cupid. Her form is somewhat more heroic than hitherto, and her head to a limited degree is inspired by ancient sculpture. The superb quality of the flesh tones is enhanced by the cloak of dark red velvet, trimmed with fur.

A group of several important pictures of mythological themes was created by the master in 1554—62 for Charles's successor, Philip II of Spain, who never bothered to remunerate Titian for any of them. From the letters of the artist to the King, it is clear that he planned the paintings in pairs, but otherwise they do not constitute a comprehensive iconographic program. The first pair (still in Madrid) consists of the "Danae with Nursemaid" and the "Venus and Adonis." The magnificent nude Danae lies upon her couch, knees raised, as Jupiter descends to her in the form of golden rain, and her nursemaid rather amusingly attempts to catch the coins in her apron. This work (of which there exist numerous replicas and copies) is undoubtedly the most voluptuous in Titian's entire repertory. In colour and technique, as well, the "Danae" is one of Titian's greatest achievements; one is tempted to say that no other artist ever equalled him in imagination and in the depiction of sheer beauty of this work. In the "Venus and Adonis," the goddess, depicted from the back, attempts to restrain her muscular young lover as he is about to depart for the hunt, his dogs straining at the leash. The rose of his costume and the red velvet cushion beneath Venus are foils in the colour composition to the flesh tones and the sunlit landscape.

The "Perseus and Andromeda" was intended to be a companion to "Medea and Jason," according to Titian's letter, but for some reason the second picture was never carried out. Andromeda, bound to the rock at the left, awaits deliverance as Perseus descends from the sky to slay the monster. Her powerful physique reflects Titian's familiarity with the work of Michelangelo, yet Andromeda's body is more feminine and graceful than any of the Florentine's masculine-looking women. Titian's sensitivity to female beauty is unfailing.

"The Rape of Europa" is surely one of the gayest of Titian's "poesies," as he called them. Taken by surprise, Europa is carried off, arms and legs flying, on the back of Jupiter in the form of a garlanded white bull. A putto (chubby, naked little boy) on the back of a dolphin appears to be mimicking her, and cupids in the sky follow the merry scene. Titian's fondness for oblique compositions is most successfully applied here, for it contributes to the sense of movement, and it allows for the extensive seascape and the mountainous shore. The sheer wizardry of Titian's technique is nowhere more fully demonstrated than in the misty distances shot through with blues and sunset rose and in the expanse of sea with its iridescent lights.

"The Rape of Europa"

In "The Rape of Europa" Titian reached the climax of his powers, and by good fortune the picture has survived in almost perfect condition. On the contrary, two other great "poesies" done for Philip II are sadly abused by time and restorers, paticularly the "Diana and Callisto," and less so the "Diana and Actaeon." The assembly of female nudes in a variety of poses, befitting the action, illustrates two episodes of the Diana legend as told by Ovid in his *Metamorphoses*, books II and III. "Diana and Actaeon" depicts Actaeon, the youthful hunter of heroic body, just as he unwittingly happens upon Diana and her nymphs as they are bathing (and before Diana punishes him by transforming him into a stag). Behind him is a great rose-coloured curtain. A landscape of extraordinary beauty and a vaulted passage form the setting within which the maidens are gathered. The organization of the rather complex design once more presages Baroque compositional methods. In the companion picture, the goddess discovers that Callisto, one of her maidens who had taken the vow of chastity, is pregnant. Though she was deceived by Jupiter's trickery, she is, nevertheless, banished and later, according to the legend, transformed into a bear. A standing and rather fulsome nude rips the drap-

ery from the reclining Callisto. The golden canopy in the trees above Diana is the cloth of honour referring to her divinity. The glorious deep blue sky with golden clouds and the green branches of the tree supply the backdrop for the nude bodies. Diana, tall and imperious, is magnificent, despite the surface damage that has destroyed much of the paint. Subtleties abound in every movement and every gesture.

The latest of these compositions carried out for Philip II was the "Tarquin and Lucretia," a dramatic work of great vigour that proves that the aged master had lost none of his creative powers. Rather than Lucretia's suicide because of her rape by Tarquin, which is the more common subject, Titian chose to represent Tarquin's violent attack upon her. Again the rich colour is equally as important as the action. Against the green curtain and white sheets the rose velvet breeches of Tarquin and his green and gold doublet stand out in rich brilliancy.

The end came on August 27, 1576, when the great master died of old age, while a plague was raging in Venice. He was interred in the church of Sta. Maria dei Frari, where two of his most famous works may still be seen.

Through his long life Titian was highly successful in all branches of the painter's art. In his interpretation of Christian iconography he was infused in his youth with the poetic styles of the elderly Giovanni Bellini and his contemporary Giorgione. Titian created new compositions such as the "Assumption" and the "Pesaro Madonna" and later in his life the "Martyrdom of St. Lawrence," and he carried out a never-ending succession of new conceptions as his career matured. He gained international fame as a portraitist, beginning as a Giorgionesque painter and developing into a major creator of the state portrait for the glorification of rulers. The revival of the culture of the ancient world lies at the root of Renaissance culture in the arts and in literature; inspired by the ancient poets such as Ovid, Catullus, and Theocritus, Titian recreated pictorially the legends of Greece and Rome in a series of incomparable masterpieces.

MAJOR WORKS

RELIGIOUS PAINTINGS: frescoes of three miracles of St. Anthony of Padua (1510-11; Scuola del Santo, Padua); "Gipsy Madonna" (*c.* 1510; Kunsthistorisches Museum, Vienna); "Salome" (*c.* 1515; Galleria Doria-Pamphili, Rome); "Assumption" (1516–18; Sta. Maria dei Frari, Venice); "Madonna and Child with SS. Francis and Alvise and Alvise Gozzi As Donor" (signed 1520; Pinacoteca, Ancona); "Resurrection Altarpiece" (signed 1522; SS. Nazaro e Celso, Brescia); "Pesaro Madonna" (1519–26; Sta. Maria dei Frari, Venice); "Entombment" (1526–32; Louvre, Paris); "Madonna and Child with St. Catherine and a Rabbit" (*c.* 1530; Louvre, Paris); "Madonna and Child with SS. John the Baptist and Catherine of Alexandria" (*c.* 1530; National Gallery, London); "The Presentation of the Virgin in the Temple" (1534–38; Accademia, Venice); "Christ Before Pilate" (signed 1543; Kunsthistorisches Museum, Vienna); three Old Testament subjects (1543–44; Sta. Maria della Salute, ceiling of the sacristy, Venice); "Christ Crowned with Thorns" (1546-50; Louvre, Paris); "Martyrdom of St. Lawrence" (1548–57; Gesuiti, Venice); "Trinity" ("La Gloria") (1554; Prado, Madrid); "Crucifixion" (1558; S. Domenico, Ancona); "Entombment" (1559; Prado, Madrid); "Magdalen" (*c.* 1560; Hermitage, Leningrad); "Annunciation" (1560–65; S. Salvatore, Venice); "Madonna and Child in Evening Landscape," (1562–65; Alte Pinakothek, Munich); "Christ Crowned with Thorns" (1570–76; Alte Pinakothek, Munich); "St. Jerome" (1575; Nuevos Museos, Escorial); "Pietà" (1576; Accademia, Venice).

MYTHOLOGICAL PAINTINGS: "Sacred and Profane Love" (1512–15; Borghese Gallery, Rome); "Flora" (*c.* 1515; Uffizi, Florence); "The Three Ages of Man" (*c.* 1515; National Gallery of Scotland, Edinburgh, lent by the Duke of Sutherland); "Bacchus and Ariadne" ("Ferrara Bacchanals," 1520–23, National Gallery, London); "Worship of Venus" (1518–19) and "The Andrians" (1523–24; both in Prado, Madrid); "Venus Anadyomene" (*c.* 1525; National Gallery of Scotland, Edinburgh, lent by the Duke of Sutherland; "Venus of Urbino" (1538–39; Uffizi, Florence); "Jupiter and Antiope," so-called "Venus of El Pardo" (*c.* 1540, perhaps finished *c.* 1560; Louvre, Paris); "Venus and Cupid with an Organist" (signed *c.* 1550; Prado, Madrid); "Venus with a Mirror" (1550–55; National Gallery of Art, Washington, D.C.); "Danae with Nursemaid" (1553–54; Prado, Madrid); "Venus and Adonis" (1553–54; Prado, Madrid); "Perseus and Andromeda" (1554–56; Wallace Collection, London); "Diana and Actaeon" and "Diana and Callisto" (1559; National Gallery of Scotland, Edinburgh, lent by the Duke of Sutherland); "The Rape of Europa" (*c.* 1559–62; Isabella Stewart Gardner Museum, Fenway Court, Boston); "Venus and the Lute Player" (*c.* 1560; Metropolitan Museum of Art, New York); "Nymph and Shepherd" (*c.* 1570; Kunsthistorisches Museum, Vienna); "Tarquin and Lucretia" (1571; Fitzwilliam Museum, Cambridge); "The Flaying of Marsyas" (*c.* 1570–76; Uměleckohistorické Muzeum, Kroměříž, Czech.).

PORTRAITS: "The Concert" (1510–12; Pitti Palace, Florence); "Gentleman in Blue," so-called "Ariosto" (signed *c.* 1512; National Gallery, London); "Young Man with Cap and Gloves" (1512–15; Earl of Halifax Collection, Garrowby Hall, London); "Man with a Glove" (1520–22; Louvre, Paris); "Federico II Gonzaga, Duke of Mantua" (*c.* 1523; Prado, Madrid); "Alfonso d'Avalos, Marques del Vasto" (1533; Marquis de Ganay Collection, Paris); "Francesco Maria della Rovere, Duke of Urbino" (1536–38; Uffizi, Florence); "Doge Andrea Gritti" (1535–38; National Gallery of Art, Washington, D.C.); "The Englishman," so-called (1540–45; Pitti Palace, Florence); "Pietro Aretino" (*c.* 1545; Pitti Palace, Florence); "Clarice Strozzi" (1542; Staatliche Museen Preussischer Kulturbesitz, Berlin); "Pope Paul III Without Cap" (1543; Museo e Gallerie Nazionali di Capodimonte, Naples); "The Vendramin Family" (1543–47; National Gallery, London); "Paul III and His Grandsons Ottavio and Cardinal Alessandro Farnese" (1546; Museo e Gallerie Nazionali di Capodimonte, Naples); "The Emperor Charles V at Mühlberg" (1548; Prado, Madrid); "Giovanni Battista Castaldo" (1548; Becker Collection, Dortmund); "Self Portrait" (*c.* 1550; Staatliche Museen Preussischer Kulturbesitz, Berlin); "Philip II" (1550–51; Prado, Madrid); "Giovanni Francesco Acquaviva, Duke of Atri" (1552; Staatliche Kunstsammlungen Kassel); "Lavinia with Fan," so-called (1555–60; Gemäldegalerie, Dresden); "Jacopo Strada" (1567–68; Kunsthistorisches Museum, Vienna); "Triple Portrait Mask," "Allegory of Prudence" (*c.* 1570; National Gallery, London).

(H.E.W.)

Titicaca, Lake

Lake Titicaca (Lago Titicaca), the world's highest lake navigable to large vessels, lies at 12,500 feet (3,810 metres) above sea level in the Andes mountains of South America, astride the border between Peru to the west and Bolivia to the east. Second largest lake of South America (after Maracaibo), Titicaca covers 3,205 square miles (8,301 square kilometres) and runs in a northwest to southeast direction for a distance of 120 miles. It is 50 miles across at its widest point. A narrow strait, Tiquina, separates the lake into two bodies of water. The smaller, in the southeast, is called Lago Uiñaimarca; the larger, in the northwest, Lago Chucuito.

Titicaca (its meaning is uncertain, but it has been variously translated as Rock of the Puma or Crag of Lead) lies between Andean ranges in a vast basin (about 22,400 square miles in area) that comprises most of the Altiplano (High Plateau) of the nothern Andes. From the snow-covered Cordillera Real Range on the northeast (Bolivian) shore of the lake, some of the highest peaks in the Andes rise to heights of more than 21,000 feet.

The lake averages 328 feet in depth, but the bottom tilts sharply toward the Bolivian shore, reaching its greatest

recorded depth of 913 feet (281 metres) off Isla Soto in the northeast corner of the lake. In contrast, the small arm of the lake beyond Tiquina averages less than 33 feet.

Drainage and water level

More than 25 rivers empty their waters into Titicaca; the largest, the Ramis, draining about two-fifths of the entire Titicaca Basin, enters the northwest corner of the lake. One small river, the Desaguadero, drains the lake at its southern end. This single outlet empties only 5 percent of the lake's excess water; the rest is lost by evaporation under the fierce sun and strong winds of the dry Altiplano.

Titicaca's level fluctuates both seasonally and over a cycle of years. During the rainy season (summer, from December to March) the level of the lake rises, normally to recede during the dry winter months. The extreme difference between high and low levels may be as much as 16 feet. It was formerly believed that Titicaca was slowly drying up, but in the early 1970s studies seemed to refute this, indicating a more or less regular cycle of rise and fall.

Titicaca's waters are limpid and only slightly brackish, with salinity ranging from 52 to 55 parts in 1,000. Surface temperatures average 56° F (14° C); from a thermocline (a layer of water separating an upper, warmer, oxygen-rich zone from a lower, colder, oxygen-deficient zone) at 66 feet temperatures drop to 52° F (11° C) at the bottom. Analyses show measurable quantities of sodium chloride, sodium sulfate, calcium sulfate, and magnesium sulfate in the water.

As in other Alpine lakes, fish life is restricted, consisting principally of two species of killifish (*Orestias*)—a kind of small fish, usually striped or barred with black—and a catfish (*Trichomycterus*). In 1939, and subsequently, trout were introduced into Titicaca. Rainbow trout predominated and, finding no competition, gorged on the native fishes. Within a few years trout of 25 to 35 pounds were common. In 1961 a fish cannery started operations, netting fish from the lake and at the mouth of spawning streams. Other canneries followed, and the catch fell off rapidly. Today a trout of eight pounds is considered large. The Peruvian and Bolivian governments now prohibit the taking of trout by any method, but poaching is frequent. A large frog (*Telmatobius*), which may reach a length of nearly a foot, inhabits the shallower regions of the lake.

Forty-one islands, some of them densely populated, rise from Titicaca's waters. The largest, Isla de Titicaca (or Isla del Sol), lies just off the tip of the Copacabana Peninsula.

Ruins on shore and on the islands attest to the previous existence of one of the oldest civilizations known in the Americas. The chief site is at Tiahuanaco, Bolivia, at the southern end of the lake. No one knows with certainty who erected the temples, stelae, and stone figures, which antedate the Christian era. On the Isla de Titicaca ruins of a temple mark the spot where, according to the tradition of the Incas (a Quechuan people of Peru who established an empire about 1100), the legendary founders of the Inca dynasty, Manco Capac and Mama Ocllo, were sent down to earth by the Sun, the Inca god.

The lakeside peoples

Aymara Indians have dwelt on the shores of Titicaca since before recorded history. Pockets of Quechua-speaking Indians scattered around the lake probably descend from peoples transferred to the high plateau by the Inca conquerors.

The Altiplano Indians, short, dark, and barrel-chested, have been the subjects of medical research because of their extraordinary adaptation to high-altitude living. Studies show their hearts, lungs, and spleens are larger than those of men who live at sea level, while their bone marrow manufactures more red corpuscles to capture oxygen molecules from the rarefied air.

The Aymara still practice their ancient methods of agriculture on stepped terraces that predate Inca times. They grow barley, quinoa (a kind of pigweed that produces a small grain), and the potato, a New World tuber that was unknown in Europe before the discovery of America and that originated on the Altiplano. The highest cultivated plot in the world was found near Titicaca—a field of barley growing at a height of 15,420 feet above sea level. At this height the grain never ripens, and the stalks furnish forage for llamas and alpacas, the American relatives of the camel that serve the Indians as beasts of burden and as a source of meat.

Remnants of an ancient people, the Uru, still live on floating mats of dried totora (a reedlike papyrus that grows in dense brakes in the marshy shallows). From the totora, the Uru and other lake dwellers make their famed balsas—boats fashioned of bundles of dried reeds lashed together that resemble the crescent-shaped papyrus craft pictured on ancient Egyptian monuments.

In 1862 the first steamer to ply the lake was prefabricated in England and carried in pieces on muleback up to the lake. Today a ship of 2,000 tons is the flagship of three vessels making regular crossings from Puno, on the Peruvian shore, to the small Bolivian port of Guaqui. A narrow-gauge railway connects Guaqui with La Paz, capital of Bolivia. The world's second highest railway runs from Puno down to Arequipa and the Pacific, completing land-bound Bolivia's principal link with the sea.

Because of its great height and the vast amount of water held by Titicaca, various schemes have been proposed for the production of hydroelectric power. Some would channel the lake waters into the Amazon Basin to the east; others would take advantage of the rapid fall to the comparatively close Pacific to the west. In either case, the water would have to traverse canals and tunnels to cross the height of the land. Estimates of the potential output of energy vary from 2,300 to 4,500,000,000 kilowatts.

BIBLIOGRAPHY. Literature concerning Lake Titicaca is scattered and sparse. See FELIX MONHEIM, *Beiträge zur Klimatologie und Hydrologie des Titicacabeckens* (1956), a well-documented, detailed treatment of the hydrological and climatological aspects of the lake and its basin; PERU, MINISTERIO DE MARINA, *Informe sobre Estudio Realizado en el Lago Titicaca durante Diciembre de 1969* (1970), a summary of the latest investigations on the chemical properties of Titicaca's waters, the vertical and lateral temperature distribution, and a detailed profile of depths; WASHINGTON CANO, *El Lago Titicaca* (1952), a general, popular monograph including legends and traditions surrounding the lake.

(Lu.M.)

Tito

Josip Broz Tito was the leader of the Yugoslav Partisans who fought against Hitler in World War II and for a Socialist regime in Yugoslavia. In 1945, he became the first president of the new Yugoslav state and directed the modernization of his country with a firm hand. He challenged all the great world powers and became the first successful heretic in the Communist world when he defied the Soviet Union in 1948. He preached the doctrine of equality of large and small states and proclaimed the right of every Socialist country to pursue its own way to Socialism.

Josip Broz ("Tito" was added in 1934) was born on May 7, 1892, in the village of Kumrovec on the border of Croatia and Slovenia, the seventh of 15 children of a poor peasant family. His father was a Croat, his mother a Slovene. (Tito's official birthday is celebrated on May 25: the exact birth dates of children are often overlooked under the poor conditions of large peasant families.)

At the age of 13 Tito went to the town of Sisak as an apprentice locksmith, and as a youth he was employed as a metalworker in Trieste, Bohemia, and Germany. On his journeys he joined the metalworkers' trade unions and the Social Democratic Party of Croatia. The outbreak of World War I found him in the 25th Regiment in Zagreb, which was sent against Serbia in August 1914. Accused of spreading anti-war propaganda, Tito was arrested and kept in the Petrovaradin jail; but in January 1915 the charges were dropped, and he was sent with his regiment to the Carpathian front, where he was later decorated for bravery. But when his regiment was transferred to the Bukovina front, he was seriously wounded—stabbed by a Cossack's lance—and captured by the Russian Army.

It was not until 1920 that Tito returned from Russia to Croatia with his Russian wife (divorced 1935) to work in

a mill near Bjelovar as a mechanic. Having joined the Communist Party (CPY), he was arrested in 1923 but was acquitted. He lived in poverty and lost two children. Working in the shipyards at Kraljevica, he was arrested again in 1925 and sentenced to seven months' probation.

Communist Party activities in the 1920s

In April 1927 he was given membership in the Zagreb Committee of the CPY, which supported the Comintern's Open Letter against factions in the CPY. In 1928 he was appointed deputy of the Politburo of the Central Committee of the CPY and secretary general of the Croatian and Slavonian committees. On August 4, 1928, he was again arrested. At his trial he denied the right of tribunal to judge him; he was sentenced to five years.

Upon his release from prison in 1934, he became a member of the Central Committee of the Communist Party of Yugoslavia (CPY) and then of the Politburo of the Central Committee. Subsequently he travelled from Yugoslavia to Moscow, Paris, Prague, and Vienna. For conspiratorial reasons, he adopted several pseudonyms, among which "Tito" was most frequently used. He worked in Moscow in 1935 in the Balkan section of the Comintern and participated in its Seventh Congress. In August 1936 Tito was named organizational secretary of the CPY Politburo. In 1937 Premier Joseph Stalin initiated a purge of Yugoslav Communists living in the Soviet Union, and about 800 were liquidated. The CPY was saved from dissolution by the high ranking Comintern official Georgi Dimitrov, and late in 1937 Tito was appointed secretary general by the Executive Council of the Comintern. Tito returned to Yugoslavia and reorganized the party, taking into its leadership young revolutionaries, such as Edvard Kardelj, Milovan Djilas, Aleksander Ranković, and Ivo Ribar. In October 1940 the Fifth Party Conference was held clandestinely in Zagreb, attended by 105 members. Tito was formally chosen secretary general of the CPY Central Committee. The party then numbered 6,000 members plus 30,000 members of the Young Communist League. In 1937 Tito helped send some 1,300 Yugoslav volunteers to fight for the Republicans in the Spanish Civil War. These volunteers later formed the nucleus of the national liberation forces in Yugoslavia.

Organization of the resistance movement

Germany attacked Yugoslavia on April 6, 1941. Early that June Serbian peasants in Hercegovina rose spontaneously against the Croatian Ustashe—members of a separatist terrorist organization that aided the Germans. Tito's resistance began after June 22, when Germany invaded the Soviet Union.

Tito issued a proclamation for a general uprising. Calling for brotherhood and unity among the Yugoslav peoples, he promised them equality after independence was won. The uprising grew so swiftly that by the end of the summer almost half of Yugoslavia was liberated; the liberated area in Serbia and Montenegro was held primarily by the Yugoslav Army of the Fatherland (often referred to as the Chetniks) and not by Tito's Partisans. Tito established his general headquarters at Užice in western Serbia. Against the wishes of Moscow, a new revolutionary administration was created in liberated areas; this and other issues deepened the conflict between Tito and the exiled royal government and its representative in the country, Dragoljub Mihajlović, called Draža. Using troops from the Russian front and Greece, the Germans launched an offensive against the Užice region at the end of November, driving out the Partisans. There were heavy casualties, and Tito, the last to leave resistance headquarters, was nearly captured fighting his way through the advancing German lines. This was the first of seven major German offensives against Tito's forces.

The Partisan movement spread throughout Yugoslavia, however, and in December Tito organized special proletarian brigades comprised of extremely mobile guerrilla shock units. Alarmed by the growth of the Partisans, Hitler launched two major offensives in early 1943—the Neretva and Sutjeska—against the main body of the Partisans and their headquarters. More than ten German divisions participated, aided by six Italian and quisling units. The Partisans, though having to transport more than 4,000 wounded through the mountains in winter, broke through all the German encirclements. These were the decisive battles of the Yugoslav revolution. At the Sutjeska battle, the Partisans lost more than 6,000 men, and many were wounded, including Tito.

After the capitulation of Italy in September 1943, the Partisans numbered over 250,000. Tito, without informing any of the great powers (including Moscow), decided to convene a Partisans Parliament (the Anti-Fascist Council of the National Liberation Committee of Yugoslavia), which set up the provisional revolutionary government and declared Yugoslavia a federal community of equal peoples. Tito was given the title of marshal of Yugoslavia. At the Teheran Conference, the Allied leaders granted the Partisans the status of allies and decided to send military missions and aid. On May 25, 1944, Hitler ordered a surprise parachute and tank attack on the Partisan headquarters at Drvar in Bosnia, and Tito once again narrowly escaped. Stalin and Winston Churchill, seeking to unify the Yugoslav émigré government with Tito's revolutionary government, agreed that each should have equal influence in Yugoslavia (the so-called 50–50 agreement). Tito showed remarkable diplomatic skill in preventing the realization of these schemes, both in his meetings with Churchill in Naples during August 1944 and with Stalin in Moscow during September of that year. Although German military power had capitulated on all fronts by May 9, 1945, German units in Yugoslavia received orders to continue fighting. They and pro-German Yugoslavs offered resistance until May 15, when they were finally annihilated.

Marshal of Yugoslavia

The war had devastated the country. War dead amounted to more than 11 percent of the population, and war damages were extensive and costly. Toward the end of the war Tito found himself at loggerheads with the West because of his attempts to seize Trieste, his support of the Communists in the Greek Civil War, his shooting down of two United States planes over Slovenia, and his establishment of an undisguished Communist regime in Yugoslavia. Nevertheless, on June 28, 1948, when Tito's relations with the West could not have been worse, Stalin broke with Tito by ejecting the CPY from the Cominform.

The conflict with Stalin

This conflict with Stalin arose out of Tito's determination to preserve Yugoslav independence. Stalin hoped to take advantage of Yugoslavia's isolation by trying to bring Tito down through economic blockade, sedition, border incidents, and threats of military invasion. These threats united the Yugoslav people behind Tito even more than in the days of World War II.

With Stalin's death in 1953, the new Soviet leaders changed their approach, and a Soviet official state and party delegation, led by Soviet premier Nikita Khrushchev, visited Belgrade on June 2, 1955, where it formally rejected Stalin's policy and acknowledged Tito's concept of the right of equality of states and their rights to choose their own road to Socialism.

Tito's conception of Yugoslav Socialism was embodied in his constitutional reforms. The first Yugoslav constitution (1946) was modelled on the Soviet constitution. Many rights obtained by each republic of Yugoslavia during the Partisan struggle were yielded to the central government, which also established administrative control over the economy. But after the break with Stalin, new reforms decentralized administration and established workers' councils in the factories. The republic was granted a greater freedom and a Council of Nationalities was created. On January 13, 1953, Tito was elected as the first president of Yugoslavia. A new constitution was enacted on April 7 for the Socialist Federative Republic of Yugoslavia. The relationship between the federation (a joint and equal community of all nationalities in Yugoslavia) and the republic (the five major Yugoslav nationalities, each constituting a sovereign Socialist republic) was to be "between two essentially equal and mutually dependent and interlinked social and political communities."

Abroad Tito conducted a policy of nonalignment with either the Soviet Union or the United States. His neutralist policy led Tito to closer ties with the conference of 25

nonaligned states convened by Tito, Jawaharlal Nehru of India, and Gamal Abdel Nasser of Egypt. The conference adopted a 27-point declaration denouncing colonialism, demanding an end to the armed action against dependent peoples, endorsing the struggle of the Algerians, and condemning the apartheid system in South Africa.

The policy of nonalignment

In the pursuit of this policy Tito travelled extensively in Africa, Asia, and Latin America between 1962 and 1970. In August 1968 Tito denounced the invasion of Czechoslovakia by the Soviet Union, stressing that this act "violated the sovereignty of a socialist country and dealt a grave blow to socialist and progressive forces all around the world." He followed this up by proposing the creation of Partisan units and territorial defenses in all parts of the country, in order to strengthen the regular army. A new law made males eligible for military service up to the age of 65, while women between the ages of 19 and 40 could be assigned to military and civil defense units. In September 1970, at the age of 78, Tito announced a plan forming a collective leadership to succeed him.

The qualities that made Tito a successful resistance leader—decisiveness, adaptability, moral and physical stamina, and a ready sense of humour—enabled him to provide Yugoslavia with nearly three decades of stable leadership. Tito travelled frequently, in Yugoslavia as well as abroad. His third wife, Jovanka Budisavljević, a former Partisan fighter, usually accompanied him on state visits both in and out of the country. In the early 1970s, he had achieved the status of an elder statesman and lived, with his wife, either in Belgrade or the island resort of Brioni. Tito's hobbies included photography, hunting, and fishing. He was considered one of the best dressed statesmen in Europe and a fine pianist.

BIBLIOGRAPHY. PHYLLIS AUTY, *Tito* (1970), is an up-to-date scholarly biography with notes, index, photographs, and four maps, by an acknowledged specialist. FITZROY MACLEAN, *Disputed Barricade: The Life and Times of Josip Broz-Tito* (1957), is a well-written straightforward biography bringing forward the subject against his political background, with map, photographs, and an index; the same author's *Eastern Approaches* (1949), an eye-witness account of the writer as observer or participant in events in the U.S.S.R., Asia, and Yugoslavia, devotes its third and last section to a brilliant account of the British mission, headed by himself, to Tito and his Partisans in Yugoslavia in 1943–45. See also VLADIMIR DEDIJER, *Josip Broz Tito—Prilozi za Biografiju* (1953), a biography with photographs and an index; and the same author's *Tito Speaks* (1952), a closeup account of Tito by one who knew him that makes use also of first-hand recollections of others and of Tito's own words to construct a vivid portrait. H.F. ARMSTRONG, *Tito and Goliath* (1951), concentrates on the significance in theory and in practical politics of Tito's career, as does F.W. NEAL, *Titoism in Action: The Reforms in Yugoslavia After 1948* (1958), an account of Tito's political and economic direction of Yugoslavia since World War II.

Tobacco Production

Tobacco is the common name of the plant *Nicotiana tabacum*, and, to a limited extent *N. rustica*, and the cured leaf that is used, usually after aging and processing in various ways, for smoking, chewing, snuffing, and extracting of nicotine. The common name was derived from an American Indian word applied both to a tube for inhaling the smoke and to a cylinder of leaf prepared for smoking. This article deals with the history of tobacco, its culture, curing, grading, and marketing, the manufacture of tobacco products, controls, world production and consumption, economic statistics, and health hazards.

Tobacco is produced commercially as a field crop in certain areas of the world where soils and climate combine to yield a product possessing certain recognized characteristics. The tobacco industry obtains various kinds of leaf from these areas for use in manufacturing products acceptable to consumers. Nicotine and the related alkaloids contained in tobacco are generally recognized as habit forming and narcotic, characteristics that help account for the worldwide popularity of tobacco products.

Though tobacco is tropical in origin, it is cultivated throughout the world. The crop is grown in the U.S.S.R. around 50° N latitude, and in Australia and New Zealand at about 40° S latitude. *N. tabacum* requires a frost-free period of 100 to 130 days from date of transplanting to maturity in the field. *N. rustica,* which is grown to some extend in the U.S.S.R. and India, matures in advance of *N. tabacum.*

HISTORY

When Christopher Columbus discovered America, he found the natives using tobacco in much the same manner as it is used today. The American Indians believed it to possess medicinal properties, which was the main reason for its introduction in Europe. Tobacco was important in Indian ceremonials, such as the smoking of the pipe of peace. Evidently the natives of North and South America had developed crude methods of tobacco culture. Its extension to practically all parts of the world began with its introduction to Europe: France, 1556; Portugal, 1558; Spain, 1559; and England, 1565. Jean Nicot, the French ambassador to Lisbon, Portugal, in whose honour the genus *Nicotiana* was named, is said to have sent the seed of *N. tabacum* to Catherine de Médicis, the queen of France. Portuguese and Spanish sailors took tobacco from Europe to all parts of the world.

There are no available records as to early culture outside Europe, but the beginnings of culture by European settlers in colonial America took place in the following areas on the dates indicated: Santo Domingo, 1531; Cuba, 1580; Brazil, 1600; Jamestown, Virginia, 1612; Maryland, 1631. Tobacco soon became the chief commodity exchanged by the colonists for European manufactured articles.

Overproduction was an economic problem from the beginning. After the American Revolution tobacco culture expanded from the colonial areas in Virginia and Maryland into Kentucky, Tennessee, North Carolina, Ohio, and Missouri. Originally the tobacco was air cured—left to dry in a barn or shed for several weeks. Later smoke from a wood fire was used (fire curing). This enabled the leaf to withstand long ocean voyages by sailing ship. About 1825 the fire-curing method was modified in parts of Virginia and North Carolina by use of charcoal, which eliminated the effect of smoke on the taste and aroma of the leaf. The method was further modified after the American Civil War by the introduction of a furnace with metal flues.

White Burley

A light, air-cured leaf known as White Burley appeared about 1864, when a farmer in Brown County, Ohio, found individual tobacco plants that were deficient in green colouring. These plants, when cured, manifested a light yellowish-red colour that was porous, extremely absorptive, and highly suitable for use in manufacturing mixtures for chewing and smoking. It has also been suitable for use in manufacturing the popular American blended cigarette.

THE MODERN INDUSTRY

Cultivation. The prime requisite for successful tobacco culture is a supply of well-developed, healthy seedlings at the proper time for transplanting. Orinoco strains of seed are sown to grow leaf for flue curing. The Pryor group are grown to produce the dark air-cured and fire-cured types. Burley and Maryland strains are seeded for the production of light, air-cured tobaccos. Broad-leaf and seed-leaf strains, Havana seed, Cuban, and Sumatra varieties are for the production of cigars. The variety grown for production of Perique resembles the Cuban-like variety used in Puerto Rico. Aromatic varieties are grown for production of this type of leaf and in some degree resemble the Cuban varieties.

Soil for a plant bed should be fertile, of good tilth and drainage, protected from chilling winds, and exposed to the sun. The soil is usually partially sterilized by burning, steaming, or using chemicals such as methyl bromide to control diseases, weeds, insects, and nematodes (a class of worms). In warm regions the small germinating seedlings are produced outdoors in cold frames covered with thin cotton cloth or a thin mulch, such as chopped grass in Rhodesia, straw, or pine needles. Glass or plastic is used in colder regions, and close attention is given to watering

and ventilation. The usual rate of seeding—*i.e.*, 28 grams of cleaned seed of high germination to 200 square yards (167 square metres) of seed-bed area can be expected, under favourable conditions, to produce 15,000 to 25,000 plants for transplanting. High analysis mixtures of commercial fertilizers are usually applied before seeding at the rate of one-half to two pounds per square yard of seed-bed area. The soil must be finely pulverized and level so the seed can be lightly covered with soil by rolling or trampling. Uniform distribution of seeds is important. In eight to ten weeks the seedlings are four to seven inches in length and ready for transplanting in the field.

Seed-bed diseases, such as blue mold, anthracnose, bacterial leaf spots, damping off, and virus are controlled by sanitation and application of sprays. Insecticides may be applied simultaneously to control insects such as flea beetles.

Transplanting machines are used extensively (see Figure 1), but most of the world's tobacco is planted by hand. When the soil is dry, adding water helps a high percentage of transplants to survive. Fumigation of soil prior to transplanting is a common practice in many areas where nematodes are common, to reduce their damage.

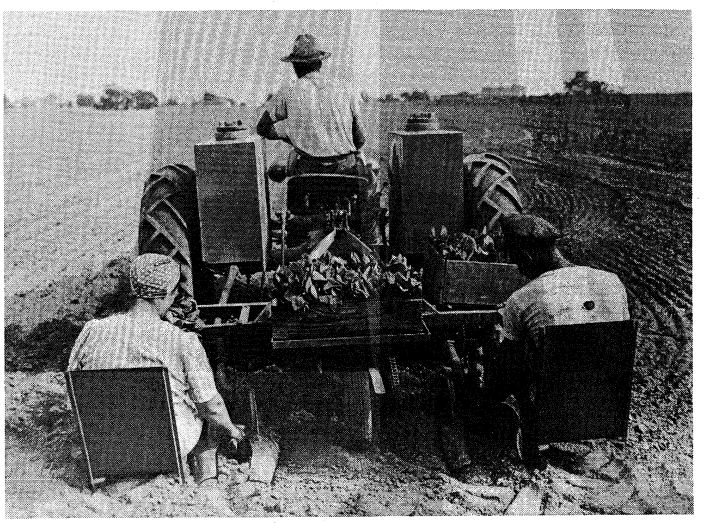

Figure 1: Two-row transplanter used to plant tobacco seedlings, Pennsylvania.

Soil and fertilizer requirements vary widely with the type of tobacco grown. Well-drained soil with a structure that assures good aeration is desirable. Flue-cured, Maryland, cigar binder, and wrapper types of tobacco are produced on sandy and sandy-loam soil, with a sandy and sandy-clay subsoil where local conditions permit. Burley, dark air-cured, fire-cured, cigar-filler, and cigar-binder types are grown on silt-loam and clay-loam soils, with clay subsoils. The type of tobacco, soil, and climate determine fertilizer requirements. If any of the chemical elements essential for growth are lacking, the tobacco plant develops nutritional deficiency symptoms. Though nitrogen, phosphoric acid, and potash may be applied in the shade cigar-wrapper area of Florida–Georgia, very little fertilizer is used on eastern European fields of aromatic tobacco, where rich soils can make the leaf grow too large and rank to be desirable commercially.

Soil must be prepared and cultivated to control weeds and promote the early and continuous growth of tobacco.

Cigar-wrapper leaf

For production of cigar-wrapper leaf, a unique method of culture is practiced in Cuba and the U.S., under artificial cheesecloth shade (see Figure 2). A high moisture content is maintained in soil and air to produce a thin, elastic leaf. In Sumatra and Java under the prevailing conditions of soil and climate, tobacco for cigar wrapper is produced for one or two years following the clearing of jungle growth. Climatic and soil conditions characterized by a moist atmosphere appear to be associated with the production of acceptable cigar-wrapper tobacco. Cuban leaf for cigar filler is produced on certain soils from special varieties in the prevailing climatic conditions.

Figure 2: Tobacco cultivated under artificial shading cloth to produce leaves suitable for cigar wrappers, Cuba.
Eastfoto

Aromatic tobacco culture in Turkey, Greece, Bulgaria, Yugoslavia, and other areas differs from that of most of the large-leafed tobaccos in that the plants are rarely topped and preferably are grown on soils of low productivity. The most acceptable aromatic leaf is produced in the Mediterranean climate, maturing during dry periods on upland soils.

Spacing of plants in the field varies widely according to the type of tobacco. Flue-cured tobacco rows are 4 feet (1.2 m) apart with plants 20 to 24 inches (50 to 60 cm) apart in the row. Burley and cigar tobaccos are 3 to 3½ feet by 15 to 27 inches. Dark air-cured and fire-cured tobaccos may be planted on the square with hills 3½ feet apart. Maryland may be planted 36 to 32 inches or closer. Aromatic tobaccos are spaced in rows 15 to 24 inches apart with 3 to 8 inches between plants in the row. Perique is spaced the widest with rows 5 feet apart and 36 to 42 inches between plants.

Large-leaf tobaccos grown in the United States and in several other countries are topped—that is, the terminal growth is removed—when the plant has reached the desired size, usually at or shortly after flowering. The number of leaves remaining varies widely. Dark air-cured and fire-cured tobaccos may have 10 to 16 leaves; Burley, flue-cured, Maryland, and cigar types may have 16 to 20 leaves. After topping, the suckers, or lateral shoots are removed to increase leaf development, providing increased yields. The work may be done by hand, in which case it must be repeated regularly, or by application of sucker-suppressing chemicals.

Diseases and pests. Common diseases are black-root rot, fusarium wilt, tobacco-mosaic, bacterial-leaf spot, downy mildew or blue mold, black shank, broomrape, and witch weed. These may be controlled by sanitation, crop rotation, the use of sprays and fumigants, and breeding of disease-resistant strains. Resistance to bacterial-leaf spot, fusarium wilt, mosaic, black shank, and black-root rot have been accomplished by breeding. Some resistant varieties of tobacco in general use have been produced by blending desired characteristics from *N. longiflora*, *N. debneyi*, *N. glutinosa*, and others with some strain of *N. tabacum*.

Common insect pests are the green June beetle larvae, cutworms, and flea beetles in the plant bed; hornworms, grasshoppers, flea beetles, cutworms, budworms, and aphids in the field. The cigarette, or tobacco, beetle damages the stored leaf and sometimes the manufactured product. Insect pests are controlled on the growing crop by using sprays and dusts, on the stored product by fumigating and trapping. Biological control often is effective. Fumigation controls nematodes in the field.

Harvest. Tobacco is harvested 70 to 130 days after transplanting by one of two methods: (1) the entire plant is cut and the stalk split or speared and hung on a tobacco

stick or lath, or (2) the leaves are removed at intervals as they mature. The leaves of cigar-wrapper and aromatic tobaccos are strung using a needle, and leaves to be flue-cured are looped, using a string tied to a lath or stick that is hung in the curing barn. To prevent breakage and bruising during the handling necessary in curing, it is desirable for the leaf to wilt without sunburning. Tobacco may be left in the field from a few hours to two days to wilt.

Curing. The three common methods of curing are by air, fire, and flue. A fourth method, sun curing, is practiced with aromatic types and to a limited extent with air-cured types. Curing entails four essential steps: wilting, yellowing, colouring, and drying. These involve physical and chemical changes in the leaf and are regulated to develop the desired properties. Air curing (see Figure 3)

By courtesy of the U.S. Department of Agriculture

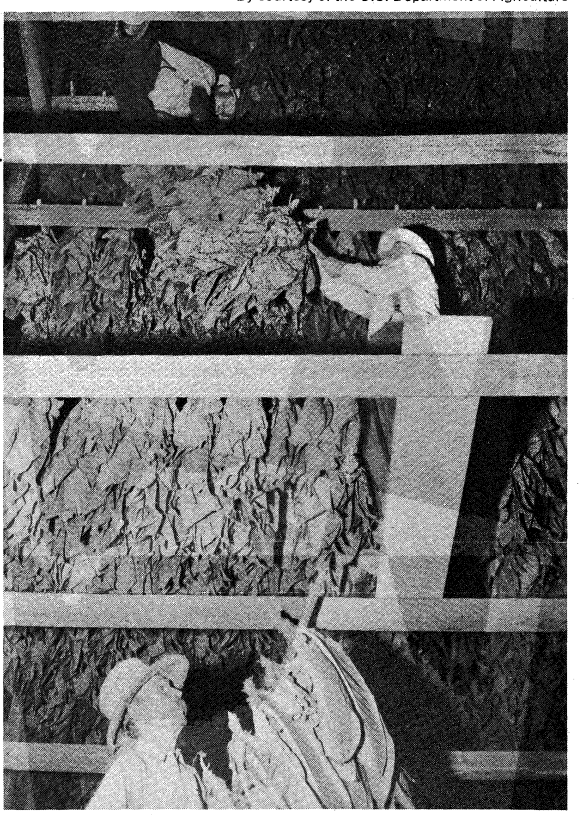

Figure 3: Hanging Maryland tobacco, cured on the stalk, in a curing barn.

is accomplished mainly by mechanical ventilation inside buildings. Coke, charcoal, or liquid petroleum gas may be burned to provide heat when conditions warrant. Air curing, which requires from one to two months' time, is used for many tobaccos, including dark air-cured types, cigar, Maryland, and Burley.

Air curing, fire curing, and flue curing

The fire-curing process resembles air-curing except that open wood fires are kindled on the dirt floor of the curing barn after the tobacco has been hanging for two to six days. The smoke imparts a characteristic creosote aroma. The firing process may be continuous or intermittent, extending from three weeks to as long as ten weeks until curing is complete and the leaf has the desired finish.

The barns for flue curing are small and tightly constructed with ventilators and metal pipes, or flues, extending from furnaces around or under the floor of the barn. Fuels used are wood, coal, oil, and liquid petroleum gas. If oil or gas heaters are used, flues are not needed. Heat is applied carefully with attention to the chemical and physical changes in the leaf. Flue-curing requires from four to eight days' time and is used for Virginia, or bright, tobacco. In bulk curing, the leaves are loaded evenly in racks in a curing chamber.

Grading and marketing. After curing, the leaf may be piled in bulk to condition for a time before it is prepared for sale. The preparation consists usually of grading the leaf and putting it in a bale or package of convenient size and weight for inspection and removal by the buyer. Except during humid periods, the leaf must be conditioned in moistening cellars or humidified rooms before it can be handled without breakage. Type of leaf and local custom determine the fineness of grading. At its most elaborate, grading may be by position of the leaf on the plant, colour, size, maturity, soundness, and other recognizable qualities; flue-cured tobacco in the United States and Rhodesia is graded this way, and each grade bulked or baled separately. Much simpler grading is usual in developing countries, where the buyer is as much concerned with the proportions of each grade as he is with the quality of the entire lot; aromatic tobaccos are an example of this. Most tobaccos entering world trade, except the aromatic, are assembled before sale into bundles or hands of 15 to 30 leaves and tied with one leaf wrapped securely around the butts.

Most United States, Canadian, Central African, and Australian tobacco is sold by farmers at auction warehouses. Buyers visiting farms or local villages purchase other tobaccos by private treaty. The purchase of entire crops under preplanting contracts is less common than bale or package buying. Much of the world's tobacco is sold noncompetitively by farmers in countries where a state monopoly is the sole purchaser. Indonesian and Cameroon cigar leaf is bought from farmers by private treaty, by middlemen who resell overseas, in Bremen and Paris, to the ultimate manufacturers.

Most tobaccos, except aromatic and cigar, are regraded if necessary and usually redried after purchase; then the exact amount of moisture needed for aging is added and the tobacco is securely packed in cases or hogsheads. Exported tobacco is shipped in this form. The trend is for the packing factories to stem the leaf—that is, remove most of the stem leaving the lamina—usually by threshing machines but sometimes by hand, before redrying it. The aging process, particularly with cigar tobaccos, is sometimes hastened by forced fermentation procedures. After purchase, aromatic tobaccos are manipulated; that is, they are factory-graded, baled, and subjected to an elaborate, in-the-bale, fermentation process before going to the ultimate manufacturer.

Manufacture of products. If leaf tobacco is not bought in ready-stemmed form, the first step in turning it into a product that the consumer can smoke, chew, or take as snuff is to remove midribs (central veins). For most products, manufacturers blend leaf of various types, origins, grades, and crop years to obtain the qualities they require and assure uniformity over the years. Cigarette manufacturers usually add sweetening preparations and flavourings, and process the tobacco in a variety of secret ways before it is fed, as finely shredded rag, into the cigarette-making machines. Preparation of tobaccos for pipe smoking and chewing is as varied as the assortment of these products. Their manufacture may involve the incorporation of additives and the application of pressure and heat. Snuff is usually made by fermenting fire-cured leaf and stem, and grinding it; salts and flavourings may be added. Cigars are made by wrapping a binder leaf around a bunch of cut filler leaf and overwrapping with a fine wrapper leaf; on all but the finest cigars the work is largely mechanized.

In the United States and increasingly elsewhere, stems and scrap are used for nicotine extractions or are ground down and made into reconstituted sheet in a process akin to papermaking. The sheet may be used as a substitute cigar binder or, more rarely, as wrapper, or it may be finely cut and used to supplement natural tobacco in cigarettes.

Production control. In an effort to correct overproduction problems, controls of various kinds have been instituted in several countries, notably the U.S., Turkey, Rhodesia, Canada, and Japan.

WORLD PRODUCTION AND CONSUMPTION

About 80 countries produce tobacco. The total production fluctuates from year to year partly because of weather and growing conditions, partly because of world demand, between about 9,000,000,000 and 10,000,000,000 pounds. The yearly production of the United States for 1960–

64 averaged 2,178,400,000 pounds; in 1967 it was 1,967,911,000 pounds; in 1968, 1,715,573,000 pounds; and in 1970, an estimated 1,906,000,000 pounds.

The preferential duty extended by the British Government to tobacco produced in Commonwealth countries greatly stimulated production in Canada, Rhodesia, and other countries under British influence. Rhodesia shows a decline in production, possibly due to Commonwealth sanctions.

Most tobacco is consumed in the countries where it is produced. During the years 1960–64, the principal countries that exported 1,685,340,000 pounds also imported 1,536,742,000 pounds. Cigarette tobaccos, such as the flue-cured and aromatic types, are increasingly in demand in world-trade channels, as are cigar tobaccos.

A high and rising proportion of all the world's tobacco is consumed in cigarette form. Cigarettes comprise almost all tobacco consumed in Mexico and Brazil; seven-eighths in Great Britain and Italy; three-quarters or more in the U.S., France, Canada, and Argentina. Even such traditionally cigar-smoking countries as Denmark and The Netherlands take half their tobacco as cigarettes and only about a quarter as cigars.

Tobacco consumption has risen faster in the developing countries than in the advanced ones. In the advanced countries consumption fell off with the publication of reports connecting smoking with cancer but quickly recovered. The ultimate effect is not yet clear. India and parts of Africa consume only about two pounds (0.9 kilograms) per adult per year, or in terms of cigarettes, about 910. The comparable figure in Great Britain is 6½ lbs (3 kg). In the U.S. 10½ lbs (4.8 kg) were consumed per adult in 1968, which was down from 12 lbs in 1962. In Switzerland 12 lbs (5.4 kg) of tobacco were consumed per adult.

ECONOMIC AND SOCIAL ASPECTS

Revenue. Tobacco has long been a source of revenue in many countries of the world. This revenue is derived from taxes on the stored leaf and on the manufactured products as in the U.S., from duties on imports as in the U.K., or from profits from the operation of government monopolies that have been in effect in many European countries, Japan, and elsewhere. In many countries the income of the governments in tax revenue collected on manufactured tobacco products, particularly cigarettes, exceeds the sale value received by farmers for the crop. In the U.S., in addition to the revenue collected by the federal and state governments, a number of cities exact a tax on tobacco products.

Tobacco and health hazards. The contention that smoking is a health hazard is almost as old as the use of tobacco. In 1604 King James I of England issued the first official condemnation of tobacco, "A Counterblaste to Tobacco." One of the first published reports on the subject, issued in 1859, showed that of 68 patients in a hospital at Montpellier, France, who had cancer of the lips, tongue, tonsils, or other parts of the mouth, all used tobacco and 66 of them smoked short-stemmed clay pipes. This type of pipe fell from favour following the release of the report.

Government warnings

Interest in the relationship between tobacco and health waned until cigarette smoking became widespread following World Wars I and II, when health authorities reported that in countries in which cigarette smoking was popular, deaths from lung cancer and certain other diseases were climbing at an alarming rate.

In 1954 the American Cancer Society and the British Medical Research Council reported independently, following separate three-year statistical studies, that death rates were higher for cigarette smokers than for nonsmokers. In 1962 the Royal College of Physicians of London summarized the evidence on the disease-tobacco relationship and called cigarette smoking a serious hazard to health. The British government then inaugurated a program of public education aimed at reducing the use of tobacco. In 1963 a second American Cancer Society report cited evidence showing that the death rate for cigarette smokers increases as the amount of smoking increases. Despite the unfavourable medical reports and adverse publicity given to smoking, the per capita consumption of cigarettes in the U.S. in 1970 was 4,000, only slightly down from 4,258 in 1965. In January 1964 a special advisory committee appointed by the United States Surgeon General ended a two-year study by reporting that cigarette smoking was associated with the 70% increase in the lung cancer death rate for American males in 1950–60. The committee described cigarette smoking as a health hazard and urged controls. The report found that cigarette smoking was associated with lung cancer, coronary artery disease, chronic bronchitis, and emphysema. Pipe smoking, the report added, is linked with lip cancer. In 1965 Federal legislation was passed requiring that all cigarette packages sold after January 1, 1966, carry health hazard warning labels. Cigarette advertising on television was banned beginning January 1, 1971, while the American Cancer Society and Heart Association used television to mount an intensive campaign against smoking.

To gather additional information on the association between health and smoking, the U.S. Department of Health, Education and Welfare in 1964 began awarding funds for research. In the same year, six tobacco companies gave the American Medical Association $10,000,000 for research. These studies are continuing on an expanded basis. Meantime the tobacco industry has been manufacturing filter and extra-length cigarettes in an attempt to lessen the health hazard of cigarette smoking.

Tocharian Language

Tocharian (Tokharian), also called Tocharish, is an Indo-European language that was spoken in northern Chinese Turkistan (Tarim Basin) during the latter half of the 1st millennium AD. Documents from about AD 500–700 attest to two dialects: Tocharian A, from the area of Turfan in the east; and Tocharian B, chiefly from the region of Kucha in the west but also from the Turfan area.

Discovery and decipherment. The first Tocharian manuscripts were discovered in the 1890s. The bulk of the Tocharian materials were carried to Berlin by the Prussian expeditions of 1903–04 and 1906–07, which explored

the Turfan area, and to Paris by a French expedition of 1906–09, which investigated chiefly in the area of Kucha. Smaller collections are in London, Leningrad, and Japan.

Tocharian is written with a north Indian syllabary (a set of characters representing syllables) known as Brāhmī, which was also used in writing Sanskrit manuscripts from the same area. The first successful attempt at grammatical analysis and translation was made by the German scholars Emil Sieg and Wilhelm Siegling in 1908 in an article that also established the presence of the two dialects, provisionally called A and B. The Berlin collection consisted of both dialects, whereas all other manuscripts discovered were in B.

Translation and analysis

The German name Tocharisch was proposed, and the language was demonstrated to be Indo-European.

Characteristics. Tocharian forms an independent branch of the Indo-European language family not closely related to other neighbouring Indo-European languages (Indo-Aryan and Iranian). Rather, Tocharian shows a closer affinity with the western (*centum*) languages: compare, for example, Tocharian A *känt*, B *kante*, *känte* "100," and Latin *centum* with Sanskrit *śatám*; A *klyos-*, B *klyaus-* "hear," and Latin *clueo* with Sanskrit *śru-*; A *kus*, B *kuse* "who," and Latin *qui*, *quod* with Sanskrit *kas*. In phonology, Tocharian differs greatly from the other Indo-European languages in that all of the Indo-European stops of each series fall together, resulting in a system of three (voiceless) stops, *p*, *t*, and *k*.

The Tocharian verb reflects the Indo-European verbal system both in stem formations and in personal endings. Especially noteworthy is the wide development of the mediopassive form in *r* (as in Italic and Celtic); *e.g.*, Tocharian A *klyoṣtär* "is heard." The 3rd person preterit plural ends in *-r*, similar to Latin and Sanskrit perfect forms and the Hittite preterit. The noun, however, shows little trace of the original Indo-European inflection. Instead, it is built up by the addition of postpositions to the oblique (accusative) form. This type of inflection (agglutination) has been attributed to the influence of non-Indo-European languages (Turkish, Finno-Ugric).

The vocabulary shows a remarkable influx of loanwords —from Turkish, Iranian, and, later, Sanskrit. Chinese has had little influence. Many of the most archaic elements of the Indo-European vocabulary are retained—*e.g.*, A *por*, B *puwar* "fire" (Greek *pyr*, Hittite *paḫḫur*); A and B *ku* "dog" (Greek *kyōn*); A *tkaṃ*, B *keṃ* "earth" (Greek *chthōn*, Hittite *tekan*), and especially, nouns of relationship: A *pācar*, *mācar*, *pracar*, *ckācar*, B *pācer*, *mācer*, *procer*, *tkācer*, "father," "mother," "brother," and "daughter," respectively.

Literature. Tocharian literature is Buddhistic in content, consisting largely of translations or free adaptations of Jātakas, of Avadānas, and of philosophical, didactic, and canonical works. In dialect B there are also commercial documents, such as monastery records, caravan passes, medical and magical texts, and the like. These are important source materials for the social, economic, and political life of central Asia.

The "Tocharian problem." Since the appearance of Sieg and Siegling's article, the appropriateness of the name Tocharian for the language has been disputed. According to Greek and Latin historical sources, the Tochari (Greek Tócharoi, Latin Tochari) inhabited the basin of the upper Oxus River (modern Amu Darya) in the 2nd century BC and were probably Iranians. Sieg and Siegling's identification of this language as belonging to these people was probably in error.

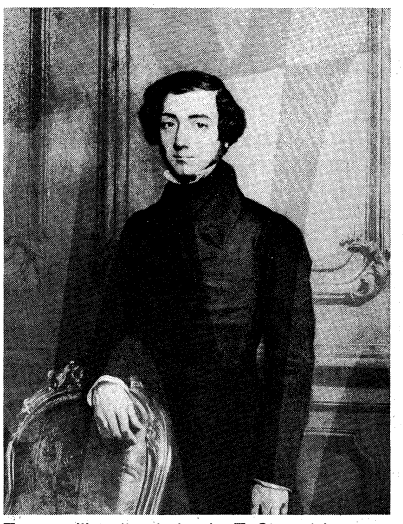
Identification of the Tocharian-speaking people

There have, of course, been numerous attempts to identify the speakers of Tocharian with this or that people or tribe mentioned in Chinese annals or in other documents dealing with the area in and around the Tarim Basin during the last half of the 1st millennium AD. One such identification that gained some adherents was with the Wu-sun. Neither this nor any other identification, however, would appear to be more than mere speculation.

Furthermore, the name *ārśi* (*ārśiype* "Arśi-country," *ārśikäntu* "Arśi-language"), once accepted as the native name in dialect A, is probably a loanword through Iranian from Sanskrit *árya*. The question of the name is, however, of little linguistic importance. Tocharian, even if generally accepted as a misnomer, will probably remain. For dialect A and dialect B, the substitution of Turfanian and Kuchean, or of East Tocharian and West Tocharian, has been suggested.

Of greater importance, at least from the linguistic point of view, is the relationship of the Tocharian language to the other Indo-European languages and the interrelationship of the two dialects themselves. In the former regard, in spite of superficial resemblances to Italic and Celtic (see above), the more fundamental shared features —*e.g.*, common vocabulary, certain verbal categories (*s*-aorists, preservation of the perfect active participle), and possible relics of common phonological developments— would appear to align Tocharian with the more southeastern branches of Indo-European; that is, with Thracian and Phrygian or even with Greek and Armenian. Those features shared with the Baltic and Slavic languages (certain present and preterit formations in particular) might be the result of later contacts.

With regard to the interrelationship of the two dialects, it is possible that dialect A was, at the time of documentation, a dead liturgical language preserved in the Buddhist monasteries in the east, whereas dialect B was a living language in the west (note that commercial or at least nonliturgical documents are found in that dialect). The presence of manuscripts in B mixed with those in A in the monasteries of the east can be accounted for by ascribing the B manuscripts to a new missionary invasion of those monasteries by Buddhist monks from the west.



BIBLIOGRAPHY. E. SIEG and W. SIEGLING (eds.), *Tocharische Sprachreste* (1921), gives the transcription of all the manuscripts in dialect A. A small companion volume, *Tafeln*, reproduces a number of the best preserved leaves in facsimile. E. SIEG, W. SIEGLING, and W. SCHULZE, *Tocharische Grammatik* (1931), is an exhaustive grammar of dialect A, with a verbal index identifying and listing all verb forms in that dialect. H. PEDERSEN, *Tocharisch vom Gesichtspunkt der indoeuropäischen Sprachvergleichung* (1941), is still the best overall comparative study from the Indo-European point of view, even though extensive published materials in dialect B were not available. E. SIEG and W. SIEGLING, *Tocharische Sprachreste, Sprache B*, 2 pt. (1949–53), contain all the Berlin manuscripts in dialect B plus a few from other collections (especially the Hoernle collection in London). Part 1 is an edition of the Udānālaṅkāra fragments with translation and glossary. W. KRAUSE, *Westtocharische Grammatik*, vol. 1, *Das Verbum* (1952), is indispensable for the verb in dialect B (a second volume was never published). W. KRAUSE and W. THOMAS, *Tocharisches Elementarbuch*, vol. 1, *Grammatik* (1960), vol. 2, *Texte und Glossar* (1964), including both dialects, now replace all earlier introductions to the study of Tocharian. Two articles by G.S. LANE, "On the Interrelationship of the Tocharian Dialects," in H. BIRNBAUM and J. PUHVEL (eds.), *Ancient Indo-European Dialects* (1966); and "Tocharian: Indo-European and Non-Indo-European Relationships," in G. CARDONA, H.M. HOENIGSWALD, and A. SENN (eds.), *Indo-European and Indo-Europeans* (1970), attempt to solve some of the problems concerning the varied uses of the two dialects and the general problem of the position of Tocharian within the Indo-European family of languages.

(G.S.L.)

Tocqueville, Alexis de

The French political scientist, historian, and politician Alexis de Tocqueville remains today best known as the author of the classic *De la démocratie en Amérique* (*Democracy in America*), an acute description and often prophetic analysis of the American political system in the early part of the 19th century.

Alexis-Charles-Henri Clérel de Tocqueville was born in Paris on July 29, 1805, of an old Norman family. He was a great-grandson of the statesman Chrétien de Malesherbes, a liberal aristocratic victim of the French Revolution and a political model for the young Tocqueville. Almost diminutive in stature, acutely sensitive, and plagued by severe bouts of anxiety since childhood, he remained close to his parents throughout his life. Outwardly proud and cold among strangers, Tocqueville was yet able to form deep and lasting friend-

H. Roger-Viollet

ships. He was most comfortable in small, informal groups, where he was listened to with respect. This ability to influence those closest to him led him to project his own experience on to the social framework and to envision local government and small-scale association as the best form of political organization.

Given the choice of a variety of careers, it is not surprising that Tocqueville chose the one most congenial to him: that of politician. Despite a frail voice in a fragile body, distaste for the daily demands of parliamentary existence, and long periods of illness and nervous exhaustion, he adhered to his original choice until he was driven from office. His decision in favour of a public career was made with some assurance of success. His father was a loyal royalist prefect and in 1827 was made a peer of France by Charles X, who had earlier called him to Versailles. At that time, young Tocqueville moved easily into government service as an apprentice magistrate. There he prepared himself for political life while observing the impending constitutional confrontation between the Conservatives and the Liberals with growing sympathy for the latter. He was strongly influenced by the lectures of the historian and statesman François Guizot, who asserted that the decline of aristocratic privilege was historically inevitable. And finally, after the manner of Liberals under the autocratic regime of the restored Bourbon kings, Tocqueville began to study English history as a model of political development.

Government service

He entered public life in the company of a close friend who was to become his alter ego—Gustave de Beaumont. Their life histories are virtual mirror images. Of similar backgrounds and positions, they were companions in their travels in America, England, and Algeria; coordinated their writings; and ultimately entered the legislature together.

The July Revolution of 1830 that put the "citizen king" Louis-Philippe of Orléans on the throne was a turning point for Tocqueville. It deepened his conviction that France was moving rapidly toward complete social equality. Breaking with the older liberal generation, he no longer compared France with the English constitutional monarchy but with democratic America. Of more personal concern, despite his oath of loyalty to the new monarch, his position had become precarious because of his family ties with the ousted Bourbon king. He and Beaumont, seeking to escape from their uncomfortable political situation, asked for and received official permission to study the uncontroversial problem of prison reforms in America. They also hoped to return with knowledge of a society that would mark them as especially fit to help mold France's political future.

America and democracy

The two men spent nine months in the United States during 1831 and 1832, out of which came first their joint book, *Du système pénitentiaire aux États-Unis et de son application en France* (1833; Eng. trans., *On the Penitentiary System in the United States and Its Application in France*, 1833); Beaumont's *Marie, ou l'esclavage aux États-Unis* (1835; Eng. trans., *Marie, or Slavery in the United States*, 1958), on America's race problems; and the first part of Tocqueville's *De la démocratie* 1835–40; Eng. trans., *Democracy in America*, 1835–40). On the basis of observations, readings, and discussions with a host of eminent Americans, Tocqueville attempted to penetrate directly to the essentials of American society and to highlight that aspect—equality of conditions—that was most relevant to his own philosophy. Tocqueville's study analyzed the vitality, the excesses, and the potential future of American democracy. Above all, the work was infused with his message that a society, properly organized, could hope to retain liberty in a democratic social order.

The first part of *De la démocratie* won an immediate reputation for its author as a political scientist. This period probably was the happiest and most optimistic of his life. Hailed as the Montesquieu (the famous 18th-century philosopher) of the century, within the next few years Tocqueville was named to the Legion of Honor, the Academy of Moral and Political Sciences (1838), and finally the French Academy (1841). With the prizes and royalties from the book, he was even able to rebuild his ancestral chateau in Normandy. Within a few years his book had been published in England, Belgium, Germany, Spain, Hungary, Denmark, and Sweden. In America, while it was sometimes viewed as having been derived from politically biased sources, it was newly accorded the status of a classic. But the greatest immediate honour came from across the English Channel. In England, which he had visited as an unknown in 1833, he was welcomed, after his book was published, in the highest political and intellectual circles when he returned in 1835. He established lifelong friendships there and found the political atmosphere so congenial that England became intellectually his second home. The tie was to be reinforced by his marriage in 1836 to Mary Mottely, an Englishwoman. The English journey also awakened his interest in the problems of industrialization, and his first essay on the old regime in France was written as a result of his conversations with the philosopher and radical reformer John Stuart Mill.

Returning to France, Tocqueville spent four more years on the final portion of *De la démocratie*, which was published in 1840. Its composition took far longer, moved farther afield, and ended far more soberly than Tocqueville had originally intended. American society slid into the background, while Tocqueville now attempted to complete a picture of the influence of equality itself on all aspects of modern society. France increasingly became his principal example, and what he saw there altered the tone of his work. He observed the curtailment of liberties by the Liberals who had come to power in 1830 as well as the growth of state intervention in economic development. Most depressing to him was the increased political apathy and acquiescence of his fellow citizens in this rising paternalism. His chapters on democratic individualism and centralization in *De la démocratie* contained a new warning based on these observations. A mild, stagnant despotism now seemed to him democracy's greatest danger.

Politics

This was also the period in which Tocqueville fulfilled his lifelong ambition to enter politics. He lost his first bid for the Chamber of Deputies in 1837, due largely to his fear of compromising his independence by accepting government support or by running an undignified campaign to woo his rural bourgeois electors. He soon broke down suspicion caused by his aloofness and aristocratic background and won the following election in 1839. Eventually, Tocqueville built up an enormous personal influence in his constituency. He won every election after the first by more than 70 percent of the vote and became president of his departmental council (a local representative body). Characteristically, at the level of local politics his quest for pre-eminence was completely fulfilled. But his need for uncompromised dignity and independence deprived him of influence in the Chamber for a much longer time.

A good committee reporter on large nonpartisan issues—prison reform, slavery, colonial policy—he could not adapt himself to the give and take of perpetual bargaining and coalitions with those whom he regarded as mediocre or untrustworthy politicians. He was neither able to follow the leadership of others nor did his oratorical style win him quick recognition as a leader himself. As a result, he had no major legislative accomplishment to his credit during the reign of Louis Philippe. His speech prophesying revolution only a few weeks before it took place in February 1848 fell on deaf ears. The biting sketches of friend, foe, and even himself in his *Souvenirs* (1893; "Recollections"), reflect his feeling of the general mediocrity of political leadership before and after 1848.

February Revolution of 1848

The February Revolution brought about a new political situation for France and for Tocqueville. Having for years decried apathy as the chief danger for France, Tocqueville recognized even before the Revolution that France was faced with a politically awakened working class that might well propel French politics into socialist and revolutionary channels. Tocqueville considered economic independence as necessary to the preservation of his own intellectual independence. He thus viewed pressures of the dependent poor for state welfare, and of the unemployed for state employment, as the initial steps to a universal and degrading dependence on the state by all social classes. Unsympathetic to revolutionaries and contemptuous of socialists before the Revolution, Tocqueville opposed the demands of the Parisian workers during the June days of 1848, when their uprising was bloodily suppressed by the military dictator General Louis Cavaignac, as well as in the debates over the constitution of 1848. The only intellectual change produced in Tocqueville by the events of 1848 was a recognition of the strength of socialist ideas and of the problematic nature of the proprietary society. But while he had sought to reconcile the aristocracy to liberal democracy in *De la démocratie*, he rejected social democracy as it emerged in 1848 as incompatible with liberal democracy.

Politically, Tocqueville's own position was dramatically improved by the February Revolution. His electorate expanded from 700 to 160,000 under universal manhood suffrage. He was elected as a conservative Republican to the Constituent Assembly by 79 percent of the voters and again in 1849 by more than 87 percent. Along with Beaumont, he was nominated to the committee that wrote the constitution of the Second Republic, and the following year he became vice president of the Assembly. He served as minister of foreign affairs between June and October of 1849. During his short tenure he worked cautiously to preserve the balance of power in Europe and to prevent France from extending its foreign involvements. His speeches were more successful and his self-confidence soared, but the results gave him little more durable satisfaction than those he had attained during the July Monarchy under Louis Philippe.

In June 1849 a government crisis produced by French armed intervention to restore papal authority in Rome was the occasion for Tocqueville's brief appointment to the Ministry of Foreign Affairs. Shortly after his dismissal from the ministry by President Louis-Napoleon in October 1849 he suffered a physical collapse. After a slow recovery he performed a final service for the Second French Republic. As reporter for the constitutional revision committee he attempted to avert the final confrontation between the President and the legislature, which ended with an executive seizure of dictatorial power. Briefly imprisoned for opposing Louis Napoleon's coup d'etat on Dec. 2, 1851, Tocqueville was deprived of all political offices for refusing his oath to the new regime. He was thrown back on a small circle of political allies and friends and felt a deeper sense of isolation and political pessimism than ever before.

Coup of 1851

Seeking to re-enter politics, he reverted to the strategy of his youthful success—the publication of a book on the fundamental themes of liberty and equality. This time he chose as his subject the French Revolution. *L'Ancien Régime et la Révolution (The Old Regime and the Revolution)* appeared in 1856, after years of research and intermittent illness, as the first part of his project study. In this work, Tocqueville sought to demonstrate the continuity of political behaviour and attitudes that made postrevolutionary French society as prepared to accept despotism as that of the old regime. In this final study the traumatic events of the years 1848–51 were clearly the source of his emphasis on the durability of centralization and class hostility in French history. France seemed less the democratic society of the future he had glimpsed in America than the prisoner of its own past. Against the pessimism of his analysis of French political tendencies, *L'Ancien Régime* reaffirmed the libertarian example of the Anglo-American world. The acclaim that greeted this study briefly dispelled the gloom of his last years. Once again his book made him a public figure. His visit to England in 1857, culminating in an audience with the prince-consort, was the last public triumph of his life. He returned to his work; but before he could finish his study of the Revolution, he collapsed and died at Cannes on April 16, 1859.

Reputation

Tocqueville's reputation in the 19th century reached its high point during the decade following his death, as the great European powers accommodated themselves to universal suffrage. He died just at the onset of a revival of liberalism in France. The nine-volume publication of his works, edited by Beaumont (1860–1866), was received as the legacy of a martyr of liberty. In England his name was invoked during the franchise reform debates of the 1860s, and in Germany it was linked to controversies over liberalization and federalization in the years preceding the empire devised by Bismarck. After 1870 his influence began to decline, a process not substantially reversed either by the posthumous publication of his *Souvenirs* in 1893 or that of his correspondence with his friend, the diplomatist and philosopher Arthur de Gobineau. By the turn of the century he was almost forgotten, and his works were generally regarded as outdated classics. They seemed too abstract and speculative for a generation that believed only in ascertained knowledge. Moreover, Tocqueville's prediction of democracy as a vast and uniformly levelling power seemed to have miscarried by not foreseeing both the extent of the new inequalities and conflicts produced by industrialization and those produced by European nationalisms and imperialism. The classless society had failed to appear in Europe and even America seemed to have become European by becoming nationalist and imperialist rather than vice versa. In France, Tocqueville's name was too closely identified with a narrowly defined Liberal tradition, which rapidly lost influence during the Third Republic. While his work as an innovative historian was acknowledged, it is significant that the revival of his ideas and reputation as a political sociologist owes so much to American, English, and German scholarship.

The 20th-century totalitarian challenge to the survival of liberal institutions produced by two world wars and by the Great Depression of the 1930s fostered a "Tocqueville renaissance." The outdated facts of his books seemed less significant than the political philosophy implicit in his search to preserve liberty in public life and his strategies for analyzing latent social tendencies. His work was found to display a wealth of fruitful philosophical and sociological hypotheses. At a popular level, the renewed upsurge of social democracy of Europe after 1945 also combined with the polarization of the Cold War to the view of Tocqueville in the West as an alternative to Marx as a prophet of social change. Again, as in the late 1850s and 1860s, Tocqueville rose to heights of great popularity. Whether changes in social and intellectual climate will cause another levelling off only time will tell. It seems certain, however, that henceforth Tocqueville will continue to be invoked as an authority and inspiration by those sharing his contempt of static authoritarian societies as well as his belief in the final disappearance of class divisions and in liberty as the ultimate political value.

BIBLIOGRAPHY. Tocqueville's major works have all been published in the new *Oeuvres complètes*, ed. by J.P. MAYER (1951–): vol. 1, *De la démocratie en Amérique*; vol. 2,

L'Ancien Régime et la révolution; and vol. 12, the *Souvenirs*. Recent English translations of these works are: *Democracy in America*, 2 vol., ed. by P. BRADLEY (1945), another one volume edition of the same work, ed. by J.P. MAYER and M. LERNER (1966); *The Old Regime and the French Revolution*, trans. by S. GILBERT (1955); and *The Recollections of Alexis de Tocqueville*, ed. by J.P. MAYER and A.P. KERR (1970). A new English edition of *Du système pénitentiaire aux États-Unis, et de son application en France* (1833; *On the Penitentiary System in the United States and Its Application in France*), was published in 1964.

There are three 20th century biographies of Tocqueville: R.P. MARCEL, *Essai politique sur Alexis de Tocqueville* (1910); A. REDIER, *Comme disait M. de Tocqueville . . .* (1925); and J.P. MAYER, *Alexis de Tocqueville: A Biographical Essay in Political Science*, rev. ed. (1960). G.W. PIERSON, *Tocqueville and Beaumont in America* (1938), marked the beginning of a generation of intense Tocqueville scholarship. There is nothing approaching a definitive biography, nor is one likely to appear until work on the new publication of his *Oeuvres* reaches the volumes on Tocqueville's private and political correspondence. For the author's correspondence with Gobineau, see *The European Revolution and Correspondence with Gobineau*, ed. and trans. by J. LUKACS (1959). With the exception of his early years, however, and the more intricate details of his personal and political life, the important episodes of his life and the periods of his creative writings have been carefully analyzed. The best study of his private life remains that of Redier, despite its avowed antiliberal and antidemocratic bias. E.T. GARGAN, *De Tocqueville* (1965), also contains an analysis of his formative studies before 1830. Tocqueville's special relationship with Beaumont is studied in Pierson, in great detail for the earlier period; and in S. DRESCHER (ed.), *Tocqueville and Beaumont on Social Reform* (1968). See also their correspondence, ed. by A. JARDIN in vol. 8 of the new edition of Tocqueville's *Oeuvres* (1968). Pierson thoroughly covers Tocqueville's journey through the United States leading to the publication of *De la démocratie*. The influence of his English visits is dealt with in S. DRESCHER, *Tocqueville and England* (1964). Tocqueville's own travel notes are ed. by J.P. MAYER and A. JARDIN as vol. 6 of Tocqueville's *Oeuvres*. They are translated as *Journey to America* (1960), and *Journeys to England and Ireland* (1958). On Tocqueville's early political career see Marcel (cited above); M. LAWLOR, *Alexis de Tocqueville in the Chamber of Deputies* (1959); and various essays in *Alexis de Tocqueville: livre du centenaire, 1859–1959* (1960). E.T. GARGAN, *Alexis de Tocqueville: The Critical Years, 1848–1851* (1955), analyzes the period of the Second Republic; R. HERR, *Tocqueville and the Old Regime* (1962), covers the period of Tocqueville's study of the French Revolution.

Interpretations of Tocqueville's thought include: J. LIVELY, *The Social and Political Thought of Alexis de Tocqueville* (1962); R. ARON, *Essai sur les libertés* (1965); M. ZETTERBAUM, *Tocqueville and the Problem of Democracy* (1967); J. FELDHOFF, *Die Politik der egalitären Gesellschaft: Zur soziologischen Demokratie-Analyse bei Alexis de Tocqueville* (1968); S. DRESCHER, *Dilemmas of Democracy: Tocqueville and Modernization* (1968); and I. ZEITLIN, *Liberty, Equality, and Revolution in Alexis de Tocqueville* (1971).

(S.Dr.)

Togo

Togo, a sovereign West African republic, consists of that part of the former German colony of Togoland that was made French mandated territory after World War I. Situated on the Gulf of Guinea, it has a total area of about 22,000 square miles (57,000 square kilometres), and a population of about 2,000,000. From its 32-mile coastline, Togo extends northward for about 320 miles between Ghana to the west and Dahomey to the east to its boundary with Upper Volta in the north. Unlike some other French-speaking African countries, Togo has refrained from extending preferential trade treatment to France. Lomé, the capital, has a population of about 150,000 and is the largest city and port in the country. (For historical aspects see WEST AFRICA, HISTORY OF.)

The landscape. *Relief, drainage, and soils.* Togo consists of six geographical regions. The coastal region is narrow and consists of a low-lying, sandy beach region with a series of inland lagoons, the largest of which is Lac Togo. Beyond the coast lies the Ouatchi Plateau, which stretches about 20 miles inland at an altitude of about 200 to 300 feet. This is the region of the so-called *terre de barre*, a lateritic (reddish, leached, iron-bearing) soil.

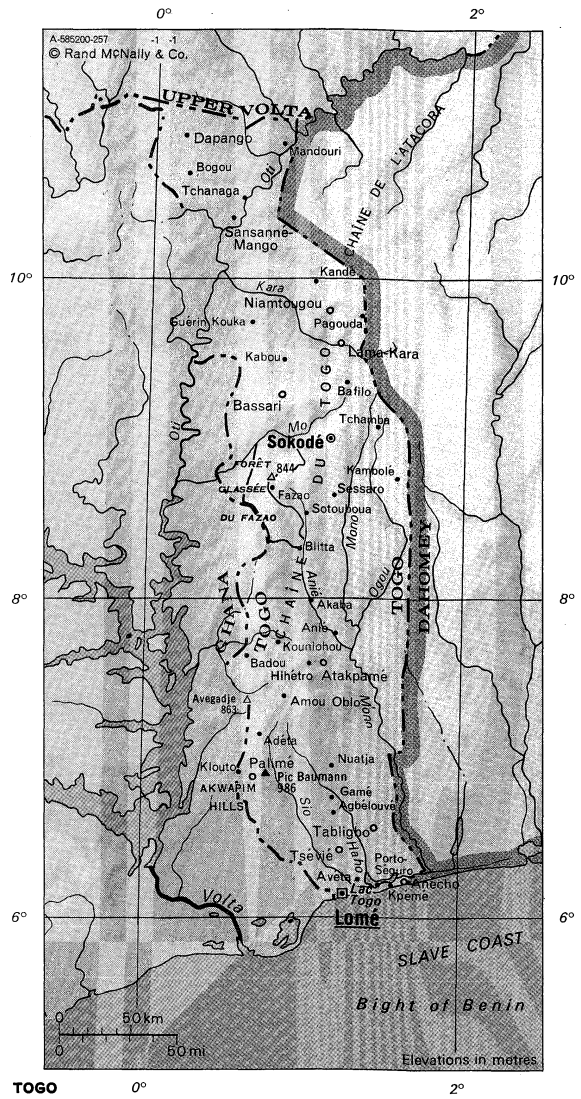
Togo's six geographical regions

To the northeast of the plateau region is a higher tableland, with the highest altitudes reaching 1,300 to 1,500 feet. This region is drained by the Mono River and its tributaries, as well as by other smaller rivers, including the Haho and Sio. From the tableland region the terrain gradually rises toward the Chaîne du Togo, which runs across the country from the southwest to the northeast. Part of a mountain chain that begins in the Chaîne del' Atacora of Dahomey, the range ends in the Akwapim Hills of Ghana. Pic Baumann, which rises to about 3,235 feet (986 metres), is the highest mountain of Togo. Beyond it, to the north lies the Oti River Sandstone Plateau. This is a savanna (grassy parkland) region and is drained by the Oti River, one of the main tributaries of the Volta River. To the far northwest is a higher region that is mainly composed of granite and gneiss (a granite-like metamorphic rock); here are located the Dapango Cliffs, a distinctive feature.

Climate. Togo has a tropical climate in which rainy and dry seasons alternate. The rainy seasons occur from mid-April to mid-July and—in the south—from October to November. The coastal zone is the driest region, which receives about 24 to 36 inches of rain annually. The region of Palimé, about 65 miles inland, receives the highest amount of rain—about 70 inches annually. The north has only one rainy season with an average rainfall of about 45 inches from April to July; during the rest of the year the warm, dry harmattan (a dust-laden wind) predominates. The mean national temperature is 78° F (26° C). Minimum temperatures of about 68° F (20° C) are recorded in the mountains in August. Maxima of about 92° F (33° C) occur in the north during March and April at the end of the long dry season.

Vegetation and animal life. Savanna-type vegetation is the dominant feature of Togo. On the southern plateaus large trees, including the baobab, are common, while they are rare in the north. The southwestern regions, in which rainfall is heaviest, are covered with tropical forests, also found along the river valleys. Because of the lagoons, the coastal zone is dotted with several mangrove and reed swamps.

Wild animals are not found in great numbers, especially in the southern and central regions. A few lions, leopards, and elephants can be seen in the north. Monkeys, snakes, and lizards are numerous in many areas, and crocodiles and hippopotamuses abound in the rivers. In the game reserve of Tchanaga, near Sansanné-Mango in the north, there are wild herds of buffalo, asses, warthogs, antelopes, and deer. All kinds of reptiles, particularly snakes and lizards, and several varieties of birds and insects can be found in many areas. Fish caught off the coast include mackerel, bass, seabream, red snapper, triggerfish, dorado, ray, and sole, while crustaceans include shrimp and lobster.



The landscape under human settlement. Only 13 percent of Togo's population live in urban centres. The majority live in small villages scattered throughout the rural areas.

Rural settlement. In the coastal zone, the most familiar landscape is that of rectangular houses built either of clay and timber or of coconut or palm branches and topped by double-eaved thatched roofs. Scattered throughout the coconut plantations, they are not far from the sandy beaches, on which lie the fishermen's dugout canoes. Inland in the south, thatched rectangular huts made of adobe are clustered around big trees and surrounded by either earthen walls or fences made of palm branches. These clusters are linked by narrow lanes that converge toward the main roads and highways.

Regional architecture

In the north, the traditional adobe or stone huts are circular and are topped by conical roofs or thatched turrets. They are usually gathered in units corresponding to family groups; often enclosed by earthen walls, they are sometimes interlinked. One of the distinctive features of the northern Kara region is the high density of villages that stretch along the highway or climb up the slopes of the many hills.

Urban settlement. Lomé, the largest urban centre, is widely spread along the coast. At its centre, there is a

mixture of old and new commercial and administrative buildings. To the west, the residential area along the shore contains most of the white population. Eastward and northward are residential areas with modern houses and bungalows. The traditional housing unit is the big, walled compound composed of a group of isolated rooms, each opening onto a courtyard.

Anécho, another coastal town, was once the country's European trade centre but is now declining. Other main towns include Palimé, Tsévié, and Atakpamé in the plateau region; Sokodé and Bassari in the central region; and Sansanné-Mango and Dapango in the north.

People and population. *Ethnic and linguistic groups.* The population of Togo is composed of about 30 ethnic groups, many of whom are immigrants from other parts of West Africa. The groups indigenous to Togo live in the north and southwest. The northern groups include the following Gur-speaking Voltaic peoples: the Gurma; the Natimba, Dye, Bu-Bankam, Bu-Kombong, and Konkomba; the Tamberma; the Basari; the Moba; the Naudeba (Loso), who speak Moré, the language of the Mossi of neighboring Upper Volta; the Kabre and the Logba; and the Namba (Lamba), whose language, Tem-Kabre, is similar to that of the Kabre; a small number of West Atlantic-speaking Fulani; and the Kebu (Akebu) who are a Kwa-speaking people of central Togo. In the southwest the indigenous Kwa peoples also belonging to the central Togo group are the Akposo, the Adele, and the Ahlo.

The immigrants came from east, west, and north. The Ewe, who emigrated from Nigeria between the 14th and 16th centuries, form the major ethnic group. There are also some scattered Yoruba, mainly Ana. Groups who emigrated from present-day Ghana and Ivory Coast since the 17th century include the Ane (or Mina), who are members of the Ge group, and who have adopted a variant of the Ewe language; the Ga-Adangme, who speak a dialect similar to the Ga language of Ghana; the Kepelle (Kpesi) and the Anyana; the Chakossi; and the Dagomba. The northern groups of the Tem (Kotokoli and Temba), Gurma, and Mossi came from the north, mainly from areas in Upper Volta.

The Ewe immigrants

Most of the nation's 4,000 aliens live in Lomé. Mainly French, they include a few mulattoes of Brazilian, German, and French ancestry. Brazilians, or Portuguese of Brazilian birth, constituted the original trading settlement in Togo, and today Brazilian mulattoes are closely associated with economic and political development.

Religious affiliations. Although Christianity has profoundly marked the country, about three-quarters of the

population still adhere to traditional animistic beliefs. There are about 400,000 Christians and 150,000 Muslims. The main Protestant (Calvinistic) church has been governed for a long time by Togolese moderators. Since independence, the Roman Catholic Church in Togo has been headed by a Togolese archbishop.

Demography. The population numbers about 2,000,000, the majority of which are women. The coast is the most populated region, and numbers generally decrease northward. The average annual growth rate is 2.5 percent. The rate of population growth ranges from 1.7 percent in the central region to 3.4 percent in the plateau region. Density of population averages 89 persons per square mile but is only about 65 per square mile in the savanna region of the extreme north, compared with 500 or more in some coastal areas. Togo's population is comparatively young; 54 percent of the total are under 20 years of age.

The national economy. Togo is essentially an agricultural country. Agriculture, including animal husbandry, fishing, and forestry, accounted for 58 percent in 1963 and 47 percent in 1966 of the country's gross domestic product and employs about 85 percent of the economically active population. Exports of agricultural products account for almost 66 percent of the country's total exports. The contribution of agriculture, however, has declined steadily since the 1960s because of the growing importance of mining, manufacturing, public utilities, and commerce.

Agriculture. A great variety of soils and climates enables Togo to grow a whole range of intertropical African products. Export crops include cocoa, palm kernels, peanuts (groundnuts), and cotton, while staple crops are corn, cassava, rice, yams, sorghum, and millet. Only one-fifth of the land area is cultivated, while one-fifth is left fallow. Greater production could be obtained by extension of the cultivated area, coupled with the widespread adoption of improved methods of cultivation.

Cattle, sheep, and pigs are raised in the plateau region and the north. Fishing is carried out on the coast and in the well-stocked inland rivers and ponds. Most of the catch is consumed locally. Forests, which cover about 10 percent of Togo's total area, are a source of tropical hardwoods and other products.

A government agency, the Office of Agricultural Products (Office des Produits Agricoles du Togo; OPAT) has a monopoly on the foreign sale of Togolese products. Export sales are made by local firms in Paris and London, acting as agents of the Office.

The phosphate industry

Mineral resources and exploitation. Phosphate is the major mineral resource and the country's second leading export item after cocoa. The deposits, which are estimated at 50,000,000 tons, are mined by the Compagnie Togolaise des Mines du Bénin, in which a United States firm holds 47 percent of the shares. Marble, with deposits of considerable size, is being quarried by SOTOMA (Société Togolaise de Marbres et de Materiaux), a mixed economy company with shares held by the Togolese government and an Italian firm.

Potential mineral resources include oil, iron ore, bauxite, uranium, chromite (an oxide of iron and chromium), gold, diamonds, rutile (titanium dioxide), manganese oxide, and kaolin (China clay). While the iron ore reserves are large, the metal content is only slightly more than 50 percent. The bauxite has a low mineral content.

Manufacturing. Manufacturing increased during the 1960s when a textile plant and a brewery were added to such existing enterprises as a tapioca and starch mill and a palm oil mill.

Foreign trade. The value of exports more than doubled during the 1960s, partly because of the rapid increase in phosphate exports. Coffee and cocoa, the leading agricultural export crops, represented 59 percent of the value of recorded exports in 1970. Togo's main customers are France, The Netherlands, West Germany, Belgium, and Luxembourg. There are also unrecorded exports, represented, for example, by the cocoa that is smuggled over the frontier for sale in Ghana.

Main imports include foodstuffs, beverages, tobacco, capital goods, raw materials and intermediate products, manufactured consumer goods, and fuel. The major sources of imports are France, the United Kingdom, and Japan.

Foreign financial aid. During the 1960s foreign financial assistance took the form of grants for investment, technical assistance, agricultural development and diversification, social investment, and education. The major donors were France, West Germany, other European Economic Community countries, the United States, and the United Nations.

Management of the economy. Economic development planning has been carried out by the National Commission for Planning, a governmental agency.

Under the first five-year plan (1966 to 1970), public investment was used to develop roads and other facilities and to improve education, as well as to promote rural development; a substantial part of private investment was devoted to housing, town planning, trade, and industry. The second five-year plan (1971–75) aims at continuing progress toward economic independence, while maintaining the present growth rate of the gross domestic product at 7 percent per annum.

In order to encourage foreign and domestic private investment, the Investment Code of 1965 guarantees foreign investors the right of freely transferring abroad all investment capital and income. The code also provides for tax benefits for priority enterprises.

Taxation. Indirect taxes, almost entirely on imports and exports, account for most of the government's ordinary budget revenues. Direct taxes consist of an income tax, a progressive tax on all profits, a tax on wages paid by employers, a tax on rental values, a land tax, and a head tax.

Economic prospects. Judging from the improvements made during the first five-year plan, further economic progress is anticipated. Unlike other former French territories, Togo has not extended preferential trade treatment to France and subsequently to the European Economic Community. This open-door, nondiscriminatory trade policy—together with the expanded production of phosphate and tropical produce—will, it is hoped, contribute toward development.

The open-door trade policy

Transport and communications. *Roads.* The road network covers more than 4,450 miles. The three main road systems are the coastal road between Ghana and Dahomey, which carries international traffic between Ghana and Nigeria; the road from Lomé north to Upper Volta; and roads serving the cocoa and coffee producing area of Palimé, Badou, and Atakpamé. This network includes about 1,000 miles of national highways and 3,300 miles of regional roads; about 3 percent of the roads are paved.

Rail system. The government-owned national railway consists of three main lines. These are the line carrying cocoa from Palimé to Lomé, the copra line from Anécho to Lomé, and the cotton line from Blitta to Lomé. The network is about 300 miles long and is of metre gauge. There is a project to build a 12-mile railroad to link Avéta, the site of a planned cement factory, with the Lomé–Blitta line. There is also a 16-mile private system, which links the phosphate mine in Kpémé with Lomé.

Port facilities. Lomé is Togo's principal port. Its artificial harbour, inaugurated in 1968, has an annual capacity of 500,000 tons. A second port at Kpémé, about 22 miles northeast of Lomé, is used exclusively to handle phosphate shipments.

Air transport. An airport at Lomé is open to jet traffic. It is used by domestic and foreign airlines. There are local airports in Atakpamé, Sokodé, Sansanné-Mango, and Dapango.

Communications. A department of posts and telecommunications is a governmental agency that manages the main post office in Lomé, in addition to 24 post offices throughout the country and several part-time post offices and rural delivery circuits.

The central telephone system in Lomé is connected with all other cities. A telecommunications link is to be established between Lomé and Accra in Ghana. International connections can be made by telephone or telegraph.

Administration and social conditions. *National government.* Since the coup d'etat of 1967 the constitution has been abolished and the National Assembly dissolved. The Togolese People's Rally (Rassemblement du Peuple Togolais), the only political party, was established in 1969. The chief executive and head of state appoints the members of his government and can dismiss them as well. He presides over a Council of Ministers with which he occasionally associates the central committee of the party.

The military government

Local government. The country is divided into four regions—Maritime, des Plateaux, Centrale, and des Savanes—which are supervised by inspectors who are appointed by the president. (For purposes of economic planning, however, the country is divided into five regions; the fifth region of de La Kara is created from Centrale and des Savanes.) The four regions are subdivided into 19 *circonscriptions,* each of which is headed by a district chief assisted by a district council. Seven communes have been established—for the cities of Anécho, Atakpamé, Bassari, Lomé, Palimé, Sokodé, and Tsévié, respectively.

Traditional authorities and justice. The administrative apparatus still has to reckon with traditional authorities, which include tribal kings or chiefs, village chiefs, and heads of family groups. These traditional authorities play a role in the judicial system, dealing with certain questions of customary law. The judicial system, headed by a Supreme Court, consists of a number of law courts in which civil, commercial, administrative, and criminal cases are heard.

Education. Education is modelled after the French system. Togolese teachers, who are replacing French personnel in increasing numbers, are expected to adapt the system to the Togolese context. Primary and secondary education is provided by public or parochial schools. The rate of school attendance, which in the early 1970s amounted to about 45 percent of the school-age population, has increased steadily since the mid-1960s.

Technical courses are given mainly by government-operated technical colleges at Lomé and at Sokodé. There are also private professional schools. Training is also organized by government agencies, and a number of Togolese technicians are trained abroad. A Regional Training Centre for Heavy Equipment is located at Lomé. Because of its bilingual (French and English) teaching, the centre receives students from about 20 African countries.

While continuing to send university students abroad on scholarships, mainly to France, Togo opened its own university in 1970. Some courses in the liberal arts and sciences are given in Lomé to some 400 students. In the early 1970s there were 16 hospitals, and some 60 doctors of whom 45 were Togolese.

Cultural life. *Radio and press.* The government operates three centres from which radio programs are transmitted throughout the country; they may also be heard in the whole of West Africa and Central Africa. Most programs are broadcast in French, the official language; a few are in English and in the main Togolese languages—Ewe, Kotokoli, Kabre, Basari, and Moba. Most weekend radio programs are devoted to cultural themes. There is no television.

Togo's only daily newspaper, *Togo-Presse,* is published by a governmental agency in French and Ewe. It is widely distributed throughout the country. Other publications include the government's *Journal Officiel; Espoir de la Nation,* an illustrated monthly magazine; *Présence Chrétienne,* a bimonthly published by the Catholic Church; and *Realités Togolaises,* a monthly printed in Dahomey.

The arts. Like other African peoples, the Togolese have a strong oral tradition. Little has been done, however, to promote vernacular literature. Before independence there were a few Togolese writers using French. Since independence, regional literature emerged with the works of several novelists and playwrights. Founded in 1967, the *Ballets Africains du Togo* has aimed at popularizing the finest traditional dances of the various ethnic groups.

Traditional culture

Prospects. Since the military coup d'etat of 1963—the first to occur in an African state south of the Sahara—Togo has not known the kind of political stability that promotes economic progress. Some progress toward economic development—such as the opening of the harbour at Lomé—has, however, been achieved. The government entertains hopes that the formation of the Togolese People's Rally may foster national reconciliation and unity, thus encouraging further economic progress.

BIBLIOGRAPHY. ROBERT CORNEVIN, *Histoire du Togo,* 3rd ed. (1969), an exhaustive work on the history of Togo, including some geographic data; *The World and Its Peoples: Africa South and West,* 2 vol. (1967), includes a detailed article on Togo.

(M.K.P.)

Tokugawa Ieyasu

Tokugawa Ieyasu, who founded a dynasty that was to give Japan more than two centuries of uninterrupted peace, was born in 1543 into the family of a local warrior situated several miles east of modern Nagoya, one of many such families struggling to survive in a brutal age of endemic civil strife. At his death 73 years later he was the ruler of a tranquil and prospering Japan. In the course of his rise to power he fashioned a political system that his successors inherited, modified, and managed with sufficient skill to preserve the Tokugawa hegemony and the peace of Japan until 1867.

Tokugawa Ieyasu, colour on paper by an unknown artist. In the collection of the Daiyo-ji (Daiyo Temple), Tokyo.

Early life and fortunes. Ieyasu's childhood was scarcely auspicious. His father was involved in a network of shifting alliances that repeatedly drew him into battle. When Ieyasu was two his mother was permanently separated from his father's family because of one such change in alliances, and when he was seven military adversity compelled his father to send him away as hostage to the Imagawa family, powerful neighbours headquartered at Sumpu (modern Shizuoka) to the east.

Conditions at Sumpu were more settled, and Ieyasu was trained in the military and governmental arts and developed a great love for falconry. In the late 1550s he took a wife, fathered the first of several sons, and began to acquire military experience by leading forces on behalf of Imagawa. Despite his personal comfort, however, Ieyasu's years at Sumpu had been worrisome ones. He had learned that his father had been murdered by a close vassal in 1549 and had observed helplessly from afar the subsequent disintegration of his family fortunes.

In 1560 Imagawa was slain during a battle with Oda Nobunaga, a powerful neighbour to the west, and young

Ieyasu head of the Tokugawa

Ieyasu seized the opportunity to return to his family's small castle and assume control of his surviving relatives and vassals. Within months he took steps to ally himself with Nobunaga, at the same time pacifying the new and inept leader of the Imagawa house long enough to recall his wife and son from Sumpu. Freed for a few years from warring with neighbours, he directed his military efforts to crushing rebellious Buddhist sectarian groups within his domain. Concurrently, he devoted much energy to improving his small army's command structure, appointing civil administrators, and formulating and enforcing procedures of taxation, law enforcement, and litigation.

During the later 1560s the Imagawa domain disintegrated, and Ieyasu expanded to the east as opportunity permitted. In 1570 this expansion led him to move his headquarters eastward to Hamamatsu, a small coastal town that he developed into the commercial and strategic centre of a thriving domain. Relying heavily on his alliance with the mighty Nobunaga, Ieyasu survived the vicissitudes of endemic war and slowly extended his territory until, by the early 1580s, he had become an important daimyo (feudal baron), in control of the fertile and populous area stretching from Okazaki eastward to the mountain barrier at Hakone.

Rise to pre-eminence. In 1582 Nobunaga was murdered by a rebellious subordinate, and Toyotomi Hideyoshi, his most brilliant general, quickly avenged the murder and moved to assume Nobunaga's pre-eminent political position. Ieyasu, then in the prime of life, emerged as his principal rival. After a few bloody but indecisive skirmishes, however, the cautious Ieyasu offered a vow of fealty, and Hideyoshi was content to leave Ieyasu's domain intact. During the rest of the 1580s, while Hideyoshi busily extended his control over the daimyo of southwestern Japan, Ieyasu strengthened himself as best he could. He continued to enlarge his vassal force, increase his domain's productivity, and improve the reliability of his administration. And in 1586, for greater security, he moved his headquarters even farther to the east, away from Hideyoshi, to Sumpu, the town he had known years before as a hostage.

Conquest of the Hōjō

In 1589 Hideyoshi determined to obtain vows of subordination from the Hōjō daimyo, who held a large district east of the Hakone mountain barrier. When Hōjō refused to submit, Hideyoshi and Ieyasu mobilized a great army and navy that blockaded the Hōjō forces in their seaside castle at Odawara. After a long and patient siege the Hōjō were starved into capitulation. At Hideyoshi's suggestion Ieyasu then surrendered his coastal provinces west of Hakone in return for the Hōjō domain to the east. As rapidly as possible he moved thousands of vassals, their military equipment, and their households to the little fort and farmlands near the fishing village of Edo (modern Tokyo), nearly a month's march from Hideyoshi's headquarters near Kyōto.

During the 1590s Ieyasu, unlike several great daimyo from western Japan, avoided involvement in Hideyoshi's two disastrous military expeditions to Korea. Instead he grasped the opportunity afforded by his transfer to his new lands to deploy his forces rationally and to make his domain as secure as possible. He stationed his most powerful vassals on the perimeter of his territory and along main access routes, keeping the least powerful—and least dangerous to himself—nearer Edo. He then placed large tracts of land close by the town under direct administration by appointed officials, thereby assuring his castle inhabitants easy access to the largest possible supply of foodstuffs, and made detailed land and property surveys in order to regularize taxation. He also confiscated the weapons of all villagers, thereby reducing the likelihood of peasant rebellion, and moved vigorously to attract skilled artisans and businessmen to his new castle town. He undertook engineering projects to enlarge his castle, facilitate urban growth, and assure a water supply for the town populace. When Hideyoshi died in 1598, Ieyasu had the largest, most reliable army and the most productive and best organized domain in all Japan.

Hideyoshi's death precipitated another daimyo power struggle, and Ieyasu, as the most powerful and most respected of Hideyoshi's former vassal advisers, became the head of one faction in that struggle. The armies assembled in the autumn of 1600 at Sekigahara, some 50 miles (80 kilometres) northeast of Kyōto, and in the ensuing battle Ieyasu's eastern army triumphed.

Ieyasu master of Japan

This triumph left Ieyasu the undisputed master of Japan, and he moved swiftly to make his mastery permanent. Just as, in earlier years, he had consistently secured every military gain by adjusting administrative arrangements to fit his new needs, so, after the battle of Sekigahara, he initiated an extensive project of shifting daimyo about. In the process he stripped many erstwhile enemies of their lands, placed a number of his allies in strategic locations near surviving enemies, and secured for himself and his most faithful vassals direct control of much of central Japan. Then, having secured the strategic heartland, he proceeded over the next several years to make his control more sure by issuing regulations and establishing supervisory organs to constrain daimyo, imperial court nobles, and clerics, as well as his own vassals.

In 1603 the powerless but prestigious imperial court, which over the years had dutifully assigned Ieyasu titles that reflected his growing power, appointed him shogun (generalissimo), thereby acknowledging that this most powerful daimyo in Japan was the man officially authorized to keep the peace in the emperor's name. Two years later Ieyasu formally retired, left Edo for the more pleasant surroundings of his old home at Sumpu, and had the shogunal title assigned to his son Hidetada, intending thereby to assure that the title was recognized as a hereditary Tokugawa prerogative.

Consolidation of the dynasty. As shogun, and then as retired shogun, Ieyasu assumed responsibility for foreign affairs, a responsibility he seems to have welcomed. Because the Ming dynasty in China was faltering and was without much influence abroad, the conduct of Japanese foreign affairs, which would normally have been mainly with China, involved responding to Portuguese, Dutch, and English requests for trade and to Portuguese and Spanish requests for the right to proselytize in Japan. Ieyasu welcomed the trade, seeing in it a means of acquiring firearms, commercial profits, and general information. By 1612, however, certain diplomatic incidents had convinced the old soldier that the missionaries were, potentially at least, part of a secular threat to the political order that he had so labouriously constructed, and in the next two years he took steps to stop missionary activity and discourage the practice of their religion. Ieyasu started a trend that his successors were to pursue for three decades, until Christianity was nearly eradicated in Japan and only a token foreign trade survived at Nagasaki.

Ieyasu's daimyo transfers and political reforms of the years after the battle at Sekigahara had greatly strengthened his position, but he remained wary of the daimyo, and from 1604 until 1614 he had his son Hidetada keep them at work building and enlarging the castle at Edo. Thousands of ships and tens of thousands of men were employed for years on end hauling huge stones and great logs from distant points to Edo. By the time of his death Ieyasu had built the largest castle in the world, a sprawling network of broad moats, towering stone walls, long wooden parapets, huge gatehouses, and great fireproof warehouses full of rice and coin. Around it lay mansions in which the daimyo lived as hostages. Edo became a bustling town and port, full of artisans, traders, clerks, and labourers.

Elimination of remaining rivals

This great construction effort left Ieyasu stronger, and the cost involved left the daimyo much poorer. Yet Ieyasu still did not feel that his family fortunes were secure, for he knew full well that the undoubted military might of the Tokugawa family must evolve into undoubted political right. Although Hidetada was shogun, that did not necessarily settle the question of rightful authority, because Hideyoshi had been survived by a child son, Hideyori; and even as he was growing up in his great castle at Ōsaka, the boy gradually acquired more warrior followers and began to appear as a real threat to Tokugawa legitimacy. By 1614, however, many of the powerful former followers of Hideyoshi had died, and Ieyasu appar-

ently felt that he could safely undertake to destroy this last potential rival. After sufficient tension had developed, he mobilized his armies, and in two desultory and unimpressive campaigns, the old warrior finally reduced the great castle and destroyed its inmates. He then made more territorial adjustments favourable to the Tokugawa forces and returned again to his home at Sumpu. A year later, in 1616, he sickened and died, having accomplished what a century of warriors had attempted and failed: he brought enduring pre-eminence to his own family and a lasting peace to Japan.

BIBLIOGRAPHY. A.L. SADLER, *The Maker of Modern Japan: The Life of Tokugawa Ieyasu* (1937), is the only extended work in English; contains mostly battle stories and anecdotes. C.D. TOTMAN, *Politics in the Tokugawa Bakufu, 1600–1843*, ch. 1 (1967), summarizes the administrative aspects of Ieyasu's rise to power. KOYA NAKAMURA, *Ieyasu den* (1965), is a sympathetic scholarly biography by the pre-eminent scholar of Ieyasu (in Japanese).

(C.D.T.)

Tokyo–Yokohama Metropolitan Area

The Tokyo–Yokohama metropolitan area is an urban agglomeration on the Pacific coast of central Japan, including the capital city of Tokyo, the port city of Yokohama, and the manufacturing centre of Kawasaki. Tokyo means eastern capital, the name given the city when the capital of Japan was moved eastward in 1868 from Kyōto, meaning capital. The name Yokohama derives from the fact that the original fishing village was situated on a lateral (*yoko*) beach (*hama*) of Tōkyō-wan (Tokyo Bay).

The inmost part of the Tokyo–Yokohama metropolitan area is the central city of Tokyo (with a 1970 population of 9,000,000), a part of the urban prefecture (*fu*) of Tokyo, with a population of more than 11,000,000—comprising Tokyo, neighbouring industrial and residential cities, and rural districts, including the Bonin Islands (Ogasawaraguntō) in the Pacific. Tokyo-fu is not entirely contained in the Tokyo–Yokohama metropolitan area, which is a conurbation comprised of Tokyo proper, Yokohama, Kawasaki, and their contiguous urbanized municipalities; the metropolitan area's population in 1970 was over 22,000,000.

HISTORY OF THE TOKYO AREA

The eastern part of the present central city of Tokyo was originally called Edo ("estuary"), because it stood at the point where the Sumida-gawa (Sumida River) enters Tōkyō-wan. A castle was built overlooking the marshy lowland of the river in 1457. The river separated the ancient provinces of Musashi in the west and Shimohusa in the east, and the castle occupied an important strategic position.

The area had been inhabited in prehistoric times by peoples of the Jōmon (2500–250 BC) and the Yayoi (250 BC–250) cultures. The Yayoi lived on uplands and cultivated rice on marshy deltas and in valley bottoms. With the consolidation of a Japanese empire in the 6th century, the area became part of Musashi Province. Musashi and its surrounding regions were peripheral because the central government was located farther west. They rose in importance when the Tokugawa shoguns (supreme military commanders) established their military government in Edo in 1603. The old castle was rebuilt and enlarged. The town was laid out in the 17th century and became the residence of the whole Tokugawa hierarchy. By the mid-19th century Edo had become a metropolis with a population of 1,200,000. After the fall of the Tokugawa shoguns and the re-establishment of the authority of the emperor, the capital of Japan was moved from Kyōto to Edo in 1868; the city was then renamed Tokyo.

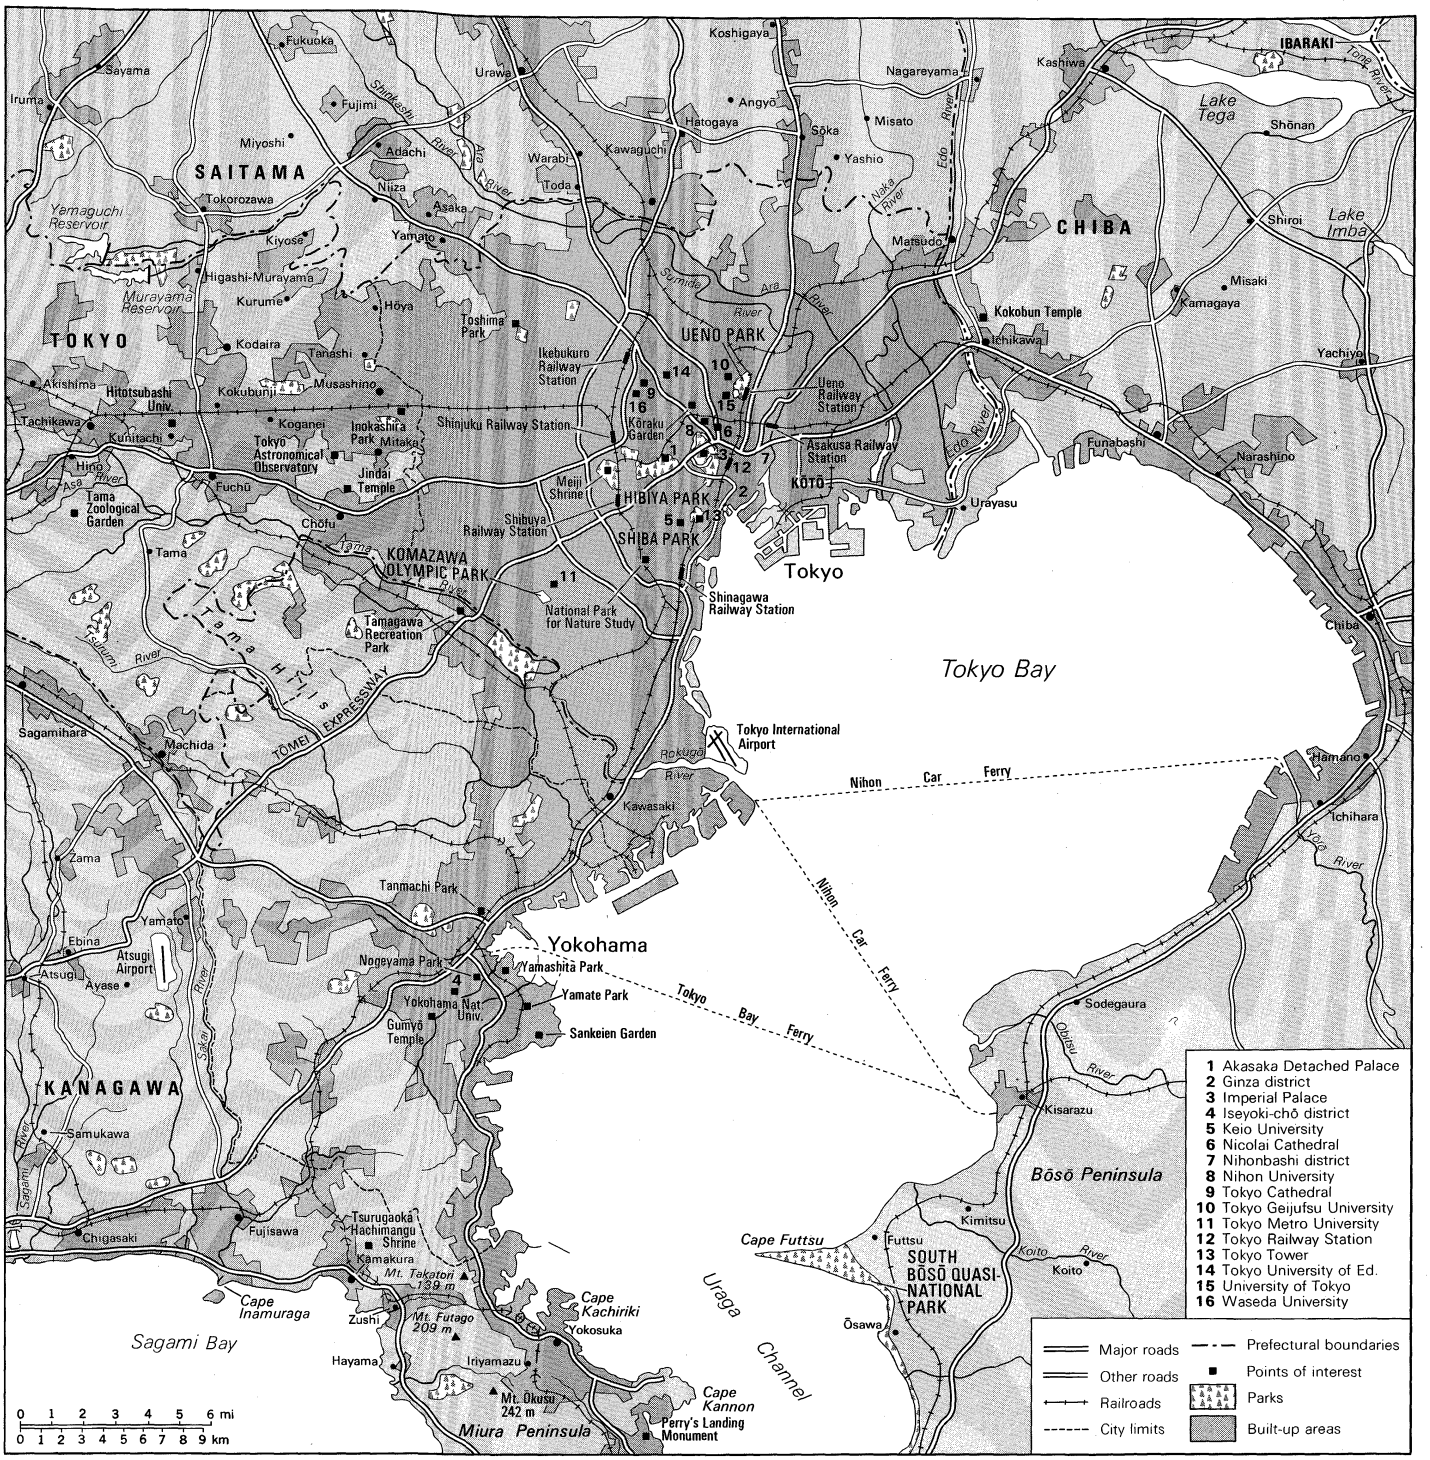
Growth of Tokyo area

The municipal area of Tokyo city at the end of the 19th century consisted of 15 wards (*ku*). Together with the surrounding counties, it formed Tokyo Urban Prefecture. It had become not only the political but the commercial and financial centre of the country. Its growth was checked by the great earthquake and fire of September 1, 1923, which severely damaged the downtown areas of Tokyo and Yokohama. During Tokyo's reconstruction the streets were widened, and many steel-and-concrete buildings were put up. At the same time, there was a growth of suburbs. At the beginning of the 1930s Tokyo city had 2,000,000 people and the suburban municipalities 3,000,000. In 1932, 20 new wards were added. During World War II, metropolitan Tokyo (Tōkyō-to), was established by amalgamating the city and its surrounding suburbs and counties. Large parts of Tokyo and Yokohama were destroyed by U.S. air raids in 1944 and 1945. After the war, starting in the 1950s, the Tokyo area grew enormously with the expansion of the Japanese economy.

The port of Kanagawa (later Yokohama), which was opened in 1859, expanded along with Japan's export trade. The city was completely new and Western in its characteristics. In 1872 it was connected to Tokyo by railroad. Along with Tokyo it was largely destroyed in the great earthquake and fire of 1923 and severely damaged by U.S. air raids in 1945. By 1970 Yokohama was the third largest city in Japan, after Tokyo and Ōsaka.

Kawasaki, situated between Tokyo and Yokohama, was formerly a post town on the Tōkaidō Highway. The Tokyo–Yokohama railway had a station there, and it became a centre of industrial development. The city expanded rapidly during the 1930s, was almost completely destroyed in World War II, and was subsequently rebuilt. The coastal area is the centre of heavy industry, including iron and steel, petroleum refining, chemicals, and thermoelectric power. Electrical machinery, food, and other light industries are in the centre of the city. In the 1970s Kawasaki was the leading industrial city of Japan. Its inland area was becoming a residential suburb of Tokyo.

THE CONTEMPORARY CITY



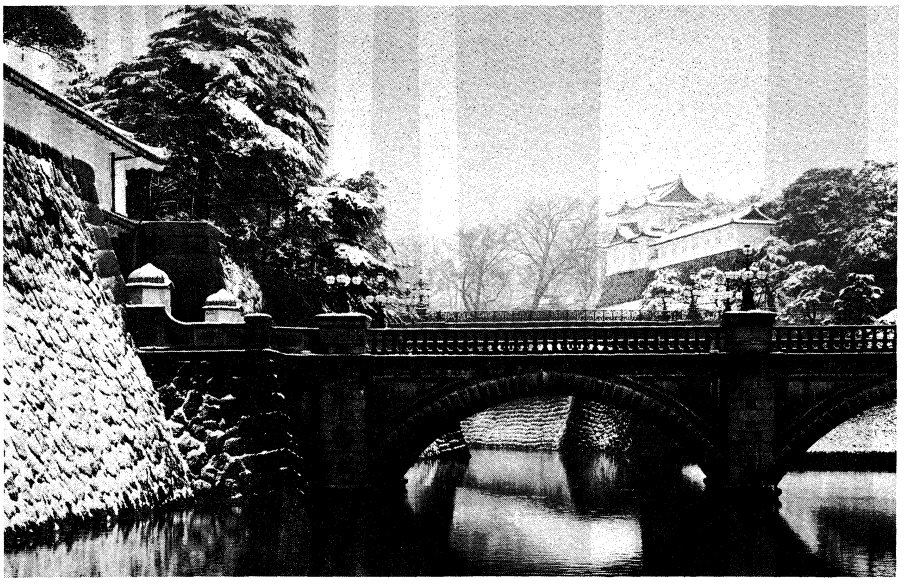
The Tokyo–Yokohama metropolitan area extends inland from the western coast of Tōkyō-wan. The city of Tokyo lies at the mouth of the Sumida-gawa. To its east, around the northern end of Tōkyō-wan, are suburbs comprising the prefecture of Chiba, which is separated from Tokyo by the Edo-gawa (Edo River). To the north of Tokyo city are the suburbs of Saitama Prefecture (Saitama-ken). South of Tokyo, separated from it by the Tama-gawa, is the great industrial centre of Kawasaki. The port of Yokohama (Yokohama-kō) lies southwest of Kawasaki. Still farther south, on Miura-hantō (Miura Peninsula) and around Sagami-wan (Sagami Bay), are other municipalities that are part of the Tokyo–Yokohama metropolitan area. The metropolitan boundary in the southwest is roughly delimited by the Sagami-gawa.

Terrain

The original terrain consisted mostly of marshy river deltas and a few areas of sand dune. The present coastline is lined with warehouses, docks, and industrial sites. To the southeast of Yokohama is the rocky coast of Miura-hantō, with the naval harbour of Yokosuka (Yokosuka-kō). Farther south, on Sagami-wan, are the historic town of Kamakura and other resort places. The southern coast of Sagami-wan is crowded with vacationers in summer.

Soil and environment. The east side of the Sumida-gawa consists of thick alluvial soil, which has settled as much as 13 feet in some places as the groundwater has been drawn off for industrial purposes. In the early 1970s efforts were being made to contain this process by regulating the use of groundwater. Higher land in the metropolitan area consists of layers of volcanic origin on top of sand and gravel, sloping gently upward toward the mountains in the west.

To the south of Tokyo lies a hilly section varying in height from 164 to 656 feet. In the 1960s it was developed as a residential area expected to accommodate a population of 500,000. Farther south and west, these plains and hills end in the steep Okutama and Chichibu mountains, consisting of old geologic formations cut by the Tama-gawa and its tributary valleys. The steeper slopes are wooded, and the foothills are terraced with cultivated fields; the river supplies water to Tokyo. The mountains form part of the Chichibu-Tama National Park.



The Tokyo–Yokohama metropolitan area.

The climate of Tokyo is generally mild, although the summers are hot and humid. The annual mean temperature is 58.5° F (14.7° C). The January mean is 38.7° F (3.7° C), and the August mean is 79.5° F (26.4° C). Japan's climate is controlled by the summer and winter monsoons: in summer, masses of warm, humid air from the Pacific; in winter, a flow of cold, dry air from Siberia. There are rainy seasons in early summer and mid-autumn. Tokyo usually experiences two or three typhoons a year during the rainy seasons. The average annual rainfall is about 62 inches (1,563 millimetres), compared to 25–32 inches in London and about 40 inches in New York.

In mid-winter, temperatures may fall below freezing in the mornings. From January to March there are several snowfalls. The plum and camelia bloom in January on the southern coast of the metropolitan area, and Tokyo's spring reaches its climax in March and April with cherry blossoms and many varieties of flowers. The iris and azalea blossom in May, followed by the gloomy monsoon month of June. In the summer months the blue and purple hydrangea appear. After the autumnal rains, the trees begin to turn—the maples red, the ginkgo yellow. This is the season when chrysanthemum shows are held.

Wild animals are rare in the metropolitan area, except in the mountains where wild boars, foxes, and monkeys are found. Trout live in the mountain streams; in the lowlands the streams are too polluted for fish. Birds are relatively abundant in the residential areas, particularly doves, sparrows, crows, gulls, and swallows that winter in southern countries. The Imperial Palace moats are visited by several kinds of duck from northern regions. The

Shinichiro Morimoto—Orion Press

Japanese bush warbler, great tit, dusky thrush, bull-headed shrike, grey starling, and others are seasonal visitors, and in the suburbs one can see the white egret and hear the song of the skylark.

Industrialization, motorization, and population growth have brought water and air pollution. Fujiyama (Mt. Fuji), about 55 miles away, used to be visible on a clear day in winter from the centre of Tokyo, but today it can be seen only when the factories are shut down for the January holidays or when a strong wind blows away the smog. The prefectural and municipal governments have established Public Damage or Environment Conservation offices in an effort to combat pollution.

Plan of the old city

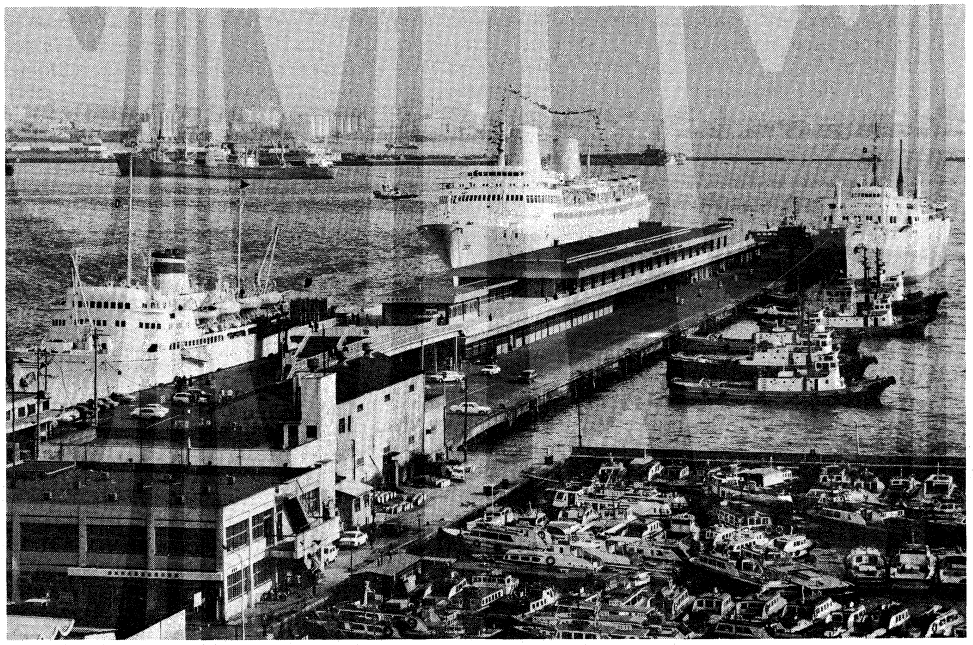
City plan. The inner part of Tokyo was the old town of Edo. The town was dominated by the castle of Edo, now the Imperial Palace where the emperor lives. The castle and the adjacent area where the high feudal lords had their dwellings was encircled by two moats, the *uchi-bori* ("inner moat") and *soto-bori* ("outer moat"). Unlike European medieval cities, Japanese castle towns had no walls. The warriors and lords lived between and outside the moats, forming the *yashiki-machi* ("residential town"). Along the roads and in the town area were merchants' shops and the houses of nonwarriors, comprising the *machiya* ("town house") section. Shintō shrines and Buddhist temples formed *tera-machi* ("temple town") on the urban fringes. These religious buildings were not only places of worship, amusement, and shopping on festival days but were also used for defense.

The castle and the residences of the feudal lords had beautiful gardens, some of which have been preserved and are now open to the public. The town area was divided into rectangular blocks named after various occupational groups: *gofuku-chō* ("silk-goods town"), *sakana-machi* ("fish town"), *kaji-chō* ("blacksmith town"). The residential areas of the lower samurai class also had their functional names: *okachi-machi* ("infantry town"), *takasho-machi* ("hunters with hawk"). There were also landscape names: *ta-machi* ("paddy town"), *hayashi-chō* ("wood town"), *komagome* ("horse grazing"), and *fujimi-chō* ("town from which Fujiyama can be seen"). Some of these names are preserved today, but most have disappeared with urban reorganization.

The centre of trade was Nihonbashi ("Japan Bridge"), from which five main highways began and which is still the zero-mile mark of the national-highway system. Nihonbashi and its vicinity was a busy wholesale marketplace and also a retail and financial area. The banks of the rivers and canals were crowded with boats coming from Ōsaka and other coastal regions of Japan. On the highways there were post towns every few miles. The first post towns from Edo were Shinagawa, Shinjuku, Itabashi, and Senju, all now part of Tokyo city.

The marshy downtown area had to be drained with canals, and the Tone and Ara rivers had to be prevented from flooding. As Edo grew, water for its 1,000,000 inhabitants was brought in by aqueduct and distributed through wooden pipes; this system became the basis of modern Tokyo's water supply.

The early houses were made of wood, and Edo was so repeatedly in flames that fires were called the flowers of Edo. A great fire in 1657 damaged large parts of Edo, destroyed the main tower of the castle, and killed 100,000 inhabitants. After the earthquake and fire of 1923, the downtown area was largely rebuilt, and it was rebuilt again after World War II.



The main shopping street is Ginza Street, running northeast to southwest and lighted brightly at night. A stroll on the Ginza is popularly known as Ginbura. The northern extension of Ginza is Nihonbashi Street, a busy central shopping area that includes the best department stores. It passes through Tokyo's financial district. From Ginza a street leads westward to Hibiya Park and the Imperial Palace. Nearby are the government-office district and the Yūrakuchō amusement centre.

The Marunouchi district

To the east of the Imperial Palace, separated from it by broad gardens and a moat, lies the Marunouchi business district, the heart of Japanese business activity, with offices and banks, the Chamber of Commerce, the railroad station, the Central Post Office, and the International Telephone and Telegraph Corporation building.

Tokyo's Metropolitan Government Office is situated at the southern end of Marunouchi district. To the north, across the outer moat, is the Kanda area, with many universities, bookstores, publishers, and hospitals. Other important areas are Taitō, in the north, and Shiba, in the south—commercial and residential areas of high population density. To the east of the Sumida-gawa is Kōtō, a low-lying marshy area drained by canals that create a checkerboard effect, which is an industrial and working class district.

In the western part of Tokyo is the uplands residential area, a quiet, tree-shaded section where most foreign embassies are located. The University of Tokyo, Waseda University, Keio University, and other universities and research institutes are in this area. Farther west, and southwest, of the Yamanote electric railroad, are middle class residential neighbourhoods the growth of which began after the earthquake of 1923 when city dwellers moved outward into the upland fields. In these areas the houses are generally frame, with some multistoried apartment houses. With the improvement of commuting

Yokohama harbour,
Takanori Ishii—Bon

facilities, Tokyo's eastern and northeastern suburbs have also been growing as middle class residential areas.

Yokohama

The growth pattern of Yokohama and Kawasaki has been similar to that of Tokyo. The whole area within 20 to 30 miles of Tokyo's central station has become a commuting area. Older towns have become suburbs of Tokyo. Yokohama's business district is concentrated around its port. At the northern end of the business district, near Sakuragi Street Station, is the central shopping street of Isezaki. South of the business district is the hilly Yamate residential area, separated by Moto-machi Street where there are many exotic shops. The northern coast of Yokohama is an industrial area. Just south of the port, new industrial and port facilities have been established along the coast at Honmoku and Negishi.

Tokyo and Yokohama are divided into wards (*ku*), composed of towns (*machi*) having several thousand inhabitants each; some towns are further divided into smaller towns or districts known as *chō*. Originally these towns and districts were neighbourhood units, but they now function only as postal addresses and for purposes of registration. The older towns each have a tutelary deity (*uji-gami*) with a shrine. Residents of a town visit the shrine on festival days to pray for safety and prosperity. These festivals are full of colour: stalls are set up, and there is music and dancing. Among the more famous shrines are the Asakusa, Sano, Kanda Myojin, Nezu, and Fukagawa, dating from the Edo period. The Meiji Shrine in Tokyo, dedicated to the Emperor Meiji and his consort, is a kind of national monument and centre of pilgrimage for the whole country.

Transportation. Tokyo is the national traffic centre; it is also an important international nodal point of the western Pacific and the Far East. The metropolitan area is spanned with a dense network of electric railways, bus lines, and motor highways. Tokyo Station is not only the central railroad station of the metropolis but also central for all Japan. Trains to Ōsaka and beyond start from Tokyo Station. Another important Tokyo terminal is Ueno Station, from which lines run to various parts of northern Japan. Shinjuku Station is the terminus of trains from central Honshu and some trains from the east. Interurban service in the Tokyo area is by the Japan National Railways and various privately owned electric lines.

Tokyo and Yokohama formerly had trains that have now been replaced by buses and subway lines. The Tokyo subway system had 80 miles of line in the early 1970s. A subway was under construction in Yokohama.

Tokyo's system of automobile expressways consists of a loop around the central business district and seven radial lines connecting with the national expressways. There were 2,025,000 registered automobiles of all kinds in greater Tokyo in the late 1960s, and in the Yokohama area there were 724,000. The ratio of persons to automobiles in Tokyo was about 10.1 to one.

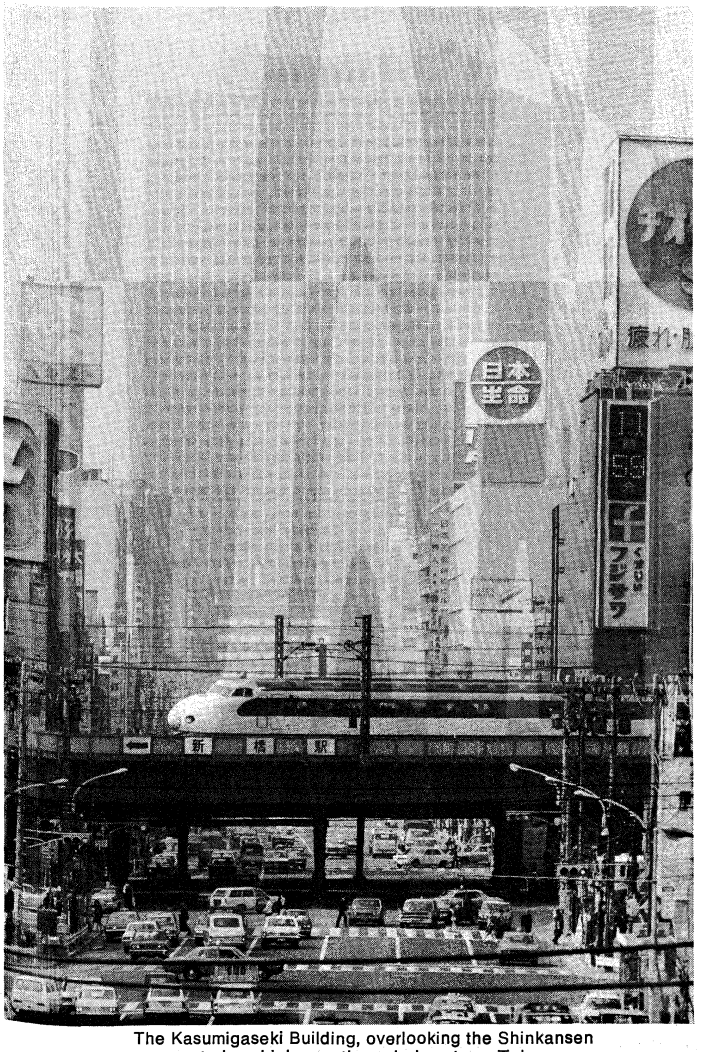
The city's airports

The Tokyo International Airport is at Haneda, about eight miles southwest of the city. It is the terminus of overseas airlines from Asia, North and South America, Australia, and Europe, as well as of domestic lines from Ōsaka, Fukuoka, Okinawa, Chitose on Hokkaido, and many other cities. Atsugi Airport, west of Yokohama, is used by some domestic lines. A new international airport under construction near Narita, 30 miles east of Tokyo, was opened in 1972.

Tōkyō-wan has four major ports. Yokohama is the largest, handling 163,000 tons of cargo annually in the late 1960s. Kawasaki and Chiba are industrial ports, with tonnages of 61,000 and 51,000 respectively. The port of Tokyo handled 40,000 tons of cargo. Ferryboats carrying cars have several lines across Tōkyō-wan.

Building styles. In Tokyo Urban Prefecture there were 3,100,000 dwellings in the late 1960s. The city of Yokohama had 500,000 and Kawasaki 250,000. These dwellings vary from the tiny wooden house of two or three stories sandwiched between high office buildings to the large suburban homes of the well-to-do. Some people live over their shops or behind them. The best residential area is in the Yamanote Loop, once the site of feudal residences in the Edo period but now given over to middle class frame houses with gardens. As part of social and economic reforms instituted after World War II, the large estates in this area were subdivided into small lots or adapted to such other uses as clubs or restaurants; some of them became public gardens. The uplands are now being invaded by office buildings and apartment houses. Throughout the metropolitan area there are many housing developments, ranging in size from several hundred homes to more than 10,000. Building is carried on by the Japan Housing Corporation, municipalities, prefectures, and private companies.

About three-fourths of the dwellings in Tokyo Urban Prefecture are made of wood, although the number of fireproof concrete-and-steel houses is increasing. Building styles are a mixture of Eastern and Western. While few purely Japanese buildings remain, even a modern apartment will have one or two rooms with a tatami (reed-mat) floor and sliding doors. In Kawagoe, an old castle



town about 23 miles from Tokyo, are traditional merchant houses with heavy tile roofs and plaster walls.

The central business districts of Tokyo, Yokohama, and other cities consist mainly of steel-and-concrete buildings. Their maximum height was formerly limited to about 100 feet to prevent earthquake damage, but taller buildings were permitted in the late 1960s. In 1971 Tokyo had three 40-story office buildings. Outside of the central business district, buildings tend to be small in area because of the high price of land.

Central Tokyo. In the governmental district of Kasumigaseki, southwest of the Imperial Palace, one can study building styles by eras. The Sakurada Gate, formerly one of the entrances to the castle of the shoguns, leads across the moat to the outer garden of the palace. The entrance passage is crooked for reasons of defense. To the left, in Hibiya Park, is the Supreme Court building of reddish brick, put up in the 19th century; to the right of it are the dun-coloured Metropolitan Police Board and the ministry of local government, built in the 1920s. Next to the latter is the ministry of foreign affairs, a postwar building with wide glass windows and central heating and air conditioning. The National Diet Building beyond is made of granite from the islands of the Inland Sea (Seto-naikai). Overlooking these governmental buildings is the Kasumigaseki Building, rising 482 feet (147 metres).

Government buildings

Toichi Sakakibara

The Kasumigaseki Building, overlooking the Shinkansen express train, which runs through downtown Tokyo.

The Marunouchi district to the east of the Imperial Palace was developed as a business centre on vacant land formerly owned by the government. Marunouchi means inside castle; in this district is the outer-moat zone of the Edo castle, where the feudal lords had their mansions. A commercial centre was built there around the turn of the 20th century, consisting of red-brick buildings of three or four stories. These gave way in the 1920s and 1930s and after World War II to steel-and-concrete office buildings that are resistant to fire and earthquake. The Mitsubishi Bank and the Dai-Ichi Life Insurance Building are in Renaissance style. The postwar buildings are of lighter and taller construction, an example being the Tokyo Metropolitan Government Office. The former Imperial Hotel, designed by Frank Lloyd Wright in 1916, withstood the earthquake of 1923 and was torn down in 1967 and replaced by a plainer, taller structure in 1970.

The uptown area to the south has changed much less; many older buildings are still preserved. The old lecture hall of Keio University, of wooden construction with black-and-white-checkerboard walls, belongs to the early Meiji period. The Akasaka Detached Palace was completed in 1909.

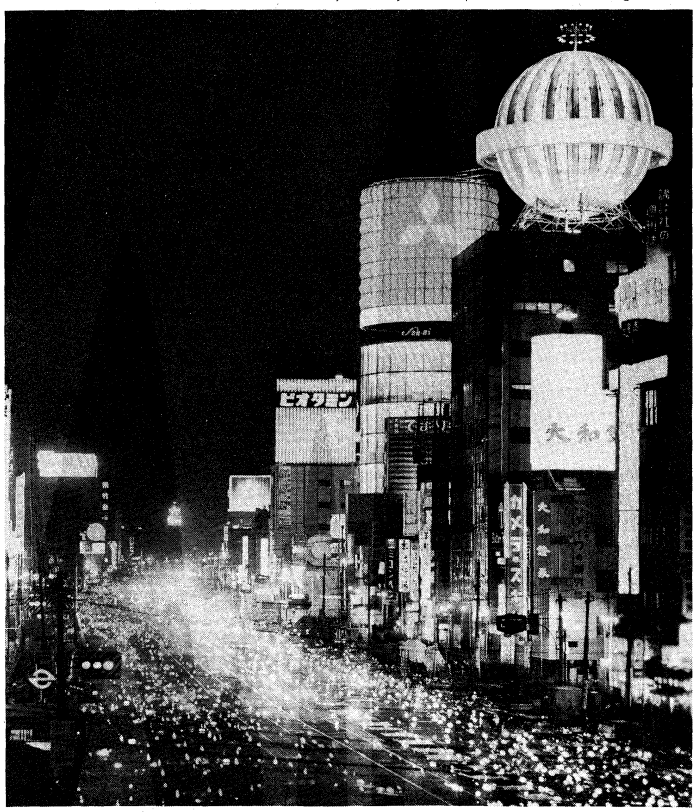
To the north, near the Kanda-gawa (Kanda River), one finds a contrast of building styles and civilizations in the Seidō (a Confucian shrine rebuilt in 1935), the Kanda Myojin Shrine (a Shintō shrine rebuilt in 1934), and the Nicolai Cathedral (Greek Orthodox, dating from 1884).

New building. Recent buildings include the Palace-side Building adjacent to the northern moat, occupied by the Mainichi Press; Tokyo Cathedral with a sky-piercing tower, and the National Theatre. One of the highest structures in the world is a 1,092-foot (333-metre) TV tower, erected in 1958 and modelled on the Eiffel Tower in Paris; it dominates the Tokyo skyline. The Shinjuku Railway Station on the western Yamanote line was being developed in the early 1970s as a civic centre. The complex includes the station, two department stores, and other buildings with offices and shops. Nearby will be a second Marunouchi commercial district. Towering above it is the 46-story Keio Plaza Hotel. Similar complexes were being developed elsewhere in the metropolitan area —for example, at the Shimbashi Station in the central business district and at Yokohama Station. Department stores have decentralized by locating at railway stations throughout Tokyo—Shinjuku, Shibuya, Ikebukuro, Veno, and Asakusa—where they compete with the stores of the central business district of Ginza–Nihonbashi.

The Shinjuku development

Demography. The total population of the Tokyo–Yokohama metropolitan area in 1970 was about 22,000,000. The city of Tokyo proper had slightly less than 9,000,000; Yokohama had about 2,200,000, and Kawasaki had nearly 1,000,000. Each day another 1,000,000 entered the area to work. The average population density of Tokyo proper was 40,207 persons per square mile. The density for Yokohama was 13,761 and for Kawasaki 19,399.

The population of the metropolitan area is growing, partly through migration from other parts of Japan and partly from natural increase. While the central city's population declined slightly from 1965 to 1970, that of other parts increased; growth rates were highest in the outer suburbs, some of which increased by more than half in the period 1965–70. Generally speaking, the western part of Tokyo and the uplands are middle and upper class residential areas. Blue-collar workers live east of the Sumida-gawa and in the industrial areas of Kawasaki and Yokohama. Tokyo is a melting pot for all Japan, and in the downtown area one can hear the Kwansai (Ōsaka–Kyoto) accent and the Tōhoku (northeastern region) dialect. Most of the many foreigners in the metropolis do not live in national enclaves. Exceptions are the Chinese in Yokohama and Koreans in several areas.



Economic life. The Tokyo metropolitan area is the largest commercial centre of Japan, and its port of Yokohama is the country's largest. Most important businesses and banks have their head offices in the central business district, as do foreign companies and banks. Before World War II, Tokyo was Japan's second industrial city after Ōsaka, but since the war Ōsaka has declined in comparison to Tokyo. In the late 1960s Tokyo Urban Prefecture accounted for 12.1 percent of the country's annual manufactures and Kanagawa Prefecture (including Yokohama, Kawasaki, and neighbouring cities) for another 10.4 percent.

Manufacturing. The Tokyo–Kawasaki–Yokohama manufacturing zone, also known as Keihin, is one of the four major industrial agglomerations in Japan. In the late 19th century, manufacturing developed within the cities of Tokyo, Kawasaki, and Yokohama. It later expanded into the suburbs: along the Tōkaidō Line (a railroad) to the southwest; westward to Sagamiōno, Tachikawa, Hino, and Hachiōji; along the Ara-kawa to the northwest; along the Takasaki and Tōhoku rail lines to the north; along the Jōban line to the northeast; and around the northeastern coast of Tōkyō-wan into Chiba Prefecture. If one includes in this industrial area the four prefectures of Tokyo, Kanagawa (Yokohama), Saitama (to the west of Tokyo), and Chiba (to the northeast), there were in the early 1970s a total of about 130,000 manufacturing enterprises with more than 2,800,000 workers.

Tokyo itself has much light manufacturing, including textiles, toiletries, and printing and publishing. It is a centre of cultural activity and information. It also produces goods requiring an abundant labour force, such as electrical products, cameras, and automobiles. A large proportion of the establishments are family-size or relatively small shops with fewer than 30 workers, most of them subcontracting to larger concerns. The Yokohama–Kawasaki district is an area of heavy industry specializing in chemicals, machinery, metallurgy, petroleum refining, ships, motor cars, and fabricated metal products. A new centre for iron and steel, petroleum refining, petrochemicals, electric power, and other heavy industries is the Chiba–Ichihara coast at the northeast end of Tōkyō-wan. Another heavy-industrial centre has sprung up at Kashima about 60 miles northeast of Tokyo on the Pacific coast. The machinery and light industries have been decentralizing inland from Tokyo in the area 30 to 60 miles from the city, where a number of industrial parks have been established.

Commercial and service industries. Tokyo is a centre of wholesaling, drawing goods from all over the country and abroad and distributing them into the surrounding area. It is also Japan's financial centre. The banks, insurance companies, stockbrokers, and similar establishments are concentrated in the central business district.

Utilities. The water used in Tokyo, Yokohama, Kawasaki, and other parts of the metropolitan area is supplied by aqueduct systems. Local waterworks and private industrial and residential systems supplement the supply. Tokyo draws its water from the Tama and Edo rivers; there are reservoir dams at Murayama and Yamaguchi and at Ogōchi on the upper Tama. To meet increasing demand, new dams have been built on the upper Ara and Tone rivers, which are connected by a canal with the Murayama–Yamaguchi reservoirs. Yokohama, Kawasaki, Yokosuka, and neighbouring towns get their water from the Sagami-gawa, which is dammed at two points. Most of the metropolitan area is supplied with gas by the Tokyo Gas Company. Gas plants are located mainly on the coast, where domestic and imported coal, petroleum, liquid gas, and natural gas are brought in by ship. Petroleum and bottled propane gas are also widely used for heating and cooking.

The city's electric supply

The Tokyo Electric Company serves the whole Kantō region, as well as Yamanashi Prefecture and the eastern half of Shizuoka Prefecture. About 35 percent of the power comes from hydroelectric stations on the Tone and Kinu rivers in Kanto, the rivers Katsura, Shinano, and Azusa in central Honshu, and Inawashiro-ko (Lake Inawashiro) in the Tohoku region of northern Honshu. Another 65 percent of the Tokyo area's power comes from thermal stations located on Tōkyō-wan and at Kashima to the northwest. To meet future needs of the metropolitan area, one 960,000-kilowatt hydroelectric station and three thermoelectric stations with a combined output of 2,700,000 kilowatts were under construction in the early 1970s. Tokyo also drew from two atomic power stations, one at Tokai, 65 miles northeast, and another on the Fukushima coast, 120 miles northeast, of Tokyo.

Public institutions and services. Tokyo is not only the national capital but also the centre of the Kanto region, which comprises the prefectures of Ibaraki, Tochigi, Gumma, Saitama, Chiba, and Kanagawa. It houses all the institutions of the national and regional governments, as well as the offices of the local government and of government corporations, such as the telephone and telegraph corporation. Most of these are located near the Imperial Palace. Foreign embassies and international institutions have their offices in the central business district and in the western part of the city.

Because Tokyo is the place of political decision, nearly all of Japan's prefectures have offices there. Major cities and towns have their Tokyo offices. Federations of local government, such as the Mayors' Association, are located in Tokyo, as are the headquarters of political parties and many other semigovernmental institutions.

Efforts to break up and decentralize this massive agglomeration of power have never succeeded. The migration of governmental offices out of Tokyo will apparently be limited to research sections. In the early 1970s a new university-and-research town was under construction in Tsukuba, about 40 miles northeast of Tokyo.

Public health. The Tokyo–Yokohama metropolitan area shares the problems of other large urban areas with respect to pollution, noise, and lack of air and sunlight. Its inhabitants nevertheless live better than people in small cities and towns because they enjoy superior medical care and social services.

Because the population is relatively young, the birth rate in Tokyo, Kawasaki, and Yokohama is higher than the national average; in 1969 the birth rate in Tokyo Urban Prefecture was 20.3 per thousand, and in Kanagawa Prefecture it was 22.7, as compared with the 1969 national average of 18.5. The death rate was likewise lower, being 4.9 per thousand in both prefectures as compared with the national average of 6.8. The infant mortality rates were 12.0 and 11.9 per 1,000 live births, a little lower than the national average of 14.2. In 1970 there were about 758 persons for every physician in the prefecture of Tokyo and 1,174 in the prefecture of Kanagawa. In Tokyo city there were 105 persons per hospital bed. These ratios are very low for an Asian country and compare favourably with those of western Europe. The medical school of the

Shinichiro Morimoto—Orion Press

University of Tokyo, founded in the latter part of the 19th century, is known for its Institute of Medical Science. The medical school of Keio University is another research hospital. A number of university hospitals in Tokyo are open to the public, but most hospitals are run by the national, prefectural, and municipal governments or public organizations such as the Red Cross. There are special hospitals for children, the aged, and patients suffering from cancer, tuberculosis, or heart disease.

Tokyo has always been a city of fires, stemming from crowded conditions and flammable building materials. In Tokyo Urban Prefecture there were 8,844 fires in 1969. The fire departments of all Japanese municipalities fight fires and other hazards such as traffic accidents, floods, and earthquakes. Tokyo has a metropolitan police agency to maintain order in the capital city. There are also mobile police that can be called in case of large-scale violence. Kanagawa Prefecture has its own police force, as do Yokohama and other large municipalities.

Education. In Tokyo as in other large cities more than 90 percent of the ninth-year graduates go on to high school. In the late 1960s there were more than 1,600 primary schools with 1,265,000 pupils in Tokyo and Kanagawa prefectures together; more than 1,000 junior high schools with 554,000 pupils; and more than 550 high schools with 598,000 students. There are also public and private kindergartens.

Colleges and universities

In the early 1970s the Tokyo metropolitan area had 116 universities and 110 junior colleges, with enrollments in the late 1960s of 608,000 and 75,000 students respectively. Almost half of all Japan's university and college students are to be found in the prefectures of Tokyo and Kanagawa. The century-old University of Tokyo has ten faculties and many research institutes. Other leading universities are Tokyo Kogyo University (engineering), Hitotsubashi University (trade and commerce), Tokyo University of Education, and Tokyo Geijutsu University (music and arts). There are also national universities for industry and agriculture, languages, medicine, dentistry, the merchant marine, and other fields. The prefectural and municipal universities are Tokyo Metropolitan and Yokohama Municipal. Among private universities, Waseda and Keio are the oldest and most highly regarded, especially in the fields of literature, politics, and business. The largest university is Nihon, with 72,000 students.

Culture and recreation. Tokyo is at the centre of national cultural activity. It is also the home of various institutions for national and international cultural communication. Modern Japan has been strongly influenced by the West, to which Tokyo and Yokohama have been gateways; Western technology and life styles first took root in those cities.

Museums

If Tokyo has been less a centre of Japanese traditions than have Kyōto, Ōsaka, and Nara, it has many valuable cultural properties from the past. The Imperial Household Agency Library and the Tôyô Bunko hold collections of classical books. There are the National Archives and the National Diet Library. The National Museum in Ueno Park concentrates on the art and history of Japan and Asia. The Kokuritsu Kagaku Hakubutsukan (National Science Museum), the Zoological Garden, and the National Museum of Western Art are also located in Ueno Park, as is the Metropolitan Gallery of Fine Art. Elsewhere in Tokyo there are numerous smaller collections and galleries. Near the Imperial Palace are the National Museum of Modern Art and the Technical and Engineering Museum. Tokyo and Yokohama also have their own local historical records and exhibits, such as the museum of folkways, in the city of Musashino, and the museum of old houses, in Kawasaki.

A whole range of theatre is available, from the traditional Kabuki to modern drama. Symphonic works, operas, and various other kinds of Western music and dance are performed.

The media. Tokyo is the information centre of Japan. Nationwide radio and TV programs originate there. The three largest nationwide newspapers, *Asahi, Mainichi,* and *Yomiuri shimbun,* are issued in Tokyo. A daily economic newspaper, several English-language papers, and papers in Korean are all published there. Hundreds of other daily and weekly papers are printed and distributed, as well as more than 40 weekly magazines.

In the early 1970s Tokyo had seven television channels, including two UHF channels. There were 65 radio stations, including two FM and one shortwave. Colour TV was rapidly becoming popular.

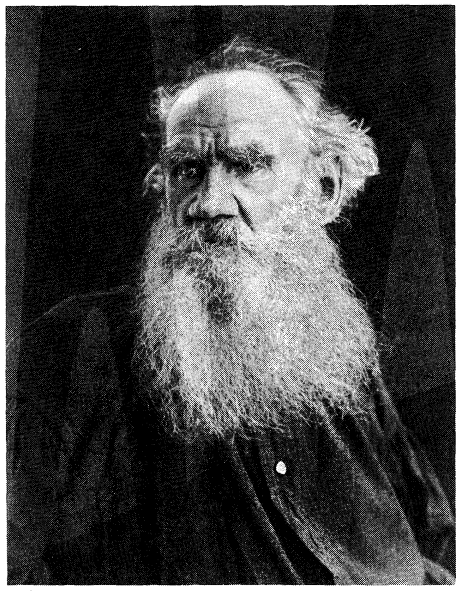
Parks

Recreation. Tokyo's parks are not as large as those of European and American cities, but they are numerous. Among the better known are the outer garden of the Imperial Palace, Hibiya Park, Ueno Park (with its zoo), and the Meiji Shrine's Outer Garden (with its baseball stadium and other playing fields). The latter along with Komazawa Olympic Park and Yoyogi Sports Centre, was one of the main centres of the Olympic Games in 1964. In the western part of Tokyo are the smaller natural parks of Inokashira, Zenpukuji, and Shakujii, with lakes. Some of the larger private gardens of the Edo period are now open to visitors. The most impressive of these is the Inner Garden of the Meiji Shrine with its irises and water lilies, a favourite spot of the emperor Meiji. There are also several botanical gardens.

In Yokohama, the best parks are Nogeyama and Yamate, on hills overlooking the harbour, and Yamashita Park on the coast. Sankei-en (Sankei Garden), formerly a private estate, contains a collection of historic buildings brought from other parts of the country.

Suburban recreation areas include the Tama Zoological Garden, where visitors can ride by bus through the lion section, and near it the *kodomo-no kuni* ("children's country"). Places of excursion from Tokyo and Yokohama include the Okutama and Sagami valleys, the Chichibu and Tanzawa mountains, the Fuji-Hakone-Izu National Park, the Izu-hantō (Izu Peninsula) with its many hot springs, the islands of Oshima and Miyake, the Miurahantō, and many others. There are also amusement parks with roller coasters and similar rides, such as Kōrakuen, Tamagawa, Toshimaen, and Yomiuri.

The most popular sport in Japan is baseball. Tokyo has four professional teams and Kawasaki one. There are also university teams, and the Waseda–Keio games are followed intently. There are a number of golf courses in the suburbs.



BIBLIOGRAPHY. A comprehensive source, in English, is the INTERNATIONAL GEOGRAPHICAL UNION, REGIONAL CONFERENCE, *Geography of Tokyo and Its Planning* (1957), although now somewhat dated. The ASSOCIATION OF JAPANESE GEOGRAPHERS, *Japanese Cities* (1970), contains many useful studies of Tokyo. A German-language discussion is S. KIUCHI, "Tokio als Weltstadt," in J.H. SCHULTZE (ed.), *Zum Problem der Weltstadt* (1959). The TOKYO METROPOLITAN GOVERNMENT has published an atlas, *Regional and City Planning for Tokyo* (1964). H. AONO and S. BIRUKAWA, *Tokyo-to* (1967), is an academically written study of the Tokyo region (in Japanese). S. KIUCHI, *Tokyo* (1968) and *Kanagawa, Saitama, Chiba* (1969), contain colour photographs and maps. K. KODAMA and H. SUGIYAMA, *Tōkyō-to ne rekishi* (1969), is a history (in Japanese). Statistical data may be found in the *Statistical Yearbook of Japan*, published by the national government, and the *Yearbook of the City of Tokyo*, published by the Tokyo Metropolitan Government.

(S.K.)

Tolstoy, Leo

The enduring fame of Leo Tolstoy, Russian author, reformer, and moral thinker, rests mainly on two novels, *War and Peace* and *Anna Karenina*. A deeply contradictory man, Tolstoy was an individualistic aristocrat who in his later years tried unsuccessfully to lead the life of a poor peasant, a sensualist who ended up as an intransigent puritan, a man of singular vitality who feared death at almost every step. This extraordinary duality of character led him in middle life to abandon his career of a mere writer of fiction to become a radical Christian who propagated his belief in a life of love and faith and his rejection of property and such man-made institutions as governments and churches by a stream of essays and pamphlets and largely didactic short stories and plays.

Early years and marriage. Lev Nikolayevich, Count Tolstoy, was born on September 9 (August 28, old style), 1828, on his family's estate at Yasnaya Polyana, about 100 miles (160 kilometres) south of Moscow, in Tula Province. Tolstoy's parents died when he was a child, and he was raised by relatives. Private tutors had charge of his early education. At 16 he entered the Kazan University (now Kazan [V.I. Lenin] State University), but, disappointed with the formal instruction there, he returned to Yasnaya Polyana in 1847 to manage his estate and conduct his own education. In neither did he achieve much success, preferring the social whirl of Moscow and St. Petersburg to life in the country. In his diary, which he kept during most of his life, he recorded his moral transgressions. In his youthful entries there is already evidence of an unusual analytical talent in his realistic probing into the suppressed motives of his own behaviour.

Tolstoy
The Bettmann Archive

Disgusted with this shiftless existence, Tolstoy in 1851 joined his soldier brother Nikolay in the Caucasus. In the following year he also entered the army and acted with bravery in several engagements against the hill tribes. Much of his leisure he spent in writing, completing his first published work, *Detstvo* (*Childhood*), which appeared in the magazine *Sovremennik* ("The Contemporary"). The material of *Childhood* is treated with conventional realism, except for digressive lyrical passages in the manner of the English novelist Laurence Sterne, whose *Sentimental Journey* Tolstoy partially translated at this time. He is autobiographical in this and in later works, for he often draws upon his own life, or the lives of those he knew well, for the content of his fiction; but what captivates readers of *Childhood* is its fresh and precise choice of significant detail and the amazing reliving of forgotten common experiences of childhood that, once recalled, exert a nostalgic charm. Sequels to *Childhood—Otrochestvo* (*Boyhood*) and *Yunost* (*Youth*)—lack this special charm, perhaps because an analysis of the moral failings of youngsters tends to dominate these two works. Tolstoy's experiences in the Caucasus are reflected in "Nabeg" ("The Raid") and "Rubka lesa" ("The Woodfelling"), his first short stories dealing with war. The theme is treated in a youthful spirit, but the exacting realistic analysis of military activity is tinged with that critical awareness of false heroics that became a central feature of his *Sevastopolskiye rasskazy* (1855–56; *Sevastopol*).

Sketches of military life

Transferred to the Danube front in 1854, Tolstoy participated in the siege of Sevastopol during the Crimean War. He described these experiences in his *Sevastopol* sketches, in which he contrasted the simple heroism of the common soldier with the false heroics of military leaders. At the end of the fighting in 1856, he left the army and went to St. Petersburg, where he became the idol of competing literary groups that sought his support of their social and aesthetic views. A pronounced individualist, he rebuffed the coteries and left for Yasnaya Polyana.

He went abroad in 1857, to France, Switzerland, and Germany. The criticism of stories based on his travels (*e.g.*, "Lyutsern" ["Lucern"]) caused him to lose interest in literature. Yet he continued to write. Between 1855 and 1863 he wrote a series of short stories—including

Early short stories

"Zapiski markera" ("The Memoirs of a Billiard-Marker"), "Dva gusara" ("Two Hussars"), "Albert," "Tri smerti" ("Three Deaths"), "Semeynoye schastye" ("Family Happiness"), "Polikushka," and "Kholstomer" (not published until 1886)—in which he concentrated mainly on moral problems. These stories anticipate his later concern with the harm a materialistic society inflicts on the natural, unspoiled man but represented no artistic advance on his earlier writing. In fact, the subjective moralistic emphasis is a defect, although many passages are persuasively argued. Only in the "Two Hussars" did Tolstoy avoid this pervasive subjectivism. There, the evil influences of society on one of the characters are artistically suggested rather than didactically argued. "Kholstomer," a satire on human beings from the point of view of a horse, is also something of an exception, for by his art Tolstoy somehow convinces the reader that the noble horse's natural life is superior to man's absurd, unnatural existence. The contrast between the natural man and the spoiled product of sophisticated society deeply interested Tolstoy, and he treated the theme with brilliant artistry in *Kazaki* (*The Cossacks*). The highly civilized protagonist suffers in comparison with the freedom-loving uninhibited Cossacks of the village in which he lives. Several of them are among Tolstoy's most memorable characterizations.

In the late 1850s Tolstoy became concerned with the poor state of education among the peasantry, and, on returning from his travels, he started a school for peasant children at Yasnaya Polyana. The success of his original teaching methods, which anticipated modern progressive education, drew him deeper into pedagogical studies. He journeyed to Europe again in 1860–61, visiting Germany, France, Italy, England, and Belgium and investigating educational theory and practice. Absorbed by this interest, he published an educational magazine, in which he developed his pedagogical theories, and compiled textbooks that won wide acceptance because of their simplicity and attractive approach.

In 1862 Tolstoy married Sonya (Sofya) Andreyevna Bers, a girl from a middle class family with wide intellectual interests. He dropped his educational activities and for the next 15 years devoted himself with all his ardent nature to married life. For the most part it was an intense but happy existence, and 13 children were born. He now managed his estate with much success and resumed writing, creating his two greatest masterpieces, *Voyna i mir* (*War and Peace*) and *Anna Karenina.*

The great novels. It took Tolstoy almost seven years to write his vast epic *War and Peace,* generally regarded as one of the two or three greatest novels in world literature. In this supreme effort he went far beyond his previous writings both in scope and treatment. In it, all the stuff of life is woven in enormous tapestry, and the rich material and numerous characters are handled with unsurpassed objectivity. Perhaps in no other novel does the mastery of realistic detail and the amazing subtlety and variety of psychological analysis so successfully create the total impression of life being lived completely and naturally.

The scheme of *War and Peace*

War and Peace, covering the period 1805–14, is primarily concerned with the histories of five aristocratic families, the members of which are portrayed against a vivid background of Russian social life and the titanic struggle of clashing armies during Napoleon's invasion of Russia. In this huge panorama appear the aristocracy and the peasantry, officers and privates of the army, the Russian and French emperors, diplomats and courtiers, town life and country life, and realistic pictures of war. The theme of war, however, is subordinated to the story of family existence, which at that time involved Tolstoy's optimistic belief in the life-asserting pattern of the natural stages of man—birth, childhood, maturity, love, marriage, birth again, and death. As models for two of the families, Tolstoy drew upon members of his own family, and the unforgettable heroine Natasha is modelled on his sister-in-law Tanya Bers. One has only to read her published diary, however, to realize how the witchery of his art has transformed her into the vital, poetic, "natural" woman of the novel. The moral conflict between two of the main protagonists (bumbling, questing Pierre and polished, intellectually proud Andrey) is also Tolstoy's—Andrey's conviction that one should live for the sake of doing good for oneself being opposed to Pierre's ultimate belief that one should live for the sake of serving others. Tolstoy varied his realistic method of individualizing characters in accordance with the human types portrayed: it may be brilliant externalization, as in the case of a shallow society beauty; or psychological analysis in depth, as in that of an emotionally complex woman supposedly patterned after Tolstoy's mother; or acute symbolism, as in the creation of the peasant Platon Karatayev, who exists as a personification of the simplicity and truth living in the gray masses of Russia.

The sections of the novel that critics have frequently objected to are those in which Tolstoy set forth his philosophy of history and theorized about war and its architects. He anticipated these objections, and in 1868 he published an article explaining his views on these matters. There are two kinds of actions, he declared: those that do, and those that do not, depend upon individual will. In the historical process, he wrote, there is a minimum of freedom; the actions of so-called makers of history and leaders of war depend on the actions of countless other people and to this extent are predetermined. What troubled him was the historians' practice of fixing responsibility for what occurs in life upon individuals whom they call "great men" and endow with heroic virtues and vices. On the contrary, Tolstoy argued, natural law—the principles of right or justice regarded by many thinkers as common to all mankind and thus independent of formal law—determines the lives of human beings no less than the processes of nature itself. There is no free choice; all is ruled by an inexorable historical determinism. But it can hardly be denied that his labouring of such subjects interferes with the unity of *War and Peace* and represents an artistic lapse.

Though it is similar to *War and Peace* at least in narrative method and style, *Anna Karenina* has more artistic unity. Tolstoy's philosophy of life was in the process of changing between the writing of the two books. *War and Peace* is a life-loving, optimistic novel, and its main characters are morally robust and masters of their inner conflicts; *Anna Karenina,* which deals with Russian society in the 1860s, is pessimistic, and the inner conflicts of its characters, often unresolved, sometimes bring about human disaster. There is an inevitability about the tragic fate that hangs over the adulterous love of Anna and Vronsky. "Vengeance is mine, I will repay" is the epigraph of the novel and the leitmotiv of the whole story. Anna pays not so much because she transgresses the moral code but because she refuses to observe the proprieties customarily exacted in such liaisons by the hypocritical high society to which she belongs. Her love for Vronsky is a deep and lasting passion, and, unable to play the hypocrite, she unhesitatingly confronts high society with the sincerity of her love. Society's smug condemnation assures the tragic consequences of the affair. The sinful romance of Anna and Vronsky is effectively contrasted with the happy love and marriage of Kitty and Levin, which appears to have been inspired by Tolstoy's own experiences in marriage. Further, Levin's anguished doubts about the meaning of life, his haunting thoughts of suicide, and his desire to sympathize with the peasants are clear echoes of Tolstoy's own struggle at this time.

The moral basis of *Anna Karenina*

Last years as Christian reformer. Though happily married, famous as a novelist, and enjoying a large income, Tolstoy had become dissatisfied with himself by the time he finished *Anna Karenina.* An incessant probing into the purpose of life, which had troubled him since his youth, drove him to a state of spiritual crisis. In *Ispoved* (*A Confession*) he poignantly relates the moral and spiritual suffering he endured in his search for an answer to the meaning of life. The crisis came to a head in 1879. At one point he contemplated suicide. He found little help in the writings of philosophers, theologians, and scientists that he systematically examined, but the peasants, for whom he felt a deep sympathy, gave him a

clue. One must serve God, they told him, and not live for oneself.

Ultimately Tolstoy became convinced that the teachings of Christ, as revealed in the New Testament, contained the answer to his question about the meaning of life. There is a power in each of us, he declared, that enables us to discern what is good, and we are in touch with that power. Our reason and conscience flow from it, and the purpose of our conscious life is to do its will; that is, to do good. From what he believed to be Christ's real utterances, corrected as he felt they should be if they were to retain their original substance, he formulated five commandments to guide him: do not be angry; do not lust; do not bind yourself by oaths; resist not him that is evil; be good to the just and the unjust. These commandments, with some modifications, became the basis for his future activities and teachings.

Conversion to Christian anarchism

Tolstoy's new convictions took a form of Christian anarchism that led him to disavow immortality and reject the authority of the church, which in turn was to excommunicate him in 1901. Further, he opposed organized government because it maintained itself through coercion, and he condemned private property because he believed that ownership was secured by force. He would have preferred to divest himself of his own property, but, bowing to the wishes of members of his family, he legally transferred his estate to them.

Following his spiritual crisis, Tolstoy devoted much time after 1880 to writing books, pamphlets, and articles on various aspects of his religious, social, moral, and artistic views. Though they lack the absorbing interest of the personal experience he related in *A Confession*, they are written in the same clear prose and often reveal his remarkable gift for logical and persuasive argumentation. The most important of these many discursive writings are *Kritika dogmaticheskogo bogoslaviya* (*An Examination of Dogmatic Theology*), a powerful attack on the Russian Orthodox Church; *V chyom moya vera* (*What I Believe*), an attempt to systematize his views on religion; *Tak chto zhe nam delat?* (*What Then Must We Do?*), a vivid account of his experiences in the slums of Moscow and an analysis of the causes of poverty; and *Tsarstvo bozhiye vnutri vas* (*The Kingdom of God is Within You*), the fullest statement of his Christian anarchism, in which he developed his belief in nonresistance to evil and reached the conclusion that governments exist largely for the sake of the rich and powerful and by their use of force persecute the masses of mankind and murder them in the violence of war. Some essays attack specific social and governmental practices, such as the use of intoxicants and tobacco in "Dlya chego lyudi odurmanivayutsya?" ("Why Do Men Stupefy Themselves?") and the execution of revolutionists in "Ne mogu molchat!" ("I Cannot Be Silent!"). Others call for reforms, advocating, for instance, the land tax proposed by the American economist Henry George (*Pisma o genre dzhorzhe* [*Letters on Henry George*]).

Religious and social essays

In 1897 Tolstoy completed *Chto takoye iskusstvo?* (*What is Art?*), an attempt to develop an aesthetic system in terms of his religious, moral, and social views. He maintained that a work is art only when it "infects" the reader, hearer, or viewer with the condition of the artist's soul. If there is no union between the artist and his audience through "infection"—that is, if a communication of sympathetic feelings is not conveyed—then the work has failed as art. Among the several degrees of art that Tolstoy recognized, the highest is "religious art"—that which infects people with feelings "flowing from the love of God and man." On this basis, he rejected as art some of the works of, for example, Shakespeare and Wagner. With that maddening consistency that is as much the hallmark of pride as of humility, he relegated his own great works of fiction up to this point to the category of "bad art," because they did not conform to the moral purpose of his new theory.

After his spiritual crisis Tolstoy, apart from his voluminous nonfiction, wrote several tales with a moral purpose, in a bare style devoid of the abundant details of his previous fiction. "Chem lyudi zhivy" ("What Men Live By"), "Dva starika" ("Two Old Men"), "Vrazhye lepko, a bozhye krepko" ("Evil Allures, but Good Endures"), "Mnogo li cheloveku zemli nuzhno?" ("How Much Land Does a Man Need?"), and "Tri voprosa" ("Three Questions") are cast in this new manner. These little masterpieces of construction, which focus on peasant life, belong to his category of "good universal art." Though a moral is present, it is never allowed to obtrude on the artistic unity of the story. Another series of tales, different in manner because they are intended to appeal to educated readers, are closer to the style of his earlier fiction. The finest are the unfinished "Zapiski sumasshedshego" ("Notes of a Madman"), a mystical treatment of man's despair in the face of life's defeats, and "Smert Ivana Ilicha" ("The Death of Ivan Ilich"), in which the hero, a symbolic Everyman, discovers the inner light of faith and love only when confronted by death. The problem of sex, which deeply concerned Tolstoy in his new belief that man's moral health depended on his ability to approach closer to the ideal of chastity, becomes the central theme of "Kreytserova Sonata" ("The Kreutzer Sonata"), a convincing artistic study of jealousy and ill-tempered polemic against society's sexual education of young men and women. Sex is also the main concern of "Dyavol" ("The Devil"), a story inspired by an episode in Tolstoy's life: a man, deeply in love with his young wife, cannot overcome his lust for a pretty peasant girl. The husband's despairing struggle with carnal desire is told with all Tolstoy's psychological mastery.

Sexual themes

A full-length novel, *Voskreseniye* (*Resurrection*), written when he was 71, was Tolstoy's major artistic effort after his "conversion." It is the story of a nobleman who seduces a young girl. She becomes a prostitute and is convicted of a crime that she did not commit, and the conscience-stricken hero, determined to marry her, follows her to Siberia. Though his love redeems her, in the end she refuses to marry him. There are many fine things, especially in the first part, where the account is cast in a bewitching poetic atmosphere. And the trial scene is a brilliant piece of realistic narrative. But *Resurrection* represents a marked falling off, artistically, from *War and Peace* and *Anna Karenina*. It bears evidence of haste, and the moral preaching and sharp attacks on the judicial and penal systems—however deserved—and on the religious services of the church are in the spirit of Tolstoy the polemicist rather than the literary artist.

After his "conversion" Tolstoy strove, by no means with complete success, to bring his daily existence into conformity with his altered views. He abandoned smoking and drinking, became a vegetarian, and often dressed in simple peasant clothes. Since he now believed that no one should depend upon the labour of others, he became as self-sufficient as possible, cleaning his own room, working in the fields, and making his own boots. In the hope of approaching closer to his ideal of chastity, he tried to conquer fleshly desires in his relations with his wife. He also engaged in philanthropic activities, such as the organization of famine relief. The eloquence of Tolstoy's moral and religious writings, his fame, and his vital personality attracted many adherents. Disciples organized colonies in which they endeavoured to live together according to his precepts. Tolstoy distrusted such organized efforts. The truth that brings happiness cannot be preached, he declared; it can be achieved only by individuals who honestly look within themselves. As his own reputation increased and knowledge of his views spread throughout Russia and abroad, hundreds of people from all over the world made their way to Yasnaya Polyana to see and talk with him.

But the older sons, and his wife especially, had little sympathy for Tolstoy's views and his altered way of life. Endless visits of "converts"—the "dark people," his wife called them—and the interference of one of them, V.G. Chertkov, in family affairs caused frequent quarrels between husband and wife. Contrary to his hopes, she refused to surrender her possessions and join him in a life of comparative asceticism. In fact, to secure the family's comfortable existence, she obtained, much against his will, the copyrights of his works printed before 1880, and

these writings provided considerable income from editions that she herself published.

During the last part of his life Tolstoy withheld from publication various works, either because he was dissatisfied with them or because he wished to avoid quarrelling with his wife over copyright ownership. In 1911, a year after his death, several of them appeared; they are among his best creations. One is a short novel, *Khadzhi-Murat*, the story of a brave Caucasian warrior who deserts to the Russians and is killed attempting to see his son in secret. The vivid narrative method and psychological revelation of mutual misunderstandings entitle it to a place among the most superb examples of his art. Equally effective, though shorter, are "Otets Sergy" ("Father Sergius"), the story of an aristocrat who conquers his lust and spiritual pride and becomes a hermit-monk; "Falshivy kupon" ("The False Coupon"), a study in fictional form of how the example of goodness, in contrast with the evil-begetting power of evil, inspires good deeds; and "Alyosha Gorshok," a perfect short story of a peasant youth who finds contentment with his lot through submission to all adversities.

Posthumous stories and plays

Several plays were included in the first posthumous collection of his works. Tolstoy believed that drama was "probably the most influential province of art," and at various periods he devoted much effort to writing plays. But he lacked certain of the qualifications necessary to the dramatist, and, though in some instances he succeeded, his plays are inferior, artistically, to his fiction.

Vlast tmy (*The Power of Darkness*), Tolstoy's highest achievement in drama, was first performed in 1888. It is a realistic tragedy of peasant life conceived as an illustration of one of his favourite later themes, suggested by the subtitle, "If a Claw is Caught, the Whole Bird is Lost." The initial evil action of the protagonist—his seducion of another man's wife—leads him to commit further sins, including the final sin of murder. A striking contrast is *Plody prosveshcheniya* (*The Fruits of Enlightenment*), a comedy that genially satirizes the foibles of aristocratic society. Tolstoy never finished *I svet vo tme svetit* (*The Light Shines in Darkness*), though it had a special autobiographical importance, for it concerns the hero's failure to convince his family of the wisdom of his beliefs. *Zhivoy trup* (written 1902; *The Living Corpse*) deals with the tragedy of a drunkard. Conscience stricken over the harm he has caused his wife, he pretends to have died so that she may marry the man she loves. When the police reveal that he is actually alive, he kills himself. The moralizing that appears in Tolstoy's writing in his old age is absent from his play, which is filled with kindness and sympathetic understanding of the erring ways of mankind.

The aging Tolstoy felt keenly the painful contradiction between the life of ease that the family lived and the life he wanted to live—the simple existence of a religious hermit, free of worldly goods and dedicated to service to others. He realized that his position made a mockery of his professed faith. Finally, the worsening domestic situation forced him to leave home stealthily one night, accompanied by his doctor and youngest daughter, Aleksandra, in search of, he hoped, a refuge where he could live quietly and closer to God. A few days later, on November 20 (November 7, O.S.), 1910, he died of pneumonia at the remote railway junction of Astapovo, in Ryazan Province.

Assessment. Tolstoy's eminence as a literary artist has never been seriously questioned by critics; he is universally accepted as one of the greatest writers of fiction in the world. Although never dependent on preceding Russian authors, he may have been influenced by foreign writers, such as Jean-Jacques Rousseau, Sterne, Stendahl, and later, William Thackeray. But there has never been unanimity about his reputation as a thinker. The dualism of Tolstoy's moral and intellectual development, however, has come to be more thoroughly understood by modern students of his thought. In his tireless search for truth he sought for absolutes in a world of incomplete knowledge and imperfect men. As a consequence, his unwillingness to compromise, his compulsive need to achieve the ultimate rational explanation, often led him to push theory to the limits of absurdity, which many believe he came very close to doing in his views on history, nonviolence, education, and art. But any systematic study of his thought reveals its relation to the concepts of 19th-century liberalism. He believed that the whole history of the last 2,000 years had been shaped essentially by the moral development of individuals and the demoralization of governments. Tolstoy placed his faith in the moral development of the people as a final answer to what he regarded as the universal oppression of the many by the few. For him, the progressive movement toward a classless and stateless condition of mankind depended, contrary to the economic determinism and violent class struggle of Marxism, upon the growing moral perfection of each individual through observance of the supreme law of love and the consequent repudiation of every form of violence. Despite the extreme to which he carried his rationalism, Tolstoy is today generally considered to be among the foremost thinkers of the 19th century.

MAJOR WORKS

NOVELS: *Voyna i mir* (1865–69; *War and Peace*, trans. by Louise and Aylmer Maude in "Great Books of the Western World," vol. 51, 1952; trans. by Constance Garnett, 1961); *Anna Karenina* (1875–77; trans. by R.S. Townsend, 2 vol., 1958); *Voskreseniye* (1899; *Resurrection*, trans. by Louise Maude, 1957).

STORIES: *Detstvo* (1852; *Childhood* in *Childhood, Boyhood, Youth*, trans. by R. Edmonds, 1964); "Nabeg" (1853; "The Raid," trans. by Constance Garnett in *Tolstoy Tales*, 1947); *Otrochestvo* (1854; *Boyhood*); "Rubka lesa" (1855; "The Woodfelling" in complete works: *Tolstoy Centenary Edition*, trans. by Louise and Aylmer Maude, 1928–37); "Dva gusara" (1856; "Two Hussars" in complete works); *Yunost* (1857; *Youth*); "Kholstomer" (written 1863, first published 1886; in complete works); *Kazaki* (1863; *The Cossacks; The Death of Ivan Ilyich; Happy Ever After*, trans., by R. Edmonds, 1960); "Chem lyudi zhivy" (1881; "What Men Live By" in *Tolstoy Tales*, trans. by Louise and Aylmer Maude, 1947); "Dva starika" (1885; "Two Old Men"); "Mnogo li cheloveku zemli nuzhno?" (1886; "How Much Land Does a Man Need?"); and "Tri voprosa" (1903; "Three Questions") —all in translation in complete works; "Zapiski Sumasshedshego" (1884; "Notes of a Madman" in *Notes of a Madman and Other Stories*, trans. by S.S. Koteliansky, 1943); "Smert Ivana Ilicha" (1886; "The Death of Ivan Ilich" in complete works); "Kreytserova sonata" (1891; "The Kreutzer Sonata" in *The Kreutzer Sonata, The Devil, and Other Tales*, trans. by Aylmer Maude, 1940) "Dyavol" (1889; "The Devil" in *The Kreutzer Sonata*); "Otets Sergy" (written 1898, first published 1911; "Father Sergius" in complete works); *Khadzi-Murat* (written 1904, first published 1911; trans. in complete works); "Falshivy kupon" (written 1904, first published 1911; "The False Coupon" in complete works); "Alyosha Gorshok" (written 1905, first published 1911; "Alyosha the Pot").

PHILOSOPHICAL AND SOCIAL WRITINGS: *Ispoved* (written 1878–79, first published 1882; *How I Came to Believe—"My Confession,"* trans. 1921); *Kritika dogmaticheskoga bogoslaviya* (written 1880, first published 1891; *An Examination of Dogmatic Theology*); *V chyom moya vera* (written 1883, banned 1884; *What I Believe*, trans. by Aylmer Maude, 1940); *Tak chto zhe nam delat?* (finished 1886, first published 1902; *What Then Must We Do?*); *Tsarstvo bozhiye vnutri vas* (1894; *The Kingdom of God Is Within You*); "Dlya chego lyudi odurmanivayutsya" (1890; "Why Do Men Stupefy Themselves?"); "Ne mogu molchat!" (1908; "I Cannot Be Silent!"); *Pisma o genre dzorzhe* (1897; *Letters on Henry George*); and *Chto takoye iskusstvo?* (1898; *What Is Art?*) —all translations in complete works.

BIBLIOGRAPHY

Editions, selections, letters, and diaries: В.Г. ЧЕРТКОВ (ed.), *Л.Н. Толстой: полное собрание произведений*, 90 vol. (1928–58), is the most complete Russian edition of Tolstoy's works, the so-called Jubilee Edition, including his letters, notebooks, and diaries. Of editions in English translations none is complete; the most useful are *The Complete Works of Count Tolstoy*, trans. by LEO WIENER, 24 vol. (1904–05); and *Tolstoy Centenary Edition*, trans. by LOUISE and AYLMER MAUDE, 21 vol. (1928–37). Translations of single fictional works are also available in the Everyman's Library and in Penguin Classics. See also *The Journal of Leo Tolstoi, 1895–1899*, trans. by ROSE STRUNSKY (1917); *The Diaries of Leo Tolstoy: Youth, 1847–1852*, trans. by C.J. HOGARTH and A. SIRNIS (1917); *Leo Tolstoy: Last Diaries*, ed.

by LEON STILMAN (1960); PAUL BIRYUKOV (ed.), *Tolstoi's Love Letters*, trans. by S.S. KOTELIANSKY and VIRGINIA WOOLF (1923); *The Private Diary of Leo Tolstoy, 1853–1857*, trans. by LOUISE and AYLMER MAUDE (1927); *The Letters of Tolstoy and His Cousin Countess Alexandra Tolstoy, 1857–1903*, trans. by LEO ISLAVIN (1929).

Tool and Die Making

Tool and die making is the industrial art of manufacturing stamping dies, plastics molds, and jigs and fixtures to be used in producing parts on a mass-production basis. The words "tool" and "die" are generic, and strictly speaking, redundant, because dies are also tools.

History. The development of modern tools and dies can be traced to the American inventor and manufacturer Eli Whitney, who was the first man to implement the concept of the planned manufacturing of interchangeable parts. Each part was manfactured to prescribed dimensions with the aid of tooling, so that the highly skilled craftsmen previously required for manufacturing were no longer needed since no additional fitting or selective assembly of the parts was necessary.

Contribution of Eli Whitney

Whitney's tooling consisted of templates (tool-guiding patterns) and rudimentary fixtures—the antecedents of today's tools and dies—and he successfully demonstrated the feasibility of manufacturing interchangeable parts by mass-producing firearms for the War of 1812.

The successful introduction of interchangeable manufacturing and the development of machine tools, both in the 19th century, brought the modern machine shop into being. Then, as still in the early 1970s, the independent machine shop was called a job shop, which meant that it had no product of its own but served large industrial facilities by fabricating tooling, machines, and machine-part replacements. Eventually, some machine shops began to specialize in tooling to the exclusion of other work.

The development of the power press gave rise to a demand for another form of tooling, the press die, the function of which is to cut and form sheet metal into predetermined shapes and configurations. The work of fabricating press dies is similar to, but not identical with, that of producing jigs, fixtures, and other tooling, which led to many of the specialized machine shops labelling themselves tool and die shops.

The 20th-century developments of die casting and injection molding have brought about the demand for still other forms of tooling—the dies used in die casting and plastic molding. The making of these tools has also been taken over by the tool and die shops.

In the second half of the 20th century, however, the traditional tool and die shop was gradually replaced by specialized job shops that produce only one form of tooling. This trend can be attributed to the growing sophistication of tooling, for shops with the skills and equipment necessary to fabricate one form of tooling are seldom equipped for another. Even the single form of toolmaking called diemaking is becoming specialized; some shops now limit themselves to dies for special applications, such as automotive body dies. There is also a trend, although not a strong one, toward specialization according to die material. Some shops make tungsten carbide dies only; others exclude tungsten carbide entirely and work only with tool steel.

Despite the trend toward specialization, the fabrication of the tools of mass production is still referred to as tool and die making and its practitioners as tool and die makers.

Pressworking dies. The fabrication of pressworking dies constitutes the major part of the work done in tool and die shops. Most pressworking dies are utilized in the fabrication of sheet-metal parts that range in size from the finger stop on a dial telephone to the panels of an automobile body. Each pressworking die consists of two sections, called punch and die, or male and female. Both sections are mounted firmly in an electrically or hydraulically driven press. In a working cycle the press ram, on which the male section is mounted, descends into the fixed female section. Any metal interposed between the sections is cut or shaped to a prescribed form.

Like the dies, the presses range in size from extremely small to gigantic. A bench press is often small enough to be picked up manually; but the press that stamps out the roof of a car is generally about three stories high and capable of exerting tons of force.

Blanking dies. The most basic and fundamental of the pressworking dies, the blanking die, is designed to cut a shaped part out of a flat piece of sheet metal. The punch, driven downward by the press ram, pierces a flat part out of an incoming strip of sheet metal. The stamping thus produced is usually subjected to subsequent operations in more complex dies.

Forming dies. A sectional view of a forming die is shown in Figure 1, a simple example, presented here to show the elements and principles involved. As with blanking dies, the press tool consists of a male punch and a female die section. In this case, however, the descending punch forms a precut blank into a desired configuration. Correct positioning of the blank prior to forming is effected by gauges mounted on the lower die section.

Draw dies. Drawing, one of the most difficult but most frequently encountered press operations, requires a die

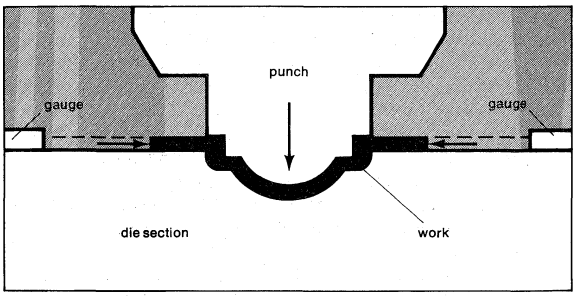

Figure 1: Forming die.

capable of inducing plastic flow in a sheet-metal part. The need for plastic flow stems from the fact that some parts cannot be formed by bending. A metal cup, a cartridge case, and the rear quarter panel of an automobile are examples. The reason that these parts cannot be formed without plastic flow is that flat sheet metal forced onto a curvilinear die surface cannot resist wrinkling. This problem can be visualized by attempting to force a sheet of paper into a drinking tumbler so that it adheres evenly and with uniform thickness to the surfaces of the sides and bottom.

Significance of plastic flow

A solution to the problem is found in a device called a holding ring, or binder (Figure 2). Before the punch contacts the metal to force it into the die cavity, the holding ring—which is pressurized—grips the edges of the metal sheet. Since the metal is restrained, the descending punch sets up a plastic flow process that enables the metal to be drawn into the die. While the physics involved in this process is rather complex, it may be said that sheet metal can be made to flow into a difficult configuration if sufficient binding pressure is exerted upon it. Without this capability, fabrication of complex sheet-metal shapes such as the modern automobile body would be difficult if not impossible. The square-cut look of vintage automobiles is not due to the early designer's preferences but to the fact that the draw process was not perfected in the early days of the automobile.

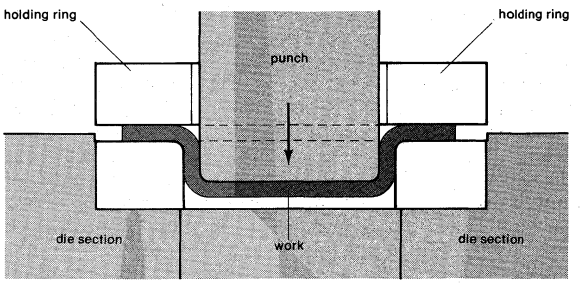

Figure 2: Draw die.

Coining dies. These dies impart embossed configurations to sheet metal parts. Obvious examples are the dies used in making coins. A strip of metal is fed through a die mounted in a small press. With each cycle of the press, an inscription is made on the sheet. Subsequently, the inscribed area is cut from the sheet by blanking to produce a coin.

Progressive dies. Such basic operations as blanking, forming, and drawing are normally performed individually. Depending on their complexity, some parts must go through a sequence of as many as 20 different operations, requiring as many as 20 different dies.

During World War I it was discovered that many different operations can be combined in a single die. The result was the progressive die, so named because the part is made by advancing through a progressive sequence of operations.

The design rationale of the progressive die is that a part outline can be defined in an incoming strip of metal by blanking or cutting away certain portions of the strip. The strip serves to carry the part through the sequence of operations, the last of which is a cutoff operation that severs the completed part. The implications of this form of tooling can be appreciated by considering that in a ten-station progressive die the press cycles ten times before the first part emerges from the die. But starting with the tenth "hit," a finished part is produced with every cycle.

Press brake dies. This form of tooling is designed for bending and forming relatively long, slender parts, such as the frames and casements of steel and aluminum windows. The dies used to form these elements may have a length-to-width ratio of 100:1, hence a specialized press is required. Called a press brake, this machine has a very narrow, bladelike ram. A variety of extremely complex forming operations can be performed in press brake operations.

Hydroforming. This recently developed process replaces the upper die half with a fluid pressure-forming chamber as shown in Figure 3. As the ram of the Hydro-

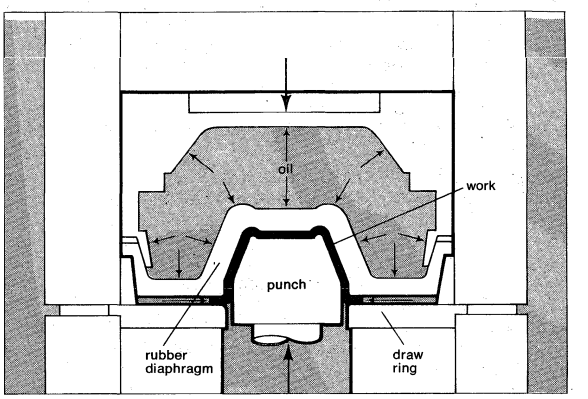

Figure 3: Hydroform die.

form machine descends, the diaphragm of the pressure chamber contacts the workpiece and forces it over a punch located in the lower half of the press. The operation performed is essentially that of drawing, but the capabilities of Hydroforming vastly exceed those of conventional drawing.

Plastic molds. The fabrication of plastic molds is another of the many forms of tool and die making. They are not properly referred to as dies, however, even though in many cases there is a visual resemblance.

The major plastic molding processes are injection molding, compression molding, transfer molding, and casting. The principal distinction between the molding processes and casting is that molding requires force while casting does not. Otherwise, the tooling involved is often quite similar.

Molding versus casting

Injection molding. As in sheet metal pressworking, two units are required—one mounted on a stationary platen, the other on a movable platen. The latter resembles the ram in a metalworking press, although the configuration of the machine is horizontal rather than vertical.

Design of the two mold halves is such that—when brought together—they make up a system of closed cavities linked by passages called runners. The runners, in turn, are linked to a central orifice called a sprue. Upon closure of the two mold units, a device called a reciprocating screw forces liquid plastic into the sprue. Continuing pressure from the screw forces the plastic into the runners, then into the cavities. The plastic then solidifies, the molds open, and the finished parts—along with their connecting runners—are ejected.

Parts formed by injection molding can be either thermoplastic or thermosetting. The distinction is that a thermoplastic can be resoftened by the application of heat whereas a thermosetting material cannot. This makes relatively little difference in mold design, but it does make a substantial difference in the design of the injection-molding machine.

Compression molding. Seldom used for thermoplastics, compression molding is one of the more commonly used methods of processing thermosetting materials. In this technology a plastic material in powdered form is placed in a mold. The mold halves then close, subjecting

the powder to high compressive forces. At the same time, heat emanating from the dies liquefies the plastic, causing it to fill all recesses of the mold. Subsequent cooling by water circulating through the mold causes the plastic to harden. The mold then opens and the finished part is removed.

Fabrication of these molds is relatively simple. They must be highly polished, however, since any imperfection in the mold cavity is duplicated in the finished product. Polishing is generally accomplished by buffing the surfaces with diamond dust.

Other plastics molds. Casting, blow molding, extrusion molding, and high-pressure laminating are other plastics-working processes that require tooling fabricated in tool and die shops. It is worth noting, however, that the increasing specialization previously referred to has resulted in the emergence of the mold shop. These shops generally limit the work they accept to jobs associated with the plastic-fabricating industries.

Die-casting dies. Die-casting dies are of basically the same design as the injection mold. Two die halves are used; the two units establish a system of runners and cavities when closed. Liquid metal, usually zinc, is forced into the system by a plunger. Once in the cavities, the molten metal solidifies into a number of parts connected by solidified metal from the runners. The die-casting machine, a variation of the press, then opens and the parts are freed.

Jigs and fixtures. These two forms of tooling now constitute a small portion of the work done in tool and die shops. They are still important, but their range of applications is diminishing.

Drill jigs. Drill jigs are used when holes must be drilled in a specified relationship to various part features. Generally—although not always—a jig is a receptacle in which the workpiece can be placed and securely clamped. Precision guidance of the drill is accomplished with drill bushings. These are hardened steel devices just large enough for the drill to enter.

The ultimate form taken by any drill jig depends upon part shape and size, which means that the number of possibilities is infinite. The advent of numerically controlled machining in the early 1950s, however, largely obviated the need for jigs. In many cases hole patterns are now programmed into punched tape. Acting upon tape instructions, the machine table automatically moves the workpiece for precise positioning relative to a machine spindle, which is then activated—also by taped instructions—to machine the hole.

Use of punched tape for hole patterns

Fixtures. No really consistent semantic distinction separates a jig from a fixture. The drill jig previously discussed is often referred to as a "drill fixture." A fixture designed exclusively for drilling operation is a jig, which means that the phrase "jigs and fixtures" is as implausible as "apples and fruit." Nonetheless, this is the terminology of the industry.

When a workpiece is of such a shape that it cannot be held in a standard work-holding device such as a vise or a chuck, a special fixture is necessary. Fixtures are used to locate and position parts for virtually all machining operations, as well as for assembly and welding operations.

Tool-and-die-making facilities. *Contract shops.* Tools and dies are generally fabricated by job shops that work on a contract basis. The shops, which in many countries are family-owned, may have as few as ten men and as many as 100. For the most part they obtain their contracts to fabricate tooling through a process of competitive bidding.

To be competitive a tool and die shop must be equipped with all of the standard types of machine tools for the machining of metal parts to precise dimensions. It must also have adequate inspection devices. Finally, if a shop is in the business of building stamping dies, it must be equipped with one or more tryout presses. Thus even a small shop represents a sizable capital investment.

Shop routine

When a contract for a job is obtained, the superintendent orders the necessary steel and stock parts (screws, dowel pins, die shoes, etc.), and assigns the job to a leader, who in turn assigns it to a bench hand who subdivides it among his crew. The various parts—now referred to as details—are then laid out according to the customer's blueprint and routed to the machine leaders. After machining, the details are returned to the leader. Subsequently, they are sent to a heat-treating facility for hardening. After hardening, they are finish-ground to specified size and assembled into the finished tool.

If the job is a stamping die, it must be proved acceptable by successful operation in a tryout press. This phase of the operation is often the most difficult because it is virtually impossible to predict die performance.

Manufacturing plants. Every manufacturing plant that uses tools and dies must maintain a small tool and die facility. The work performed in these facilities is generally limited to tool maintenance. The only exceptions to this are certain very large manufacturers who can maintain a continuous flow of work in their shops and may wish for security with respect to new designs, since design plans are revealed with blueprints are released for bidding.

Topological Groups and Differential Topology

The interaction of classical and modern mathematical methods have been most productive in that area of analysis (see ANALYSIS, REAL; ANALYSIS, COMPLEX; ANALYSIS, FOURIER; ANALYSIS, FUNCTIONAL) in which topological methods (see TOPOLOGY, GENERAL) play a role. In turn, the result has stimulated much work in topology and other branches of mathematics and has important applications in theoretical physics.

It is advantageous to consider topological methods in analysis under three headings and in rather different manners. The first section, the theorems of Tikhonov (also spelled Tychonoff) and Ascoli, considers two basic theorems that can be proved in a quite general setting and the importance of which cannot be overstressed. The second section, continuous groups, after some preliminary remarks, starts from the definition of a topological group and develops a theory that is gradually seen to encompass a whole range of general results. The third section, analysis on manifolds, is largely concerned with working from some important problems in classical analysis, discusses the methods topologists have employed in tackling them, and shows how the body of theory so developed has built itself into a coherent whole. Then in the discussion of differential topology, basic concepts, methods, and classification of manifolds are treated in detail. In this way a broad view of the areas of topological groups and differential topology is presented.

The use of topology in analysis

Before proceeding, however, some elementary and general remarks on the role of topology in analysis will be helpful. A distinctive feature of topological arguments in analysis is that they are qualitative and non-numerical. A simple instance of topological reasoning is the following. A ball is thrown vertically upward and a few moments later it falls back to its starting point: one deduces that at some point on the way it must have been stationary. This observation depends, of course, on certain preconceptions about gravity and the continuity properties of space and time. When suitably formulated, they form the foundation of analysis and topology. Now in such a simple example as a falling ball an elementary ap-

plication of the Newtonian calculus will give full information about the whole motion, while the topological argument merely asserts the obvious. If, however, a single ball is now replaced by a large number of balls, moving in more complicated ways, then direct analytical computation may become too lengthy or difficult. In such a situation one may settle for some qualitative aspects of the various motions, which may be derived by topological arguments but which may be far from self-evident because of the complexity of the situation. In fact, if the various balls are replaced by planets and one proceeds to study the Newtonian motion of several bodies under their mutual gravitational attraction, extremely difficult and unsolved mathematical problems are met. It was precisely the analytical difficulties of the many-body problem that motivated the French mathematician Henri Poincaré in his pioneering work on topology around the beginning of the 20th century.

Differential topology
Basic concepts: the differentiable category
Problems and methods of differential topology
Results on the classification of manifolds

Topological methods in analysis

THE THEOREMS OF TIKHONOV AND ASCOLI

These theorems of the 20th-century Soviet mathematician Andrey Nikolayevich Tikhonov and of the 19th-century Italian mathematician Giulio Ascoli, which have far-reaching consequences throughout analysis, both make statements about the compactness of a topological space following hypotheses of compactness of spaces from which the space is constructed. A topological space is compact if every covering by open sets has a finite subcovering, and, in the case of a metric space (a space in which one can define a distance between any two points; see further TOPOLOGY, GENERAL), this is equivalent to every sequence having a convergent subsequence. If $\{X_\lambda : \lambda \in \Lambda\}$ is an arbitrary family of topological spaces, then the product topology on the product set (consisting of all functions x on Λ such that $x(\lambda) \in X_\lambda$ for each λ in Λ; see Box, equation 1) is that family containing all sets that are unions of sets of the form $\pi\{T_\lambda : \lambda \in \Lambda\}$, in which all of the sets T_λ are open in X_λ and all but a finite number of the sets T_λ are such that $T_\lambda = X_\lambda$. When the family consists of only two spaces X_1 and X_2, the product topology on $X_1 \times X_2$ consists of sets that are unions of sets of the form $T_1 \times T_2$ in which T_1 is open in X_1 and T_2 is open in X_2. Tikhonov's theorem states that the topological space consisting of the product set X with the product topology is compact whenever each X_λ is compact.

Compact spaces

Because of the importance of compact spaces, it is often useful to be able to imbed a topological space as a subspace of a compact space, thus obtaining a compactification of the original space. The construction of the compactification due to the 20th-century Czech mathematician Eduard Čech and the 20th-century U.S. mathematician M.H. Stone, which is the one most frequently employed in analysis, leans heavily on Tikhonov's theorem. It imbeds an arbitrary completely regular Hausdorff space [that is, a Hausdorff space X such that, for each element x in X and each open set U in X containing x, there exists a continuous real-valued function f such that $f(x) = 0$ and $f(X - U) = 1$] in a topological space that is a product of compact intervals of the real line. Another application of Tikhonov's theorem is in proving that the set of linear functionals of norm less than or equal to unity (one) is compact in the Banach space Y of all bounded linear functionals on a Banach space Z when Y is given the weak-star topology.

Suppose now that F is a family of continuous functions f from a topological space X to a uniform space Y. The compact-open topology on F is that topology generated by sets of the form of the set of all f such that f belongs to F and the map of f of C is contained in U (see 2) in which C is a compact subset of X and U is an open subset in the uniform topology on Y. F is said to be an equicontinuous family if, for each x in X and for each entourage V of the uniformity on Y, there exists an open set T in X containing x such that $f(T)$ is contained in the collection of all y such that y belongs to Y and the pair $f(x)$ and y belongs to V (see 3) for each $f \in F$. A general form of Ascoli's theorem asserts that when the family G of all continuous functions from X to Y is made into a topological space by being given the compact-open topology, and when F is an equicontinuous subfamily closed in this topology and such that $\{f(x) : f \in F\}$ is a compact subset of Y for each x in X, then F is a compact subset of G. One important application of Ascoli's theorem is in proving the existence of eigenvalues of Fredholm operators (see ANALYSIS, FUNCTIONAL) in the theory of integral equations. (An integral equation is one in which a function to be determined appears in the integrand of some integral.)

(1) $X = \Pi\{X_\lambda : \lambda \in \Lambda\}$

(2) $\{f : f \in F \text{ and } f(C) \subset U\}$

(3) $f(T) \subset \{y : y \in Y \text{ and } (f(x), y) \in V\}$

The English mathematician Peter John Collins has shown that both Tikhonov's theorem and Ascoli's theorem are corollaries of a single very general compactness theorem. (Ed.)

CONTINUOUS GROUPS

The name continuous groups has been employed since the 19th century for a variety of mathematical structures, some of which are not even groups. Roughly speaking, the study arose from situations in which there is an infinite number of symmetries present. The set of symmetries is called "the group of transformations admitted by" the situation. In the early days of the theory, which was fathered largely by the Norwegian mathematician Sophus Lie, much of the research was devoted to applications to the theory of differential equations. (A differential equation is an equation involving one or more derivatives of some function to be determined; see DIFFERENTIAL EQUATIONS.) As one might expect, the presence of symmetries serves to reduce many difficulties by drastically limiting possibilities. Toward the end of the 19th century, the work of a French mathematician, Élie-Joseph Cartan, shifted the course of investigation toward a deeper analysis, both algebraic and topological, of the continuous group itself. So fruitful were some of Cartan's ideas that they molded some of the basic notions of algebra and topology. The threefold structure of continuous groups—algebraic, topological, and analytic—has attracted a variety of methods of attack, some of them marked by brilliant developments. The work of Lie and of Cartan had revealed many of the fundamental properties of continuous groups before the end of the 19th century. Rather than retrace their steps, this section begins by introducing some 20th-century terms; the early developments in the relations between groups and differential equations are presented later.

The work of Élie-Joseph Cartan

Topological groups. A topological group G is a group G the elements of which are the points of a topological space for which the group operations are continuous. In greater detail, the multiplication and inverse defined in G satisfy the postulates:

- G1. The associative law: $(xy)z = x(yz)$ for all x, y, z, of G.
- G2. Existence of an identity: There is an identity element 1, such that $1x = x1 = x$ for every x of G.
- G3. Existence of an inverse: for every x of G there is an element x^{-1} such that $x^{-1}x = xx^{-1} = 1$, in which 1 is the identity element.
- G4. The mapping $x \to x^{-1}$ from G to G is continuous.
- G5. The mapping $(x, y) \to xy$ from $G \times G$ to G is continuous.

The conditions (G1)–(G3) say that G is a group. The condition that G is a topological space for which the group operations are continuous means that there is a notion of "nearness" among the various elements of G so that if x' is near x then x'^{-1} is near x^{-1} (G4) and if y' is near y then $x'y'$ is near xy (G5).

Examples of topological groups

The following are familiar examples of topological groups:

Example 1. G is the set of all real numbers with addition as the group product.

Example 2. G is the set of all complex numbers z with $|z| = 1$ and with multiplication as the group product.

Example 3. G is the set of all rigid motions in Euclidean space (the space of ordinary geometry; see TOPOLOGY, GENERAL) that keep some point O fixed. Here the group product is taken as composition of motions; that is, if T_2 and T_1 are in G, $T_2 \cdot T_1$ is the motion that takes any point p into $T_2(T_1(p))$.

Example 4. G is the group of all $n \times n$ matrices with complex coefficients and nonzero determinant, the group product being the usual matrix multiplication.

The groups in examples 1 and 2 above are Abelian; that is, $xy = yx$ for any two elements x and y. The groups in examples 2 and 3 above are compact; that is, any infinite sequence of elements $x_1, x_2, \cdots, x_n, \cdots$ contains a subsequence converging to an element of the group. The group in example 4 above is neither Abelian nor compact, but it is locally compact; that is, each element has a compact neighbourhood. Each of the groups in the examples is locally Euclidean; that is, each point has a neighbourhood resembling topologically a solid ball in Euclidean space of dimensions 1, 1, 3 and n^2, respectively.

Topological group theory

The theory of topological groups has developed in three principal directions: the theory of the algebraic structure, of the topological structure, and of representations by transformation groups.

The algebraic structure of a topological group is especially accessible to investigation in case the group operations are analytic. In greater detail, in a topological space, a continuous function can be defined as any real-valued function f with the property that $f(x')$ is close to $f(x)$ if x' is close to x. One cannot speak, however, of differentiable or analytic functions on a locally Euclidean topological space in a self-consistent fashion unless one is given a rule by which to pick out from the totality of continuous functions the differentiable and analytic functions. A locally Euclidean space with such a rule is called a differentiable or analytic manifold, as the case may be. For simplicity, this article deals with analytic manifolds.

An analytic coordinate system around a point p in an analytic manifold is a finite sequence of functions $(x_1, \cdots, x_k)$ defined near p with the property: a function f is analytic around p if, and only if, it is expressible as a convergent power series in $x_1 \cdots, x_k$ in some neighbourhood of the point p. In an analytic manifold M there is of course an analytic coordinate system around each point, but in general the coordinate system is not defined throughout the manifold.

If $(x_1, \cdots, x_k)$ is an analytic coordinate system, the map Φ: $p \to (x_1(p), \cdots, x_k(p))$ is a map of a neighbourhood of p onto a neighbourhood in Euclidean k-space E^k and the map Φ is a topological equivalence or homeomorphism of some neighbourhood of p onto a solid ball in E^k.

A map φ (taking possibly many points into a single point) of a manifold M into a manifold N is called an analytic map if for any analytic function f defined in a region of N, the composite function $f \circ \varphi$ is analytic in M [note that $f \circ \varphi(m) = f(\varphi(m))$].

A Lie group G is a topological group of a special kind: the underlying space is an analytic manifold for which the group operations are analytic. That is, the map $(x, y) \to xy$ of the analytic manifold of ordered pairs $G \times G$ into G is an analytic map, and the map $x \to x^{-1}$ of G into G also is analytic.

Infinitesimal transformations. One of the basic notions in the theory of Lie groups is that of infinitesimal transformation. If M is an analytic manifold and m is a point of M, then it is possible to speak of a tangent vector to M at m. In case M is a surface in Euclidean space, a tangent vector to a surface is regarded as a vector in the containing Euclidean space.

It is possible, however, to make a mathematically satisfactory intrinsic definition of a tangent vector to a manifold (*i.e.*, without reference to a containing Euclidean space) by means of the following consideration: a tangent vector X is completely determined once it is known how functions vary along it; that is, the directional derivative of functions along X. Hence for all purposes the notion of tangent vector X can be equated with the operation of taking the directional derivative along X. In this pragmatic spirit the following definition is adopted: a tangent vector X to a manifold M at a point m is an operator that assigns to each real-valued function f analytic around m a real number Xf, called the directional derivative of f along X, such that the effect of X upon the sum of two functions, the product of two functions, and a constant times a function are specified by certain formulas (see 4).

$$(4)\quad \begin{cases} X(f+g) = Xf + Xg \\ X(fg) = (Xf)g(m) + f(m)X(g) \\ X(af) = aXf, \text{ for analytic functions } f, g \text{ and constant } a \end{cases}$$

$$(5)\quad \partial/\partial x_i = (\partial y_1/\partial x_i)(\partial/\partial y_1) + (\partial y_2/\partial x_i)(\partial/\partial y_2) + \cdots + (\partial y_k/\partial x_i)(\partial/\partial y_k)$$

$$(6)\quad \begin{cases} X(f+g) = Xf + Xg \\ X(fg) = Xf \cdot g + f \cdot Xg \\ X(af) = aXf \end{cases}$$

It is easily proved that the set of all tangent vectors at a point m of a k-dimensional manifold constitutes a linear or vector space the dimension of which is k (over the field of real numbers). This linear space is called the tangent space to M at m, and it is denoted by $\dot{M}_m$. A vector field on a manifold M is a rule that assigns to each point m of M an element of $\dot{M}_m$. To illustrate, let $(x_1, \cdots, x_k)$ be an analytic coordinate system on a neighbourhood V of manifold M; $(\partial/\partial x_i)(m)$ denotes the operator that assigns to the analytic function $f(x_1, \cdots, x_k)$ the value of $\partial f/\partial x_i$ at the point m. Then $(\partial/\partial x_i)(m)$ is a tangent vector to M at m, and $(\partial/\partial x_1)(m), \cdots, (\partial/\partial x_k)(m)$ form a base for the vector space $\dot{M}_m$. $\partial/\partial x_i$ denotes the vector field $p \to (\partial/\partial x_i)(p)$ on the neighbourhood V. The most general vector field on V has the form $\Sigma_i A_i \partial/\partial x_i$, in which $A_1, \cdots, A_k$ are functions on V. An infinitesimal transformation on an (analytic) manifold is a vector field X such that for any analytic function f on M, the function Xf: $p \to X(p)f$ is analytic. An infinitesimal transformation on the neighbourhood V above is any vector field $X = \Sigma A_i \partial/\partial x_i$ such that the functions $A_1 \cdots, A_k$ are analytic. If $(y_1, \cdots, y_k)$ is a second coordinate system, then $\partial f/\partial x_i = \Sigma_j (\partial f/\partial y_j)(\partial y_j/\partial x_i)$, so that the form of the differential transformation is determined (see 5). An infinitesimal transformation X can also be equated with the operation $f \to Xf$ taking any analytic function f into the analytic function Xf. Indeed, any operation X assigning to any analytic function f an analytic function Xf such that the algebraic properties already specified for the directional derivative hold (see 6) for any analytic functions f and g, a being any constant, determines a unique infinitesimal transformation.

A map φ of an analytic manifold M into an analytic manifold N induces a map of the tangent space $\dot{M}_m$ into the tangent space $\dot{N}_{\varphi(m)}$ called the differential of φ at M and denoted by $d\varphi_m$, as follows: $d\varphi_m(X)f = X(f\varphi)$ for any function f analytic in M around the point m.

For example, if φ is an analytic curve in N—*i.e.*, an analytic map of the manifold of real numbers (t) into

N—then $d\varphi_t((d/dt)(t))$ is the tangent vector at the point $\varphi(t)$ that assigns to any function f on N the value $df(\varphi(t))/dt$; $d\varphi_t((d/dt)(t))$ is called the tangent to the curve φ at the point $\varphi(t)$. In case φ is a map of an analytic manifold into the real numbers—*i.e.*, φ is a real-valued function on M—then for any tangent vector X in $\dot{M}_m$, $d\varphi(X)$ is a numerical factor of the tangent vector $(d/dt)(\varphi(m))$; the numerical factor is also denoted by $d\varphi(X)$. By this convention, $d\varphi$ becomes a real-valued function of tangent vectors in case φ is an analytic (or differentiable) real-valued function on M; this $d\varphi$ coincides with the classical definition of differential.

If X is an infinitesimal transformation on an analytic manifold M, then, by the fundamental existence and uniqueness theorem of ordinary differential equations, there passes through each point p of M a unique trajectory to X with initial point p; that is, an analytic curve $\varphi(p, t)$ in M with $\varphi(p, o) = p$ and the tangent to the curve at any point q coinciding with the tangent vector $X(q)$; more explicitly, $df(\varphi(p, t))/dt = Xf(\varphi(p, t))$ for any t and for any function f analytic in M. The notation $\exp tX$ is used to denote the map $p \to \varphi(p, t)$; for any point p, $\exp tX$ is defined for suitably small values of t (but not necessarily all). Thus an infinitesimal transformation can be thought of as the velocity field of a steady flow on a manifold, and $\exp tX$ is the displacement of points after t units of time.

In the special case that M is the set of real numbers and $X = \partial/\partial x = d/dx$, $(d/dt)x(\exp tX(p)) = dx/dx = 1$ and $\exp tX(p) = p + t$. If $X = x^2 d/dx$, then $\exp tX(p)$ is the trajectory to $dx/dt = x^2$, and $\exp tX(p) = p/(1 - pt)$, which is not defined for $t = 1/p$. The term infinitesimal transformation owes its origin to the fact that for small values of the parameter t, the transformation $\exp tX$ consists of the displacement (see 7) up to infinitesimals of order t^2 if $X = \Sigma_i A_i \partial/\partial x_i$. If X is an infinitesimal transformation on a manifold, then $f(\exp tX(p)) = \Sigma(1/n!)t^n X^n f(p)$, the sum taken from $n = 0$ to ∞, whenever both sides are defined. This identity can be stated in a more familiar form when the following notational convention is adopted: if φ is a map of a space M into a space N, $\varphi(f)$ denotes the composite function $f \circ \varphi$ where f is a function on N. Thus by definition, $f(\varphi(m)) = (\varphi(f))(m)$. By this convention φ is regarded not only as a map of points of M into points of N but also as the equivalent indicated map of functions on N into functions on M. Adhering to this convention, the identity above states the formal expansion of the exponential (see 8) as operators on analytic functions on M, whenever both sides can be applied.

It is clear from (8) that a point m is fixed under the transformation $\exp tX$ for all t if, and only if, the point m is a zero of X; *i.e.*, $X(m) = 0$ or $Xf(m) = 0$ for any analytic function f.

Local (pseudo-) groups of transformations. If G is a topological group and M a topological space and $P(M)$ denotes the set of all permutations of M (*i.e.*, all transformations of M onto M which have inverses), then an operation of G on M is a rule T that assigns to each g in G an element $T(g)$ in $P(M)$ in such a way that multiplication in G corresponds to composition in $P(M)$ (see 9). Moreover, the element $T(g)(m)$ should depend continuously on g and m. If G is a Lie group and M is an analytic manifold, an operation is called analytic if the point $T(g)(m)$ depends analytically on g and m. An important variation on this idea is that of a local pseudo-group (sometimes called simply local group) operating on a manifold. Briefly, a local Lie group is a structure that resembles a neighbourhood N of the identity in a Lie group; products are not always defined, but, when they are, the group postulates are fulfilled. The celebrated first and second fundamental theorems of Lie describe the relation between local Lie groups on a manifold and infinitesimal transformations.

An analytic family N of transformations of M is a one-to-one map T of N into $P(M)$ such that $T(n)(m)$ depends analytically on n and m. It is assumed that for some n_0 in N, $T(n_0)$ is the identity transformation of M. The map T_n is considered, which assigns to each tangent vector

(7) $(x_1, \cdots, x_k) \to (x_1 + tA_1, \cdots, x_k + tA_k)$

(8) $\exp(iX) = \sum_0^\infty (n!)^{-1} i^n X^n$

(9) $T(g_1 g_2) = T(g_1) \circ T(g_2)$

(10) $T_n(X)(m) = d\phi_n(X)$

(11) $\begin{cases} X = \Sigma_i A_i \dfrac{\partial}{\partial x_i}, \qquad Y = \Sigma_i B_i \dfrac{\partial}{\partial x_i} \quad \text{and} \\ [X, Y] = \Sigma_{ij}\left(A_j \dfrac{\partial B_i}{\partial x_j} - B_j \dfrac{\partial A_i}{\partial x_i}\right)\dfrac{\partial}{\partial x_i} \end{cases}$

(12) $\begin{cases} [X, Y] = -[Y, X] \quad \text{and} \\ [[X, Y], Z] + [[Y, Z], X] + [[Z, X], Y] = 0 \end{cases}$

(13) $\exp(t_1 X_1) \cdot \exp(t_2 X_2) \cdot \ldots \cdot \exp(t_r X_r)$

(14) $\{\exp X; X \in \mathfrak{F}\}$

$X \in \dot{N}_n$ an infinitesimal transformation $T_n(X)$ by the rule that involves the differential of φ (see 10) in which $\varphi: p \to (T(p) \cdot T(n)^{-1})(m)$ maps N into M and n into m. Roughly speaking, the infinitesimal transformation $T_n(X)$ describes how $T(p)$ differs from $T(n)$ as the point p moves away from the point n along a path the tangent vector of which at n is X.

Lie's first fundamental theorem

Lie's first fundamental theorem states that $T_n(\dot{N}_n)$ is independent of the point n if, and only if, N is a local Lie group and T is an analytic operation of N on M. If this is the case, the family of infinitesimal transformations $T_n(\dot{N}_n)$ is called the infinitesimal generator of the local Lie group of transformations $T(N)$.

It is readily verified that if X and Y are infinitesimal transformations on M, the operator $XY - YX$ is an infinitesimal transformation. $XY - YX$ is denoted by $[X, Y]$ and is called the Poisson bracket of X and Y. If $(x_1, \cdots, x_k)$ is an analytic coordinate system on a neighbourhood in M, then the specific forms for the infinitesimal transformations X and Y lead to an explicit structure in the Poisson bracket (see 11).

Directly from definitions, it may be seen that two identities follow (see 12); the latter one is known as the Jacobi identity.

If $\mathfrak{F}$ is a set of infinitesimal transformations it is called a Lie algebra of infinitesimal transformations if (1) $\mathfrak{F}$ is a linear family—that is, $\mathfrak{F}$ contains any linear combination of its elements with constant coefficients; and (2) $\mathfrak{F}$ contains the Poisson brackets of any of its elements.

Lie's second fundamental theorem

Lie's second fundamental theorem states that a family of infinitesimal transformations $\mathfrak{F}$ is the infinitesimal generator of a finite-dimensional local Lie group of transformations if, and only if, $\mathfrak{F}$ is a finite-dimensional (over the field of constants) Lie algebra of infinitesimal transformations. The corresponding local Lie group of transformations is the set of all transformations of the form of a product of exponentials (see 13) in which $X_1, \cdots, X_r$ is a base for $\mathfrak{F}$ and $t_1, \cdots, t_r$ is any set of real numbers that are suitably small. The elements of the corresponding local group can also be described as the set of all transformations of exponential type with X belonging to the family of infinitesimal transformations (see 14). It may happen that the corresponding local group G is indeed a genuine group. In that case neither the elements of the form (6) nor (7) necessarily exhaust G; they merely cover a neighbourhood of the identity in G in general.

In case the family $\mathfrak{F}$ of Lie's second fundamental theorem is infinite-dimensional, there arises a so-called infinite Lie pseudo-group. These pseudo-groups were studied extensively by Cartan, but basic questions about the nature of such structures were left unanswered. In the

1950s several independent investigations into some of these questions were initiated. In this article, however, the term Lie group is reserved for the finite-dimensional case alone.

With the help of his second fundamental theorem, Lie was able to determine all the local groups of transformations depending on a finite number of parameters (constants that distinguish special cases) that operate on the line, plane, and, in certain cases, on higher dimensional spaces. For example, it is relatively easy to show that the only finite-dimensional Lie algebras of infinitesimal transformations on the line that have no common zeros have in suitable coordinates one of three bases (see 15). These are the generators of three basic groups (see 16). These three are thus up to equivalence the only finite-dimensional local Lie groups operating transitively on the line.

The last example shows clearly that a local group of transformations of the line need not be a piece of a global group of transformations of the line. It is true, however, that any local Lie group has a neighbourhood of its identity that is *in abstracto* isomorphic (in a one-to-one correspondence) to a neighbourhood of the identity in some genuine (global) Lie group.

The Lie algebra of a Lie group. Consider now a Lie group G. For each g in G, $T(g)$ denotes the left translation map $x \to gx$ of G onto G. Then T is an analytic operation of G on G. By Lie's first fundamental theorem, the group $T(G)$ has an infinitesimal generator, and by Lie's second fundamental theorem, the infinitesimal generator is a Lie algebra of infinitesimal transformations; this infinitesimal generator is denoted by $\dot{G}$ and is called the Lie algebra of G. It is readily proved that $\dot{G}$ consists of precisely those infinitesimal transformations on G that are left unchanged by the right translations $x \to xg$ of G into G. It follows at once that each infinitesimal translation in G is uniquely determined by its value at the origin. Thus as a linear space, $\dot{G}$ is equivalent to $\dot{G}_e$, the tangent space of G at the identity element e. If X is an element of G_e, and $\overline{X}$ is the element of G determined by X, then one defines $\exp \overline{X}(e)$. Also, $[X, Y]$ is defined to be the value at e of $[\overline{X}, \overline{Y}]$, in which $\overline{X}$ and $\overline{Y}$ are the elements of G with $\overline{X}(e) = X$ and $\overline{Y}(e) = Y$.

In the special case that G is the group $GL(n)$ of all inversible linear transformations of an n-dimensional linear space V_n over the real numbers, the tangent space to G at the identity element can be identified with the set of all linear transformations of V_n. Then for any $X \in \dot{G}_e$, $\exp X$ coincides with the classical exponential of the transformation X; that is, $\exp X = \Sigma_i X^i/i!$. For any X and Y in $\dot{G}_e$, $[X, Y] = XY - YX$, in which the multiplication on the right is the usual multiplication of linear transformations.

If the algebraic structure alone is abstracted from $\dot{G}$, it is seen to be an algebra with Poisson brackets as multiplication. This multiplication is nonassociative, but the structure of such algebras is capable of a virtually exhaustive description. On the other hand, there is a very close connection between the algebraic structure of a Lie group and the algebraic structure of its Lie algebra. Indeed, there is a one-to-one correspondence between the subalgebras of the Lie algebra $\dot{G}$ and the connected Lie subgroups of G, the correspondence being: a connected Lie subgroup H corresponds to the subalgebra of $\dot{G}$ that is determined by the tangent subspace H_e to H at the identity. A connected Lie subgroup H is normal in G if, and only if, the corresponding subalgebra $\dot{H}$ is an ideal in G; that is, $[\dot{G}, \dot{H}]$ is contained in $\dot{H}$. To the commutator subgroup of G generated by the elements of the form $xyz^{-1}y^{-1}$, there corresponds the derived subalgebra that is generated by the elements $[X, Y]$ with X and Y in $\dot{G}$. In particular, a connected Lie group G is Abelian if, and only if, $[X, Y] = 0$ for all X and Y in $\dot{G}$.

The most elementary type of Lie algebra is one wherein the multiplication is trival; *i.e.*, $[G, G] = 0$. Such a Lie algebra is called Abelian. Next in complexity is a Lie algebra wherein the product of some finite number of any elements is zero; *i.e.*, if setting $G^{(1)} = G$, $G^{(n+1)} = [G^{(n)}, G]$, then $G^{(n)} = 0$ for some n. Such a G is called nilpotent. One step more complex are Lie algebras G that have a decreasing sequence of ideals, $G \supset G_1 \supset \cdots \supset G_n \cdots$ with the quotient algebra G_i/G_{i+1} Abelian and $G_n = 0$ for some n; such a Lie algebra is called solvable. The maximum solvable ideal of a Lie algebra is called its radical. If G is a Lie algebra and R denotes its radical, then G/R has no nonzero radical; such a Lie algebra is called semisimple. If a Lie algebra has no nonzero properly smaller ideal, it is called simple.

Theorems describing the structure of Lie algebras

The basic theorems describing the structure of Lie algebras over any field of characteristic zero areas may be stated as follows:

Any Lie algebra is a semidirect sum of its radical and a semisimple subalgebra.

Any semisimple Lie algebra is a direct sum of simple Lie algebras.

Any simple Lie algebra over the field of complex numbers is one of the following type:

A_n: the Lie algebra of the group of all $n+1$ by $n+1$ complex-valued matrices of determinant 1.

B_n: the Lie subalgebra of A_{2n} that annihilates the quadratic form composed of a sum of squares of $\{x_k\}$ (see 17).

C_n: the Lie subalgebra of A_{2n-1} that annihilates the alternating bilinear form (see 18).

D_n: the Lie subalgebra of A_{2n-1} that annihilates the quadratic form composed to a sum of squares of $\{x_k\}$ (see 19).

The five exceptional simple Lie algebras G_2, F_4, E_6, E_7, E_8 discovered by the mathematician W. Killing are of dimensions 14, 52, 78, 133, 248, respectively. This remarkable classification is achieved by a study of the so-called root diagram of the Lie algebra.

Although each Lie group has a unique Lie algebra, a Lie algebra in the abstract (*i.e.*, divorced from its presentation as the infinitesimal generator of a Lie group) may arise from inequivalent or nonisomorphic groups. For example, the one-dimension Abelian Lie algebra over the field of real numbers is the Lie algebra of both example G1 and example G2 above. The problem of determining the relation between the various connected Lie groups having abstractly isomorphic Lie algebras was solved by the mathematician Otto Schreier.

The situation may be described in this way: to each abstract Lie algebra g (over the field of real numbers) there corresponds a unique (up to isomorphism) simply connected Lie group G—that is, a connected Lie group in which every closed curve can be deformed continuously to a point; any other Lie group G_1 the Lie algebra of which is isomorphic to g is obtained from G by a homomorphism with a discrete kernel. Thus G_1 is evenly covered by G, and all connected Lie groups the Lie algebras

(15) (*a*) $\frac{d}{dx}$; (*b*) $\frac{d}{dx}, x\frac{d}{dx}$; or (*c*) $\frac{d}{dx}, x\frac{d}{dx}, x^2\frac{d}{dx}$

(16)
- (*a*) one-parameter translation group: $x \to x + t$
- (*b*) two-parameter affine group: $x \to ax + b$
- (*c*) three-parameter projective group: $x \to \frac{ax+b}{cx+d}$, $\det\begin{vmatrix} a & b \\ c & d \end{vmatrix} \neq 0$

(17) $x_1^2 + x_2^2 + \cdots + x_{2n+1}^2$

(18) $x_1y_{n+1} - y_1x_{n+1} + x_2y_{n+2} - y_2x_{n+2} + \cdots + x_ny_{2n} - y_nx_{2n}$

(19) $x_1^2 + \cdots + x_{2n}^2$

of which are isomorphic to G have the same simply connected covering group. The spin representation of physics provides another example of this phenomenon.

It should be emphasized, however, that in a neighbourhood of the identity, any two Lie groups having isomorphic Lie algebras are isomorphic. This can be seen from the Baker–Campbell–Hausdorff formula (see 20) that identifies the product of exponentials with the exponential of an algebraic form involving an infinite sum of terms built from X and Y with Poisson brackets. By a process known as complexification it can be proved that the classification of complex simple Lie algebras also applies to compact Lie groups.

The topological structure of Lie groups. It has been shown that to a given abstract Lie algebra there may correspond Lie groups that are not topologically equivalent. Therefore, it cannot be expected that the abstract Lie algebra $\dot{G}$ of a Lie group G determines the topological structure of G completely. One of the greatest contributions of Cartan to mathematics, however, was his demonstration that the Lie algebra G determines the important topological invariants called Betti numbers of the group G in the very important case that the Lie group G is compact and connected.

Cartan's researches on this problem led him to invent his theory of exterior differential forms and to conjecture the celebrated de Rham theorems, which were proved by his student Georges de Rham.

Exterior differential calculus. If V is a vector space, then the exterior algebra over V is understood to be an associative algebra $E(V)$ generated by the elements of V together with a unit element 1 such that the product of p elements $x_1 \cdot x_2 \cdot \cdots \cdot x_p$ is not zero in $E(V)$ if, and only if, $x_1, \cdots, x_p$ are linearly independent in V. Because $x^2 = 0$ for any x in V, it follows that $x \cdot y = -y \cdot x$ for any x and y in V. If V^* denotes the dual space of linear functions on V, then $E(V^*)$ can be identified in a natural way with the set of skew-symmetric multilinear functions on V, the product of two forms φ_p and Ψ_q, respectively p-linear and q-linear, being given by a formula (see 21). The algebra $E(V^*)$ is called the Grassmann algebra of V—after the 19th-century German mathematician Hermann Günther Grassmann. An exterior differential p-form on an analytic manifold M is a rule that assigns to each point m of M an element of degree p of the Grassmann algebra $E(\dot{M}_m{}^*)$, $\dot{M}_m$ being the tangent space to M at m. In the language of tensors, an exterior differential p-form is a covariant skew-symmetric tensor field of degree p. The novel operation introduced by Cartan is exterior differentiation of exterior differential forms. This operation assigns to any exterior differential p-form w a $(p+1)$-form dw such that:

D1. d is linear.
D2. d applied to a function or zero form is the usual differential.
D3. $d(w_1 \cdot w_2) = dw_1 \cdot w_2 + (-1)^p w_1 \cdot dw_2$, in which p is the degree of w_1.
D4. $ddw = 0$ for any form w.

For example, if w is given as a differential of degree one or two, its differential is easily computed (see 22). The geometric significance of exterior differentiations is seen in the generalized Green-Stokes theorem (named after the 19th-century British mathematicians George Green and George Gabriel Stokes): If S is a p-dimensional hypersurface bounding the $(p+1)$-dimensional solid region R, then the surface integral of w and the volume integral of dw are equal (see 23).

Exterior differentiation has the fundamental property that it commutes with maps. That is, suppose that φ is a map of a manifold M into a manifold N, and that ω is an exterior differential p-form on N. Extending the notational convention that was adopted above, one denotes by $\varphi(\omega)$ the p-form on M that is the "pullback" of the exterior differential p-form ω (see 24). It follows from the properties D1 through D4 that for any analytic map φ, this maps the differential into the differential of the "pullback" (see 25). In addition, because φ preserves the addition and multiplication of exterior forms, it is possible to say that φ yields a differential algebra homomorphism.

Closed forms

An exterior differential form ω is called closed if $dw = 0$; it is called exact if $w = du$. Because $d^2 = 0$, every exact form is closed. Conversely, if w is exact, then in any suitably small neighbourhood V there is a form u such that $du = w$ in V. Nevertheless, a closed form does not necessarily have to be exact. The set of closed forms constitutes a vector space and the set of exact forms is a subspace.

De Rham's theorem states that the quotient space of closed exterior p-forms by the exact p-forms is the p-dimensional Betti group, so that the dimension of this space is the pth Betti number of M, which is denoted $\beta_p(M)$. Because, locally, every closed form is exact, the number $\beta_p(M)$ must clearly depend on the global structure of M. Cartan showed that for a compact connected Lie group G, $\beta_p(G)$ is determined by the Lie algebra $\dot{G}$. This success of Cartan encouraged a closer study of the topological structure of Lie groups in an attempt to determine for them the various finer topological invariants that were being introduced in topology.

The central position occupied by compact groups in topological questions concerning Lie groups was clearly established when it was discovered that any Lie group with a finite number of connected components is topologically a product of any of its maximal compact subgroups and a Euclidean space. Thereby the question of topological structure of Lie groups was reduced to the case of compact Lie groups, which are more amenable to topological treatment.

The principal results on topological structure of compact groups are that the structure called a cohomology ring with real coefficients of a compact Lie group is isomorphic to the cohomology ring of a direct product of spheres; but a compact Lie group is not, in general (even in the simply connected case), topologically equivalent to a direct product of spheres. This last result follows from a computation of the Steenrod reduced power operations in compact Lie groups that was carried out in 1954 by the mathematicians Armand Borel (Swiss) and Jean-Pierre Serre (French).

The torsion groups of nearly all compact Lie groups have also been determined. The compact Lie groups $\mathrm{So}(n)$ and $\mathrm{Sp}(n)$ (the special unitary group and symplectic group, respectively) have no torsion; Spin (n), the two-sheeted covering group of the orthogonal group, has no torsion for $n \leq 6$. $\mathrm{So}(n)$ $(n \geq 3)$ and Spin (n) $(n \geq 7)$ have 2-torsion and all their torsion coefficients are equal to 2.

Representations as transformation groups. It is natural to compare general topological groups with special ones, and in particular much attention has been devoted to the study of homomorphisms of topological groups into groups of linear transformations or matrix groups. This study has achieved far-reaching results that throw fresh light on the classical Fourier transform (see ANALYSIS, FOURIER) and the theory of special functions (see DIFFERENTIAL EQUATIONS). Only two results will be mentioned here.

A. The theorem of the 20th-century mathematicians Fritz Peter (German) and Hermann Weyl (German-born U.S.) states that any compact Lie group is isomorphic to a subgroup of the unitary group.

B. The theorem of the Russian mathematician I. Ado states that any real Lie algebra is isomorphic to a Lie algebra of matrices. Thus any Lie group has a neighbourhood of its identity in which multiplication is isomorphic to multiplication in some matrix group.

Turning now to more general types of representations, there have been several investigations of the global relations between topological groups and the types of spaces in which they can operate as groups of continuous transformations, as well as special properties of the operations themselves. In order to indicate the scope of such investigations, several of the results may be mentioned; these are as follows:

A. The only two-dimensional surfaces on which a Lie group can operate transitively (*i.e.*, carrying any point into any other point) are the plane, sphere, torus (a doughnut-shaped object), projective plane, cylinder, Mö-

bius band (a one-sided surface; see TOPOLOGY, GENERAL), and Klein bottle (a one-sided surface in the shape of a bottle).

B. A compact connected Lie group operating transitively and effectively (*i.e.*, so that each element other than the identity moves some point) on an even-dimensional sphere is simple; more generally, if M is a manifold the Euler-Poincaré characteristic of which $(\Sigma(-1)^p\beta_p(M))$ is a prime number, then any compact connected Lie group operating on M is simple.

C. If a Lie group G operates transitively on a compact simply connected space M, then some compact subgroup of G operates transitively on M.

D. If a Lie group operates transitively on a space M having no "holes," then M is topologically Euclidean space.

E. If a compact Lie group G operates on a manifold M, then the operation is topologically equivalent to the operation of a group of rotations of some (higher dimensional) Euclidean space on a subspace that is topologically equivalent to M.

F. If a compact connected Abelian Lie group operates on Euclidean space, then it must leave some point fixed, and the set of fixed points resemble a plane topologically in three or more dimensions.

Hilbert's fifth problem. Among the celebrated 23 problems for research that were proposed by the German mathematician David Hilbert in his address to the International Mathematical Congress of 1900 was the conjecture that any locally Euclidean topological group can be given the structure of an analytic manifold so as to become a Lie group. In 1929, the Hungarian-born United States mathematician John von Neumann was able to exploit the theory of integral equations on a Lie group that had been developed in 1927 by Peter and Weyl because he was able to introduce integration on general compact groups; thereby von Neumann succeeded in solving the Hilbert problem for compact groups.

The next great inroad on this problem came with the discovery by the Hungarian mathematician Alfréd Haar in 1932 that in any locally compact topological group one can introduce a measure and an integral invariant under all group translations $x \to yx$; that is, for any function f defined on a locally compact group G, the integral over G, $\int f(x)dx$, satisfies, in addition to the usual rule of linearity, also the condition that it equals the integral over G of the same function with yx substituted for x (see 26).

In 1934 the Soviet mathematician Lev Semyonovich Pontryagin was able to prove Hilbert's conjecture for Abelian groups as a by-product of his theory of characters on locally compact Abelian groups.

The final complete solution of Hilbert's fifth problem came in 1952 as a result of the work of the U.S. mathematicians Andrew Mattei Gleason, Deane Montgomery, and Leo Zippin. Indeed, it was found that any locally compact topological group is a limit of Lie groups. This profound result affirmed the central position of Lie groups in the theory of continuous groups.

Algebraic linear groups. An algebraic linear group is a subgroup of the group of all nonsingular $n \times n$ matrices $L(n)$ defined by the vanishing of polynomials (see ALGEBRA, ELEMENTARY AND MULTIVARIATE) in the matrix coefficients (see ALGEBRA, LINEAR AND MULTILINEAR), which is a subgroup of $L(n)$ that is the intersection of $L(n)$ with an algebraic variety. If the underlying field is the field of real or complex numbers, then any algebraic linear group is a Lie group, but not conversely. On the other hand, most of the questions involving linear groups that arise in mathematics reduce to problems concerning groups that are algebraic. It is natural, therefore, to seek the special properties that characterize algebraic linear groups and their Lie algebras. This study was initiated by the mathematician L. Maurer in the 19th century and resumed in mid-20th century by the mathematician Claude Chevalley, and others.

The theory of algebraic linear groups has thrown fresh light on the relation between an arbitrary Lie group and the set of all its finite-dimensional linear representations; this development was initiated by the mathematician T. Tannaka in an effort to generalize Pontryagin's duality theory of characters, and it was carried further by the mathematicians Gerhard Paul Hochschild and George Daniel Mostow.

Chevalley's theory of algebraic groups was carried out for arbitrary ground field, even fields of prime characteristic p. This theory in characteristic p rested on very different considerations from the classical theory in characteristic zero but arrived at identical conclusions about the classification of simple groups. Moreover, Chevalley's work established a significant connection between finite simple groups and simple Lie groups.

Invariants of an exterior differential system. The principal application of continuous groups to the solution of differential equations consists in forming first integrals of a system of differential equations from the infinitesimal generators of a group admitted by the system. The number of unknowns involved in the system is thereby reduced.

For simplicity of illustration, only systems of the type characterized by all $\{w_k\}$ vanishing (see 27) will be considered, in which $w_1, \cdots, w_n$ are independent differential 1-forms (*i.e.*, linear differential forms) on an $(n+1)$-dimensional manifold. The solutions of (27) are called integral curves, functions that are constant on solutions are called first integrals, and differential forms expressible in terms of first integrals and their differentials are called invariant forms. A first integral is thus an invariant 0-form. The system (27) is said to admit a transformation φ if φ carries solutions of (27) into solutions and to admit the infinitesimal transformation X if it admits the transformation $\exp tX$ for all small t.

The passage from groups of transformations admitted by (27) to first integrals of (27) is via invariant forms of (27). There are three simple principles for the formation of invariant forms out of given ones:

(A) If w is an invariant form, then dw is also invariant.

(B) If the system (27) admits the infinitesimal transformation X, and if w is an invariant form, then Xw is an invariant form.

(C) Under the hypotheses of (B), the form $\partial_x w$ is an

(20) $$(\exp X)(\exp Y)=\exp(X+Y-\tfrac{1}{2}[X,Y]+\cdots)$$

(21)
$$\begin{cases} \phi_p\cdot\psi_q(X_1,\cdots,X_{p+q}) \\ \quad=(p+q)!^{-1}\sum_\sigma(-1)^{\epsilon(\sigma)}\phi_p(X_{\sigma(1)},\cdots,X_{\sigma(p)})\cdot \\ \qquad\cdot\psi_q(X_{\sigma(p+1)},\cdots,X_{\sigma(p+q)}) \\ \text{where } \sigma \text{ ranges over all permutations of } 1,\cdots,p+q \\ \text{and } \epsilon(\sigma)=\pm1 \text{ is the sign of } \sigma \end{cases}$$

(22)
$$\begin{cases} w=P\,dx+Q\,dy+R\,dz, \qquad dw=\left(\frac{\partial Q}{\partial x}-\frac{\partial P}{\partial y}\right)dx\,dy+ \\ \quad+\left(\frac{\partial P}{\partial y}-\frac{\partial Q}{\partial z}\right)dy\,dz+\left(\frac{\partial P}{\partial z}-\frac{\partial R}{\partial x}\right)dz\,dx; \\ \text{if} \quad w=R\,dx\,dy+Q\,dy\,dx+P\,dz\,dx, \quad \text{then} \\ dw=\left(\frac{\partial P}{\partial x}+\frac{\partial Q}{\partial y}+\frac{\partial R}{\partial z}\right)dx\,dy\,dz. \end{cases}$$

(23) $$\int_S w=\int_R dw$$

(24) $$\phi(\omega)(X_1,\cdots,X_p)=\omega(d\phi(X_1),\cdots,d\phi(Xp))$$

(25) $$\phi(d\omega)=d(\phi(\omega))$$

(26) $$\int_G f(yx)dx=\int_G f(x)dx$$

(27) $$w_1=\cdots=w_n=0$$

invariant form, in which, for any p-form w, $\partial_X w$ is the $(p-1)$-form defined by "contraction" of the p-form w with x (see 28).

Suppose the system (27) admits an n-dimensional Lie group of transformations G whose Lie algebra $\mathfrak{G}$ has a base $X_1, \cdots, X_n$ such that the determinant $w_i(X_j)$ is not zero.

The forms $w_1, \cdots, w_n$ are replaced by linear combinations $w_1', \cdots, w_n'$ such that $w_i'(X_j) = \delta_{ij}$—for $i, j = 1, \cdots, n$. The linear forms $w_1', \cdots, w_n'$ are invariant forms of (27) and are called the forms dual to $X_1, \cdots X_n$. If $[X_i, X_j] = \Sigma_s c_{ijs} X_s$, then $dw_s' = -\sum_{ij} c_{ijs} w_i' w_j'$. It follows that if G is solvable, then the equation (27) can be solved by n successive quadratures. This is an analogue of the 19th-century French mathematician Évariste Galois's celebrated theorem on the solution of algebraic equations by radicals. Consider, for example, the specific equation (29) that is invariant under the group G generated by translations along the x-axis and by uniform stretching; this second-order differential equation is put in form (27) by introducing the new variable y' and (29) then becomes two equations in differentials (see 30).

The group G operates in (x, y, y')-space, and its infinitesimal generators are the differential operator with respect to x and a generator that is formed with differential operators with respect to x and y (see 31). The dual forms are expressed in terms of F (see 32). Because $[X_1, X_2] = X_1$, it follows that the differentials (see 33) are such that w_2' is exact and gives by integration the first integral u_2 with $du_2 = w_2'$. On the surface $u_2 = C_1$, $w_1' = 0$, and thus $w_1' = 0$ can be integrated. The results of the two successive integrations are expressed in terms of exponentials with integrals involving the function F (see 34).

The Poincaré invariant integral and Cartan's associated form. The French mathematician Henri Poincaré has shown that for any Hamiltonian system (see 35) the form $w = \Sigma_i dp_i dq_i$ has the property that $\int_D w$ over any two-dimensional manifold D in $(p_1, \cdots, p_n, q_1, \cdots, q_n)$-space is independent of t. A differential form with such a property is called a Poincaré integral invariant. If $F(x_1, \cdots, x_k, t, dx_1, \cdots dx_k)$ is a Poincaré integral invariant of a system in which derivatives are identified with functions of the variables and t (see 36), then $F(x_1, \cdots, x_k, t, dx - A_1 dt, \cdots, dx - A_k dt)$ is an invariant form of the system expressible in terms of differentials and the functions A_k (see 37) and it is called the associated Cartan form.

The associated Cartan form of $\Sigma_i dp_i dq_i$ is therefore expressible in terms of the differentials of H (see 38). This Cartan form is not only an invariant of the system in associated differential form (see 39), but it also actually determines the system, which is the first Pfaffian (or associated characteristic) system of w'. Any infinitesimal transformation admitted by the equations of motion leads to an invariant 1-form by way of the principle in (C) applied to w'. Quite frequently, such 1-forms are exact, and by integration first integrals are obtained. In this way the known first integrals of the n-body problem can be derived.

Poisson parentheses and contact transformations. A nondegenerate bilinear form B on a finite-dimensional vector space V determines a one-to-one linear map B_1 of V onto its dual space of linear functions V^* by the rule that $B_1(v)(w) = B(v, w)$. This map produces, out of functions on V, functions on V^*. In particular, it is the case that the function B produces the bilinear function B^* in V^* (see 40).

Now if M is a manifold (necessarily of even dimension) on which there is defined an exterior differential closed 2-form β that is nondegenerate at all points and if f and g are functions on M, it is possible to form the function (f, g) in terms of differentials (see 41); the function (f, g) is called the Poisson parentheses of f and g with respect to β. In the neighbourhood of any point, coordinates $(p_1, \cdots, p_n, q_1, \cdots, q_n)$ can be found such that $\beta = \Sigma_i dp_i dq_i$. A simple computation gives the Poisson parentheses (see 42). The function (f, g) is characterized by an identity (see 43) in which the dot is exterior multiplication and $2n = \dim M$. Poisson parentheses may be defined alternatively in terms of Poisson brackets (see 44). Transformations of a manifold of dimension $2n$ or $2n+1$ preserving an exterior 2-form β of maximum possible rank were called by Lie restricted nonhomogeneous contact transformations with respect to β. Lie studied more general nonhomogeneous contact transformations that preserve the equation $w = 0$ in which w is a differential 1-form on a $(2n+1)$-dimensional manifold such that $w(dw)^n \neq 0$; also, homogeneous contact transformations of a $2n$-dimensional manifold preserving a 1-form w such that $(dw)^n \neq 0$. The best example of a

(28) $$\partial_X w(X_1, \cdots, X_{p-1}) = w(X, X_1, \cdots, X_p)$$

(29) $$y\frac{d^2y}{dx^2} = F\left(\frac{dy}{dx}\right)$$

(30) $$\begin{cases} dy - y'dx = 0 \\ ydy' - F(y)dx = 0 \end{cases}$$

(31) $$X_1 = \frac{\partial}{\partial x}, \qquad X_2 = x\frac{\partial}{\partial x} + y\frac{\partial}{\partial y}$$

(32) $$\begin{cases} w_1' = dx - \dfrac{x}{y}dy - \dfrac{y - xy'}{F(y')}dy' \\ w_2 = \dfrac{dy}{y} - \dfrac{y'}{F(y')}dy \end{cases}$$

(33) $$\begin{cases} dw_2' = 0 \\ dw_1' = w_1' w_2' \end{cases}$$

(34) $$\begin{cases} y = C_1 \exp \displaystyle\int \frac{y'dy'}{F(y')} \\ x = C_1 \exp\left(\displaystyle\int \frac{1}{F(y')}\left(\exp \int \frac{y'dy'}{F(y')}\right)dy'\right) + C_2 \end{cases}$$

(35) $$\begin{cases} \dfrac{dp_i}{dt} = -\dfrac{\partial H}{\partial q_i} \\ \dfrac{dq_i}{dt} = \dfrac{\partial H}{\partial p_i}, \qquad i = 1, \cdots, n \end{cases}$$

(36) $$\frac{dx_i}{dt} = A_i(x_1, \cdots, x_k, t), \qquad i = 1, \cdots, k$$

(37) $$\frac{dx_1}{A_1} = \frac{dx_2}{A_2} = \cdots = \frac{dx_k}{A_k}$$

(38) $$\begin{cases} w' = \displaystyle\sum_i \left(dp_i + \frac{\partial H}{\partial q_i}dt\right)\left(dq_i - \frac{\partial H}{\partial p_i}dt\right) \\ \quad = \Sigma_i dp_i dq_i - dH\,dt \end{cases}$$

(39) $$\frac{dp_1}{-\dfrac{\partial H}{\partial q_i}} = \cdots = \frac{dq_n}{\dfrac{\partial H}{\partial p_n}}$$

(40) $$B^*(x, y) = B(B_1^{-1}(x), B_1^{-1}(y)), \qquad x, y \in V^*$$

(41) $$(f, g) = \beta^*(df, dg)$$

(42) $$(f, g) = \sum_i \frac{\partial f}{\partial p_i}\frac{\partial g}{\partial q_i} - \frac{\partial f}{\partial q_i}\frac{\partial g}{\partial p_i}$$

(43) $$df \cdot dg \cdot \beta^{n-1} = (f, g)\beta^n$$

one-parameter group of restricted nonhomogeneous contact transformations is given by the movement of a wave front according to the principle of Christiaan Huygens, a 17th-century Dutch mathematician and physicist.

Another example is the motion of a conservative dynamical system in Hamiltonian form—the mathematical foreshadowing of quantum mechanics (see MECHANICS, QUANTUM). If H is the Hamiltonian of a conservative dynamical system, then the infinitesimal transformation defined by equations (35) is the operator X_H, in which X_g denotes the infinitesimal transformation defined by the operator $f \to (g, f)$, parentheses being with respect to the Poincaré integral invariant $\beta = \Sigma_i dp_i dq_i$. The most general (analytic) infinitesimal transformation of $(p_1, \cdots, p_n, q_1, \cdots, q_n)$-space that preserves β is of the form X_g with g an arbitrary analytic function. The Hamiltonian form (39) of the equations of motion is preserved by any contact transformation with respect to β, and the equations (39) admit the infinitesimal contact transformation X_g only if g is a first integral or if X_g preserves the associated Cartan form of β. Thus if g_1 and g_2 are first integrals of (39), then their Poisson parentheses are a first integral by principle (B). (G.D.M.)

ANALYSIS ON MANIFOLDS

Traditional analysis, the integral and differential calculus, is of a local character; that is to say, it deals primarily with small variations of the numbers or parameters involved. This section concentrates on global analysis, in which topological considerations play a significant role. For example, the study of geometry on a small piece of the Earth's surface involves only local analysis, whereas the study of great circles right around the Earth involves global analysis. The most important areas in which topological ideas have been applied in problems of global analysis are now considered.

Morse theory. One of the most basic questions in the differential calculus has always been the investigation of maxima and minima of functions. For a function $f(x)$ of a real variable this means investigating the points for which the first derivative df/dx vanishes. For a function $f(x_1, x_2)$ of two variables, both partial derivatives $\partial f/\partial x_1$ and $\partial f/\partial x_2$ must vanish, but in this case the conditions also occur at saddle-points. For example, if f gives the height above sea level, then maxima are mountain peaks, minima are in the valleys, and saddle-points are mountain passes.

On an idealized Earth in which f is smooth and nondegenerate (see below) there is a global formula (see 45) and an inequality (see 46) in which m_0, m_1, m_2 are, respectively, the numbers of minima, saddle-points, and maxima. This is a simple example of the global theory of critical points initiated by the U.S. mathematician Marston Morse around 1930. In general this theory deals with a smooth real-valued function f defined on a closed n-dimensional manifold M (the higher-dimensional analogue of a surface) and relates the number of critical points of f with the topology of the manifold. Near any point p of M, local coordinates $(x_1, x_2, \cdots, x_n)$ can be chosen; and p is called critical if all partial derivatives $\partial f/\partial x_i$ vanish there: it is called nondegenerate if the matrix $H(f)$ of second derivatives $\partial^2 f/\partial x_i \partial x_j$ at p has a nonzero determinant. In this case the local coordinates can always be chosen so that, near p, f is given by the formula expressed as a combination of squares of the coordinates (see 47) in which r is some integer between 0 and n called the index of the critical point. A maximum has index n while a minimum has index 0. In dimension 2 a saddle-point has index 1. Formula (45) for the 2-dimensional sphere generalizes to give an expression for the alternating sum of the numbers m_r of critical points of index r (see 48), in which the alternating sum $E(M)$ is an integer depending only on M and not on the particular function f.

Moreover, $E(M)$ is the famous Euler-Poincaré characteristic that is defined as the alternating sum of the Betti numbers $b_r(M)$ (see 49). The Betti number $b_r(M)$ is the number of independent r-dimensional cycles with respect to homology. Thus, for the 2-dimensional sphere, $b_0(M) = b_2(M) = 1$, and $b_1(M) = 0$ so that $E(M) = 2$; and for the 2-dimensional torus (surface shaped like a bicycle tire), similar values can be computed (see 50). Formula (48) for these two cases can be applied, for instance, to the height function when the sphere or bicycle tire is resting on the ground. Exterior points are maxima and minima; interior ones are saddle-points. Thus for the sphere and for the bicycle tire the values of the m_k can be computed (see 51 and 52). In this simple example $m_r = b_r(M)$, but in a more complicated situation this does not hold, as illustrated by a kidney-shaped surface in which there are two maxima, one minimum, and one saddle-point so that $m_2 > b_2(M)$; but still the alternating sum of the m_r equals the alternating sum of the $b_r(M)$ as indicated by formulas (48) and (49). In general, it is always the case that $m_r > b_r(M)$ and, on the lines of formula (47), there are further inequalities (see 53).

Betti numbers

(44) $\begin{cases} X_f = B_1^{-1}(df), \quad X_g = B_1^{-1}(dg) \\ [X_f, X_g] = X_{(f,g)} \end{cases}$

(45) $m_0 - m_1 + m_2 = 2$

(46) $m_1 - m_0 \geq -1$

(47) $f(x_1, \cdots, x_n) = -x_1^2 - x_2^2 - \cdots - x_r^2 + x_{r+1}^2 + \cdots + x_n^2$

(48) $m_0 - m_1 + m_2 - m_3 + \cdots + (-1)^n m_n = E(M)$

(49) $b_0(M) - b_1(M) + b_2(M) - \cdots = E(M)$

(50) $b_0(M) = b_2(M) = 1, \quad b_1(M) = 2, \quad E(M) = 0$

(51) sphere: $m_0 = m_2 = 1, \quad m_1 = 0$

(52) bicycle tire: $m_0 = m_2 = 1, \quad m_1 = 2$

(53) $\begin{cases} m_0 \geq b_0(M) \\ m_1 - m_0 \geq b_1(M) - b_0(M) \\ m_2 - m_1 + m_0 \geq b_2(M) - b_1(M) + b_0(M) \\ \cdots \end{cases}$

What has been described so far is the basic elementary part of Morse theory. It connects critical points of a function with the homology of a manifold (the Betti numbers). A manifold, however, has much more structure than just homology and more invariants than Betti numbers. It has a homotopy structure and finally a differential structure, each giving rise to more refined invariants. One of the remarkable features of Morse theory has been the success that it has achieved in connecting these deeper aspects of a manifold with the behaviour of nondegenerate functions. More than just the critical points are involved at this stage. Essentially, consideration is given to the way in which the level surfaces $f =$ constant alter as the constant is varied, paying particular attention to the levels containing critical points. It is interesting to observe that the whole viewpoint is now reversed; whereas traditionally Morse theory considered a general function f on a given manifold M, the Betti numbers of which were assumed known, and derived restrictions on the behaviour of f, the modern development by the U.S. mathematician Stephen Smale and others has been to construct a nice function f on any M and deduce properties of M from those of f. This program has now led to very substantial progress in the general problem of classifying manifolds.

In another direction, also initiated by Morse, the theory was applied to the study of the loop space ΩM of M; that is, the space the points of which represent closed paths on M beginning and ending at a fixed point. If M is endowed

with a metric (for example, if it sits inside a high-dimensional Euclidean space) the length of a path can be defined, and in this way a function f obtained on the loop space ΩM. The critical points of f correspond to geodesics on M (paths that locally minimize length); the study of these is an old and basic question of differential geometry. One would like to apply Morse theory on ΩM so as to relate questions about geodesics on M to the homology of ΩM. Unfortunately, ΩM is infinite-dimensional and so Morse was led to approximate ΩM by finite-dimensional manifolds based on the approximation of any path by a piecewise geodesic path, analogous to the way one approximates a plane curve by a polygon. This method proved successful and was later applied by the Hungarian mathematician Raoul Bott to derive homotopical properties of the loop space. More recently, with the development of more confidence in the treatment of infinite-dimensional manifolds, it has been shown that the original Morse program can be carried out directly on ΩM without resorting to approximations.

Hodge–de Rham theory. One of the most important branches of analysis on manifolds concerns the periods of integrals. As a basic example consider first a function of one variable $f(x)$. This has an indefinite integral, namely, the function $g(x)$ (see 54) and satisfying therefore the relation that is basic to calculus (see 55). If the interest is in periodic functions, $f(x)$ has to satisfy the equation that identifies its values for argument displaced by 2π (see 56). Then the function $g(x)$ will also be periodic provided the mean value of f is zero (see 57). If x is interpreted as the angular coordinate on a circle, then the periodicity condition on $f(x)$ simply asserts that it is a well-defined single-valued function on the circle. The expression $f(x)dx$ is called a differential form on the circle, and the integral of $f(x)$ from 0 to 2π (see 57) is called its period. The equation setting $f(x)$ equal to the derivative of $g(x)$ (see 55) is written equivalently as $dg(x) = f(x)dx$, and $dg(x)$ is called the differential of $g(x)$. It is then possible to say, briefly, that a differential form ω on the circle is the differential of a function if, and only if, its period vanishes.

The systematic extension of these notions to higher dimensions was carried out by de Rham in the early 1930s. The circle is replaced by an arbitrary manifold of n dimensions, and p-fold multiple integrals are considered for any integer p between 0 and n. The theory allows one to say that the homology properties of a manifold are completely mirrored in the calculus of differential forms, the connection being made via the periods. For a discussion of de Rham's theorem, see above *Exterior differential calculus.*

An important refinement of the de Rham theory was introduced by the British mathematician Sir William Vallance Douglas Hodge and has led to extremely fruitful developments. In the Hodge theory the manifold is assumed closed and endowed with a Riemannian metric. Using the metric, one then defines a second-order differential operator Δ acting on differential forms. For Euclidean n-space with its usual flat metric this coincides with the Laplace operator (see 58) applied to each component of the form. In analogy with the theory of harmonic functions, a differential form φ is said to be harmonic if it satisfies the equation $\Delta\varphi = 0$. The main theorem of Hodge then asserts that there is a unique harmonic form with prescribed periods; *e.g.*, on the 2-dimensional torus parameterized by angular coordinates (x, y) modulo 2π and with the natural flat metric, dx and dy are the unique harmonic 1-forms with periods $(2\pi, 0)$ and $(0, 2\pi)$ on the basic circles, and $dxdy$ is the unique harmonic 2-form with total integral $4\pi^2$. The theory of harmonic forms has particularly interesting applications in the case of complex manifolds, considered below.

Curvature and characteristic classes. A large class of analytical problems with global topological implications arises in Riemannian geometry. Among these are those related to the notion of curvature. For an oriented surface M in three-dimensional Euclidean space, the Gauss curvature K is a function on M defined geometrically as follows. For each point p of M a unit vector $n(p)$ is drawn through the origin in a direction perpendicular to the tangent plane to M at p. As p moves over a very small portion A of M around a fixed point, p_0, $n(p)$ moves over a corresponding portion $n(A)$ of the unit sphere. The curvature $K(p_0)$ is defined as the ratio of the area of $n(A)$ to A. Thus for a sphere of radius a the curvature is a constant function equal to a^{-2}.

The Gauss-Bonnet theorem for a closed surface asserts that the total integral of the Gauss curvature is independent of the metric and is always equal to $2\pi E$, in which E is the Euler-Poincaré characteristic. For a sphere, $E = 2$ and so $\int K = 4\pi$. The Gauss-Bonnet theorem

In higher dimensions the curvature is described not simply by a function but by a suitable tensor. Taking certain polynomial functions of this tensor produces closed differential forms of various degrees. The generalized Gauss-Bonnet theorem asserts that the periods of these differential forms over any given cycle are independent of the metric and so define invariants of the manifold that generalize the Euler-Poincaré characteristic. These invariants are called characteristic classes and are viewed formally as elements in the cohomology groups of the manifold, the duals of the homology groups. Characteristic classes can also be defined purely topologically by investigating the global motion of the tangent space as the manifold is traversed. They measure to some extent the failure of the manifold to possess a globally defined notion of parallelism: for example, a global parallelism exists on the torus in which $E = 0$, but not on the 2-dimensional sphere in which $E = 2$.

A large class of interesting Riemannian manifolds in which much explicit work has been done are the homogeneous manifolds, those that admit rigid motions taking any point into any other point. All the rigid motions form a group (in fact, a Lie group), and the curvature and characteristic classes can be expressed in terms of the group theory. Many of the familiar manifolds such as spheres and projective spaces fall within this class.

Complex manifolds. Just as a differentiable manifold is a space with a collection of real local coordinates, so a complex manifold has complex local coordinates. The important characteristic is that the change from one coordinate system to another is effected by holomorphic transformations; that is, by convergent power series. Thus complex manifolds are the natural domain in which to develop a global theory of analytic functions of several complex variables. They arise naturally in algebraic geometry. Thus an algebraic curve, given by a polynomial equation (see 59), defines a one-dimensional complex manifold provided it has no singularities; that is, provided the equations requiring that the function value vanish along with its first two partial derivatives (see 60) have no common solution. If equation (59) is regarded as defining z_2 as a function of z_1 (an algebraic function), then this complex manifold appears as a multi-sheeted covering of the complex z_1 plane, and this is the original point of view concerning Riemann surfaces. If "points at infinity" are added in the equation for an algebraic curve (see 59), the passing to the projective plane has the effect of making the Riemann surface closed (or compact), and algebraic geometry is mainly connected with the theory of compact complex manifolds.

All the topics discussed so far, differential forms, harmonic forms, curvature and characteristic classes, acquire further refinement in the presence of a complex structure. Thus differential forms can now be expressed in terms of dz and $d\bar{z}$ if $z = x + iy$, instead of dx and dy; and a differential r-form is said to be of type (p, q), in which $p + q = r$, if it involves products of p of the dz_i and q of the $d\bar{z}_i$. Thus on a Riemann surface 1-forms can be of type (1, 0) or (0, 1). Hodge showed that this decomposition into types extended to the harmonic forms provided a metric is used that is appropriately related to the complex structure. In this way he was led to introduce the space $H^{p,q}(M)$ of harmonic forms of type (p, q) and its dimension $h^{p,q}(M)$ as new invariants of a complex manifold. They are related to the Betti numbers

$b_r(M)$ by a formula (see 61). In addition, they satisfy the symmetry condition $h^{p,q} = h^{q,p}$. The case $q = 0$ is particularly interesting because the space $H^{p,q}(M)$ turns out to be just the space of holomorphic differential p-forms; that is, forms involving only the dz^i and the coefficients of which are holomorphic functions.

The tangent space of a complex manifold is naturally a complex vector space, and so the obstruction to finding a global complex parallelism can be studied. This leads to a more refined set of characteristic classes than in the real case. More precisely, there is one class c_i (the ith Chern class) in each even dimension. Every monomial in the c_i of total dimension equal to the real dimension of M gives rise to an integer invariant of M (by integration of the corresponding differential form over the whole of M). An important problem, unsolved for many years, was to find relations between the numbers given by Chern classes and the numbers $h^{p,q}(M)$. This will be explained shortly.

Sheaf theory. In complex analysis the basic questions concern the existence of holomorphic or meromorphic functions with given properties. For example, a classical problem on a compact Riemann surface M is to find how many independent meromorphic functions exist with a given set of poles. Locally all such functions are known (given by power series in a local complex coordinate), but the problem is how to piece together local solutions to obtain a global solution. More precisely, if M is covered by a finite collection of coordinate patches U_i and if local solutions φ_i are taken in each U_i, then the differences $f_{ij} = \varphi_i - \varphi_j$ measure the obstruction to getting a global solution. If holomorphic functions g_i in U_i can be found so that the differences equal the measure of the obstruction (see 62), then $\varphi_i - g_i = \varphi_j - g_j$ in the intersection $U_i \cap U_j$, and so the functions $\varphi_i - g_i$ give a global solution. In any case, the functions f_{ij} clearly satisfy the equation that requires the sum of the functions to equal zero in a certain region (see 63). Now equations (62) and (63) are formally similar to those used in defining homology, or rather cohomology, the only difference being that the g_i and f_{ij} are now holomorphic functions rather than constants. Proceeding with this analogy, a new kind of cohomology group can be defined by taking collections of functions f_{ij} satisfying (63) modulo the subgroup (see ALGEBRAIC STRUCTURES) of those for which (62) has a solution. These new cohomology groups provide a convenient formal framework in which global analytic obstructions can be treated. The general setting here is that of the cohomology theory of sheaves. Interestingly enough, although this theory was first developed by the French mathematician Jean Leray in a purely topological context, its most significant application has been in the domain of complex analysis in which it has become an indispensable tool following the pioneering work of Cartan and Serre in the 1950s.

A sheaf S on a space X is, roughly speaking, some class of functions characterized by local properties. Cohomology groups $H^q(X, S)$ are then defined for each integer $q \geq 0$, $H^0(X, S)$ being just the global functions of the class. If S is the sheaf of constant functions, the usual cohomology groups (dual of homology) is obtained; but if S is the sheaf of holomorphic functions on a complex manifold M, the groups indicated above are obtained. More generally, the sheaf Ω^p of holomorphic p-forms on M can be taken. The resulting groups $H^q(M, \Omega^p)$ are finite-dimensional if M is compact and turn out to be isomorphic to the Hodge groups $H^{p,q}(M)$ when M is algebraic. Sheaf theory thus provides an alternative or supplement to harmonic form theory.

The meromorphic functions with given poles also form a sheaf S. The main interest is in the global functions $H^0(M, S)$, but the higher cohomology groups intervene automatically in many places. For example, it is difficult in general to compute the dimension of $H^0(M, S)$, but the alternating sum of the dimensions for higher cohomology groups (see 64) is much easier to deal with. The famous Riemann-Roch theorem, as generalized and proved by the German mathematician Friedrich Ernst Peter Hirzebruch in 1954, gives an explicit topological formula for $\chi(M, S)$ in terms of the Chern classes of M and the homotopy class of the set of poles. For a Riemann surface this formula reduces to a difference of dimension for two cohomology groups expressed in terms of g and d (see 65) in which g is the genus of M and d is the number of poles. The term involving H^1 is called the index of specialty (of the set of poles) and is known to vanish when $d > 2g - 2$. For a general algebraic manifold M the Hirzebruch formula applied just to the sheaf of holomorphic functions (no poles) gives a formula in terms of c_i and I_n (see 66) in which the c_i are the Chern classes of M and T_n ($n = 1, 2, \cdots$) is a certain sequence of polynomials now known as the Todd polynomials (after the English mathematician John Arthur Todd, who introduced them in the 1930s). Examples of T_n with n equal to one, two, and three are easily displayed (see 67). It is a remarkable fact that these Todd polynomials, originating in algebraic geometry, and certain other closely related polynomials have played a very important role in the study and classification of manifolds. Their arithmetical properties, which involve the Bernoulli numbers, reflect in a deep and mysterious manner the differential properties of manifolds. For instance, the 28 different differentiable structures that have been shown to exist on the seven-dimensional sphere by the U.S. mathematician John Milnor and others are distinguished by numerical invariants based essentially on the Todd polynomials.

(54) $$g(x) = \int_0^x f(t)\, dt$$

(55) $$\frac{dg(x)}{dx} = f(x)$$

(56) $$f(x + 2\pi) = f(x)$$

(57) $$\int_0^{2\pi} f(x)\, dx = 0$$

(58) $$\Delta = \sum_{i=1}^{n} \frac{\partial^2}{\partial x_i^2}$$

(59) $$f(z_1, z_2) = 0$$

(60) $$f(z_1, z_2) = 0, \qquad \frac{\partial f(z_1, z_2)}{\partial z_1} = 0, \qquad \frac{\partial f(z_1, z_2)}{\partial z_2} = 0$$

(61) $$b_r(M) = \sum_{p+q=r} h^{p,q}(M)$$

(62) $$f_{ij} = g_i - g_j$$

(63) $$f_{ij} + f_{jk} + f_{ki} = 0 \quad \text{in} \quad U_i \cap U_j \cap U_k$$

(64) $$\chi(M, S) = \sum_q (-1)^q \dim H^q(M, S)$$

(65) $$\dim H^0(M, S) - \dim H^1(M, S) = 1 - g + d$$

(66) $$\sum_q (-1)^q h^{0,q}(M) = T_n(c_1, \cdots, c_n)$$

(67) $$T_1 = \frac{c_1}{2}, \qquad T_2 = \frac{c_1^2 + c_2}{12}, \qquad T_3 = \frac{c_1 c_2}{24}$$

Other applications of sheaf theory

Sheaf theory in complex analysis has a very wide range of application far beyond algebraic manifolds. In particular, it can be applied on non-compact manifolds and also to complex analytic spaces, in which singularities are allowed. Because such spaces do not have good systems of local coordinates, the Hodge theory of harmonic

forms does not exist in this context. On the other hand, the methods of partial differential equations, of which the Hodge theory is a noteworthy case, are not restricted to complex manifolds and have therefore considerably greater flexibility, as will be explained below.

Elliptic operators. The Laplace operator (see 58) and its generalization by Hodge to the Riemannian case are examples of elliptic partial differential operators. They are characterized by a non-degeneracy condition on their highest order terms, which for the Laplace operator is just the fact that the equation identifying a sum of squares of the ξ_i with zero (see 68) has no real solutions except for $\xi_i = 0$ (all i). All elliptic operators share certain basic features, notably the finite-dimensionality of their spaces of solutions on a compact manifold. Moreover, the adjoint D^* of an elliptic operator D is also elliptic, and the index of D, defined as the difference between the number of independent solutions of the equations $Du = 0$ and $D^*u = 0$, has the property of being stable under small perturbations of D. On a Riemann surface M if D is taken to be the Cauchy-Riemann operator (see 69) the solutions of $Du = 0$, $D^*u = 0$ can be identified with the sheaf cohomology groups $H^0(M, S)$, $H^1(M, S)$, in which S is the sheaf of holomorphic functions. Thus the Riemann-Roch theorem gives in this case a formula for the index in topological terms, namely, index $D = 1 - g$. Quite generally the Hirzebruch-Riemann-Roch theorem can be viewed as giving a formula for the index of a certain elliptic operator (generalizing the Cauchy-Riemann operator) in terms of characteristic classes.

(M.F.A.)

Differential topology

The aim of differential topology primarily is the study of differentiable manifolds and of differentiable maps between them. It also is concerned with geometric objects (such as vector fields, foliations, group actions), which one can associate with manifolds. Differential topology is thus in a position midway between differential geometry on the one hand and classical differential calculus on the other. The chief divergence from the spirit of differential geometry is that the latter only considers manifolds equipped with more precise structures (*e.g.*, Riemannian metrics, connections) and has thus a basically quantitative aspect, whereas differential topology is purely qualitative in its aims. It borders on analysis in the study of differentiable maps and their singularities: this is the subject that one could call differential analysis and is the study of maps that are required to be only differentiable, rather than analytic. Differential analysis was not yet recognized as an independent subject in the 1970s.

Differential topology has been studied as such only since the mid-1930s. Mathematicians have from the start made use of low-dimensional manifolds (such as points, curves, surfaces), but the idea of developing a general theory of objects defined by conditions that are merely differentiable, as opposed to analytic or algebraic, was slow to appear. The French mathematician Joseph-Louis Lagrange in his *Mécanique Analytique* (1788; "Analytic Mechanics") considers such manifolds as the phase spaces of a dynamical system, and the canonical transformations met with in dynamics contain the idea of structure-preserving coordinate transformations. It is only in the work of the 19th-century German mathematician Bernhard Riemann, however, that the general notion of an n-dimensional manifold is first formulated. He called it an "*m-fach ausgedehnte Mannigfaltigkeit*" (m-fold extended manifold). The impetus of Italian algebraic geometry, the theory of algebraic surfaces and of analytic ones led the German-born U.S. mathematician Hermann Weyl, in *Die Idee der Riemannischer Fläche* (1913; Eng. trans. *The Concept of a Riemann Surface*, 1964), to the first precise definition, within the particular context of an algebraic curve, of a manifold defined by coordinate charts and transformations, and thus to the idea of analytic structure. Only a little later, the theory of general relativity, with its insistence on the concept of curved space-time, gave a tremendous impulse to tensorial differential geometry. At the same time, the topological theory of Lie groups, due to Cartan, also drew attention to the notion of manifolds. The first modern definition of a manifold, by local coordinate systems and transformations, is due to the mathematicians Oswald Veblen (U.S.) and Henry Whitehead (British). It is with the fundamental work of Hassler Whitney in 1935 that differential topology as such was born.

Early definitions

From that time on differential topology took its inspiration from two opposite sources: on the one hand, differential analysis brought very powerful tools to bear, from 1935–40 onward: the theorem on the zero measure of the set of critical values of a differentiable map (since referred to as Sard's theorem, although Anthony Paul Morse had previously proved it in special cases); the extension theorem and spectral theorem of Whitney; then later the generalization of the implicit function theorem known as the transversality lemma (a lemma is a theorem, usually proved to use in the proof of another theorem); and, finally, a C^∞ (C^∞ mapping is a mapping that is continuously differentiable an infinite number of times) generalization of the Weierstrass preparation theorem for analytic maps. On the other hand, algebraic topology was itself developing at the same time: the foundations of singular homology and cohomology theories; the theory of fibre spaces and of their characteristic classes; spectral sequences; and homotopy theory. So, about 1950, the techniques necessary for a detailed investigation of differentiable manifolds were available.

By 1935 Marston Morse had shown by means of his theory of critical points of functions and the inequalities that bear his name what sort of purely topological information about a manifold M could be deduced just from an inspection of the singularities of a real-valued function $f : M \to \mathfrak{R}$. A more detailed study of his methods, making use of gradient trajectories, has succeeded in an extremely direct fashion in associating to a generic function $f : M \to \mathfrak{R}$ a partition of M into cells, each cell of dimension k having its centre in a critical point of f, of index k; and in fact this cellular decomposition satisfies the homotopy-theoretical properties of a C–W complex. This representation of any manifold as a union of balls was to play a basic role in the appearance of surgery techniques (see below *Surgery techniques*), which study the possibility of transforming a given manifold M into another M' of the same dimension, generalizing the process by which one passes from a sphere to a torus by adding a handle.

An outline of the principal stages in the development of differential topology is given in the *Bibliography*. In the 1970s, the status of the subject is a little ambiguous. Many important problems, connected with the classification of manifolds up to diffeomorphism, remain unsolved; these problems, however, are hard, and in general they are not decidable; it seems more likely that differential topologists will turn more toward the topological study of groups of diffeomorphisms, introducing a new point of view into functional analysis. The works of the French mathematician Jean Cerf provide an excellent example of this trend, which seems very promising.

BASIC CONCEPTS: THE DIFFERENTIABLE CATEGORY

If $\mathfrak{R}^n$ and $\mathfrak{R}^p$ are Euclidean spaces, with coordinates $(x_1, \cdots, x_n)$ and $(y_1, \cdots, y_p)$, respectively, a system of functions expressed in terms of f_j (see 70) defines a mapping F from $\mathfrak{R}^n$ to $\mathfrak{R}^p$. If all the f_j are r-times continuously differentiable, then the mapping is said to be of class C^r. It is to be noted that if F and G (see 71) are two such mappings, then the composite mapping $G \circ F$ (see 72) is also of class C^r.

A mapping $F : \mathfrak{R}^n \to \mathfrak{R}^n$ is known to be locally invertible at 0 if the Jacobian determinant (see 73) is nonzero at 0 (inverse function theorem). F is then said to be a local diffeomorphism.

The notion of a jet. Two germs of mappings $\mathfrak{R}^n \overset{F}{\underset{G}{\rightrightarrows}} \mathfrak{R}^p$ [F defined by (f_i) and G by (g_i)] are said to be equivalent to rth order if $D_\omega f_i(0) = Dg_i(0)$ for every multi-index $\omega = (i_1, \cdots, i_d)$, of total degree $d(\omega) = d \leq r$. This defines an equivalence relation on germs of map-

pings. The set of equivalence classes, which is parameterized by the values $c_\omega{}^i$ $(d(\omega) \leq r)$ of the partial derivatives, makes up the space $J^r(n, p)$ of local jets of $\mathfrak{R}^n$ into $\mathfrak{R}^p$ of order r. In particular, a germ of a curve is a germ of a mapping $(\mathfrak{R}', 0) \to (\mathfrak{R}^n, 0)$; the space of all first-order jets $J'(1, n)$ consists of the usual tangent vectors to $\mathfrak{R}^n$ at 0.

If F is a differentiable mapping of $\mathfrak{R}^n$ into $\mathfrak{R}^p$, it can be extended in a canonical manner into a mapping from the set of tangent vectors $T(\mathfrak{R}^n)$ into the set of tangent vectors $T(\mathfrak{R}^p)$: if the tangent vector z is represented by the curve $f : \mathfrak{R}' \to \mathfrak{R}^n$, $F(z)$ is the equivalence class of the composite curve $F \circ f$.

In a general way, if X, Y are open subsets of $\mathfrak{R}^n$, $\mathfrak{R}^p$, respectively, the space of jets of rth order of $\mathfrak{R}^n$ into $\mathfrak{R}^p$ is defined as being the set of local jets of C^r mappings that take a point x of X into a point y of Y; it is thus just the product $X \times Y \times J^r(n, p)$; the projection map $r : z \to (x, y)$ is the mapping that takes a jet z into its source x and its target y.

For a given mapping $F : X \to Y$, of class C^r, to every point $x \in X$ can be associated in $J^r(n, p)$ the jet $J^r(F_x)$ of the germ of F at x; one also has defined a section of the (trivial) vector bundle r over the graph of F; this section is the rth derivative of F.

Imbedded manifolds and intrinsic manifolds. An n-dimensional Euclidean space $\mathfrak{R}^n$ is considered, with coordinates $(x_1, \cdots, x_n)$, together with a system of $p \leq n$ differentiable functions $(f_1, \cdots, f_p)$, and the equations that result by setting the functions equal to zero (see 74): If V denotes the subset $V \subset \mathfrak{R}^n$ defined by the vanishing of these equations and at a point $x \in V$ at least one of the minors of order p of the Jacobian matrix $J = D(f_1, \cdots, f_p)/D(x_1, \cdots, x_n)$ is nonzero, say the one relative to the first p coordinates $(x_1, \cdots, x_p)$, then, according to the implicit function theorem, there is a neighbourhood of x in $\mathfrak{R}^n$ such that the system (E) may be resolved in terms of the variables $(x_{p+1}, \cdots, x_n)$, thus transforming into an equivalent linear system (see 75).

In other words, a neighbourhood W of x in V is $(n - p)$-dimensional, parameterized by the values of the $(n - p)$ variables $(x_{p+1}, \cdots, x_n)$. In this case one says that, locally at x, V is an imbedded manifold of dimension $(n - p)$ and codimension p. If at all points x of V it is possible to choose such a nonzero Jacobian minor so that every point has such an $(n - p)$-dimensional neighbourhood, then V is said to be an imbedded manifold, of dimension $n - p$. V is said to be closed if V, imbedded in $\mathfrak{R}^n$, is compact (*i.e.*, bounded). A set of functions such as $x_{p+1}, \cdots, x_n$ is a system of local coordinates; it defines a diffeomorphism of a neighbourhood W of x onto an open subset $U \subset \mathfrak{R}_{n-p}$. Any such diffeomorphism is called a coordinate chart about x. For an imbedded manifold, there exist a great many local coordinates (in fact, any set of functions $y_1, \cdots, y_d$ with $dy_1 \wedge \cdots \wedge dy_d \neq 0$ at x defines a coordinate chart about x).

Now two coordinate charts U, U' at x satisfy the following property: that on the open subset $U_1 \subset U$ in which the composite $f' \circ f^{-1}$ is defined, it is a diffeomorphism onto an open subset $U' \subset U'$, hence the following intrinsic definition of a manifold.

A differentiable n-dimensional manifold of class C^r is a (Hausdorff paracompact) topological space X such that every $x \in X$ has a neighbourhood V, together with a homeomorphism $h : V \to U$ onto an open neighbourhood U of 0 in $\mathfrak{R}^n$ (coordinate chart). Whenever two local charts V_1 and V_2 have a non-empty intersection, then the mapping $h_2 \circ h^{-1}$, taking $h_1(V_1 \cap V_2) \subset U_1$, onto $h_2(V_1 \cap V_2) \subset U_2$, which is anyway a homeomorphism, is required to be a diffeomorphism, of class C^r. It is to be noted that if three charts V_1, V_2, and V_3 have a non-empty intersection, then the transition functions $h_{ij} = h_i \circ h_j^{-1}$ satisfy $h_{31} = h_{32} \circ h_{21}$ where they are all defined. In the case in which the diffeomorphisms h_{ij} are in fact analytic, then the manifold is said to be an analytic manifold. A C^0 manifold is a topological manifold.

Manifolds with boundaries. A manifold with boundary M^{n+1}, of class C^r, is a topological space that has an n-dimensional manifold ∂M of class C^r as a subspace, in such a way that:

(A) the complement $(M - \partial M)$ is an $(n + 1)$ manifold, of class C^r;

(B) every point $x \in \partial M$ has a neighbourhood W in M, together with a homeomorphism h of W into Euclidean upper half space (see 76) mapping W onto an open neighbourhood U of the origin, mapping $W \cap \partial M$ diffeomorphically onto a set of specific structure (see 77), and $M \cap W$ diffeomorphically onto another set of specific structure (see 78).

Isomorphisms of differentiable structures. A differentiable structure (class C^r) on a manifold M is completely determined by the knowledge of the set $(\mathfrak{H})$ of differentiable functions on M. Two structures (ξ) and (ξ') are said to be equivalent if there exists a homeomorphism h taking the set $(\mathfrak{H})$ into the set $(\mathfrak{H}')$.

The fundamental theorems of Whitney. In his basic articles of 1935–36, Hassler Whitney establishes that every differential manifold (n-dimensional, paracompact—*i.e.*, the union of countably many compact sets) can be imbedded in a Euclidean space $\mathfrak{R}^n$, of sufficiently high dimension.

The proof is in fact fairly simple: one first establishes that for the manifold M equipped with a locally finite covering $\mathfrak{N}$ by coordinate neighbourhoods U_i, one can always construct a subordinate partition of unity $\{\mathfrak{N}_i\}$. This allows the extension of every coordinate function x_i, originally only defined on the coordinate neighbourhood U_i, into a function globally defined on M. This gives an imbedding i of M into a large-dimensional Euclidean space $\mathfrak{R}^N$ (one may map two of the x_i's onto the same coordinate of $\mathfrak{R}^N$ if their supports are disjoint); it now remains to cut down $\mathfrak{N}$ as far as possible. A general position argument concerns linear projections

(68) $$\sum_{i=1}^{n} \xi_i^2 = 0$$

(69) $$\frac{\partial}{\partial x} + i\frac{\partial}{\partial y}$$

(70) $$y_i = f_i(x_1, x_2, \cdots, x_n)$$

(71) $$\mathfrak{R}^n \xrightarrow[f_i]{F} \mathfrak{R}^p \xrightarrow[g_j]{G} \mathfrak{R}^q$$

(72) $$z_k = g_k(f_j(x_i))$$

(73) $$D(f_i)/D(x_j) = \det|\partial f_i/\partial x_j|$$

(74)
$$\begin{cases} f_1(x_1, \cdots, x_n) = 0 \\ f_2(x_1, \cdots, x_n) = 0 \\ \cdot \\ \cdot \\ \cdot \\ f_p(x_1, \cdots, x_n) = 0 \end{cases}$$

(75)
$$\begin{cases} x_1 = g_1(x_{p+1}, \cdots, x_n) \\ \cdot \\ \cdot \\ \cdot \\ x_p = g_p(x_{p+1}, \cdots, x_n) \end{cases}$$

(76) $$H^{n+1} = \{x \in \mathfrak{R}^{n+1} | x_{n+1} \geq 0\}$$

(77) $$U \cap \{x | x_{n+1} = 0\}$$

(78) $$U \cap \{x \in \mathfrak{R}^{n+1} | x_{n+1} \geq 0\}$$

(see 79). The composite $L \circ i$ is an imbedding for properly chosen L. In fact, the dimension can even be pushed down as far as $2n$, by a surgery type of argument, which can eliminate any possible points of self-intersection.

Whitney's work also contains smoothing theorems. Every C^1 manifold M is also a C^r manifold, the C^r structure inducing a C^1 structure equivalent with the original one; one can even provide M with an analytic structure. The idea here is the following: one imbeds the manifold M into a Euclidean space $\mathfrak{R}^N$ and constructs a tubular neighbourhood of M in $\mathfrak{R}^N$ using a field of transverse $(N - n)$-planes F_x of class C^{r-1}. This defines a locally surjective map (see 80). One then smooths this field of $(N - n)$-planes F into a nearby field F', keeping it transverse to $i(M)$. On taking another tube $\mathfrak{T}'(M)$, possibly smaller, one can pass to the quotient by the planes defined by F', thus providing M with a C^r-structure.

PROBLEMS AND METHODS OF DIFFERENTIAL TOPOLOGY

The differentiable category has as objects differentiable manifolds, and as morphisms differentiable maps. The problems concerning the objects are those of topology; those concerning the morphisms belong more to the realm of analysis.

Problems about differentiable manifolds. The essential problem is that of equivalence: given two manifolds M and M' (say imbedded ones for definiteness), to be able to recognize whether M and M' are isomorphic; and in a general way, to organize algebraically (if possible) the set of equivalence classes.

For M and M' to be isomorphic, they must at least be homeomorphic as topological spaces, so that they must have the same topological invariants: dimension; fundamental group π_1; homology groups; homology type. It is known that in its most general form, this problem is not decidable; it is therefore quite reasonable to make simplifying hypotheses (in particular on the group π_1) to make the problem more accessible. Among the weaker equivalence relations between manifolds, that which has turned out to be the most accessible is that known as cobordism (see below *Cobordant manifolds*).

A second type of problem is that of invariance. To what extent are the invariants of a manifold, constructed using the differentiable structure, in fact invariant under topological equivalence? Historically, this problem has arisen especially in the context of characteristic classes of the tangent bundle.

A third type of problem is that of the existence and classification of further structures that can be put on a given manifold. The most interesting problems here concern complex or almost complex structures, foliations, and imbeddings or immersions between two given manifolds.

Problems concerning the morphisms. The problem of the topological equivalence of two maps between manifolds is a difficult problem and is possibly not sufficiently motivated. It has not been systematically tackled up to now. An extensive literature, however, does exist concerning the local problem of to what extent the topological type of a germ of a mapping is determined by its jet. As far as differential equivalence (modulo diffeomorphism of the domain and the range) is concerned, a complete theory has now been developed by the mathematician J. Mather, which answers the question, at least in principle. The fundamental problem here is that of the density of topologically stable maps; some results on this subject have been announced.

In a general way, the theory of differentiable mappings requires an elucidation of the structure (in a nontechnical sense) of the set of singular points and values. This study was started by Whitney, who described the generic singularities of certain mappings (see 81). A particular case, the theory of functions, is included in Morse theory. An essential tool of this subject is the notion of stratified set in Euclidean space; here again, Whitney's work on the stratification of analytic sets played a decisive role. The notion of stratified set allows a considerable extension of the transversality techniques, which will now be taken up.

The methods. From analysis, differential topology has borrowed the technique of transversality; from algebraic topology, that of the universal object. It is not an exaggeration to say that the combination of these two techniques has provided differential topology with its most powerful tools.

Transversality and the universal object

The idea of the universal object had its origin in homotopy theory; its use in the classification of vector bundles on a given space is a typical example, although it is known how to prove the existence of universal objects in much greater generality.

The technique of transversality is in principle nothing more than an intrinsic reformulation of the implicit function theorem: given a submanifold $Q \subset \mathfrak{R}^n$, of codimension q, at each pt $y \in Q$, Q is defined by a local morphism $\pi: U \to \mathfrak{R}^q$, which is a submersion (see 82). A differentiable mapping $f : M \to \mathfrak{R}^q$ is said to be transverse to Q if for all points $x \in f^{-1}(Q)$, the composite map (see 83) has maximal rank [$= \max(m, q)$]. If f is a transversal mapping, then $f^{-1}(Q)$ is a submanifold of M, of codimension q, and with normal bundle induced by f from the normal bundle of Q in $\mathfrak{R}^n$. In the space of differentiable mappings $C^r(M, \mathfrak{R}^n)$ $(r \geq m)$, the set of mappings transverse to Q is a dense open set; in other words, transversality is a generic property.

Transversality techniques admit two types of generalizations:

(A) One may replace the smooth manifold Q by a set with singularities, such as analytic or algebraic sets. This is the starting point of the theory of stratified sets.

(B) Considering, instead of the map f itself, its derivative $J^r(f)$ in the space of jets, if $\mathfrak{J}$ is a submanifold of the space of jets $J^r(m, n)$, then generically the derivative $J^r(f)$ is transversal to $\mathfrak{J}$.

The notion of transversality is nothing but a formulation of the old notion of general position, well-known in algebraic geometry and combinatorial topology. Note that if f and g are both transversal to Q and if they can be imbedded in a homotopy itself transversal to Q, when considered as a mapping (see 84), then the inverse images $f^{-1}(Q)$ and $g^{-1}(Q)$ are isotopic in M. (The same theorem can even be extended to the case of Q a set with singularities.) Mather has introduced for differentiable mappings the notion of infinitesimal stability: if $f : X \to Y$ is a differentiable map, denoting θ_f the vector bundle induced on X by the f from $T(Y)$ certain maps result (see 85). A section σ of $\pi : \theta_f \to X$ is an infinitesimal deformation of f, because it associates to every point $x \in X$ a tangent vector to Y at $y = f(x)$; f is said to be infinitesimally stable if all infinitesimal deformation σ can be written in the form $\sigma = f(\xi) + f^{*-1}(\eta)$, in which ξ and η are sections of π_X and π_Y, respectively.

The fundamental results of Mather's theory are the following:

(A) Every infinitesimally stable mapping belonging to an open $W \subset (X, Y)$ is stable (*i.e.*, two nearby maps g, f are connected by diffeomorphisms of X and Y).

(B) The infinitesimal stability of a mapping f is equivalent with the transversality of its derivative $J^r(f)$ to the orbits in $J^r(n, p)$ defined by the action of the groups of local diffeomorphisms of the domain and the range.

An important special case of these results is the fibration theorem of C. Ehresmann: if $f : X \to Y^n$ is a proper morphism, f everywhere of maximal rank n, then f is a fibration.

Surgery techniques. Of a more elementary nature (in principle), but nevertheless extremely powerful, surgery of manifolds is based on a generalization of the construction of a surface of genus p from one of genus $p - 1$, by the addition of a handle. Here, the basic model comes from Morse theory: one considers a function $f : M^n \to \mathfrak{R}$, taking a point O into 0, and having there a critical point of a rank k that is expressible in terms of local coordinates about zero (see 86). Letting M^+ and M^- be the level manifolds $f^{-1}(\pm\varepsilon)$, respectively, and considering the trajectories of the gradient field of f, the trajectories ending at O from $f(\leq \varepsilon)$ form a ball of dimension k the boundary of which in M^- is a $(k - 1)$ sphere σ^{k-1}. Similarly, the gradient trajectories starting from O form an $(n - k)$

ball the boundary of which in M^+ is an $(n-k-1)$ sphere σ^{n-k-1}. A tubular neighbourhood of σ^{k-1} in M^-, of boundary $S^{n-k-1}\times\sigma^{-1}$, is mapped (by following the gradient trajectories [not going through O]) onto a tubular neighbourhood of σ^{k-n-1} in M^+. One has therefore passed from M^- to M^+ by the following operation: one chooses a sphere σ^{k-1} with trivial normal bundle, the boundary of the tubular neighbourhood of which is therefore $\sigma^{k-1}\times S^{n-k-1}$. One then replaces this tubular neighbourhood $\sigma^{k-1}\times D^{n-k}$ by the product $D^k\times\sigma^{n-k-1}$. In this process the cycle σ^{k-1} has been killed because it can now be contracted to zero across the new D^k; of course, one has introduced a new cycle σ^{n-k-1}.

Example of surgery. If M is an oriented manifold of dimension $n\geq 4$, one can, by a succession of surgeries of index 1, kill the whole fundamental group π_1 of M. Indeed, if any generator g of π_1 is considered, realized as an imbedded circle S^1, with trivial normal bundle, this cycle can be killed by an elementary surgery. This introduces a new cycle of dimension $n-1-1\geq 2$, and so this operation does not introduce anything more into π_1. If M' is the new manifold, obtained by this surgery from M, then $\pi_1(M')$ is the quotient of $\pi_1(M)$ by the normal subgroup generated by g.

A refinement of the technique is provided by Smale's theory of handlebodies, in which one associates the manifold $f\leq -\varepsilon$ to the effect of surgery on $f=-\varepsilon$.

Cobordant manifolds. Two open manifolds M^n and M'^n are said to be cobordant if there exists a manifold with boundary W^{n+1} such that an acceptable restrictive relationship holds (see 87). This defines an equivalence relation between manifolds, and the set of equivalence classes is provided (by topological sum) with the structure of an Abelian group denoted Ω^n.

Morse theory applied to a function g on W with $g(M)=0$, $g(M')=1$ shows that every cobordism can be realized as a finite sequence of surgeries; conversely, a sequence of surgeries gives a cobordism. If f and g are two homotopic mappings of X into Y, transverse on a submanifold Q of Y, then the submanifolds $f^{-1}(Q)$ and $g^{-1}(Q)$ are cobordant (as can be seen if one considers a homotopy from f to g, transverse to Q). Consequently, the cobordism class of such an inverse image is homotopy invariant of the mapping f. (In the case where $\dim X=\dim Y$, Q reduced to a point, $\dim f^{-1}(Q)=0$ and Browder's notion of the degree of the mapping f is recovered.)

The concept of cobordism between manifolds is a weakening of the notion of homotopy equivalence. The transition between the two is the notion of h-cobordism: two manifolds M^n and M'^n are said to be h-cobordant if there exists a manifold with boundary W^{n+1} (see 87) such that each of the manifolds M and M' is a deformation retract of W^{n+1}.

RESULTS ON THE CLASSIFICATION OF MANIFOLDS

Cobordism. The essential tool of cobordism theory is the Pontryagin-Thom construction; given a manifold M^n imbedded in a sphere S^{n+k} of possibly high dimension, one considers the normal bundle $T_\nu(M^n)$, the class of which does not depend on the chosen imbedding for k large enough; ν is the mapping of M into the Grassmannian $G(k)$ of k-planes in $\mathfrak{R}^{n+k}$, which induces the normal bundle $T_\nu(M)$ from the universal vector from the universal vector bundle U. Denote by $MSO(k)$ the so-called Thom space, constructed by compactifying the space U by one point at infinity. The map ν can then be extended into a mapping $\bar{\nu}$ from a tubular neighbourhood of M into U; $\bar{\nu}$ can then be extended into a mapping $\bar{\bar{\nu}}: S^{n+k}\to MSO(k)$. From the general theorem it now can be seen that two manifolds M and M^1 are cobordant if, and only if, the corresponding maps $\bar{\bar{\nu}}$ and $\bar{\bar{\nu}}_1: S^{n+k}\to MSO(k)$ are homotopic. Consequently an equality involving Ω_n holds (see 88) for k large.

Topological product makes the Abelian group $\Omega=\Sigma\Omega_n$ into a graded ring. The structure of the algebra Ω has been studied at length. The ring $\mathfrak{N}$ of cobordism classes of manifolds without orientation $\mathfrak{N}_m=\pi_{m+k}((MO)(k))$ can also be considered, as before. The structure of $\mathfrak{N}_n$ can be completely determined because the homotopy groups

(79) $L:\mathfrak{R}^N\to\mathfrak{R}^{2n+1}$

(80) $\mathfrak{I}(M)|_W\to\mathfrak{R}^N$

(81) $\mathfrak{R}^n\to\mathfrak{R}^{2n},\qquad \mathfrak{R}^{2n}\to\mathfrak{R}^{2n-1},\qquad \mathfrak{R}^2\to\mathfrak{R}^2$

(82) $U\cap Q=\pi^{-1}(0)$

(83) $\pi_y\circ f:M_x\to\mathfrak{R}^q$

(84) $M\times I\to\mathfrak{R}^n\times I$

(85)
$$\begin{array}{ccccc} T(X) & \xrightarrow{f} & \theta_f & \xrightarrow{f^*} & T(Y) \\ {\scriptstyle\pi_X}\searrow & & \downarrow & & \swarrow{\scriptstyle\pi_Y} \\ & & X & \to & Y \end{array}$$

(86) $f=-X_1^2-X_2^2-\cdots-X_k^2+X_{k+1}^2+\cdots+X_n^2$

(87) $\partial W^{n+1}=M^n-M'^n$

(88) $\Omega_n=\pi_{n+k}(MSO(k))$

(89) $\Omega\to\Omega\to W\to\Omega\to\Omega\to W\cdots$

(90) $z\in H_i(M;Z_2),\qquad i<\dfrac{n}{2}$

(91) $\varphi^*H_n(X)\to H_{n+N}(T(\nu))$

$\pi_{n+k}((MO)(k))$ can be calculated. It is a polynomial algebra over Z_2 having one generator in every dimension not of the form 2^m-1. The algebra $\Omega\otimes_Z Q$, with real coefficient is a polynomial algebra with one generator u in every dimension of the form $4k$.

There is an exact sequence involving W (see 89) in which W is the subring of $\mathfrak{M}$ consisting of those classes that admit a representative for which the W_1-Stiefel-Whitney class can be represented as an integral class. The ring Ω has been determined by the English mathematician Charles Terence Clegg Wall; the nonprojective generators of $\mathfrak{N}$ have been constructed by the German mathematician Albrecht Dold.

Cobordism theory has had many extensions; in particular, the complex cobordism groups, $\pi_{n+k}(MU(k))$, as well as the spin-cobordism ring have been calculated.

The complexes $MSO(k)$ are useful for resolving the problem of realizing homology classes as submanifolds. The following are the principal results: it is possible to specify classes z that (see 90) can be realized as a submanifold (not necessarily oriented). In real cohomology, the classes of dimension less than 7 are realizable, but there do exist homology classes of dimension 7 that are not realizable. Finally, the cobordism class of a manifold is determined by a knowledge of its characteristic numbers: a manifold, all of the characteristic numbers of which vanish, necessarily bounds. (A characteristic number is the value taken by a characteristic class on the fundamental cycle of the manifold.)

Classification up to homotopy. Remarkable results of the mathematicians P.S. Novikov and W. Browder have allowed a characterization of the homotopy types of manifolds.

Given a Poincaré complex X (*i.e.*, a complex satisfying Generalised Poincaré Duality), with fundamental class $z\in H_n(X)$, one can associate to it (Spivak's theorem) a topological vector bundle ν playing the role of a normal bundle; now suppose that this normal bundle admits an orthogonal structure. One can construct the Thom complex $T(\nu)$ of the vector bundle ν, and thus obtain a mapping $f: S^{n+N}\to T(\nu)$ such that the image $f^*(s)$ of the fundamental class s is the image $\varphi(Z)$ of Z by a bundle isomorphism (see 91). If one then takes a mapping

$f_1 : S^{n+k} \to T_X(\nu)$ transverse to X, and homotopic to f, one constructs a manifold $M_1 = f_1^{-1}(X)$ that is mapped onto X by a map f_1 of degree one. The problem is then to simplify M, as far as possible by surgery, to make it have the same homotopy type as X. If M is simply connected, this can be done except possibly for the middle dimension, in which one meets an obstruction. If this obstruction vanishes, then the homotopy type of X as a manifold can be realized. These results have been extended to piece-wise linear and topological manifolds.

Classification up to diffeomorphism. An essential result is the so-called h-cobordism theorem, which generalizes results of Smale. If M and M' are two simply connected manifolds of dim ≥ 5, and there exists an h-cobordism W between them, then W is a product $M \times I$, and M and M' are diffeomorphic. A particular case is the Poincaré conjecture in dimension ≥ 5; every manifold M^n, $n \geq 5$, homotopy equivalent to a sphere S^n, is in fact homeomorphic to one. The proof of the h-cobordism theorem is by a surgery argument, which eliminates critical points in pairs of index i, $i - 1$. In the case $\pi_1(M) \neq 0$, the theorem no longer holds. One can then define an obstruction to the elimination of the critical points of a Morse function, defined by Whitehead torsion of the h-cobordism (s-cobordism theorem).

The problem of classification of manifolds, at least of those that are simply connected, is thus reduced to the problem of recognizing whether two given manifolds are h-cobordant; this problem reduces to the problem of simplifying a given cobordism into an h-cobordism. Here again, obstructions are met in the middle dimension. This is in fact the origin of Milnor's examples of exotic spheres, a discovery that has been at the source of all subsequent progress, in particular Michel Kervaire's construction of a manifold of dimension 10, which can be triangulated, but which does not admit a differentiable structure. The general problem of the classification of manifolds, stuck in dimensions three or four (because the Poincaré conjecture is still open in these dimensions), has been attempted in dimensions five and six by C.T.C. Wall. The considerable algebraic difficulties, however, have not allowed a great deal of progress.

Finally, it is as well to add that all these techniques have been generalized to the piecewise linear and topological categories, which has permitted the solution of major problems, such as the Hauptvermutung. (R.F.T.)

Topology, Algebraic

Topology is a branch of mathematics that deals with selected properties of collections of related physical or abstract elements. It had its beginnings in the study of those properties that endure when the collection undergoes distortion but remains intact.

Topology is so fundamental that its influence is apparent in almost every other branch of mathematics. It has even been found useful in disciplines that are not considered parts of mathematics proper. An intimate relation exists between aspects of topology and symbolic logic. Applications of so-called fixed-point theorems (see below) are made in mechanics. Topology contributes to the design of geographical maps; of networks for the distribution of electrical power, water, and natural gas; and of systems for industrial automation, guided missiles, and automobile traffic control.

To assign a topological character to a collection, it is sufficient to identify the subcollections that are to be open sets; that is, the subcollections that are similar in certain features (excluding the precise shape) to the interiors of circles in the familiar Euclidean plane. A collection so assigned a topological character is called a topological space. Topological spaces, on the other hand, are not limited to a Euclidean framework, because any collection at all may be made a topological space by assigning the open sets. These assignments are usually made with a definite object in view, such as an application to some particular problem in mathematics, physics, or technology. Consequently, in practice the characterization of a particular topological space is usually accomplished with the help of axiomatic methods.

Algebraic topology applies algebraic methods to study certain questions about topological spaces. The questions studied are usually of a qualitative nature, and the phenomena studied are usually "global"; that is, they belong to the space as a whole but are not inherent in any small part of it.

Certain intuitive notions can be analyzed, clarified, and classified topologically. A plane closed curve that does not cross itself has an inside and an outside; this intuitive idea can be made precise and can even be proved. The properties of knottedness and unknottedness of closed curves in three-dimensional space can be defined and analyzed, and this analysis is far from trivial.

Topology deals not only with spaces but also with maps;

that is, continuous functions from one space to another. The notation $f:X \to Y$ means that f is a map taking points of X to points of Y. Consider, for example, the Brouwer fixed-point theorem, asserted by the 20th-century Dutch mathematician L.E.J. Brouwer: if D^n is the unit disc in coordinate n-space R^n, it can be defined by an inequality (see Box, inequality 1). The theorem states that any map from the disc to itself has a fixed point (see 2). This asserts that a given equation has a solution, a useful conclusion.

The fixed-point theorem

More can be proved. With any map $f:X \to X$ (intuitively a function that redistributes the points of X) satisfying suitable assumptions such as continuity, the Lefschetz number $L(f)$ can be introduced. On the one hand, this is the total number of fixed points of f, counted with appropriate multiplicities; in particular, if $L(f)$ is nonzero, then f has a fixed point. On the other hand, $L(f)$ can be calculated without detailed knowledge of f; for example, if $X = D^n$, then $L(f) = 1$ for all f.

The Lefschetz number is a first example of an algebraic invariant to be discussed immediately below.

Invariants. A quantity depending on a space X or a map is an invariant if it is not changed when X or f is changed in some specified way. Invariants play a central role in the classification of spaces or maps. To prove the existence of a space or map satisfying specified requirements, it is usually possible to construct it; to prove the nonexistence of some hypothetical space or map, it may be possible to show that if it did exist, some invariant would be involved in a contradiction.

A suitable example of an invariant is the degree (to be defined) of a map $f:S^1 \to S^1$ from the unit circle S^1 to itself. If the argument point x moves once around the circle, then the image point $f(x)$ will move around the circle some whole number of times, say $d(f)$. This integer $d(f)$ is called the degree of f. On this foundation can be based almost the whole of plane topology. The "winding number," for example, of a closed plane curve Γ around a point x can be defined. If Γ is simple, its outside is the set of points x around which the winding number is zero.

The unit sphere S^{n-1} in n-space R^n is defined by an equation (see 3); it is the boundary of the unit disc D^n. The degree of a map from the sphere to itself can be defined; for $n - 1$ greater than 1 this is usually done using homology theory (see below *Homology and cohomology*). The Lefschetz number of a map is easily stated (see 4). The degree of a map from the unit sphere to itself is unchanged by small perturbations of f. This leads to the notion of homotopy.

Homotopy theory. If X and Y are two spaces, and f_0 and f_1 two maps from X to Y, then it is said that f_0 and f_1 are homotopic, and $f_0 \sim f_1$ is written, if f_0 can be perturbed or deformed continuously into f_1. More precisely, homotopy requires that there should be intermediate maps (see 5). Such a family of maps f_t is called a homotopy.

The relation $f_0 \sim f_1$ is an equivalence relation; thus it is possible to classify the maps from X to Y into homotopy classes. It is usual to write $[X, Y]$ for the set of such homotopy classes. Take, for example, both X and Y to be the circle S^1, or more generally the sphere S^n, and assign to each map its degree. This assignment gives a one-to-one correspondence between the set $[S^n, S^n]$ of homotopy classes and the set Z of integers.

In homotopy theory those questions are studied in which it makes no difference if all the maps in sight are replaced by homotopic ones. Two spaces X and Y, for example, are definable as homotopy-equivalent (see 6). A map between two homotopy-equivalent spaces is called a homotopy-equivalence; it is analogous to a homeomorphism, except that equality of maps has been replaced by homotopy. A space X is called contractible if it is homotopy-equivalent to a point.

For various reasons, the domain of homotopy theory is larger than might be expected. First, invariants of a map f usually take values in some algebraic object, such as the group of integers; typically it is discrete. If an invariant $d(f)$ of f is continuous in any sense, then $d(f_t)$ must be constant as t varies, so that $d(f_0) = d(f_1)$, and homotopic maps must have the same invariant. This is the case for the Lefschetz number and for all the most usual invariants; thus they belong to homotopy theory.

Extension problems

Second, the so-called extension problem starts with a space X, a subspace A of X, and a map $g:A \to Y$ from the subspace A to Y. (A space X together with a subspace A is often called a pair X, A.) It can be asked whether there is a map from the whole space X to the same image space Y that extends the given map g of A in a specific way (see 7). (It is usual to write $g = f|A$.) As a special case, it is possible to take X as the unit n-dimensional ball, Y as its boundary, A as identical to Y, and g as the identity mapping of S^{n-1} onto itself (see 8). The problem then asks whether there is a so-called retraction of the ball on its boundary. If the Brouwer fixed-point theorem is assumed to be false, it is easy to show that such a retraction would exist. It can be proved (using the degree) that there is no such retraction; and this immediately implies the Brouwer fixed-point theorem. Many other appealing geometric problems can be reduced to extension problems.

Extension problems belong to homotopy theory, at least for suitable pairs X, A. This classification follows from Borsuk's so-called homotopy extension theorem (see 9), which implies that given two homotopic maps of A, either they both extend, or neither does.

Third, numerous geometrical problems that do not appear to lie in homotopy theory have been successfully reduced to homotopy theory. This is done, for example, for the classification of fibre bundles by a classification theorem (see below *Fibrings*); it is also done for the computation of groups called cobordism groups by another theorem. Reduction to homotopy theory whenever possible is now a standard method in differential and geometric topology.

To obtain concrete results in homotopy theory, it is normal to require invariants that are computable. This requirement leads to homology.

Homology and cohomology. The basic idea of homology theory, which goes back to the French mathematician Henri Poincaré, is to divide a space up into points, line segments, triangles, and other geometric components and then to measure the number and the interrela-

(1) $x_1^2 + \cdots + x_n^2 \leq 1$

(2) Fixed point theorem for the disk D^n: Given $f: D^n \to D^n$, there exists x in D^n such that $f(x) = x$.

(3) $S^{n-1}: x_1^2 + \cdots + x_n^2 = 1$

(4) If $f: S^{n-1} \to S^{n-1}$ then $L(f) = 1 - (-1)^n d(f)$.

(5) Requirement of homotopy: There should be $f_t: X \to Y$ for $0 < t < 1$ such that $f_t(x)$ is a continuous function of the two variables t and x for $0 \leq t \leq 1$, x in X.

(6) X is homotopy-equivalent to Y if and only if there are maps $f:X \to Y$ and $g:Y \to X$ such that $fg \sim 1:Y \to Y$ and $gf \sim 1:X \to X$.

(7) For subspace A of X, the map $f: X \to Y$ extends $g: A \to Y$, if $f(a) = g(a)$ for a in A.

(8) $X = E^n$, $A = Y = S^{n-1}$, $g: S^{n-1} \to S^{n-1}$

(9) Borsuk's homotopy extension theorem: Given a map $f_0: X \to Y$, and a homotopy $g_t: A \to Y$ starting from the restriction of f_0 to A, $g_0 = f_0|A$, the theorem extends the homotopy from A to X so as to give a homotopy f_t of f_0.

tionships of these parts in a suitable algebraic way. If, for example, a surface M^2 is divided into vertices (V in number), edges (E in number), and triangular faces (F in number), then the Euler characteristic of M^2, which is also the Lefschetz number of the identity map 1: $M^2 \to M^2$, may be defined as $V - E + F$.

The Euler characteristic

The simplest figure obtained by connecting two points is a simplex in one dimension, a line segment. Adjoining one point in a second dimension results in a two-dimensional simplex (triangle). To this, the adjunction of a point in a third dimension yields a three-dimensional simplex (tetrahedron). To this, the adjunction of a point in a fourth dimension yields a four-dimensional simplex, and so on. More generally, the standard n-simplex σ^n can be precisely defined (see 10). The ith face of σ^n is the subspace $x_i = 0$. A finite simplicial complex is a space that can be assembled from a finite number of simplexes in the obvious way. Homology theory was first set up for finite simplicial complexes; but starting in the 1930s it was extended to maps from compact spaces to finite simplicial complexes and later to maps from simplexes to all spaces.

The modern approach to homology theory is axiomatic. The business of homology theory is to assign to each space some invariants that are (Abelian) groups and to assign to each map some invariants that are homomorphisms of groups (see 11). In the construction of these groups and homomorphisms, it can be proved that they satisfy seven axioms of the U.S. mathematicians Samuel Eilenberg and Norman E. Steenrod. Everything else follows from these axioms.

From the axioms, theorems can be deduced that allow the calculation of homology groups of all the spaces arising in practice. The study of position in manifolds, for example, is based on theorems that relate the (co)homology of a subspace to the homology of its complement, a result due to a number of mathematicians. Homology provides the first weapon in geometrical problems of homotopy theory (see above *Homotopy theory* and below *Further homotopy theory*). Singular homology can be constructed (see 12).

The difference between cohomology and homology

Cohomology differs from homology formally, in that a map induces a homomorphism in the opposite direction from that in homology (see 13). At the same time, cohomology can be introduced with coefficients in an Abelian group G (see 14).

Cohomology operations give extra structure to cohomology groups and can be used to resolve geometric problems. A good example is the Steenrod square, which is a homomorphism Sq^i mapping one cohomology group to another (see 15).

Homotopy groups. If it is desired to study maps from a simplicial complex W to a space X, it is natural to divide the problem into two parts: first, to study the possible ways of mapping simplexes into X; and, second, to assemble the information about maps of simplexes so as to obtain information about maps of the whole complex W. Homotopy groups serve to formalize the first part of the problem; obstruction theory serves to formalize the second part.

In what follows, it is convenient to agree that spaces have base points and that maps and homotopies preserve the base points. If X, A is a pair, it is possible to consider maps (see 16) from the cell E^n to X that carry the boundary sphere S^{n-1} into the subspace A. It is usual to take the set of homotopy classes of such maps; by geometrical constructions with the cell E^n, this set is turned into a group $\pi_n(X, A)$ (see 17). For $n \geq 3$ it is Abelian. If A is taken to the base point, the absolute homotopy group, written $\pi_n(X)$, is obtained. It coincides with $[S^n, X]$, the homotopy classes of maps from the sphere S^n to the space X. It is Abelian for $n \geq 2$. For $n = 1$ it coincides with what is called the fundamental group of X, introduced by Poincaré. For example, $\pi_n(S^n)$ is the group of integers Z.

A map $f: X, A \to Y, B$ induces a homomorphism of relative homotopy groups. Each pair X, A gives rise to an exact sequence, which is called the exact homotopy sequence of the pair (see 18).

(10) The standard n-simplex σ^n is the subspace of R^{n+1} given by: $x_1 + \cdots + x_{n+1} = 1, \quad x_1 \geq 0, \cdots, x_{n+1} \geq 0$.

(11) Relative homology groups can be assigned to pairs X, A. The homology group said to be in dimension n is written $H_n(X, A)$. The subspace A may be the empty set ϕ, in which case $H_n(X)$ can be written for $H_n(X, \phi)$. For example, $H_n(S^n)$ turns out to be the group of integers Z (if $n > 0$). If X, A and Y, B are two pairs, it is usual to write $f: X, A \to Y, B$ to mean that f is a map from X to Y which carries the subspace A into B. Homology-theory is then used to define the induced homomorphism $f_*: H_n(X, A) \to H_n(Y, B)$. If f maps for example S^n to S^n, then the induced homomorphism f_* is an endomorphism of $H_n(S^n) \cong Z$; it must be multiplication by some integer d; this integer d is the degree of f.

(12) To construct singular homology, it is usual first to take the set of all maps $f: \sigma^n \to X$. The free Abelian group generated by these maps is the chain group $C_n(X)$. By using the faces of σ^n it is possible to define a boundary homomorphism $d_n: C_n(X) \to C_{n-1}(X)$. The homology group $H_n(X)$ is then defined as $\ker d_n / \operatorname{im} d_{n+1}$.

(13) In cohomology a map $f: X, A \to Y, B$ induces a homomorphism $f^*: H^n(Y, B) \to H^n(X, A)$.

(14) In the construction of cohomology $H^n(X, A; G)$ with coefficients in an Abelian group G, the chain groups $C_n(X)$ are replaced by the cochain groups $C^n(X; G) = \hom(C_n(X), G)$.

(15) $Sq^i: H^n(X, A; Z_2) \to H^{n+i}(X, A; Z_2)$

(16) $f: E^n, S^{n-1} \to X, A$.

(17) The set of homotopy classes of maps f, defined in (16), is turned by geometrical construction into a group called the nth relative homotopy group of X mod A, and written $\pi_n(X, A)$.

(18) $\cdots \to \pi_n(A) \xrightarrow{i^*} \pi_n(X) \xrightarrow{j^*} \pi_n(X, A) \xrightarrow{d} \pi_{n-1}(A) \to \cdots$

(19) A space X or pair X, A is said to be n-connected if the homotopy groups $\pi_r(X)$ or $\pi_r(X, A)$ are zero for $r \leq n$. The Hurewicz isomorphism theorem states that if X is $(n-1)$-connected, where $n \geq 2$, then an isomorphism $\pi_n(X) \cong H_n(X)$ is obtained.

(20) Examples: $\pi_3(S^2) = Z$; $\pi_6(S^3) = Z_{12}$, The group of integers modulo 12.

(21) Freudenthal suspension theorem states that the homotopy group $\pi_{n+r}(S^n)$ is independent of n for $n > r + 1$; more precisely, there is an isomorphism $\pi_{n+r}(S^n) \cong \pi_{n+r+1}(S^{n+1})$.

The Hurewicz isomorphism theorem

The isomorphism theorem due to the U.S. mathematician Witold Hurewicz states that for a certain space X, such as the sphere, an isomorphism is obtained between the first nonvanishing homotopy and homology groups (see 19). There is a corresponding theorem for relative groups.

If the spheres are treated as some of the most basic spaces in homotopy theory, it is natural to seek the structure of the homotopy groups of spheres. Some examples are known (see 20). Although much effort has been devoted to this problem, no pattern or general formula has been produced.

Stability and suspension. A phenomenon in algebraic topology is said to be stable if it happens in the same way in any dimension or in any sufficiently large dimension. The suspension theorem due to the Dutch mathematician

Hans Freudenthal provides an example expressed in terms of an isomorphism (see 21). This isomorphism is given by the geometrical construction of suspension. The suspension SX of X is the union of two cones with common base X, for which simple examples exist (see 22). Further reasoning is technical (see 23). It is useful to give sets of homotopy classes an algebraic structure whenever it is possible (see 24).

The homology and cohomology groups of a suspension can be given (see 25), and homology and cohomology are considered stable. The Steenrod square (see 15) is a homomorphism between cohomology groups that is defined in every dimension and commutes with the suspension isomorphism; it is therefore considered stable.

Fibrings. If $p:E \to B$ is a map, then the counter-images $p^{-1}\, b$ of the points in B are called the fibres of p; they are regarded as a continuous family of subspaces in E, indexed or parameterized by the points of B. It may be required that each fibre be homeomorphic to a fixed space F; even so, it may not be possible to choose the homeomorphisms to vary continuously as the parameter b is varied. Further structure or further axioms may be required.

The Möbius band

The Möbius band, for example, may be regarded as a family of intervals, parameterized by the points of a circle. Another example is given by the family of tangent spaces to a manifold. In this example every fibre is a vector space; such examples are called vector bundles; they are important in differential topology. Whitney sums can be defined (see 26). A vector bundle with fibres of (real) dimension n is a fibre bundle with structural group $GL\,(n, R)$, in the sense of Steenrod.

In the applications, it is important to be able to classify the bundles over X with group G. This is a problem in homotopy theory; such bundles are in one-to-one correspondence with homotopy classes of maps $f:X \to BG$. Here BG is a space called the classifying space of G; its characteristic property is that there is a fibring $EG \to BG$, called the universal bundle, in which EG is contractible and G acts freely on EG, with quotient BG.

The most practical invariants of a bundle, ξ, over X with group G are characteristic classes (see 27). These classes have convenient properties, and many results in the topology of manifolds are expressed in terms of them. Characteristic classes defined for G-bundles and satisfying an obvious naturality axiom are in one-to-one correspondence with elements of $H^*(BG)$; and $H^*(BG)$ has been calculated for the most useful groups G (see below *Spectral sequences*).

In a lifting problem, it is usual to give a map $f:X \to B$ and ask whether there is a map $g:X \to E$ such that $pg = f$. The problem, for example, of finding a continuous field of nonzero tangent vectors on a manifold is a problem of this type. Lifting problems belong to homotopy theory; this classification is guaranteed by what is called the homotopy lifting theorem, the statement of which is analogous to that of the homotopy extension theorem (see 9).

It follows from the homotopy lifting theorem that a fibring gives rise to an exact homotopy sequence (see 28). It is possible therefore to obtain information on homotopy groups from fibrings that arise in nature, so to speak, such as the Hopf fibrings.

The French mathematician Jean-Pierre Serre proposed that the word fibring should be used for any map that has the homotopy lifting property. He thus greatly increased the range of useful fibrings by admitting fibrings involving function spaces, particularly loop spaces (see 29). There is a natural relationship involving loop spaces such that suspension theory may be reduced to the study of loop spaces (see 30).

Fibring involving function spaces

Serre used essentially similar constructions to show that any map $f:X \to Y$ may be factored in the form $X \xrightarrow{e} E \xrightarrow{p} Y$, in which e is a homotopy-equivalence and p is a fibring. This factoring provides enough fibrings for all the purposes of homotopy theory.

Sheaf cohomology. A sheaf over a space X may be viewed in two lights. The first is the viewpoint of the case of functions on a Riemann surface X. To each open set U in X can be associated the ring of complex functions analytic on U; but as U gets bigger the ring gets smaller, and vice versa. In general, it is possible to associate to each open set U in X a ring or group $\Gamma(U)$ satisfying suitable axioms. Second, it is possible to view a sheaf as a parameterized family of coefficient groups indexed by the points of X. To a point x of a Riemann surface, for example, can be associated the group of those functions that are analytic around x.

The sheaves over X may be considered as the objects of a category; homological algebra can then be done in this category. The entity called a function that associates to each sheaf Γ the group $\Gamma(X)$ of functions on the whole space is not exact, but it has derived functors. These provide the cohomology groups $H^n(X;\, \Gamma)$ of X with coefficients in the sheaf Γ. From the point of view of algebraic topology, this situation is the appropriate version of cohomology when the coefficient group is replaced by a sheaf.

Cohomology with local coefficients

Sheaf cohomology is useful in algebraic geometry. A simple special case is that in which the sheaf is a fibring, so that the coefficient groups corresponding to the different points of x are all isomorphic to a fixed group. This gives cohomology with local, or twisted, coefficients, useful, for example, in studying nonorientable manifolds.

Spectral sequences. Since the pioneering work of the French mathematician Jean Leray and the celebrated work of Serre, algebraic topology has made much use of spectral sequences. A spectral sequence is an algebraic construct comparable with an exact sequence, but more complicated. Although the existence of a spectral sequence may not provide an algorithm or rule for computing the groups concerned, the experts succeed with it more often than not.

(22) Example: $SS^n = S^{n+1}$

(23) A map $f:X \to Y$ induces a map $SF:SX \to SY$. This yields a function $S:[X, Y] \to [SX, SY]$. The space Y may be $(n-1)$-connected; when this is the case it can be shown that this function is a bijection if X is at most $(2n-2)$-dimensional, a surjection if X is $(2n-1)$-dimensional.

(24) If SX is a suspension, then the set of homotopy classes $[SX, Y]$ may be made into a group. The common value of the groups $[S^{m+r}X, S^mY]$ for sufficiently large values of m is the group $\{X, Y\}_r$ of "stable homotopy classes of maps from X to Y."

(25) The homology and cohomology groups of a suspension: $\tilde{H}_{n+1}(SX) \cong \tilde{H}_n(X)$; $\tilde{H}^{n+1}(SX) \cong \tilde{H}^n(X)$. (Here the "reduced" homology of X is defined by $\tilde{H}_n(X) = H_n(X, pt)$.)

(26) If $p:E \to B$ and $q:E' \to B$ are vector bundles; their Whitney sum is a vector-bundle, in which the fibre over b is the direct sum $(p^{-1}b) \oplus (q^{-1}b)$.

(27) If G is a unitary group $U(n)$ the Chern classes $c_i(\xi) \in H^{2i}(X; Z)$ are obtained; if G is an orthogonal group $O(n)$ the Stiefel-Whitney classes $w_i(\xi) \in H^i(X; Z_2)$ and the Pontrjagin classes are obtained.

(28) $\cdots \to \pi_n(F) \to \pi_n(E) \to \pi_n(P) \to \pi_{n-1}(F) \to \cdots$

(29) If X is a space with base-point x_0, then the path-space LX is the space of maps $\omega:I \to X$ from the unit interval I to X such that $\omega(0) = x_0$ (paths starting at the base-point). A map $p:LX \to X$ is defined by $p(\omega) = \omega(1)$; it is a fibering with LX contractible; it is analogous to the fibering $EG \to BG$. The loop-space ΩX is the fibre $p^{-1}(x_0)$; that is, the space of paths starting and finishing at the base-point.

(30) $[SX, Y] \cong [X, \Omega Y]$

A spectral sequence consists of groups together with boundary homomorphisms between these groups (see 31). The spectral sequence is said to converge toward a limit, if certain conditions are satisfied (see 32).

Suppose, for example, there is a fibring with fibre F, total space E, and base B. The result is the Serre spectral sequence (see 33), which converges toward the homology of the total space, and its initial term is the homology of the base with coefficients in the homology of the fibre. There is a similar spectral sequence in cohomology.

Since the introduction of the Serre spectral sequence, mathematicians have been able to work effectively with the homology of fibrings. One application, originally due to Borel, led to the calculation of the cohomology of the classifying space BG for each of the classical Lie groups G. This calculation led to a complete understanding of the theory of characteristic classes. If, for example, G is the unitary group $U(n)$, then the cohomology ring $H^*(BU(n))$ is a polynomial algebra generated by the Chern classes $c_1, \cdots, c_n$ of the universal bundle.

Other spectral sequences are also useful. A celebrated calculation of the cohomology of Eilenberg–MacLane spaces by Henri Cartan of France (see below *Further homotopy theory*) led eventually to the Rothenberg-Steenrod spectral sequence (see 34). In this case the cohomology of a classifying space BG (with coefficients in a ring R) can be computed using a spectral sequence, in which the initial term is obtained from the homology of G by homological algebra.

The Eilenberg–Moore spectral sequence

To proceed in the opposite direction, there is obtained the Eilenberg–Moore spectral sequence (see 35), in which the homology of a loop space ΩX can be computed from that of X using homological algebra and a spectral sequence. In fact, Eilenberg and Moore also give their result at what is called the chain level and give their spectral sequence in greater generality, to compute the homology of induced fibrings.

Further homotopy theory. A considerable advance in homotopy theory became possible by using spectral sequences to prove results on the homology of fibrings (following Serre). An example (see 36) in suspension theory leads to an easy proof of the result mentioned above in *Stability and suspension*. More advanced results in suspension theory have been obtained in England from the study of loop spaces by the United States mathematician George W. Whitehead and English and Japanese, respectively, mathematicians Ioan Mackenzie James and Hiroshi Toda.

A process similar to the calculation of the cohomology of classifying spaces but involving many steps instead of one led, in the hands of Serre and Cartan, to the calculation of the homology of Eilenberg–MacLane spaces. A space Y is an Eilenberg–MacLane space of type (π, n) if its homotopy groups are all zero except for the nth, which is π. The circle S^1, for example, is an Eilenberg–MacLane space of type $(Z, 1)$. If Y is of type (π, n), then its loop space is of type $(\pi, n-1)$. If Y is of type (π, n), then $[X, Y] = H^n(X; \pi)$; the group of homotopy classes of maps from X to Y is isomorphic to the nth cohomology group of X with coefficients in π. It follows that the cohomology of the Eilenberg–MacLane space Y gives an enumeration of those cohomology operations that can be defined on $H^n(X; \pi)$ for all X. In particular, for any prime p, the mod p Steenrod algebra A is defined to be the set of all stable cohomology operations defined on cohomology with coefficients Z_p: its structure is determined by the results on Eilenberg–MacLane spaces.

Use of Eilenberg–MacLane spaces

Any space X can be approximated by an iterated fibring in which the building blocks are Eilenberg–MacLane spaces of type $(\pi_n(X), n)$, which is the Postnikov decomposition of X. In principle, then, if the homotopy groups of X were known, the homology of these Eilenberg–MacLane spaces would be known, and thus the homology groups of X could be calculated. In practice, the method is usually applied in the reverse direction, by knowing the homology of X, and by calculating its first few homotopy groups. This is the so-called method of killing homotopy groups of Cartan and Serre.

The method of killing homotopy groups may be applied to gain general information without computing specific groups. This method leads to Serre's C-theory, by which it can be shown on a priori grounds that the homotopy groups of a given space are finite, or finitely-generated. The theorems also show that different primes play independent roles in homotopy theory; the 3-primary component of a given group can be calculated without considering its 2-primary component.

In stable homotopy theory, it is possible to formalize the method of killing homotopy groups. The Adams spectral sequence can be obtained (see 37). As a result, the groups of stable homotopy classes of maps can be computed, starting from homological data, using homological algebra and a spectral sequence. This spectral sequence has been used to compute stable homotopy groups of spheres and (following the method of the mathematician John W. Milnor of the United States) to compute cobordism groups.

Generalized homology. A generalized homology or cohomology theory is a functor that assigns to any space X groups $K_n(X)$ or $K^n(X)$ and that satisfies the first six axioms of Eilenberg and Steenrod already referred to (see above *Homology and cohomology*) but that does not necessarily satisfy the seventh axiom, which would restrict the resulting groups when X is a point. One example of such a functor that has become important in algebraic topology is the K-theory of Alexander Grothendieck of France, Michael F. Atiyah of the United States, and others. The groups $K^n(X)$ are constructed in terms of vector bundles. The isomorphism classes of complex vector bundles over X, for example, form a monoid or semigroup under Whitney sum. Consider all homomorphisms that map this semigroup to an Abelian group; among them is one that is universal: the group into which it maps is the 0th K-cohomology group $K^0(X)$.

Further examples are provided by bordism and cobordism. It is possible to construct the singular homology group $H_n(X)$ by using maps from the n-simplex to X; it is also possible to construct the bordism group $MSO_n(X)$ by a comparable use of maps from oriented n-manifolds to X. These functors are often relevant in questions on the topology of bundles and manifolds, and they have been used to prove geometrical results of a nontrivial nature.

Bordism and cobordism

Calculation of generalized homology groups is often based on the spectral sequence of G.W. Whitehead–Atiyah–Hirzebruch (see 38). This sequence starts from the ordinary homology groups of X with coefficients in the generalized homology of a point and converges to the generalized homology of X (similarly for cohomology). To apply this sequence, it is necessary to know the generalized homology of a point; that is, the groups $K_q(pt)$. In the case of K-theory, these groups are determined by the Bott periodicity theorem.

There is an analogy between the group $K^n(X)$ and the set $[X, Y]$ of homotopy classes of maps from X to a fixed space Y. If $f: A \to X$ is a map, it is possible to construct $X \cup_f CA$ by taking X and the cone CA with base A and identifying each point a in A with $f(a)$ in X. The sequence $A \xrightarrow{f} X \longrightarrow X \cup_f CA$ is called a cofibring. If either the group $K^n(X)$ or the set $[X, Y]$ is taken and X is varied along a cofibring, an exact sequence is obtained.

The representability theorem of E.H. Brown, a mathematician of the United States, gives necessary and sufficient conditions on a functor K from spaces to sets in order that it have the form $K(X) = [X, Y]$. These conditions are always satisfied by the groups $K^n(X)$ of a generalized cohomology theory. For complex K-theory, for example, it follows that $K^0(X) = [X, BU]$, in which BU is the "limit" as $n \to \infty$ of the classifying spaces $BU(n)$.

Conversely, ideas from generalized cohomology are useful in stable and, to a less extent, in unstable homotopy theory. The set of homotopy classes $[X, Y]$, or the group of stable homotopy classes $\{X, Y\}_r$, is considered as a generalized cohomology functor of X; the spectral sequence of G.W. Whitehead–Atiyah–Hirzebruch then serves as a modern substitute for obstruction-theory.

(31) A spectral sequence consists of groups $E^r_{p,q}$ (depending on three indices p, q, r), together with boundary homomorphisms $d^r: E^r_{p,q} \to E^r_{p-r,q+r-1}$ between these groups.

(32) It is usual to start with the groups $E^2_{p,q}$ for $r=2$. The higher terms $E^r_{**} = \sum_{p,q} E^r_{p,q}$ are determined by $E^{r+1}_{**} = \ker d_r / \operatorname{im} d_r$ as r tends to infinity the group $E^r_{p,q}$ tends to $E^\infty_{p,q}$. The spectral sequence is said to converge toward $L_* = \sum_n L_n$ if the groups $E^\infty_{p,q}$ with $p+q=n$ are the subquotients arising from a suitable filtration of L_n. The notation $E^2_{p,q} \Rightarrow L_n$ indicates such a spectral sequence.

(33) The Serre spectral sequence: $H_p(B; H_q(F)) \Rightarrow H_n(E)$.

(34) The Rothenberg-Steenrod spectral sequence: $\operatorname{ext}_{H_*(G;R)}(R,R) \Rightarrow H^*(BG;R)$.

(35) The Eilenberg-Moore spectral sequence: $\operatorname{cotor}^{H_*(X,R)}(R,R) \Rightarrow H_*(\Omega X, R)$.

(36) In suspension-theory there is a bijection $[SY, Z] \cong [Y, \Omega Z]$. In particular (taking $Z=SY$) the identity map $1: SY \to SY$ corresponds to an embedding of Y in ΩSY. It can be shown that if Y is $(n-1)$-connected, then the pair $(\Omega SY, Y)$ is $(2n-1)$-connected; that is, Y and ΩSY are the same in a certain sense throughout a large range of dimensions.

(37) If X and Y are spaces, and p is a prime, it is possible to obtain the Adams spectral sequence: $\operatorname{ext}^{**}_A(\tilde{H}^*(Y;Z_p), \tilde{H}^*(X;Z_p)) \Rightarrow {}_pG\{X,Y\}_*$. Here ${}_pG$ means the p-component of the group G; the algebra A is the mod p Steenrod algebra; and the reduced cohomology groups $\tilde{H}^*(Y;Z_p)$, $\tilde{H}^*(X;Z_p)$ are considered as modules over A.

(38) The spectral sequence of G.W. Whitehead-Atiyah-Hirzebruch: $H_p(X; K_q(pt)) \Rightarrow K_n(X)$.

Present outlook. In the 1970s, progress in the central and older parts of algebraic topology has been less rapid than in the past. Although, for example, detailed calculations of the homotopy groups of spheres $\pi_r(S^n)$ have been carried out for a reasonable range of dimensions, no pattern has emerged that might lead to new insights and theorems not yet suspected. The most flourishing and hopeful areas are in general the borderlines with other subjects, in which a cross-fertilization of ideas often leads to new advances.

On the frontier with algebra, ideas developed in algebraic topology have evidently had an important influence in the development of category theory, homological algebra, and algebraic K-theory. Conversely, ideas from all these subjects have proved stimulating and useful in algebraic topology; for example, the work on finiteness obstructions and surgery obstructions relies essentially on algebraic K-theory.

Similarly, on the frontier with algebraic geometry, ideas from algebraic topology have evidently had an important influence on the modern school of algebraic geometry associated with Grothendieck. Equally, ideas from modern algebraic geometry have led to significant work in algebraic topology.

The advances in the topology of manifolds made possible by a celebrated breakthrough of Kirby and Siebenmann consist of work that is geometrical in interest and method but has a large interrelation with algebraic topology.

The celebrated work of Atiyah and Singer lies on the borderline of algebraic topology and analysis. The study of systems of partial differential equations on a manifold is generalized to the study of an elliptic operator. The theorem of Atiyah and Singer, in its first form, related the behaviour of this operator to the topology of the underlying manifold. The proof used the principle that a discrete invariant does not change when the operator is continuously perturbed. A later form of the theorem embodies a far-reaching generalization of the Lefschetz number. Perhaps, while the best contemporary work often draws together several subjects, it sometimes reveals new potentialities in the most basic ideas of algebraic topology.

BIBLIOGRAPHY. EDWIN H. SPANIER, *Algebraic Topology* (1966); and DALE HUSEMOLLER, *Fibre Bundles* (1966), are two of the most generally useful standard texts. The scope of Spanier is wider; that of Husemoller is more limited. It is not easy for a student to read Spanier as a first text, but mathematically it is excellent. JOHN F. ADAMS, *Algebraic Topology: A Student's Guide* (1972), has a much longer bibliography, with a survey article and a guide to the literature.

Topology, General

An offshoot of geometry, topology was originated during the 19th century. A simple (but not entirely accurate) definition has often been used: Topology is the study of those properties that an object retains under deformation, specifically, bending, stretching and squeezing, but not breaking or tearing. Thus a triangle is topologically equivalent to a circle but not to a straight line segment. Similarly, a solid cube made of modelling clay could be deformed into a ball by kneading. It could not, however, be molded into a solid torus (ring) unless a hole were bored through it or two surfaces were joined together. A solid cube is therefore not topologically equivalent to a finger ring.

More precisely, if there are given two geometric objects or sets of points, and if some two-way transformation (or operation or mapping) takes each point p of either set into one and only one point p' of the other, and if the transformation is continuous in the sense (which can be made precise) that points close to p become points close to p', then the transformation is called a homeomorphism and the two sets are said to be topologically equivalent. Topology is, then, the study of properties that remain invariant under homeomorphisms.

This definition is intended to make it clear that the deformation concept has certain limitations. If two figures are given in Euclidean two-dimensional space, called $\Re^2$—that is, the space of ordinary plane geometry—and if one of them consists of a circle tangent internally to a larger circle, and the other consists of two externally tangent circles, then a homeomorphism exists that transforms one figure into the other, and therefore the two figures are topologically equivalent. One figure cannot, however, be changed to the other by distortion in $\Re^2$. It is possible to turn one of the circles through 180° around the common tangent line as axis, thus carrying it into three-dimensional space $\Re^3$, and effect the deformation. The extra dimension may or may not be available, depending on the conditions of the problem. An internally tangent sphere in $\Re^3$ could be continuously deformed to bring it to a position of external tangency by a rotation in hypothetical four-dimensional space $\Re^4$, which might present no difficulty mathematically but would be impossible to achieve or even visualize in a physical application. The mathematical context may also prevent the use of an additional dimension: In any case, the deformation concept is not used or needed in defining topology.

Examples of problems, methods, and applications of topology. *Euler's theorem.* An example of a topological invariant is provided by Euler's classic theorem on polyhedra. A three-dimensional polyhedron without holes or handles may be considered (it is topologically a ball). If the numbers of faces, edges, and vertices on its surface are F, E, and V, respectively, then $F - E + V = 2$. Thus a cube, with six faces, 12 edges, and eight

vertices, satisfies the property; and so do all polyhedral balls, however complicated and irregular. Furthermore, if a point is removed from a face of the surface of the polyhedral ball and the remainder is suitably mapped onto a planar figure, the property still holds, being topologically invariant; and in fact the theorem is most readily proved with the aid of such a mapping.

Though topology deals with some very generalized sets in abstract spaces that do not resemble point sets of the "real world," there are applications of topology to physics and the other sciences.

The fixed-point theorem. The fact that every direction is south to a person standing at the North Pole is a defect of the system of latitude and longitude. Because the polar regions have become more important places than they once were, it might be convenient to adopt a coordinate grid on which there would be no such singular point anywhere on Earth. On the other hand, such a grid is impossible. It is also true that at any instant there is always at least one place on the Earth's surface where the wind is not blowing. These two facts, seemingly very different from each other, are both direct consequences of the fixed-point theorem, which states that every homeomorphism of a round spherical surface onto itself either leaves at least one point fixed or sends some point into its diametrically opposite. A three-dimensional ball also has the fixed-point property: If one continuously stirs a pot of glue, no matter how long and thoroughly, and even induces slippage along the sides of the pot, so that each particle is moved about, and then stops, there will always be some particle of the glue that has returned to its starting point.

The Möbius band. A driving belt may wear because of friction over the wheels. If such a belt is given a 180° twist before the ends are sewn together, it may last longer because it wears equally on both sides. In fact, it has only one side and one edge. Such a belt is a model of a Möbius band (see MATHEMATICS AS A CALCULATORY SCIENCE). Cutting a Möbius band down the middle gives it a second edge and returns it to a single two-sided surface (with twists).

Jordan's theorem. A simple closed curve in the plane does not cross itself. (A figure-8 curve is not simple.) Jordan's theorem states, in effect, that every simple closed curve divides the plane into two compartments, one inside the curve and one outside it; and that it is impossible to pass continuously from one to the other without crossing the curve. This seemingly trivial and self-evident state of affairs has many important consequences.

The classical "utility problem" or "cranky neighbour problem" asks whether it is possible for three houses (A, B, and C) each to be connected to three utility plants, 1, 2, and 3, without having any of the lines cross. The negative answer is derived from topological considerations. It must be recognized at the outset that it makes no essential difference how the houses and plants are oriented. The lines from houses A and B to utilities 1 and 2 form a simple closed curve.

If the third house C is now placed inside the curve, it can be satisfactorily connected to 1 and 2; but then the inside will be compartmented, and no matter where 3 is placed, it will be cut off in terms of Jordan's theorem from one of A, B, or C. The same argument holds if C is placed outside.

This method of solution finds serious application in the theory of stamped electrical circuits. The lines of such stamped circuits cannot be permitted to cross. The question of what noncrossing circuits are possible is an extension of the problem of the three utilities.

The role of topology in mathematics. The applications of topology to mathematics itself are much deeper and more far-reaching than the above examples would indicate. Most of those who work in topology are not searching for immediate applications. They study it because of the challenge it offers and because they wish to learn more about the properties of real or abstract spaces. They wish to know whether one set of properties implies another set of properties. They wish to know what is true and what is possible. Topological notions and methods underlie much of modern mathematics, and the topological approach has illuminated and clarified very basic structural concepts in diverse branches of the subject.

In the same way that the Euclidean plane satisfies certain axioms or postulates, it can be shown that certain abstract spaces have definite properties without examining these spaces individually. By approaching topology from this abstract point of view, it is possible to use its methods to study things other than collections of points. Collections of entities that are of concern in analysis or algebra or collections of geometric objects can be treated as spaces and the elements in them as points.

Much use is made of the notion of open sets (subsets of a space that satisfy certain axioms) in studying topological spaces. A point p is said to be a limit point of a set Y in a topological space X, for example, if each open set in X that contains p contains a point of Y other than p. In determining whether or not p is a limit point of Y, it is of no concern whether p belongs to Y (which is stated symbolically as $p \in Y$). In physical terms, this means that p is infinitely close, in a certain sense that can be made precise, to other points of Y. The set of points that are either points or limit points of Y is called the closure of Y and is designated by $\bar{Y}$. A set is called closed if it contains each of its limit points. The closure of a set

Examples are useful in topology; they help a mathematician to discover theorems that are likely to be true and aid him in labelling others as false. Giving a counter-example is a convincing way of showing that a "proof" is wrong or that a conjecture is false. Examples of some useful topological spaces are described below, some of them being quite different from those studied in geometry.

Building topological spaces. Certain topological spaces are of historical interest because they have been widely used in the past. Others are studied because they illustrate an interesting property. On many occasions the mathematician "manufactures" a topological space to meet his immediate needs.

A topological space X is built up of a collection of sets $\{U\alpha\}$ called a basis. This collection of sets together with all their possible unions is called the open sets of the topology. In the plane, for example, each open set is the union of interiors of circles. The set of interiors of circles, therefore, is a basis for the plane. The set of interiors of rectangles is another basis. In determining whether a point p is a limit point of a set X, it makes no difference whether each interior of a circle that contains p or each interior of a rectangle that contains p contains a point on X other than p. For the line, one basis is the collection of open intervals. For Euclidean three-dimensional space, one basis is the collection of interiors of balls, and another is the collection of interiors of rectangular solids. If a distance is defined for a topological space, the basis is usually taken as the interiors of balls in which the interior of the ball with centre at p and radius r is the set of all points that have distance from p less than r.

A look at several well-known topological spaces may indicate how topological spaces are constructed and suggest which topological spaces have been considered important. Well-known topological spaces

Euclidean n-dimensional space. Points of this space are n-tuples of numbers $(x_1, x_2, \cdots, x_n)$. Basis elements are the interiors of balls in which the distance between $p = (x_1, x_2, \cdots, x_n)$ and $q = (y_1, y_2, \cdots, y_n)$ is the square root of $(y_1 - x_1)^2 + (y_2 - x_2)^2 + \cdots (y_n - x_n)^2$.

Hilbert space. Points of real Hilbert space are sequences of numbers $x_1, x_2, \cdots$ such that the infinite sum Σx_i^2 is finite. Elements of the basis are the interiors of balls in which the distance between $p = (x_1, x_2, \cdots)$ and $q = (y_1, y_2, \cdots)$ is the square root of $\Sigma(y_i - x_i)^2$.

Discrete spaces. For a collection of objects that is to be regarded as a topological space with its elements as points, it is sufficient to describe the subsets of the collection that are to be called open sets. One possibility is to define all subsets as open, even the one-point sets. The resulting topology is called the discrete topology. It is not

very useful from the topological point of view because a discrete space has no limit points.

Linear spaces. If the elements of a collection are ordered, which means that for any two elements one precedes the other, this ordering can be used to give the collection a linear topology. Basis elements are of three sorts: the set of points between some two points, the set of points before some point, and the set of points after some point. The line and interval are two conspicuous examples of linear spaces. Another example is given below.

A lexicographically ordered square. If I^2 is a square in the plane with its sides parallel to the axes, then each point p of I^2 may be designated by coordinates (x, y), and it is possible to write $p = (x, y)$. The points of I^2 are so ordered that if $p_1 = (x_1, y_1)$ and $p_2 = (x_2, y_2)$, then p_1 precedes p_2 if either $x_1 < x_2$ or $x_1 = x_2$, and $y_1 < y_2$. In this ordering the lower left-hand corner is the first point and the upper right corner is the last. Such points of I^2 are said to be the points of the lexicographically ordered square because the order is analogous to that found in a dictionary. The topology is linear. While the lexicographical square shares some properties with an interval, it differs in that it contains an uncountable collection of disjoint open sets.

Function spaces. If A and B are topological spaces, a function f that maps A into B, which is stated symbolically as $f:A \to B$, is a rule that assigns an element of B to each element of A. The point b of B associated with the point a of A is designated by $f(a)$; b is called the image of a. If $\{f_\alpha\}$ is a collection of such functions, it is sometimes convenient to regard this collection as a topological space the points of which are the functions. A collection of subsets of the collection must be selected to serve as open sets. There are many ways of doing this; the description of two of them follows.

Topologies for function space

In the first topology given for $\{f_\alpha\}$, the open sets are made to be large by restricting the basis elements with respect to only a finite number of points of A. A basis element is determined by a particular function belonging to the space—that is, an $f\alpha_0 \in \{f_\alpha\}$—a finite number of points $a_1, a_2, \cdots, a_n$ of A; and a finite collection of open sets $U_1, U_2, \cdots, U_n$ in B, such that $f\alpha_0(a_i) \in U_i$ for $i = 1, 2, \cdots, n$. The basis element determined by $f\alpha_0$, these a_i's and these U_i's, is the set of all f's in $\{f_\alpha\}$ such that $f(a_i) \in U_i = 1, 2, \cdots, n$. Other basis elements are determined by other elements of $\{f_\alpha\}$, other finite subsets of A, and other finite collections of open sets in B.

In the second topology given for $\{f_\alpha\}$ it is supposed that B is the interval [0, 1] of the real line $\mathfrak{R}^1$. The distance between each pair of elements f_β, f_γ of $\{f_\alpha\}$ is defined to be the least upper bound of $|f_\beta(x) - f_\gamma(x)|$, x varying over A. Basis elements are open balls.

Something can be learned from the fact that different topologies can be chosen for $\{f_\alpha\}$. A topology can be chosen to suit certain needs, and the choice of topology is usually made with a definite object in mind. In dealing with differentiable functions, for example, it may be advantageous to define distance so that for two functions to be close, their derivatives must also be close.

For the function spaces just described, no use was made of the topology of A; it might just as well have been discrete. The function spaces are related to Cartesian-product spaces, which are covered below.

Cartesian-product spaces. Starting with a pair of topological spaces X_1, X_2, the Cartesian product of X_1 and X_2 (written $X_1 \times X_2$) may be constructed as follows: The points of $X_1 \times X_2$ are ordered pairs (a, b) in which $a \in X_1$ and $b \in X_2$. Basis elements of $X_1 \times X_2$ are sets of the form $U_1 \times U_2$ in which U_1 is a basis element of X_1; U_2 is a basis element of X_2; and $U_1 \times U_2$ denotes the set of all points (x_1, x_2) of $X_1 \times X_2$ in which $x_1 \in U_1$, $x_2 \in U_2$. In a certain sense, the plane $\mathfrak{R}^2$ is the Cartesian product of two lines. Also $\mathfrak{R}^{m+n}$ is the Cartesian product of $\mathfrak{R}^m$ and $\mathfrak{R}^n$.

Cartesian products of topological spaces

Instead of the Cartesian product of just two spaces, the Cartesian product of a collection $\{X_\alpha\}$ of topological spaces can be studied. In this case a point in the Cartesian-product space is a collection $\{p_\alpha\}$ such that $p_\alpha \in X_\alpha$. The collections $\{p_\alpha\}$ and $\{X_\alpha\}$ have like subscripts. To get a basis element, a collection $\{U_\alpha\}$ is considered in which U_α is an open set in X_α and all but a finite number of the U_α's are the whole of the corresponding X_α. The basis element corresponding to U_α is the set of all points $\{q_\alpha\}$ of the Cartesian-product space such that $q_\alpha \in U_\alpha$.

Topological spaces. The collection of open sets of a topological space is axiomatically required to have the following properties:

1. Each point in the space is an element of (belongs to) some open set.
2. The union of any collection of open sets is an open set.
3. If two open sets share a common point, their intersection is open.

It may be shown that $\mathfrak{R}^n$, Hilbert space, discrete spaces, linear spaces, function spaces, and Cartesian-product spaces are all topological spaces. The basis elements were chosen to make this true. Had they been indiscriminately chosen, a topological space might not have resulted. The line would not be a topological space, for example, if its basis elements were defined as closed intervals. The third requirement would not be satisfied.

An unusual topology of the line. The points of an unusual topology called "E^1-bad" are the points of a horizontal line. Basis elements are half-open intervals open on the right—that is, sets of the form $[p, q)$ in which p, q are points of the horizontal line with p to the left of q, and $[p, q)$ is the set consisting of p and all points strictly between p and q. While the space E^1-bad has the same points as a line, its topology is different. It does not have the linear topology. No point of E^1-bad is a limit point of the set of points to the left of it. It will be shown below that E^1-bad differs from $\mathfrak{R}^1$ in other respects.

Topological properties. Although in what follows mention is made of such topological properties as connectedness, separability, being homeomorphic with another space, regularity, normality, and compactness, these are only a sampling of many such topological properties, many others of which can be found in textbooks on topology. Homeomorphisms preserve all topological properties, but it may be shown that mappings preserve some of them; for example, connectedness, separability, and compactness.

Mappings. Suppose A, B are topological spaces and $f:A \to B$ is a function that maps A into B. If $p \in A$, f is continuous at p if for each open set U in B containing $f(p)$ there is an open set V in A containing p such that f sends each point of V into U. This property of f is expressed imprecisely by saying that points close to p are sent close to $f(p)$. The function f is continuous if it is continuous at each point of A. Continuous functions are called mappings. Topologists are concerned with what properties are preserved by mappings. They are interested in whether or not mappings can be extended. They classify certain mappings as being differentiable, piecewise linear, or homeomorphic.

Homeomorphisms. Two topological spaces are called topologically equivalent, or homeomorphic, if there is a one-to-one correspondence between them that is continuous both ways. The vertical projection shown in Figure 1 sets up such a one-to-one correspondence between the straight interval X and the curved interval Y. If A and B

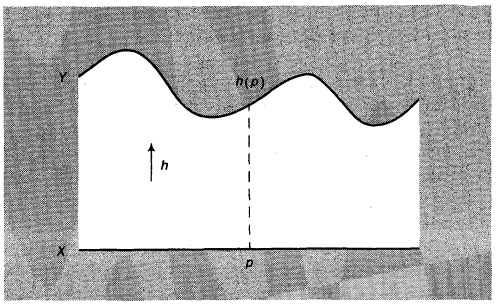

Figure 1: Vertical projection showing a one-to-one correspondence between the straight interval X and the curved interval Y (see text).

Topological equivalence

are topologically equivalent, there is a function $h: A \to B$ such that h is continuous, h is onto (each point of B is the image of a point of A), h is one to one, and the inverse function, h^{-1}, is continuous. Thus h is called a homeomorphism.

Topological properties are properties such that if one topological space has the property and a second space is topologically equivalent to the first, then the second has the property also. Properties having to do with size or straightness are not topological properties. Various topological properties will be examined in what follows.

Suppose Y is a point set in a topological space X. Regard Y as a subspace of X the open sets of which are the intersection of Y with open sets in X. The set Y has a topological property if it has the property when regarded as a subspace. A function on Y is called continuous if it is continuous when Y is regarded as a subspace.

Connectedness. A topological space X is connected if each map of it into the two-point space $\{0, 1\}$ takes all of X into one of 0 or 1. This is a complicated positive way of saying what is usually stated in a simple negative way. A space is connected if it is not the sum of two (non-null) sets neither of which contains either a point or a limit point of the other. Intuitively, this means that the space is all in one piece. It may be shown that $\mathfrak{R}^n$, Hilbert space, and the lexicographically ordered square are connected but that E^1-bad is not.

The Suslin problem. It is important to know what set of properties characterizes a line. It is known that a line is a connected linear space with no first or last point. The lexicographically ordered square with its end points removed, however, also has these properties.

Separability

A topological space is called separable if it contains a countable set of points such that each open set in the space contains some point of the countable set. It is possible to prove that any separable, connected linear space with no first or last point is topologically equivalent to a line. The Suslin problem asks whether the conditions of separability can be replaced by the condition that the space does not contain an uncountable collection of disjoint open sets. It has been shown that within the framework of the ordinary axioms of set theory, a proof cannot be constructed to show that this replacement is possible. This limitation results partially because these axioms permit the assumption that a set does not exist unless an algorithm is available for describing it and permits the labelling of some subsets of a countable model as uncountable merely because the function is missing from the model being used to match the set one to one with the integers.

Spaces like Hilbert space. Is Hilbert space homeomorphic with $\mathfrak{R}^1 \times \mathfrak{R}^1 \times \cdots$, the Cartesian product of countably many real lines? This question has been of interest, but the answer was hard to obtain. If there were a homeomorphism, it would not be direct by associating the point $(a_1, a_2, \cdots)$ in $\mathfrak{R}^1 \times \mathfrak{R}^1 \times \cdots$ with the point $(a_1, a_2, \cdots)$ in Hilbert space. The point all coordinates of which are 1 lies in $\mathfrak{R}^1 \times \mathfrak{R}^1 \times \cdots$ but not in Hilbert space. The set of points with precisely one coordinate 1 and all others 0 has a limit point in $\mathfrak{R}^1 \times \mathfrak{R}^1 \times \cdots$ but no limit point in Hilbert space. It was shown in 1966 by the U.S. mathematician R.D. Anderson, however, that, contrary to earlier claims, there is indeed a homeomorphism between Hilbert space and $\mathfrak{R}^1 \times \mathfrak{R}^1 \times \cdots$. Investigations are under way to determine what other spaces are homeomorphic with Hilbert space.

Hausdorff spaces. A topological space is called Hausdorff (after the German mathematician Felix Hausdorff) if it satisfies the following condition: For each two points, p, q there are disjoint open sets $U(p)$, $U(q)$ containing p and q, respectively. Being Hausdorff is a topological property. Not all topological spaces are Hausdorff, but most of those that are seriously studied, including all those mentioned so far in this article, are Hausdorff. It is possible to build a non-Hausdorff space by adding an ideal point to an interval as follows.

A non-Hausdorff interval with two right ends. Let pq be a closed interval with the ordinary linear topology. Basis elements are either open intervals or half-open intervals that contain either p or q. An interval is constructed with two right ends by adding another right end q' to pq as follows: A point of this enlarged space is either q' or a point of pq. A basis element is either a basis element of the original interval pq or the union of the one-point set $\{q'\}$ and an open interval of pq with q as an end. The enlarged space is not Hausdorff because there are no disjoint open sets containing q, q'.

Non-Hausdorff spaces

Other separation properties. The Hausdorff property is one of the separation properties. Two sets A, B can be separated if these two sets lie in disjoint open sets. A space is Hausdorff, therefore, if each two points can be separated. A space is regular if each point can be separated from a closed set not containing it. A space is normal if each pair of disjoint closed sets can be separated.

Sometimes a topological space has to be constructed that has one topological property but not another. To build a space that is Hausdorff but not regular, the topology of a line can be changed. Rather than using ordinary open intervals as the basis elements, they can be the set of points consisting of the centre and irrational points of open intervals. While no basis element then has more than one rational point, any closed set containing it has many rational points.

The plane is normal: If A, B are disjoint closed sets, the set of points closer to A than to B is an open set (as is the set of points closer to B than to A). The upper half-plane space described below, however, is regular but not normal.

The upper half-plane space. The points of this space are the points of the plane on or above the x-axis. The basis elements are of two sorts: the interiors of circles above the x-axis, and the union of interiors of circles tangent to the x-axis from above together with the point of tangency (see Figure 2). Physically this space may be regarded as points of an upward flow in which the rate of flow is one unit per second at the x-axis and less above. If p is a point and $r > 0$, the open set generated by p and r can be regarded as the set of points to which a person could swim from p in less time than from r if he swims at the rate of one unit per second. The current would prevent him from swimming between any two points of the x-axis. No basis element contains two points of the x-axis in the upper half-plane space.

A space regarded as points of a flow

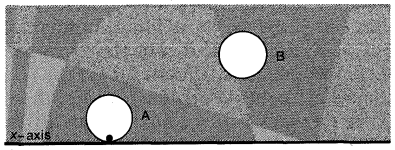

Figure 2: *Two sorts of basis elements for the upper plane space.*
(A) The interiors of circles tangent to the x-axis from above the point of tangency and (B) the interiors of circles above the x-axis (see text).

To see that the upper half-plane space is not normal, one could assign coordinates to the x-axis and let A be the set of points with rational coordinates and B the set of those with irrational coordinates. A rather involved argument shows that it is impossible to separate A from B.

Cartesian products of normal spaces. It can be seen that the Cartesian product of regular spaces is regular. Until the 1970s, one of the unsolved questions in topology asked whether the Cartesian product of a normal space and a straight-line interval is normal. In 1970 the mathematician Mary Ellen Rudin of the United States constructed an example (using box products) of a normal Hausdorff space whose Cartesian product with an interval is not normal.

The first axiom of countability. This axiom is modelled after the fact that if p is any point in the plane and U is an open set containing p, then there is an integer n such that the open ball with centre at p and radius $1/n$ lies in U. A topological space X satisfies the first axiom of countability provided the following condition holds: For each point p in X there is a sequence of open sets $U_1, U_2, \cdots$ each containing p, such that if U is any open

set whatsoever containing p, then there is an integer n such that U_n is contained in U, symbolically, $U_n \subset U$. Each of $\mathfrak{R}^n$, Hilbert space, discrete spaces, the lexicographically ordered square, E^1-bad, and the upper half-plane space satisfy the axiom. Some Cartesian-product spaces do not satisfy the axiom at any point whatsoever.

First and second axioms of countability

To get another Hausdorff space not satisfying this first axiom of countability the topology of the line $\mathfrak{R}^1$ can be changed as follows. The basis elements are defined to be of two sorts: any one point set other than the origin, or the complement of a finite set of points. Then the first axiom of countability is not satisfied at the origin.

The second axiom of countability. A topological space satisfies the second axiom of countability if it has a countable basis. The plane has a countable basis (interiors of circles with radii and centres represented by rational numbers). Neither the lexicographically ordered square, E^1-bad, nor the upper half-plane space does. One very useful theorem in topology is that any space that is regular and that satisfies the second axiom of countability is normal.

Compactness. A topological space is called compact in the limit-point sense (called countably compact by some or merely compact by others) if each infinite set of points has a limit point.

A collection $\{U_\alpha\}$ of open sets is called a covering of a topological space X if each point of X lies in some U_α. A space is called compact in the covering sense (sometimes called bicompact or even merely compact) if each open covering contains a finite number of elements that cover. It may be shown that any space that is compact in the covering sense is compact in the limit-point sense; but the converse is not necessarily true. For a space to be compact in the covering sense, it is necessary and sufficient that each infinite subset Y have a limit point p such that for each open set U containing p, $U \cap Y$ has as many points as Y. For some important spaces (such as metrizable spaces; see below *Moore spaces*), the two kinds of compactness are equivalent so that there is no confusion in omitting qualifications.

There are examples of two topological spaces such that each is compact in the limit-point sense but their Cartesian product is not. (These spaces could not satisfy the first axiom of countability.)

The Tikhonov theorem

The Tikhonov theorem, however, states that if $\{X_\alpha\}$ is any collection (perhaps even an uncountable collection) of topological spaces, the Cartesian product of the X_α's is compact in the covering sense if and only if each X_α is.
